

Mathematics

A Complete Undergraduate Course

Adam Kelly

University of Cambridge

Preface

These notes began as an act of self-defence.

A Cambridge lecture moves at about the speed of the lecturer's handwriting, which is much faster than the speed of understanding. You arrive, you copy down a definition, a theorem and a proof, and an hour later you leave with a notebook full of statements that are correct on the page and only approximately correct in your head. My response, in my first term, was to go home in the evening and write the lecture again from scratch: in my own words, in my own order, with the missing steps put back in wherever I had lost the thread. It was much slower than reading. It was also the only thing that reliably worked, because you cannot write a proof out honestly without discovering exactly which line you did not follow.

I did this for one course, and then for another, and then it became simply what I did. Three years later there were forty-four of these documents sitting in a folder, covering every course I took for Parts IA, IB and II of the Mathematical Tripos, somewhere close to three thousand pages in all. This book is that folder, bound together and given a spine.

What this book is

It is a single volume containing the complete set of my Cambridge undergraduate lecture notes: eight courses from Part IA, fifteen from Part IB, and twenty-one from Part II. Each chapter is one course, more or less exactly as I wrote it at the time. The assembling is new; the mathematics is not.

That is worth being precise about, because it gives the book a texture you would never choose if you sat down to write a textbook. The Tripos is a collection of courses, not a single narrative, and courses overlap. Cauchy's theorem is proved carefully in Complex Analysis and then used briskly in Complex Methods. The Gauss–Bonnet theorem appears once in IB Geometry and again, from a greater height, in II Differential Geometry. The Fourier transform turns up in four separate chapters wearing four separate sets of hypotheses, and the Baire category theorem is proved twice. Notation drifts between chapters, and a symbol defined in one chapter means nothing in the next.

I have deliberately left all of this alone. Smoothing it out would have meant rewriting forty-four courses into one, which is a different book and not one I have written. What you have instead is an honest record of what the subject actually looks like from inside an undergraduate degree – overlapping, repetitive in places, and occasionally inconsistent with itself. The repetitions are, I think, among the more instructive things here. Seeing the same theorem proved twice at two levels of generality tells you something about the theorem that seeing it once does not.

What this book is not

It is not a substitute for a textbook, and it is certainly not a substitute for going to the lectures. Where a textbook would motivate at length, cite the literature and give three

proofs, these notes give one proof and move on. They were written under time pressure by somebody meeting the material for the first time, and they show it.

Nor is this a light tour. The book that inspired the shape of this front matter – Evan Chen’s *An Infinitely Large Napkin* – sets out to give you the feeling of a field in forty pages, and cheerfully omits any proof that does not teach something. This book does close to the opposite, not because that approach is wrong but because these notes were written for a different purpose. They are working notes: rigorous, complete against the schedules, and in places genuinely terse. There are stretches that are close to unreadable unless you already half know what is going on, which is what happens when you write for the version of yourself who sat in the lecture that morning.

Finally, these are not transcriptions. Each chapter says so at its start, and each one means it. I reordered material, replaced proofs I did not like, and added examples that were never lectured. All lectured content should be covered, but the route through it is frequently my own, and any error you find in a proof is far more likely to be mine than the lecturer’s.

Who it is for

Mostly, honestly, for me – somewhere to look things up, and a record of what three years of work actually amounted to. But there are two other readers I had in mind while putting it together.

The first is a Cambridge student sitting one of these courses now, who wants a second account of the lectures to set beside their own notes, and would rather have all of them in one file than in forty-four. The second is anyone learning this material from outside Cambridge who wants to see what a complete and rigorous undergraduate path through pure and applied mathematics looks like when it is written down end to end. The Tripod is unusually broad – there are not many degrees in which the same student proves the Riemann–Roch theorem and computes the flow of a viscous fluid down a slope – and that breadth is most of what makes a document like this worth assembling at all.

Debts

The largest debt is to the lecturers. Almost every good idea in this book was explained to me first by somebody standing at a blackboard, and the choice of material, the order of the arguments and very often the proofs themselves are theirs. What I have added is the writing-out, and occasionally the impertinence of thinking I could arrange it better.

I owe a second debt to the other note-takers. Cambridge has a generous and slightly anarchic tradition of students typing up their courses and putting them online for everybody else, and I leaned on it constantly – Dexter Chua’s notes in particular were a fixture of my degree, and there were plenty of others whose PDFs I went to when my own record of a lecture had gone hopelessly wrong. The style file all of this is set in descends, in its turn, from Evan Chen’s and Tony Zhang’s. Very little here was invented from nothing, and that is rather the point.

Errors

There are certainly some. If you find one – a broken proof, a missing hypothesis, a figure that says the opposite of the text – I would genuinely like to hear about it, at ak2316@cam.ac.uk. The notes are kept in a public repository as well, so corrections can go there directly.

Adam Kelly

How to Use This Book

The shape of the book

The book is in three parts, matching the three years of the Cambridge Mathematical Tripos, and each part is a year's worth of lectures.

- **Part IA** (eight chapters) is the first year. Everybody takes everything; there is no choice at all.
- **Part IB** (fifteen chapters) is the second year, where the syllabus opens up and a student picks perhaps ten of the courses on offer. What is collected here is what I took.
- **Part II** (twenty-one chapters) is the third year, where the courses become genuinely specialised and largely independent of one another.

Each of the three parts opens with a short essay about what that year is doing and how its courses hang together. Those essays are the closest thing this book has to a narrative, and they are worth reading before the mathematics.

Every chapter is a course

This is the single most important thing to know about the book. Each chapter is one lecture course, written as a standalone document and then dropped in here essentially untouched. In particular:

- **Chapters do not continue from one another.** Chapter 17 does not pick up where Chapter 16 left off; it starts again from its own beginning, with its own introduction saying what the course is about.
- **Notation is local.** A macro or a piece of notation established in one chapter is dissolved at the end of it. Two chapters may use the same letter for completely different things, and two chapters covering overlapping material may well use different conventions for it.
- **Numbering is by chapter and section.** A reference to Theorem 4.2.1 means the first numbered result in the second section of the fourth chapter. Definitions, theorems, lemmas and examples share a single counter within each section, so the numbers run in reading order.
- **Occasional references point outwards.** Because these were written as separate documents, you will now and then find a phrase like “see my Numbers and Sets notes”. That means the corresponding chapter of this book.

The upside of all this is that you can open the book anywhere. The downside is that reading it front to back is not obviously the right thing to do, which brings us to the next section.

Reading order, and the dependency graphs

Only Part IA is really meant to be read from a standing start. After that the courses fan out, and by Part II several of them share no content at all – the reader of Statistical Physics and the reader of Logic and Set Theory can happily ignore each other.

My honest advice is not to read this book linearly. Pick a chapter you want, look up what it stands on, and read backwards until you hit something you already know. The diagrams below are there to make that possible. They show the main lines of dependency running through the three years: an arrow from A to B means that B genuinely leans on A , not merely that the two are thematically related. Position from left to right indicates the direction of that flow, and the colour of a box tells you which part the course belongs to.

The graphs are deliberately incomplete. Every course assumes the whole of Part IA in the background, and drawing that in would have turned each picture into a scribble, so the arrows record only the specific and load-bearing dependencies.

Algebra

The longest and cleanest chain in the book. Groups gives the objects, Linear Algebra gives the technique, Groups, Rings and Modules assembles both into a general theory of algebraic structure, and Part II then spends four courses cashing it in. Number Fields in addition wants a little Galois theory, and quite a lot of the Number Theory chapter.

Analysis

Everything here descends from the ϵ - N definition of a limit in Analysis I. Analysis and Topology is the pivot: it replaces $\mathbb{R}$ by a metric or topological space, and once that is done the three Part II analysis courses become possible. Analysis of Functions also assumes the measure theory built in Probability and Measure, and repays the Hahn–Banach and Baire theorems of Linear Analysis.

Geometry and topology

Two strands that meet in Part II. One is metric and computational, running from the curves and surfaces of Vector Calculus through Geometry to Differential Geometry; the other is the topology introduced in Analysis and Topology, which Algebraic Topology turns into a machine for telling spaces apart. Riemann Surfaces sits at the junction, needing complex analysis for its local theory and covering spaces for its global one.

Probability and statistics

Part IA Probability is combinatorial and concrete; Probability and Measure goes back and rebuilds it on the measure theory of Analysis and Topology, at which point the limit theorems become theorems rather than slogans. Stochastic Financial Models is where the whole strand, optimisation included, is put to work.

Methods and mathematical physics

The applied side of the book. Differential Equations and Vector Calculus supply the machinery, Dynamics and Relativity supplies the physics, and the Part IB courses are where the two are finally allowed to meet. Note how much converges on Methods: Fourier series, Sturm–Liouville theory and Green’s functions are the common language of almost everything applied that follows, and it is Methods that supplies Quantum Mechanics with the separation of variables and the special functions it needs in three dimensions.

Discrete mathematics, logic and computation

The most self-contained group in the book, and the natural place to start if you want to read a Part II course without first reading two years of anything. Numbers and Sets is very nearly the only prerequisite, and most of what it supplies is the habit of proof rather than any particular theorem.

The colours

The notes lean fairly heavily on coloured panels, and once you know the scheme you can navigate a chapter by scanning it. Everything in a coloured box is a formal statement; everything between the boxes is me talking.

- **Pale green, with a teal heading** is a *definition*. Axioms and physical laws share this colour, on the grounds that they too are things being stipulated rather than deduced.
- **Pale lilac, with a dark blue heading** is a *result*: theorems, propositions, lemmas, corollaries, facts and claims all live here. There is no significance to the choice between those words beyond the usual one of importance.
- **Pale pink, with a rust-coloured heading** is an *example* or a question. These are usually worked, and they are usually the fastest way into a section you find opaque.
- **Grey, with a rule down the left-hand edge**, is a *proof*. The rule runs the height of the argument, so you can see at a glance where a long proof ends and the discussion starts again.
- **Bold blue** in running text marks a term at the point where it is defined.

A word of warning about the pale green boxes in particular. Because definitions are so visually distinctive it is tempting to read only those, which is exactly the wrong way round: the prose between the boxes is where any motivation lives, and in these notes there is not so much of it that you can afford to skip it.

A closing caution

These are lecture notes, and they behave like lecture notes. Sometimes a chapter develops an idea patiently over three pages; sometimes it disposes of an entire lecture in half a column because that was all the reminder I needed. If you hit a passage that seems to assume you already understand it, that is usually because it was written by somebody who had just been told it, for somebody who was about to be examined on it. Read around it, come back, and it generally opens up.

Contents

Preface	iii
How to Use This Book	vii
I Part IA	1
About Part IA	3
1 Analysis	5
1.1 Sequences and Convergence	5
1.1.1 Limits & The Reals	5
1.1.2 Bolzano–Weierstrass	7
1.1.3 Cauchy Sequences & The General Principle of Convergence	9
1.1.4 Limits of Functions	10
1.2 Infinite Series	13
1.2.1 Convergent & Divergent Series	13
1.2.2 Convergence Tests	14
1.2.3 Absolute Convergence	18
1.3 Continuity	21
1.3.1 Continuity of Functions	21
1.3.2 The Intermediate Value Theorem	23
1.3.3 The Boundedness Theorem	26
1.4 Differentiability	28
1.4.1 Properties of Differentiable Functions	28
1.4.2 Rolle’s Theorem & The Mean Value Theorem	31
1.4.3 Inverses of Functions	34
1.4.4 Taylor’s Theorem	36
1.5 Power Series	40
1.5.1 Radius of Convergence	40
1.5.2 Differentiating Power Series	42
1.5.3 Exponential, Trigonometric & Hyperbolic Functions	43
1.6 Integration	52
1.6.1 Dissections, Upper & Lower Sums, and Riemann Integrals	52
1.6.2 Properties of Integration	55
1.6.3 Integrable Functions	58
1.6.4 The Fundamental Theorem of Calculus	61
1.6.5 Taylor’s Theorem Again	63
1.6.6 Improper Integrals & The Integral Test	65
2 Differential Equations	69
2.1 A Revision of Calculus	69
2.1.1 Differentiation	69
2.1.2 Big- O and Little- o Notation	70
2.1.3 Rules for Differentiation	71
2.1.4 Taylor Series	72
2.1.5 L’Hôpital’s Rule	73

2.1.6	Integration	74
2.2	Functions of Several Variables	75
2.2.1	Partial Derivatives	75
2.2.2	The Multivariate Chain Rule and Differentials	76
2.2.3	Exact Differentials	76
2.2.4	Implicit Differentiation and Differentiating Integrals	77
2.3	First-Order Linear Differential Equations	78
2.3.1	The Exponential Function	79
2.3.2	Homogeneous Equations with Constant Coefficients	79
2.3.3	Forced Equations	81
2.3.4	Non-Constant Coefficients: The Integrating Factor	83
2.4	Nonlinear First-Order Equations	84
2.4.1	Separable Equations	84
2.4.2	Exact Equations	85
2.4.3	Sketching Solution Curves	86
2.4.4	Equilibrium Points and Stability	87
2.4.5	The Logistic Equation	89
2.5	First-Order Difference Equations	90
2.5.1	Fixed Points and Stability	91
2.5.2	The Logistic Map	92
2.6	Second-Order Linear Differential Equations	92
2.6.1	Constant Coefficients and the Characteristic Equation	92
2.6.2	Degeneracy and Detuning	93
2.6.3	Reduction of Order	94
2.6.4	Phase Space, Linear Independence and the Wronskian	95
2.6.5	Particular Integrals	97
2.6.6	Resonance	97
2.6.7	Variation of Parameters	99
2.6.8	Equidimensional Equations	100
2.6.9	Transients and Damping	101
2.7	Second-Order Difference Equations	103
2.8	Impulses and Discontinuous Forcing	105
2.8.1	Impulses and the Dirac Delta Function	105
2.8.2	Delta-Function Forcing of Second-Order Equations	106
2.8.3	The Heaviside Step Function	107
2.9	Series Solutions	108
2.9.1	Ordinary and Singular Points	109
2.9.2	Solutions About an Ordinary Point	110
2.9.3	Solutions About a Regular Singular Point: Frobenius	111
2.9.4	When the Indices Differ by an Integer	112
2.10	The Gradient and Stationary Points	113
2.10.1	The Directional Derivative and the Gradient	113
2.10.2	Taylor Series in Several Variables	114
2.10.3	Stationary Points and Their Classification	115
2.11	Systems of Differential Equations	117
2.11.1	Linear Systems and Matrix Methods	117
2.11.2	Phase Portraits in the Plane	118
2.11.3	Nonlinear Systems and Linearisation	120
2.12	Partial Differential Equations	122
2.12.1	The First-Order Wave Equation	122

2.12.2	The Second-Order Wave Equation	123
2.12.3	The Diffusion Equation	125
3	Dynamics and Relativity	127
3.1	Newton's Laws and Forces	127
3.1.1	Particles & Inertial Frames	127
3.1.2	Newton's Laws	128
3.1.3	Galilean Transformations	128
3.1.4	Examples of Forces	129
3.1.5	Potentials in One Dimension	130
3.1.6	Potentials in Three Dimensions	134
3.1.7	Gravity	135
3.1.8	Electromagnetism	136
3.1.9	Friction	137
3.2	Dimensional Analysis	138
3.2.1	Dimensions of Physical Quantities	139
3.2.2	Scaling	139
3.3	Orbits	141
3.3.1	Central Forces	141
3.3.2	Angular Momentum	141
3.3.3	Polar Coordinates in the Plane	142
3.3.4	Reduction to One Dimension	143
3.3.5	The Effective Potential	144
3.3.6	Stability of Circular Orbits	145
3.3.7	Escape Velocity	145
3.3.8	The $u(\theta)$ Equation	146
3.3.9	The Kepler Problem	146
3.3.10	Energy and Eccentricity	148
3.3.11	Kepler's Laws	148
3.3.12	Rutherford Scattering	150
3.4	Rotating Frames	151
3.4.1	Motion in Rotating Frames	151
3.4.2	Change of Frame Operator	152
3.4.3	Velocity and Acceleration	152
3.4.4	Force in the Rotating Frame	152
3.4.5	The Centrifugal Force	153
3.4.6	The Coriolis Force	154
3.5	Systems of Particles	155
3.5.1	Centre of Mass & Conservation of Momentum	155
3.5.2	Angular Momentum of a System	157
3.5.3	Motion Relative to the Centre of Mass	157
3.5.4	The Two-Body Problem	158
3.5.5	Collisions	159
3.5.6	Variable Mass Problems & The Rocket Equation	160
3.6	Rigid Bodies	162
3.6.1	Angular Velocity	162
3.6.2	Moment of Inertia	162
3.6.3	Angular Momentum and Moments of Inertia	162
3.6.4	Calculating Moments of Inertia	163
3.6.5	Motion of Rigid Bodies	165

3.6.6	The Compound Pendulum	166
3.6.7	Rolling Without Slipping	167
3.7	Special Relativity	169
3.7.1	Axioms of Special Relativity	169
3.7.2	Lorentz Transformations	170
3.7.3	Spacetime Diagrams	171
3.7.4	Simultaneity	172
3.7.5	Causality & Light Cones	173
3.7.6	Time Dilation	173
3.7.7	Length Contraction	175
3.7.8	Composition of Velocities	175
3.7.9	Geometry of Minkowski Space	176
3.7.10	4-Vectors	178
3.7.11	The Lorentz Group	178
3.7.12	Rapidities	179
3.8	Relativistic Physics	179
3.8.1	Proper Time	180
3.8.2	4-Velocity	180
3.8.3	Transforming Velocities & Aberration	181
3.8.4	4-Momentum & Relativistic Energy	181
3.8.5	The Relativistic Doppler Effect	183
3.8.6	4-Force	183
3.8.7	Particle Collisions & Decays	184
4	Groups	189
4.1	Groups	189
4.1.1	Definition of a Group	189
4.1.2	Subgroups	192
4.1.3	Homomorphisms	194
4.2	Important Groups	199
4.2.1	Cyclic Groups	199
4.2.2	Dihedral Group	201
4.2.3	Permutation Groups	202
4.2.4	Möbius Groups	207
4.3	Lagrange's Theorem	209
4.3.1	Exploring Group Using Lagrange	212
4.4	Quotients of Groups	213
4.4.1	Normal Subgroups	213
4.4.2	Quotients	215
4.4.3	The Isomorphism Theorems	216
4.4.4	Simple Groups	219
4.5	Group Actions	219
4.5.1	Orbits and Stabilisers	221
4.5.2	Cauchy's Theorem	226
4.5.3	Important Actions	227
4.6	The Möbius Group, Revisited	233
4.6.1	Conjugation	234
4.6.2	Circles and Lines – Geometric Properties of Möbius Maps	235
4.6.3	Cross Ratios	237

4.7	Matrix Groups	238
4.7.1	Examples of Matrix Groups	238
4.7.2	Möbius Maps as Matrices	239
4.7.3	Conjugation and Changes of Basis	240
4.7.4	Geometry of Orthogonal Groups	241
4.7.5	Symmetries of the Cube Revisited	246
4.8	Groups of Small Order	246
4.8.1	Groups of Order Up To 7	246
4.8.2	Groups of Order 8	247
5	Numbers and Sets	249
5.1	Elementary Number Theory	249
5.1.1	The Peano Axioms	249
5.1.2	Strong Induction	252
5.1.3	The Integers and Rationals	252
5.1.4	Primes and Divisibility	254
5.1.5	Modular Arithmetic	259
5.2	The Reals	266
5.2.1	Why We Need Real Numbers	266
5.2.2	Sequences	271
5.2.3	Algebraic Numbers	276
5.3	Sets and Functions	277
5.3.1	Sets	278
5.3.2	Finite Sets	280
5.3.3	Finite Sets and their Sizes	281
5.3.4	Functions	284
5.3.5	Equivalence Relations	287
5.4	Countability	289
5.4.1	Countable Sets	289
5.4.2	Uncountable Sets	291
5.4.3	Bijections	292
5.4.4	Sizes of Sets	293
6	Probability	295
6.1	Setting Up Probability	295
6.1.1	Probability Spaces	295
6.1.2	Classical Probability and Counting	296
6.1.3	Conditional Probability and Independence	298
6.1.4	Continuity of Probability Measures	301
6.1.5	Inclusion-Exclusion	303
6.2	Discrete Random Variables	305
6.2.1	Probability Mass Functions	305
6.2.2	Expected Value	306
6.2.3	Indicator Functions	307
6.2.4	A Zoo of Standard Distributions	309
6.3	Multiple Random Variables	312
6.3.1	Joint Distributions and Independence	312
6.3.2	Covariance	314
6.3.3	Conditional Expectation	315

6.4	Inequalities and the Law of Large Numbers	317
6.4.1	Markov and Chebyshev	317
6.4.2	Cauchy-Schwarz	318
6.4.3	Jensen's Inequality	319
6.4.4	The Weak Law of Large Numbers	320
6.5	Random Walks	322
6.5.1	Gambler's Ruin	322
6.5.2	Expected Duration	323
6.6	Probability Generating Functions	324
6.6.1	Extracting Moments	325
6.6.2	Sums of Independent Random Variables	326
6.6.3	Random Sums	327
6.7	Branching Processes	328
6.7.1	Expected Generation Size	328
6.7.2	Generating Functions of Generations	329
6.7.3	Extinction	329
6.8	Continuous Random Variables	331
6.8.1	Distribution Functions	331
6.8.2	Expectation and Variance	332
6.8.3	The Uniform and Exponential Distributions	333
6.8.4	The Normal Distribution	335
6.8.5	Transformations of Random Variables	336
6.9	Joint Densities	337
6.9.1	Joint Densities and Independence	337
6.9.2	Sums of Continuous Random Variables	338
6.9.3	Conditional Densities	338
6.9.4	Transformations in Higher Dimensions	339
6.9.5	Order Statistics	340
6.10	Moment Generating Functions	341
6.10.1	Examples: Gamma, Normal, and a Warning	342
6.11	The Central Limit Theorem	343
6.11.1	Applications	345
6.12	The Multivariate Normal Distribution	346
6.12.1	Gaussian Vectors	346
6.12.2	Construction and Density	347
6.12.3	Independence and Covariance for Gaussians	347
6.12.4	The Bivariate Normal	348
6.13	Geometric Probability and Simulation	349
6.13.1	Bertrand's Paradox	349
6.13.2	Buffon's Needle	350
6.13.3	Simulating Random Variables	351
7	Vector Calculus	353
7.1	Notation	353
7.2	Differential Geometry of Curves	353
7.2.1	Parameterized Curves & Arc Length	354
7.2.2	Curvature and Torsion	359
7.2.3	Radius of Curvature	360
7.3	Coordinates, Differentials and Gradients	361
7.3.1	Differentials and First Order Changes	361

7.3.2	Coordinates and Line Elements	362
7.3.3	The Gradient Operator	365
7.3.4	Computing Gradients	366
7.4	Integration over Lines, Surfaces and Volumes	368
7.4.1	Line Integrals	368
7.4.2	Conservative Forces and Exact Differentials	370
7.4.3	Integration in $\mathbb{R}^2$	372
7.4.4	Integration in $\mathbb{R}^3$	375
7.4.5	Integration Over Surfaces	377
7.5	Div, Curl and the Laplacian	382
7.5.1	The Divergence and Curl	382
7.5.2	Identities in Index Notation	385
7.5.3	Div and Curl in Orthogonal Curvilinear Coordinates	387
7.6	The Integral Theorems	389
7.6.1	Green's Theorem	390
7.6.2	Stokes' Theorem	391
7.6.3	The Divergence Theorem	393
7.6.4	Proving the Integral Theorems	395
7.6.5	Conservative Fields Revisited	397
7.7	Maxwell's Equations	398
7.7.1	Conservation Laws	399
7.7.2	The Equations	399
7.7.3	Integral Forms	400
7.7.4	Electromagnetic Waves	401
7.7.5	Electrostatics and Potentials	401
7.8	Poisson's Equation and Laplace's Equation	402
7.8.1	Boundary Value Problems	402
7.8.2	Uniqueness	403
7.8.3	Gauss' Flux Method	404
7.8.4	Harmonic Functions	405
7.9	Cartesian Tensors	406
7.9.1	Changing Coordinates	407
7.9.2	Tensors and Their Rank	408
7.9.3	Operations on Tensors	409
7.9.4	Symmetric, Antisymmetric and Isotropic Tensors	410

27.1.1	Algorithms and the Entscheidungsproblem	1589

27.1.2	Alphabets, Words and Languages	1590
27.1.3	Counting Languages	1591
27.2	Rewrite Systems and Grammars	1592
27.2.1	Rewrite Systems	1592
27.2.2	Grammars	1593
27.2.3	Equivalence of Grammars	1594
27.2.4	The Chomsky Hierarchy	1595
27.2.5	Decision Problems	1596
27.2.6	Closure Properties	1597
27.2.7	The Empty Word	1599
27.3	Regular Languages	1600
27.3.1	Regular Derivations	1600
27.3.2	Deterministic Automata	1601
27.3.3	From Automata to Grammars	1604
27.3.4	Nondeterministic Automata and the Subset Construction	1604
27.3.5	The Pumping Lemma for Regular Languages	1607
27.3.6	Closure Properties	1609
27.3.7	Regular Expressions and Kleene's Theorem	1610
27.3.8	Minimisation	1612
27.3.9	The Myhill–Nerode Theorem	1614
27.3.10	Decision Problems for Regular Languages	1616
27.4	Context-Free Languages	1619
27.4.1	Trees	1619
27.4.2	Parse Trees	1620
27.4.3	Ambiguity	1622
27.4.4	Chomsky Normal Form	1622
27.4.5	The Pumping Lemma for Context-Free Languages	1624
27.4.6	Closure Properties	1626
27.4.7	Pushdown Automata	1626
27.4.8	Decision Problems for Context-Free Languages	1627
27.5	Register Machines	1628
27.5.1	The Definition	1628
27.5.2	Strong Equivalence	1630
27.5.3	Operations and Questions	1631
27.5.4	A Register Machine API	1632
27.6	Computable Functions and Sets	1634
27.6.1	Computable Functions	1634
27.6.2	Computable and Computably Enumerable Sets	1635
27.6.3	The Shortlex Ordering	1636
27.6.4	Merging and Splitting Words	1637
27.6.5	Coding of Programs	1638
27.6.6	The Universal Register Machine	1638
27.6.7	The s – m – n Theorem	1640
27.6.8	The Halting Problem	1640
27.7	Recursive Functions	1641
27.7.1	Primitive Recursion and Minimisation	1642
27.7.2	Recursion Trees	1643
27.7.3	Recursive Functions Are Computable	1644
27.7.4	Computable Functions Are Recursive	1645
27.7.5	The Church–Turing Thesis	1646

27.8	Computably Enumerable Sets	1647
27.8.1	Sets with Quantifiers	1647
27.8.2	Closure Properties	1649
27.8.3	Type 0 Languages	1650
27.8.4	Many-One Reducibility	1651
27.8.5	Degrees of Unsolvability	1652
27.8.6	Rice's Theorem	1654
27.8.7	Solvability of Decision Problems	1656
27.9	The Relationship Between the Language Classes	1657
28	Coding and Cryptography	1659
28.1	Modelling Communication	1659
28.2	Noiseless Coding	1662
28.2.1	Codes and Decipherability	1662
28.2.2	Kraft's Inequality	1664
28.2.3	McMillan's Inequality	1665
28.2.4	Entropy	1666
28.2.5	Optimal Codes and the Noiseless Coding Theorem	1668
28.2.6	Huffman Coding	1669
28.2.7	Joint Entropy	1672
28.3	Noisy Channels and Error-Correcting Codes	1673
28.3.1	Decoding Rules	1673
28.3.2	Error Detection and Correction	1674
28.3.3	Covering Estimates and Perfect Codes	1677
28.3.4	Asymptotics	1680
28.3.5	Constructing New Codes from Old	1681
28.4	Information Theory	1682
28.4.1	Sources and Information Rate	1682
28.4.2	The Asymptotic Equipartition Property	1685
28.4.3	Shannon's First Coding Theorem	1686
28.4.4	Capacity of the Binary Symmetric Channel	1687
28.4.5	Conditional Entropy and Fano's Inequality	1688
28.4.6	Mutual Information and Information Capacity	1690
28.4.7	Proof of the Noisy Coding Theorem	1691
28.4.8	An Aside: the Kelly Criterion	1693
28.5	Linear Codes	1694
28.5.1	Linear Codes, Generator and Parity Check Matrices	1694
28.5.2	Hamming Codes	1699
28.5.3	Weight Enumerators	1700
28.5.4	Reed–Muller Codes	1702
28.6	Cyclic Codes	1705
28.6.1	Cyclic Codes and Generator Polynomials	1705
28.6.2	BCH Codes	1707
28.6.3	Decoding BCH Codes	1709
28.6.4	Reed–Solomon Codes	1711
28.6.5	Linear Feedback Shift Registers	1712
28.6.6	The Berlekamp–Massey Method	1714
28.7	Cryptography	1716
28.7.1	Cryptosystems and Classical Ciphers	1716
28.7.2	Perfect Secrecy and the One-Time Pad	1717

28.7.3	Stream Ciphers	1719
28.7.4	Public Key Cryptography	1720
28.7.5	The Rabin Cryptosystem	1721
28.7.6	The RSA Cryptosystem	1722
28.7.7	Attacks on RSA	1724
28.7.8	Signatures and Hash Functions	1725
28.7.9	Diffie–Hellman Key Exchange	1726
28.7.10	The ElGamal Scheme	1727
28.7.11	The Digital Signature Algorithm	1728
28.7.12	Commitment Schemes	1729
28.7.13	Secret Sharing	1730
29	Differential Geometry	1733
29.1	Differential Topology	1733
29.1.1	Manifolds	1733
29.1.2	Tangent Spaces and Derivatives	1734
29.1.3	Regular Values and Sard’s Theorem	1736
29.1.4	Transversality	1739
29.1.5	Manifolds with Boundary	1740
29.1.6	Degree Modulo 2	1742
29.1.7	Abstract Manifolds and Whitney’s Embedding Theorem	1746
29.2	Curves in $\mathbb{R}^3$	1746
29.2.1	Regular Curves and Arc Length	1747
29.2.2	Curvature and the Frenet–Serret Formulae	1748
29.2.3	Plane Curves	1752
29.2.4	The Isoperimetric Inequality	1754
29.2.5	The Four Vertex Theorem	1755
29.3	Surfaces, Length and Area	1756
29.3.1	Smooth Surfaces	1757
29.3.2	Orientability and Tangent Planes	1757
29.3.3	The First Fundamental Form	1760
29.3.4	Isometries and Conformal Maps	1762
29.3.5	Area	1763
29.4	The Gauss Map and Curvature	1765
29.4.1	The Second Fundamental Form	1765
29.4.2	The Gauss Map and the Shape Operator	1766
29.4.3	Normal and Principal Curvatures	1767
29.4.4	Curvature in Local Coordinates	1769
29.4.5	Elliptic, Hyperbolic and Parabolic Points	1770
29.4.6	Curvature as Area Distortion	1771
29.4.7	Compact Surfaces Have an Elliptic Point	1772
29.5	The Theorema Egregium	1773
29.5.1	Christoffel Symbols	1773
29.5.2	The Gauss and Codazzi–Mainardi Equations	1774
29.5.3	Useful Special Cases	1776
29.6	Geodesics	1777
29.6.1	Length, Energy and Variations	1777
29.6.2	The Geodesic Equations	1778
29.6.3	Geodesics Are Straightest	1779
29.6.4	Planes of Symmetry	1781

29.6.5	Surfaces of Revolution	1781
29.6.6	The Covariant Derivative and Parallel Transport	1783
29.6.7	The Exponential Map	1784
29.6.8	Geodesic Polar Coordinates	1785
29.6.9	Surfaces of Constant Curvature	1787
29.7	Minimal Surfaces	1788
29.7.1	The First Variation of Area	1788
29.7.2	Examples	1789
29.7.3	Isothermal Coordinates and Harmonicity	1790
29.7.4	The Weierstrass Representation	1791
29.7.5	Interpreting the Weierstrass Data	1793
29.8	The Gauss–Bonnet Theorem	1794
29.8.1	Geodesic Curvature	1795
29.8.2	The Local Gauss–Bonnet Theorem	1796
29.8.3	Triangulations and the Euler Characteristic	1798
29.8.4	The Global Gauss–Bonnet Theorem	1799
29.8.5	Applications	1800
29.9	Total Curvature of Space Curves	1801
29.9.1	Tubes	1801
29.9.2	Fenchel’s Theorem	1802
29.9.3	The Fáry–Milnor Theorem	1803
29.10	Abstract Surfaces	1804
29.10.1	Riemannian Metrics	1804
29.10.2	The Length Metric	1806
29.10.3	The Hyperbolic Plane	1806
30	Galois Theory	1809
30.1	Introduction	1809
30.1.1	A Bit of History	1809
30.1.2	Solving Cubics and Quartics	1810
30.1.3	Notation and Revision	1810
30.2	Field Extensions	1812
30.2.1	Extensions and Degree	1812
30.2.2	The Tower Law	1813
30.2.3	Algebraic and Transcendental Elements	1814
30.2.4	Working with Degrees	1816
30.2.5	Algebraic Extensions	1818
30.3	Ruler and Compass Constructions	1819
30.3.1	What Is Constructible?	1819
30.3.2	Constructible Numbers Form a Field	1820
30.3.3	The Classical Impossibilities	1822
30.4	Splitting Fields and Normal Extensions	1823
30.4.1	Adjoining a Root	1823
30.4.2	Splitting Fields	1825
30.4.3	Normal Extensions	1827
30.5	Separability	1828
30.5.1	The Derivative Criterion	1828
30.5.2	Separable Polynomials and Perfect Fields	1830
30.5.3	Separable Extensions and the Separable Degree	1832
30.5.4	The Primitive Element Theorem	1833

30.6	Finite Fields	1835
30.6.1	The Multiplicative Group	1835
30.6.2	Existence, Uniqueness and Subfields	1836
30.6.3	Irreducible Polynomials over $\mathbb{F}_p$	1837
30.7	Algebraic Closure	1838
30.8	The Galois Correspondence	1840
30.8.1	Automorphism Groups	1840
30.8.2	Artin's Theorem	1841
30.8.3	Galois Extensions	1843
30.8.4	The Fundamental Theorem	1845
30.8.5	Worked Examples	1846
30.9	Galois Groups of Polynomials	1848
30.9.1	Symmetric Polynomials	1849
30.9.2	The Discriminant	1850
30.9.3	Cubics	1852
30.9.4	Quartics and the Resolvent Cubic	1853
30.9.5	Reduction Modulo a Prime	1854
30.9.6	The Generic Polynomial	1856
30.10	Cyclotomic Extensions	1857
30.10.1	Roots of Unity	1857
30.10.2	Cyclotomic Polynomials	1858
30.10.3	Subfields of Cyclotomic Fields	1860
30.10.4	Constructible Polygons	1861
30.11	Kummer Theory and Cyclic Extensions	1862
30.11.1	Linear Independence of Characters	1863
30.11.2	Kummer Extensions	1863
30.11.3	Artin–Schreier Extensions	1865

I

Part IA

About Part IA

The first year is the only part of the Tripos with no choices in it. Everybody sits the same eight courses, and the reason is that the year has a job to do: it has to take a room of people who arrived knowing how to differentiate and turn them into people who can write a proof. Almost everything in this part is either a foundation that later years will build on without comment, or a piece of technique that later years will assume you can execute in your sleep.

The year splits fairly cleanly in two. Numbers and Sets, Groups, Analysis I and Vectors and Matrices are the pure half, and between them they introduce essentially every kind of argument the rest of the book uses. Numbers and Sets comes first in more than just the ordering – it is where induction, the Euclidean algorithm, equivalence relations, countability and the least upper bound axiom appear, and it is the course whose real content is the idea of proof itself. Analysis I then takes the least upper bound axiom and does something startling with it, building limits, continuity, differentiation and the Riemann integral out of nothing but ϵ and N . Groups and Vectors and Matrices run in parallel as the first taste of abstraction: Groups is abstract from its first line and stays concrete in its examples, working through the dihedral, symmetric and Möbius groups by hand, while Vectors and Matrices spends most of its time on $\mathbb{R}^3$ and $\mathbb{C}^n$ before quietly showing you that a matrix is a linear map in disguise.

The applied half – Differential Equations, Vector Calculus, Dynamics and Relativity, and Probability – is deliberately less careful, and it is worth being clear that this is a choice rather than an oversight. Differential Equations solves equations without ever proving that solutions exist. Vector Calculus differentiates under integral signs and exchanges limits with abandon. Probability defines a random variable as a function on a sample space and then never worries about whether the sample space is big enough. All three of these debts are called in later, in Analysis and Topology, in Methods, and in Probability and Measure respectively; the first year buys fluency now and pays for rigour later.

There are through-lines worth watching for. Vector Calculus is the most quietly important course of the year, because the divergence theorem and Stokes' theorem are the entire grammar of Electromagnetism and Fluid Dynamics, and its chapter on curves and surfaces is the first draft of everything in Geometry and Differential Geometry. Groups is the seed of the longest chain in the book, running through Groups, Rings and Modules to Galois Theory and Representation Theory. Vectors and Matrices is the same material as Linear Algebra with the abstraction removed, which makes reading the two in succession an unusually good way to see what abstraction actually buys you. And Dynamics and Relativity, which looks at first like a physics course that wandered into the wrong degree, turns out to be where the variational and Hamiltonian ideas of the next two years get their motivation.

If you are reading this book rather than sitting the exams, Part IA is the one part that genuinely rewards being read in order.

1 Analysis

At its heart, analysis is the study of ideas that depend on the notion of *limits*. The main concepts of analysis (such as convergence, continuity, differentiation and integration) will all depend quite fundamentally on a limiting process.

This article constitutes my notes for the ‘Analysis I’ course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered¹.

§1.1 Sequences and Convergence

One of the fundamental objects of study in analysis is *sequences*. In particular, in almost all areas of this course we will be concerned (either implicitly or explicitly) with the notion of convergence.

§1.1.1 Limits & The Reals

We will define convergence as follows.

Definition 1.1.1 (Convergence)

A sequence $a_1, a_2, \dots \in \mathbb{R}$ is said to **converge** to the limit $a \in \mathbb{R}$ if given any $\epsilon > 0$, we can find an integer N such that $|a_n - a| < \epsilon$ for all $n \geq N$. We write $\lim_{n \rightarrow \infty} a_n = a$, or $a_n \rightarrow a$ as $n \rightarrow \infty$.

This definition is (notably) purely algebraic. We can sensibly define this notion of convergence for any ordered field (for example, $\mathbb{Q}$). What takes us from algebra to analysis is the fundamental property of the real numbers.

Axiom 1.1.2 (Fundamental Axiom of Analysis)

If $a_1, a_2, \dots \in \mathbb{R}$ is an increasing sequence and there exists $A \in \mathbb{R}$ such that $a_i \leq A$ for all $i \in \mathbb{N}$, then there exists $a \in \mathbb{R}$ such that $a_n \rightarrow a$ as $n \rightarrow \infty$.

In other words – an increasing sequence of real numbers that is bounded above converges. Also this clearly implies that a decreasing sequence of reals bounded below converges.

Limits obey the properties that you would naturally expect.

Proposition 1.1.3 (Uniqueness of Limits)

If $a_n \rightarrow a$ and $a_n \rightarrow b$ as $n \rightarrow \infty$, then $a = b$.

¹A tiny bit of analysis is assumed, namely the content covered in the ‘Numbers and Sets’ course at Cambridge. Specifically the reader should be aware of least upper bounds/suprema along with the least upper bound axiom. If the reader is unfamiliar with this content, they are referred to Chapter 2 of my Numbers and Sets notes

Proof. Assume that $a \neq b$. Given given any $\epsilon > 0$, we can find integers N_1 and N_2 such that

$$\begin{aligned} |a_n - a| &\leq \epsilon, & \text{for all } n \geq N_1 \\ |a_n - b| &\leq \epsilon, & \text{for all } n \geq N_2 \end{aligned}$$

Then letting $\epsilon = |a - b|/3$ and taking $N = \max\{N_1, N_2\}$, we have by the triangle inequality

$$|a - b| \leq |a_n - a| + |a_n - b| \leq 2\epsilon = \frac{2}{3}|a - b|$$

for all $n \geq N$. Thus we must have $|a - b| = 0$, and $a = b$. $\square$

Proposition 1.1.4 (Convergence of Subsequences)

If $a_n \rightarrow a$ as $n \rightarrow \infty$ and $n(1) < n(2) < \dots$, then $a_{n(j)} \rightarrow a$ as $j \rightarrow \infty$.

Proof. We note that $n(j) \geq j$. Now $a_n \rightarrow a$ implies that given some ϵ , we can find an N such that $|a_j - a| < \epsilon$ for all $j \geq N$. But then this implies that $|a_{n(j)} - a| < \epsilon$ for all $j \geq N$, since $j \geq N$ implies $n(j) \geq N$. So $a_{n(j)} \rightarrow a$ also. $\square$

Proposition 1.1.5 (Manipulating Limits)

Let a_n and b_n be sequences. Then the following hold.

- (i) If $a_n \rightarrow a$ and $b_n \rightarrow b$ then $a_n + b_n \rightarrow a + b$.
- (ii) If $a_n \rightarrow a$ then $ca_n \rightarrow ac$ for a constant c .
- (iii) If $a_n \rightarrow a$ and $b_n \rightarrow b$ then $a_nb_n \rightarrow ab$.
- (iv) If $a_n \rightarrow a$ and $a, a_n \neq 0$ for all n , then $1/a_n \rightarrow 1/a$.

Proof. We prove each individually.

- (i) Given some $\epsilon > 0$, we can find integers N_a and N_b such that $|a_n - a| \leq \epsilon/2$ for all $n \geq N_a$ and $|b_n - b| \leq \epsilon/2$ for all $n \geq N_b$.

Then letting $N = \max\{N_a, N_b\}$, by the triangle inequality we have

$$|(a_n - a) + (b_n - b)| \leq |a_n - a| + |b_n - b| \leq \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon$$

for all $n \geq N$. Thus $a_n + b_n \rightarrow a + b$.

- (ii) Given $\epsilon > 0$, we can find some N such that $|a_n - a| \leq \epsilon/|c|$ for all $n \geq N$. Then $|ca_n - ca| \leq \epsilon$ for all $n \geq N$. So $ca_n \rightarrow ca$.
- (iii) Given some $\epsilon > 0$, we can find integers N_a and N_b such that $|a_n - a| \leq \sqrt{\epsilon}$ for all $n \geq N_a$ and $|b_n - b| \leq \sqrt{\epsilon}$ for all $n \geq N_b$. Then again letting $N = \max\{N_a, N_b\}$, we have

$$|(a_n - a)(b_n - b)| \leq \epsilon,$$

for all $n \geq N$. Hence $(a_n - a)(b_n - b) \rightarrow 0$, so $a_nb_n - ab_n - ba_n + ab \rightarrow 0$, and using the previous two properties we have $a_nb_n \rightarrow ab$.

- (iv) Since the sequence converges to $a \neq 0$, there must be some $r > 0$ such that $|a_n| > r$, for all n . Then given some $\epsilon > 0$, there exists $N \in \mathbb{N}$ such that $|a_n - a| < |a|\epsilon r$ for all $n \geq N$. That is,

$$\left| \frac{1}{a_n} - \frac{1}{a} \right| = \left| \frac{a - a_n}{aa_n} \right| < \frac{|a|\epsilon r}{|a|r} = \epsilon,$$

for all $n \geq N$. Hence $1/a_n \rightarrow 1/a$. $\square$

Proposition 1.1.6 (Squeeze Theorem)

Let a_n, b_n and x_n be sequences such that $a_n \leq x_n \leq b_n$ for all n . Then if $a_n \rightarrow \ell$ and $b_n \rightarrow \ell$ as $n \rightarrow \infty$, we also have $x_n \rightarrow \ell$.

Proof. Given some $\epsilon > 0$, we can find integers N_a and N_b such that $|a_n - \ell| < \epsilon$ for all $n \geq N_a$ and $|b_n - \ell| < \epsilon$ for all $n \geq N_b$. Then letting $N = \max\{N_a, N_b\}$, we have $\ell - \epsilon < a_n \leq x_n \leq b_n < \ell + \epsilon$ for all $n \geq N$. That is, $|x_n - \ell| < \epsilon$ for all $n \geq N$. Hence $x_n \rightarrow \ell$. $\square$

With these results in the our toolbox, we can then prove our first actual analysis result.

Lemma 1.1.7 (Axiom of Archimedes)

$\frac{1}{n} \rightarrow 0$ as $n \rightarrow \infty$.

Proof. The sequence $\frac{1}{n}$ is a decreasing sequence bounded below, and thus has a limit a . Considering the sequence $\frac{1}{2n} = \frac{1}{2} \cdot \frac{1}{n}$, this tends to a limit $\frac{a}{2}$, but since $\frac{1}{2n}$ is a subsequence of $\frac{1}{n}$, it also tends to a limit a . Thus $\frac{a}{2} = a$, so $a = 0$ as required. $\square$

Now while this is an article about real analysis, we will frequently employ the complex numbers. Of course, to do that we need to be able to do some analysis with $\mathbb{C}$, and indeed the definition of a limit still makes sense in $\mathbb{C}$. All of the above properties also hold, apart from the squeeze theorem (we need to be careful because $\mathbb{C}$ cannot be ordered like $\mathbb{R}$!)

§1.1.2 Bolzano–Weierstrass

An equivalent but important and quite useful form of the fundamental axiom is the ‘Bolzano–Weierstrass theorem’, that every bounded sequence has a convergent subsequence.

Theorem 1.1.8 (Bolzano–Weierstrass)

If $a_n \in \mathbb{R}$ and there exists K such that $|a_n| \leq K$ for all n , then we can find $n_1 < n_2 < n_3 < \dots$ and $a \in \mathbb{R}$ such that $a_{n_j} \rightarrow a$ as $j \rightarrow \infty$.

Proof. Consider a real sequence a_n . We say that an element a_i of the sequence is *good* if $a_j \geq a_i$ for all $j \geq i$. If the sequence has an infinite number of good elements, then taking them as a subsequence will be increasing. If there is a finite number of good elements, then letting N be the index of the last good element, we have that for any a_j with $j \geq N + 1$, there exists some a_k with $k > j$ such that $a_k < a_j$. Then repeating this, we can get a collection of decreasing elements. Thus every real sequence has a monotonic subsequence. Since the sequence is bounded, we then have that this subsequence converges. $\square$

Remark. This theorem says nothing about the uniqueness of the subsequence's limit. For example, consider the sequence $x_n = (-1)^n$. Then $x_{2n+1} \rightarrow -1$ and $x_{2n} \rightarrow 1$.

The proof given above is quite clean but is not the only standard proof of the theorem. Another common method which involves the method of 'repeated bisection', which is colloquially known as 'lion hunting'. This method will be discussed shortly.

The Bolzano-Weierstrass theorem also holds in $\mathbb{C}$ (and the same proof method will show with a little induction that it holds in $\mathbb{R}^n$, but we won't dwell on that in this article).

Theorem 1.1.9 (Bolzano-Weierstrass in $\mathbb{C}$)

If $a_n \in \mathbb{C}$ is a bounded sequence, then it has a convergent subsequence.

Proof. Begin by writing $a_n = x_n + iy_n$. Then since a_n is bounded, the sequences x_n and y_n are also bounded. We can apply Bolzano-Weierstrass to x_n to get a subsequence $x_{n(1)}, x_{n(2)}, \dots$ with $x_{n(j)} \rightarrow x$ as $j \rightarrow \infty$, for some $x \in \mathbb{R}$. Then we can apply Bolzano-Weierstrass again to $y_{n(j)}$ to get a subsequence $y_{n(k(1))}, y_{n(k(2))}, \dots$ with $y_{n(k(j))} \rightarrow y$ as $j \rightarrow \infty$ for some $y \in \mathbb{R}$.

Thus $x_{n(k(j))} \rightarrow x$ and $y_{n(k(j))} \rightarrow y$ and thus $a_{n(k(j))} \rightarrow x + iy$ as $j \rightarrow \infty$, so we have a convergent subsequence. $\square$

Before we end our discussion of the Bolzano-Weierstrass theorem, we will take a short digression on Lion Hunting (you need to know this proof though!)

Aside: How To Hunt Lions

The term 'lion hunting' comes most likely from the satirical paper 'A Contribution to the Mathematical Theory of Big Game Hunting', by a group of mathematicians under the pseudonym 'H. Pétard'. They present the following method of hunting a lion (that we know exists) in the Sahara Desert.

Bisect the desert by a line running N-S. The lion is either in the E portion or in the W portion; let us suppose him to be in the W portion. Bisect this portion by a line running E-W. The lion is either in the N portion or in the S portion; let us suppose him to be in the N portion. We continue this process indefinitely, constructing a sufficiently strong fence about the chosen portion at each step. The diameter of the chosen portions approaches zero, so that the lion is ultimately surrounded by a fence of arbitrarily small perimeter.

While this is tongue and cheek, it does give us a method of finding things by 'bisecting intervals', which we can apply to quite a few different theorems in Analysis.

Now it's time to prove Bolzano-Weierstrass by hunting lions.

Proof (Bolzano-Weierstrass, Lion Hunting Style). We are going to define two sequences a_n and b_n inductively as follows. Begin by setting $[a_1, b_1] = [-K, K]$, and let $c_1 = (a_1 + b_1)/2$ be the midpoint of this interval.

Then there is two possibilities:

1. $x_n \in [a_1, c_1]$ for infinitely many values of n .
2. $x_n \in [c_1, b_1]$ for infinitely many values of n .

Of course both of these can hold at the same time, but if the first one holds we set $a_2 = a_1$ and $b_2 = c_1$, and if it doesn't then we set $a_2 = c_1$ and $b_2 = b_1$.

Repeating this process we construct a_n and b_n such that $x_m \in [a_n, b_n]$ for infinitely many values of m ^a. Then we have $a_{n-1} \leq a_n \leq b_n \leq b_{n-1}$, and also $b_n - a_n = (b_{n-1} - a_{n-1})/2$.

Now a_n is increasing and bounded above, and b_n is decreasing and bounded below and thus $a_n \rightarrow a \in [a_1, b_1]$ and $b_n \rightarrow b \in [a_1, b_1]$. Then we have $b - a = (b - a)/2$ using the above result, and thus $a = b$.

Since $x_m \in [a_n, b_n]$ for infinitely many values of m , we can construct a sequence n_j such that $n_{j+1} > n_j$ and $x_{n_{j+1}} \in [a_{j+1}, b_{j+1}]$. Then $a_j \leq x_{n_j} \leq b_j$, and thus $x_{n_j} \rightarrow a$. $\square$

^aThis is lion hunting! You can kind of imagine that we are hunting for a number that a subsequence converges to, using the fact that there must be infinitely many terms near that number

§1.1.3 Cauchy Sequences & The General Principle of Convergence

So far we have defined the notion of a sequence converging to some explicit limit. However, it is possible to determine if a sequence converges without considering this limit explicitly. This is done by considering how 'close' the terms in the sequence eventually get, as we shall see.

We begin by describing what it means for a sequence to be *Cauchy*.

Definition 1.1.10 (Cauchy Sequence)

A sequence $a_1, a_2, \dots \in \mathbb{C}$ is said to be **Cauchy** if for every $\epsilon > 0$ there exists an integer N such that for all $n, m \geq N$ we have $|a_n - a_m| \leq \epsilon$.

We can almost immediately write down our first lemma.

Lemma 1.1.11 (Convergence Implies Cauchy)

If a sequence converges then it is Cauchy.

Proof. Consider a convergent sequence $a_n \rightarrow a$. Given $\epsilon > 0$, we can find N such

that $|a_n - a| \leq \epsilon/2$ for all $n \geq N$. Then by the triangle inequality we have

$$|a_n - a_m| \leq |a_n - a| + |a - a_m| \leq \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon,$$

for all $m, n \geq N$. Thus the sequence is Cauchy. $\square$

The converse of this result is also true! This gives us a powerful result about convergence, which is quite widely applicable (particularly because we can avoid talking about the limit explicitly, as we said before).

Lemma 1.1.12 (Completeness)

If a sequence is Cauchy then it converges.

Proof. Let $a_1, a_2, \dots$ be a Cauchy sequence. We will first show that the sequence is bounded. Because the sequence is Cauchy, can find an integer $N \in \mathbb{N}$ such that $n, m \geq N$ implies that $|a_n - a_m| \leq 1$. This implies that if $n \geq N$ we have

$$|x_n| \leq |x_n - x_N| + |x_N| \leq 1 + |x_N|.$$

Thus we have $|x_n| \leq \max_{1 \leq r \leq N} |x_r| + 1$ for all n , so the sequence is bounded.

Applying the Bolzano–Weierstrass theorem, we then have a subsequence $a_{n_1}, a_{n_2}, \dots$ with $a_{n_j} \rightarrow a$ as $j \rightarrow \infty$.

So given $\epsilon > 0$, we can find M such that $|a_{n_j} - a| \leq \epsilon/2$ for all $n_j \geq M$. We can also find M' such that $n, m \geq M'$ implies $|a_n - a_m| < \epsilon/2$.

Then for all $n \geq M'$, choosing n_j such that $n_j \geq \max\{M, M'\}$, we have

$$|a_n - a| \leq |a_n - a_{n_j}| + |a_{n_j} - a| \leq \epsilon/2 + \epsilon/2 = \epsilon.$$

Thus the sequence converges (namely to a). $\square$

Stripping away the detail, the reason this result holds is since Cauchy sequences are bounded, we can get a convergent subsequence. Then since all of the terms get arbitrarily close, the whole sequence must converge along with the subsequence.

Combining these two lemmas gives us the ‘general principle of convergence’, a result also known as Cauchy’s criterion.

Theorem 1.1.13 (General Principle of Convergence/Cauchy’s Criterion)

A sequence converges if and only if it is a Cauchy sequence.

§1.1.4 Limits of Functions

So far we have developed the notion of a limit of a sequence, but we can sensibly come up with a definition for what limits are in the context of functions. We will need to do a little bit of setup first, however.

We first need to be able to distinguish points (element of $\mathbb{C}$) where its possible to converge to those points with a sequence of elements that are all in some set A .

Definition 1.1.14 (Limit Point)

Let $A \subseteq \mathbb{C}$ and $a \in \mathbb{C}$. We say that a is a **limit point** of A if for any $\delta > 0$ there is some $z \in A$ such that $0 < |z - a| < \delta$.

We can then define a limit of a function by its behaviour as we approach a given limit point.

Definition 1.1.15 (Limit of a Function)

Let $A \subseteq \mathbb{C}$ and let $a \in \mathbb{C}$ be a limit point of A . Then for $f : A \rightarrow \mathbb{C}$, we say that the **limit of f** as z approaches a is ℓ , written $\lim_{z \rightarrow a} f(z) = \ell$, if given $\epsilon > 0$ there is some $\delta > 0$ such that whenever $0 < |z - a| < \delta$ and $z \in A$ we have $|f(z) - \ell| < \epsilon$.

These definitions should match the informal notion of a limits that would have been given in a calculus course. The reader should note that there is no requirement that $f(a) = \ell$, or even that f be defined at a at all.

There is a natural relation between this notion of a limit point and a limit and our previous definition of limits of sequences.

Proposition 1.1.16 (Sequence Definition of Limit Points)

Let $A \subseteq \mathbb{C}$ and $a \in \mathbb{C}$. Then a is a limit point of A if and only if there is a sequence $z_n \in A$ such that $z_n \rightarrow a$ as $n \rightarrow \infty$ and $z_n \neq a$ for all n .

Proof. If a is a limit point then for every positive integer n we can take $\delta = 1/n$ and obtain a $z_n \in A$ such that $0 < |z_n - a| < 1/n$. Then by the squeeze theorem $z_n \rightarrow a$ as $n \rightarrow \infty$, and also $z_n \neq a$ for all n .

Conversely, if there is such a sequence $z_n \in A$, then given $\delta > 0$ there is an N such that $z_N \in A$ and $0 < |z_N - a| < \delta$, so a is a limit point of A . $\square$

Proposition 1.1.17 (Sequence Definition of Limits)

Let $A \subseteq \mathbb{C}$ and let $a \in \mathbb{C}$ be a limit point of A . Then for $f : A \rightarrow \mathbb{C}$ we have $\lim_{z \rightarrow a} f(z) = \ell$ if and only if $\lim_{n \rightarrow \infty} f(z_n) = \ell$ for every sequence $z_n \in A$ satisfying $z_n \neq a$ and $z_n \rightarrow a$ has $f(z_n) \rightarrow \ell$.

Proof. If $\lim_{z \rightarrow a} f(z) = \ell$, consider a sequence $z_n \in A$ where $z_n \neq a$ and $z_n \rightarrow a$. Given $\epsilon > 0$, there exists $\delta > 0$ such that $0 < |z - a| < \delta$ and $z \in A$ implies $|f(z) - \ell| < \epsilon$.

Also there exists N such that $n \geq N$ implies $0 < |z_n - a| < \delta$. Thus for $n \geq N$ we have $|f(z_n) - \ell| < \epsilon$, so $\lim_{n \rightarrow \infty} f(z_n) = \ell$.

Conversely, if $\lim_{z \rightarrow a} f(z)$ was not ℓ , then there would be some ϵ such that for every δ there is a $z \in A$ such that $0 < |z - a| < \delta$ but $|f(z) - \ell| \geq \epsilon$. Then taking $\delta = 1/n$ for each positive integer n we could construct a sequence $z_n \in A$ with $z_n \neq a$ where $0 < |z_n - a| < 1/n$ but $|f(z_n) - \ell| \geq \epsilon$ for all n . But then $z_n \rightarrow a$ and $f(z_n) \not\rightarrow \ell$, which is a contradiction. $\square$

In practice, which of these definitions is more useful will depend on context, however the sequences definition does allow us to use the results we developed at the start of this section.

Proposition 1.1.18 (Properties of Limits of Functions)

Let $A \subseteq \mathbb{C}$ and let a be a limit point of A . Then if $f, g : A \rightarrow \mathbb{C}$ are functions the following hold.

- (i) If $\lim_{z \rightarrow a} f(z) = \ell$ and $\lim_{z \rightarrow a} g(z) = m$, then $\lim_{z \rightarrow a} f(z) + g(z) = \ell + m$.
- (ii) If $\lim_{z \rightarrow a} f(z) = \ell$ then $\lim_{z \rightarrow a} cf(z) = c\ell$.
- (iii) If $\lim_{z \rightarrow a} f(z) = \ell$ and $\lim_{z \rightarrow a} g(z) = m$ then $\lim_{z \rightarrow a} f(z)g(z) = \ell m$.
- (iv) If $\lim_{z \rightarrow a} f(z) = \ell$ and $\ell \neq 0$ then $\lim_{z \rightarrow a} 1/f(z) = 1/\ell$.

Proof. These all follow directly from the sequence definition of limits along with [Proposition 1.1.5](#). □

§1.2 Infinite Series

The notion of convergence lets us talk quite sensibly about what it would mean to add up an infinite number of things, which is quite exciting.

§1.2.1 Convergent & Divergent Series

The definition of convergence for an infinite series is rather natural, and comes from considering the sequence of partial sums.

Definition 1.2.1 (Convergence of an Infinite Series)

For a sequence $a_j \in \mathbb{C}$, we say that the series $\sum_{j=1}^{\infty} a_j$ **converges** to S if the sequence of partial sums converges to S . That is, $\sum_{j=1}^n a_j \rightarrow S$ as $n \rightarrow \infty$. Otherwise we say that it **diverges**.

Remark (Notation). If a series converges, then we will typically write $\sum_{j=1}^{\infty} a_j = S$, but some care is needed as if the series does not converge then this is nonsense. We will also write S_n to denote the partial sum of a series, if it is clear from context what series is being referred to.

In this chapter we will be primarily concerned with finding ways to show whether a given series converges. But first, a few preliminaries.

Proposition 1.2.2 (Adding Series)

If two series converge, say $\sum_{j=1}^{\infty} a_j = a$ and $\sum_{j=1}^{\infty} b_j = b$, then $\sum_{j=1}^{\infty} (\lambda a_j + \mu b_j)$ also converges, and we have

$$\sum_{j=1}^{\infty} (\lambda a_j + \mu b_j) = \lambda a + \mu b.$$

Proof. Considering the sequence of partial sums we have

$$\sum_{j=1}^n (\lambda a_j + \mu b_j) = \lambda \sum_{j=1}^n a_j + \mu \sum_{j=1}^n b_j \longrightarrow \lambda a + \mu b$$

as $n \rightarrow \infty$, as required. $\square$

It should also be intuitively clear that the first few terms of an infinite series will not affect its convergence.

Proposition 1.2.3 (Ignoring Initial Terms)

Suppose there exists N such that $a_j = b_j$ for all $j \geq N$. Then either $\sum_{j=1}^{\infty} a_j$ and $\sum_{j=1}^{\infty} b_j$ both converge or they both diverge.

Proof. For $n \geq N$, we have $\sum_{j=1}^n a_n - \sum_{j=1}^n b_n = \sum_{j=1}^N a_n - \sum_{j=1}^N b_n$, which is a constant. Thus the sequences of partial sums either both converge or diverge. $\square$

We can also apply the general principle of convergence to infinite series. This gives us

another useful way of proving that a series converges, particularly when we don't know what the series converges to which is often the case.

Theorem 1.2.4 (General Principle of Convergence/Cauchy's Criterion for Series)

The infinite series $\sum_{j=1}^{\infty} a_j$ converges if and only if for every $\epsilon > 0$ there is an integer N such that for all $n, m \geq N$ we have $|\sum_{j=n}^m a_j| \leq \epsilon$.

Proof. This follows directly from the definition of the sequence of partial sums being Cauchy. $\square$

§1.2.2 Convergence Tests

In this section we will develop some 'tests' of convergence, so that given some infinite series we will have some tools to try and determine relatively quickly if it converges and diverges.

We begin with the observation that if the terms of the series do not tend to 0, then the series must diverge.

Proposition 1.2.5 (Limit of Terms in a Convergent Series)

Suppose that $\sum_{j=1}^{\infty} a_j$ converges. Then $a_j \rightarrow 0$ as $j \rightarrow \infty$.

Proof. Let $S_n = \sum_{j=1}^n a_j$. Then $S_n \rightarrow S$ for some S , and thus we must have $S_{n+1} \rightarrow S$. Adding these sequences we get $S_{n+1} - S_n \rightarrow 0$, that is, $a_{n+1} \rightarrow 0$ as $n \rightarrow \infty$ as required. $\square$

Somewhat unfortunately, while necessary this is not a sufficient condition for convergence. The most commonly cited counterexample to this is the Harmonic series.

Example 1.2.6 (Divergence of the Harmonic Series)

Consider the infinite series with $a_k = 1/k$. Then $a_k \rightarrow 0$, but $\sum_{k=1}^{\infty} a_k$ diverges.

To see this, let $H_n = \sum_{k=1}^n a_k$ be the partial sum of the series. Then we have

$$\begin{aligned} H_{2n} &= H_n + \frac{1}{n+1} + \frac{1}{n+2} + \cdots + \frac{1}{n+n} \\ &\geq H_n + \underbrace{\frac{1}{2n} + \frac{1}{2n} + \cdots + \frac{1}{2n}}_{n \text{ times}} = H_n + \frac{1}{2}. \end{aligned}$$

So if the series converged, we would have $H_n \rightarrow a$ and $H_{2n} \rightarrow a$, giving $a \geq a + 1/2$, which is a contradiction.

The result about the limit of terms in a series can be helpful though! For example, let's consider a series you are likely familiar with.

Example 1.2.7 (Convergence/Divergence of the Geometric Series)

Consider the infinite series $\sum_{j=1}^{\infty} x^{j-1}$. Writing it's partial sum as $S_n = \sum_{j=1}^n x^{j-1}$, A little bit of algebra gives us that

$$S_n = \begin{cases} \frac{1-x^n}{1-x} & \text{if } x \neq 1, \\ n & \text{if } x = 1. \end{cases}$$

So if $|x| < 1$, then $x^n \rightarrow 0$ and $S_n \rightarrow \frac{1}{1-x}$. Otherwise, if $|x| \geq 1$ then the series cannot converge since the terms do not tend to 0.

It's best to think of [Proposition 1.2.5](#) as giving the sort of a 'bare minimum' property that a series has to have in order to converge. Of course, it's also quite helpful for sanity checks!

Series of Non-Negative Terms

We just saw a necessary condition for convergence, now let's have a look at some *sufficient* conditions for convergence. For the time being we will restrict ourselves to considering infinite series where all of the terms are *real and non-negative*.

The first result we have is a direct consequence of our fundamental axiom.

Theorem 1.2.8 (Bounded Partial Sums)

If a_n is a non-negative sequence and the partial sums S_n are bounded above, then $\sum_{n=1}^{\infty} a_n$ converges.

Proof. Since all of the terms are non-negative, S_n is a bounded and increasing sequence, and thus converges by our fundamental axiom. $\square$

In a similar vein is the comparison test, which allows us to show convergence by comparing a series with another series whose convergence we know.

Theorem 1.2.9 (The Comparison Test)

Suppose that $0 \leq a_j \leq b_j$ for all j . Then if $\sum_{j=1}^{\infty} b_j$ converges, so does $\sum_{j=1}^{\infty} a_j$.

Proof. Since $B_n = \sum_{j=1}^n b_j$ is an increasing sequence whose limit is say B , we have $B_n \leq B$ for all n . Thus $\sum_{j=1}^n a_j \leq B_n \leq B$, so we have a series of non-negative terms whose partial sums are bounded. Thus $\sum_{j=1}^{\infty} a_n$ converges. $\square$

Example 1.2.10 (Using the Comparison Test)

We will prove that $\sum_{n=1}^{\infty} \frac{1}{n^2}$ converges using the comparison test.

Since $\frac{1}{n^2} < \frac{1}{n(n-1)}$ for $n \geq 2$, and $\sum_{n=2}^{\infty} \frac{1}{n(n-1)}$ converges as $\sum_{n=2}^N \frac{1}{n(n-1)} = 1 - \frac{1}{N} \rightarrow 1$ as $N \rightarrow \infty$, we get that $\sum_{n=1}^{\infty} \frac{1}{n^2}$ converges by comparison.

Using the comparison test we can derive two more useful tests, both of which come from comparing a series with the geometric series. You'll notice that the proofs for both results are relatively similar!

Theorem 1.2.11 (The Root Test)

Let a_n be a non-negative sequence and suppose $\sqrt[n]{a_n} \rightarrow a$ as $n \rightarrow \infty$. Then if $a < 1$, $\sum_{n=1}^{\infty} a_n$ converges, and if $a > 1$, $\sum_{n=1}^{\infty} a_n$ diverges.

Proof. If $a < 1$, we can choose b such that $a < b < 1$, and there exists an integer N such that for all $n \geq N$ we have $\sqrt[n]{a_n} < b$, that is, $a_n < b^n$. But then $\sum_{n=N}^{\infty} b^n$ converges since $b < 1$. Thus by comparison $\sum_{n=1}^{\infty} a_n$ converges too.

If $a > 1$, then for $n \geq N$ $\sqrt[n]{a_n} > 1$ implies that $a_n > 1$, but then the terms in the series do not tend to zero and thus $\sum_{n=1}^{\infty} a_n$ diverges. $\square$

Theorem 1.2.12 (The Ratio Test)

Let a_n be a non-negative sequence and suppose that $\frac{a_{n+1}}{a_n} \rightarrow \ell$ as $n \rightarrow \infty$. Then if $\ell < 1$, $\sum_{n=1}^{\infty} a_n$ converges, and if $\ell > 1$, $\sum_{n=1}^{\infty} a_n$ diverges.

Proof. If $\ell < 1$, we can choose b such that $\ell < b < 1$, and there exists an integer N such that $\frac{a_{n+1}}{a_n} < b$ for all $n \geq N$. Therefore

$$\begin{aligned} a_n &= \frac{a_n}{a_{n-1}} \cdot \frac{a_{n-1}}{a_{n-2}} \cdots \frac{a_{N+1}}{a_N} \cdot a_N \\ &< (a_N b^{-N}) b^n, \end{aligned}$$

for $n > N$. But then $\sum_{n=N+1}^{\infty} b^n$ converges as $b < 1$, and since $a_N b^{-N}$ is a constant, $\sum_{n=1}^{\infty} a_n$ converges by comparison.

If $\ell > 1$, then $a_{n+1} > a_n$ and the terms in the series do not tend to zero and thus $\sum_{n=1}^{\infty} a_n$ diverges. $\square$

Remark (A Deadly Sin). In both the root and ratio test, if we find that either $a = 1$ or $\ell = 1$, we *cannot draw any conclusions about the convergence of the series*. To see this, consider $\sum \frac{1}{n}$ and $\sum \frac{1}{n^2}$.

Some examples of using the root and ratio tests are shown below, but we won't do too many since there's a most likely a few already on your example sheets (and there's not really much to the basic technique).

Example 1.2.13 (Using the Ratio Test)

We will prove that $\sum_{n=1}^{\infty} \frac{n}{2^n}$ converges using the ratio test.

Let $a_n = n/2^n$. Then we have $\frac{a_{n+1}}{a_n} = \frac{n+1}{2^{n+1}} \cdot \frac{2^n}{n} = \frac{n+1}{2n}$, and thus $\frac{a_{n+1}}{a_n} \rightarrow \frac{1}{2} < 1$ as $n \rightarrow \infty$. Then by the ratio test $\sum_{n=1}^{\infty} \frac{n}{2^n}$ converges.

Example 1.2.14 (Using the Root Test)

We will prove that $\sum_{n=1}^{\infty} \left(\frac{n+1}{3n+5}\right)^n$ converges using the root test.

Let $a_n = \left(\frac{n+1}{3n+5}\right)^n$. Then $\sqrt[n]{a_n} = \frac{n+1}{3n+5}$, and thus $\sqrt[n]{a_n} \rightarrow \frac{1}{3}$ as $n \rightarrow \infty$. Then by the

root test $\sum_{n=1}^{\infty} \left(\frac{n+1}{3n+5}\right)^n$ converges.

In the case that we have our sequence of non-negative terms is decreasing, we can determine the convergence by looking at a related series involving a relatively small subsequence of terms.

Theorem 1.2.15 (Cauchy's Condensation Test)

If a_n is a decreasing sequence of positive numbers, then $\sum_{n=1}^{\infty} a_n$ and $\sum_{n=0}^{\infty} 2^n a_{2^n}$ either both converge or both diverge.

Proof. It suffices to show that the partial sums of both series are either both bounded or both unbounded. Let $S_n = \sum_{j=1}^n a_j$ and $T_n = \sum_{j=0}^n 2^j a_{2^j}$ be the partial sums of each series.

If $n < 2^k$ we have

$$\begin{aligned} S_n &\leq a_1 + (a_2 + a_3) + \cdots + (a_{2^k} + \cdots + a_{2^{k+1}-1}) \\ &\leq a_1 + 2a_2 + \cdots + 2^k a_{2^k} = T_k, \end{aligned}$$

thus $S_n \leq T_k$. So if T_n is bounded so is S_n . Also if $n > 2^k$, we have

$$\begin{aligned} S_n &\geq a_1 + a_2 + (a_3 + a_4) + \cdots + (a_{2^{k-1}+1} + \cdots + a_{2^k}) \\ &\geq \frac{1}{2}a_1 + a_2 + 2a_4 + \cdots + 2^{k-1}a_{2^k} = \frac{1}{2}T_k, \end{aligned}$$

so $2S_n \geq T_k$. So if S_n is bounded so is T_k . Thus S_n and T_n are either both bounded or both unbounded. $\square$

You may notice that this proof somewhat resembles our proof that the harmonic series diverges, and indeed you can show the following stronger result.

Theorem 1.2.16 (Convergence of $\sum n^{-\alpha}$)

$\sum_{n=1}^{\infty} \frac{1}{n^\alpha}$ converges if and only if $\alpha > 1$.

Proof. If $\alpha \leq 0$ then the terms in the series do not tend to zero, so the series diverges. So for $\alpha > 0$ we apply Cauchy's condensation test. This series converges if and only if the series

$$\sum_{k=0}^{\infty} 2^k \cdot \frac{1}{2^{\alpha k}} = \sum_{k=0}^{\infty} 2^{(1-\alpha)k}$$

converges. By comparison with the geometric series, this will converge if and only if $2^{1-\alpha} < 1$, that is, $\alpha > 1$. $\square$

In a way Cauchy's condensation test is slightly different to the others convergence tests since it just gives us a different series that may be easier to show convergence or divergence for.

Still, it is natural to reach for Cauchy's condensation test when the root or ratio tests fail. For example, all of the series below cannot be shown to converge or diverge using

the root or ratio tests:

$$\sum_{n=1}^{\infty} \frac{1}{n^{\alpha}}, \quad \sum_{n=2}^{\infty} \frac{1}{n \log n}, \quad \sum_{n=2}^{\infty} \frac{1}{(\log n)^2}, \quad \sum_{n=2}^{\infty} \frac{1}{n(\log n)^2}, \quad \text{and} \quad \sum_{n=2}^{\infty} \frac{\log n}{n^2}.$$

If you try, you will find that these tests are inconclusive. However, all can be shown to converge/diverge using Cauchy's condensation test.²

Alternating Series

We will now look at a convergence test for series whose terms alternate from positive to negative.

Theorem 1.2.17 (Alternating Series Test)

If a_n is a decreasing sequence of positive numbers with $a_n \rightarrow 0$ as $n \rightarrow \infty$ then $\sum_{j=1}^{\infty} (-1)^{j+1} a_j$ converges.

Proof. Let $S_n = \sum_{j=1}^n (-1)^{j+1} a_j$ denote the partial sum of the series. Then $S_{2n} = S_{2n-2} + (a_{2n-1} - a_{2n}) \geq S_{2n-2}$. Also

$$S_{2n} = a_1 - (a_2 - a_3) - \cdots - (a_{2n-2} - a_{2n-1}) - a_{2n} \leq a_1.$$

Therefore S_{2n} is increasing and bounded above, and thus converges. Now let $S_{2n} \rightarrow S$ as $n \rightarrow \infty$. Then $S_{2n+1} = S_{2n} + a_{2n+1} \rightarrow S + 0 = S$ as $n \rightarrow \infty$. Thus $S_n \rightarrow S$, and $\sum_{j=1}^{\infty} (-1)^{j+1} a_j$ converges. $\square$

Example 1.2.18

We will prove that $\sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n}$ converges using the alternating series test.^a

We note that $\frac{1}{n}$ is a decreasing sequence of positive numbers with $\frac{1}{n} \rightarrow 0$. Thus by the alternating series test $\sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n}$ converges.

^aLater on we will see that this is equal to $\log 2$.

§1.2.3 Absolute Convergence

To finish our discussion on infinite series (for now!) we will introduce the stronger notion of *absolute convergence*. The main motivation for introducing this will become clear as we develop some of the properties of absolute convergence, but informally knowing that a series converges absolutely will allow us to be a little less careful when working with the series.

Definition 1.2.19 (Absolute Convergence)

For some sequence $a_n \in \mathbb{C}$, we say that the series $\sum_{n=1}^{\infty} a_n$ converges **absolutely** if the series $\sum_{n=1}^{\infty} |a_n|$ converges.

²You could also use the integration test (which we have not discussed), but that's most likely going to be slower as you have to integrate things.

We can see that absolute convergence is a strictly stronger property than ‘regular’ convergence. Indeed absolute convergence implies convergence, but not the other way round.

Theorem 1.2.20 (Absolute Convergence Implies Convergence)

If $\sum_{j=1}^{\infty} a_j$ converges absolutely then it converges.

Proof. By the triangle inequality we have

$$\left| \sum_{j=n}^m a_j \right| \leq \sum_{j=n}^m |a_j|,$$

and thus by Cauchy’s criterion $\sum_{j=1}^{\infty} a_j$ converges. $\square$

To see that the converse isn’t true (and that indeed it is a strictly stronger notion), consider the series $\sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n}$, which converges but does not converge absolutely. We sometimes say such series converge **conditionally**.

When trying to determine whether a series converges absolutely, since $|a_n| \geq 0$ we are free to apply all of the results that we developed in the previous subsection. We will see this in the next example.

Example 1.2.21 (Showing Absolute Convergence)

Consider the infinite series $\sum_{n=1}^{\infty} z^n/2^n$. We will determine for which values of z this infinite series converges absolutely.

By the root test, we know that $\sum_{n=1}^{\infty} |z^n/2^n|$ converges if $|z| < 2$ and diverges if $|z| > 2$. Also for $|z| = 2$ we can see that the terms of the series do not go to zero, so the series diverges.

Thus $\sum_{n=1}^{\infty} z^n/2^n$ converges absolutely for $|z| < 2$ and diverges for $|z| \geq 2$.

Now it was claimed at the start of this subsection that absolute convergence allows us to be a ‘little less careful’. Allow me to elaborate on this.

In general, *you must be very careful when manipulating infinite series*. To see why, consider this informal example.

$$\begin{aligned} 1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \frac{1}{5} - \frac{1}{6} + \cdots &= \log 2 \\ 1 + \frac{1}{3} - \frac{1}{2} + \frac{1}{5} + \frac{1}{7} - \frac{1}{4} + \cdots &= \frac{3}{2} \log 2 \end{aligned}$$

The two series above both converge, and they both have all of the same terms. The only difference is that the terms are in a different order, and this change has completely altered the value of the series.

What’s nice about absolutely convergent series is that *we don’t have to worry about this*.

Definition 1.2.22 (Rearrangement)

A **rearrangement** of the series $\sum_{n=1}^{\infty} a_n$ is another series $\sum_{n=1}^{\infty} a_{\sigma(n)}$, where $\sigma : \mathbb{N} \rightarrow \mathbb{N}$ is a bijection.

Theorem 1.2.23 (Rearranging Absolutely Convergent Series)

If $\sum_{j=1}^{\infty} a_j$ is absolutely convergent then any rearrangement of the series will converge to the same value.

Proof. Let $\sum_{j=1}^{\infty} a_{\sigma(j)}$ be a rearrangement of the series. Given $\epsilon > 0$, we wish to show that there exists an integer N such that $|\sum_{j=1}^{\infty} a_j - \sum_{j=1}^n a_{\sigma(j)}| < \epsilon$ for all $n \geq N$.

By Cauchy's criterion there exists an integer m such that $\sum_{j=m+1}^{\infty} |a_j| < \epsilon$. We then choose N such that $\{a_1, a_2, \dots, a_m\} \subseteq \{a_{\sigma(1)}, a_{\sigma(2)}, \dots, a_{\sigma(N)}\}$. This can be done by setting $N = \max_{1 \leq i \leq m} \sigma^{-1}(i)$. Then if $n \geq N$ we have

$$\sum_{j=1}^{\infty} a_j - \sum_{j=1}^n a_{\sigma(j)} = \sum_{j \in A_n} a_j,$$

where $A_n \subseteq \{m+1, m+2, \dots\}$. Then applying the triangle inequality we have

$$\left| \sum_{j=1}^{\infty} a_j - \sum_{j=1}^n a_{\sigma(j)} \right| = \left| \sum_{j \in A_n} a_j \right| \leq \left| \sum_{j=m+1}^{\infty} a_j \right| \leq \sum_{j=m+1}^{\infty} |a_j| < \epsilon,$$

as required. □

To see just how not-true this is for series that do not converge absolutely, we just need to read the statement of Riemann's Rearrangement Theorem.

Theorem 1.2.24 (Riemann's Rearrangement Theorem)

Let $a_j \in \mathbb{R}$. Suppose that $\sum_{j=1}^{\infty} a_j$ is convergent but not absolutely convergent. Then given any $x \in \mathbb{R}$ there is a rearrangement of this series such that $\sum_{j=1}^{\infty} a_{\sigma(j)} = x$.

Proof. Left as an exercise – it's on the example sheet! □

§1.3 Continuity

The next idea we will develop is that of ‘continuity’.

§1.3.1 Continuity of Functions

Continuity is all about the behaviour of a function around a point. For a function to be continuous at some x , we need $f(y)$ to be close to $f(x)$ whenever y is sufficiently close to x .

Definition 1.3.1 (Continuity)

Let $A \subseteq \mathbb{C}$ and $f : A \rightarrow \mathbb{C}$. We say that f is **continuous at** $a \in A$ if given any $\epsilon > 0$ we can find a $\delta > 0$ such that $|f(x) - f(y)| < \epsilon$ for all $y \in A$ such that $|x - y| < \delta$.

We say that f is **continuous** if it is continuous at every $a \in A$.

You may notice that this definition uses exactly the definition of the limit of a function mentioned in [subsection 1.1.4](#). This immediately gives us two more equivalent definitions of continuity.

Proposition 1.3.2 (Limit Definition of Continuity)

Let $f : A \rightarrow \mathbb{C}$. Then f is continuous at $a \in A$ if and only if $\lim_{z \rightarrow a} f(z) = f(a)$.

Proposition 1.3.3 (Sequence Definition of Continuity)

Let $f : A \rightarrow \mathbb{C}$. Then f is continuous at $a \in A$ if and only if for every sequence $a_n \in A$ with $a_n \rightarrow a$ we have $f(a_n) \rightarrow f(a)$.

Each of the definitions have various advantages or disadvantages. Still it is worth noting that the sequential/limit continuity definitions can be used to quite easily show certain properties of continuity that would otherwise be quite fiddly with the ϵ - δ definition. Using sequential continuity is also a natural way to show that a function *is not* continuous at a point. Let’s take a look at some examples.

Example 1.3.4 (The Constant Function is Continuous)

If $f(x) = c$ then f is continuous. To see this, we can take any value of δ in the definition.

Example 1.3.5 ($f(x) = x$ is Continuous)

If $f(x) = x$ then f is continuous. To see this, we can take $\delta = \epsilon$ in the definition.

Example 1.3.6 (Step Functions are Discontinuous)

Consider the function $f : \mathbb{R} \rightarrow \mathbb{R}$ with

$$f(x) = \begin{cases} -1 & \text{if } x < 1, \\ 1 & \text{if } x \geq 1. \end{cases}$$

This function is not continuous at 1. To see this, note that $1 - 1/n \rightarrow 1$ but $f(1 - 1/n) \rightarrow -1 \neq f(1)$ as $n \rightarrow \infty$.

Example 1.3.7 (The Domain Matters)

Consider the function $f : \mathbb{Q} \rightarrow \mathbb{R}$ with

$$\begin{cases} 1 & \text{if } x^2 > 2, \\ 0 & \text{if } x^2 < 2. \end{cases}$$

This function is continuous, since for every $a \in \mathbb{Q}$ there is an interval about a for which f is constant, so f is continuous at a . If f was defined on $\mathbb{R}$ instead of $\mathbb{Q}$, then it would be discontinuous only at $\pm\sqrt{2}$. But these points are not in our domain, so we don't need to worry about them.

Example 1.3.8 (Continuity of $\sin 1/x$)

Consider the function^a $f : \mathbb{R} \rightarrow \mathbb{R}$ with $f(x) = \sin(1/x)$ if $x \neq 0$ and $f(0) = 0$.

This function is not continuous at $x = 0$. To see this, consider the sequence $a_n = \frac{1}{2\pi n + \pi/2}$. Then $a_n \rightarrow 0$, but $f(a_n) = 1 \rightarrow 1 \neq f(0)$ as $n \rightarrow \infty$.

^aI know that we haven't defined what $\sin$ is, but we will use it in examples because they are instructive. If this bothers you, feel free to come back after our discussion of power series.

Example 1.3.9 (A Functional Equation with Continuity)

We wish to find all continuous functions $f : \mathbb{R} \rightarrow \mathbb{R}$ such that $f(x) + f(2x) = 0$.

Letting $x = 0$ we get $f(0) = 0$. Then rearranging we have $f(x) = -f(x/2)$, and repeatedly using this gives

$$f(x) = -f\left(\frac{x}{2}\right) = f\left(\frac{x}{4}\right) = -f\left(\frac{x}{8}\right) = \cdots = (-1)^n f\left(\frac{x}{2^n}\right).$$

Then since f is continuous we have $f(x) = \lim_{n \rightarrow \infty} (-1)^n f(x/2^n) = f(0) = 0$. Thus $f(x) = 0$ is the only such function, which clearly works.

When attempting to determine if a function is continuous, one should keep in mind the following properties of continuity (all of which follow directly from our basic properties of limits).

Proposition 1.3.10 (Sums, Products and Reciprocals of Continuous Functions)

Let $f, g : A \rightarrow \mathbb{C}$ be functions. Then the following hold.

- (i) If f and g are continuous at a , then so is their sum $f + g$.
- (ii) If f and g are continuous at a , then so is their product fg .
- (iii) If f is continuous at a and $f(a) \neq 0$ then so is $1/f$.

Proof. We prove each individually using the limit definition of continuity.

- (i) If $\lim_{z \rightarrow a} f(z) = f(a)$ and $\lim_{z \rightarrow a} g(z) = g(a)$ then $\lim_{z \rightarrow a} (f + g)(z) = (f + g)(a)$.
- (ii) If $\lim_{z \rightarrow a} f(z) = f(a)$ and $\lim_{z \rightarrow a} g(z) = g(a)$ then $\lim_{z \rightarrow a} (fg)(z) = (fg)(a)$.
- (iii) If $\lim_{z \rightarrow a} f(z) = f(a)$ and $f(a) \neq 0$, then $\lim_{z \rightarrow a} 1/f(z) = 1/f(a)$. □

Along with the fact that $f(x) = x$ and $f(x) = c$ are continuous, these properties imply that all polynomials are continuous.

Proposition 1.3.11 (The Composition of Continuous Functions is Continuous)

Let $f : A \rightarrow B$ and $g : B \rightarrow \mathbb{C}$ with $A, B \subseteq \mathbb{C}$. Then if f is continuous at $a \in A$ and g is continuous at $f(a)$, then $g \circ f$ is also continuous at a .

Proof. If $a_n \rightarrow a$ then by the continuity of f we have $f(a_n) \rightarrow f(a)$, and by the continuity of g we have $g(f(a_n)) \rightarrow g(f(a))$. So $g \circ f$ is continuous at a . □

§1.3.2 The Intermediate Value Theorem

Continuous functions are nice because they have a few nice properties. The first of these that we will prove is the *intermediate value theorem*, a central theorem in elementary analysis. The idea of the intermediate value theorem is that if a continuous function starts at one value and ends at a different value, then it must take on all of the values in between.

In the proof below we will employ suprema³, but we will give another proof afterwards that does not use this (at the expense of being slightly longer).

Theorem 1.3.12 (The Intermediate Value Theorem)

Let $f : [a, b] \rightarrow \mathbb{R}$ be a continuous function. Then for every t between $f(a)$ and $f(b)$ there is an $c \in [a, b]$ with $f(c) = t$.

Proof. Suppose without loss of generality^a that $f(a) < t < f(b)$. Consider the set $S = \{x \in [a, b] : f(x) < t\}$. This set is bounded and since $a \in S$ it is non-empty. So we can let $c = \sup S$, and note that $a \leq c \leq b$.

Let $n \geq 1$ be an integer. Then since c is the supremum there must exist some $x_n \in S$ such that $c - \frac{1}{n} < x_n \leq c$. By the squeeze theorem we have $x_n \rightarrow c$ as $n \rightarrow \infty$. Also f is continuous so $f(x_n) \rightarrow f(c)$. We also constructed x_n to be in S , giving $f(x_n) < t$ for all n . This implies that $f(c) \leq t$.

We know that $c \in [a, b]$ but $c \neq b$, so there is some integer N such that for $n \geq N$ we have $c + 1/n \leq b$. Using that c is the supremum, we have $c + 1/n \notin S$ for all $n \geq N$, that is, $f(c + 1/n) \geq t$ for all $n \geq N$. Then by continuity we have $f(c) \geq t$.

But then $f(c) \geq t$ and $f(c) \leq t$, so we must have $f(c) = t$. $\square$

^aIf $t = f(a)$ or $t = f(b)$ then we are done. Also the case $f(a) > t > f(b)$ follows similarly.

Before we look at some examples of using the intermediate value theorem, there's a few things worth noting about the intermediate value theorem.

First of all, we say absolutely nothing about uniqueness in the theorem. It is very much possible for a function to take on an intermediate value multiple times. Second of all, when applying the intermediate value theorem (commonly abbreviated to IVT) a good general problem solving technique is trying to apply IVT to other related functions such as $g(x) = f(x) - x$ or $g(x) = f(x) - t$ and things like that. You will see this 'trick' show up in the examples below, and also again when we get to Rolle's theorem and the mean value theorem.

Example 1.3.13 (Fixed Points of Continuous Maps from $[0, 1]$ to Itself)

We will prove that if $f : [0, 1] \rightarrow [0, 1]$ is a continuous function then there is some $c \in [0, 1]$ such that $f(c) = c$.

Consider the function $g(x) = f(x) - x$. Then g is continuous with $g(0) = f(0)$ and $g(1) = f(1) - 1$. Since $0 \leq f(x) \leq 1$, we must have $g(0) \geq 0$ and $g(1) \leq 0$. Thus by

³If you are unfamiliar with this term and/or the least upper bound principle, feel free to have a look at Chapter 2 of my 'Numbers and Sets' course notes.

the intermediate value theorem there exists some $c \in [0, 1]$ such that $g(c) = 0$. But then we have $f(c) - c = 0$, that is, $f(c) = c$ as required.

Example 1.3.14 (Existence n th Roots)

We will show that for any positive integer n and $y > 0$ there exists a real number x such that $x^n = y$.

Consider the function $f(x) = x^n$. This function is continuous on $[0, 1 + y]$, and since $f(0) = 0$ and $f(1 + y) = (1 + y)^n$, we have $f(0) < y < f(1 + y)$. Thus by the intermediate value theorem there is some $x \in [0, 1 + y]$ such that $f(x) = y$, that is, $x^n = y$.

Now before we look on let's have a look at an alternative proof for the intermediate value theorem. This proof uses the same idea as the previous proof (try to see why) but avoids the use of suprema.

Aside: Hunting For Lions Intermediate Values

It was mentioned before that the ‘lion hunting’ technique that we used to prove the Bolzano–Weierstrass theorem could also be used to prove other theorems in Analysis. One such example is the intermediate value theorem.

The steps in the proof are quite similar to that of the proof of the Bolzano–Weierstrass theorem, the only difference is what we are ‘hunting for’, which in this case is our intermediate value, and how we finish off the proof.

Proof (Intermediate Value Theorem, Lion Hunting Style). Again suppose without loss of generality that $f(a) < t < f(b)$. We are going to define two sequences a_n and b_n inductively as follows. Begin by setting $a_1 = a$ and $b_1 = b$, and let $c = (a_1 + b_1)/2$ be the midpoint a_1 and b_1 .

Then there is two possibilities:

1. $f(c_1) \geq t$.
2. $f(c_1) < t$.

If the first one holds, we set $a_2 = a_1$ and $b_2 = c_1$, and if it doesn't then we set $a_2 = c_1$ and $b_2 = b_1$. Repeating this process, we construct a_n and b_n such that $f(a_n) \leq t \leq f(b_n)$, $a_{n-1} \leq a_n \leq b_n \leq b_{n-1}$, and also $b_n - a_n = (b_{n-1} - a_{n-1})/2$.

Now a_n is increasing and bounded above, and b_n is decreasing and bounded below and thus $a_n \rightarrow c \in [a, b]$, and $b_n \rightarrow c' \in [a, b]$. Then we have $c - c' = (c - c')/2$ using the above result, and thus $c = c'$.

Since f is continuous at c and $a_n \rightarrow c$, we know that $f(a_n) \rightarrow f(c)$ as $n \rightarrow \infty$. Since $f(a_n) \leq t$, we also know that $f(c) \leq t$. Similarly we also have $f(b_n) \geq t$, so $f(c) \geq t$. But then $t \leq f(c) \leq t$, and thus $f(c) = t$, and we are done. $\square$

To get a feel for the construction, try drawing a rough sketch of the process. If you consider the case of a function that takes on the desired intermediate value multiple times, you should also see that this proof does not give the same value for c as the

previous proof.

A natural question upon learning of the intermediate value theorem is if it is equivalent to definition of continuity. The answer to this question is no – there are functions that have the ‘intermediate value property’, without being continuous. One example is $\sin(1/x)$ which we showed is discontinuous at $x = 0$ in [Example 1.3.8](#). Another more elaborate example is ‘Conway’s Base-13 Function’, which has the intermediate value property but is discontinuous everywhere. You can read more about this function on [Wikipedia](#).

§1.3.3 The Boundedness Theorem

The last result about continuous functions that we will prove is the *boundedness theorem*, another central theorem in elementary analysis. The statement of this result is straightforward: a continuous function on a closed bounded interval is bounded and attains its bounds.

First we will prove that a continuous function defined on some closed interval is indeed bounded.

Lemma 1.3.15 (Continuous Function on Closed Interval is Bounded)

If $f : [a, b] \rightarrow \mathbb{R}$ is continuous then there exists K such that $|f(x)| \leq K$ for all $x \in [a, b]$.

Proof. If f was unbounded, then given any integer $n \geq 1$ there exists $x_n \in [a, b]$ such that $|f(x_n)| > n$. By Bolzano–Weierstrass, x_n has a convergent subsequence $x_{n_j} \rightarrow x$. Also since $a \leq x \leq b$, we must have $x \in [a, b]$. By continuity of f , $f(x_{n_j}) \rightarrow f(x)$, but $|f(x_{n_j})| > n_j$, and thus does not tend to a limit. Thus we have a contradiction. $\square$

Now we can prove that such a continuous function attains its bounds, giving us the boundedness theorem.

Theorem 1.3.16 (Boundedness Theorem)

If $f : [a, b] \rightarrow \mathbb{R}$ is continuous then there exists $x_1, x_2 \in [a, b]$ such that $f(x_1) \leq f(x) \leq f(x_2)$ for all $x \in [a, b]$.

Proof. By our previous lemma, we know that f is bounded. Now we define the set

$$A = \{f(x) : x \in [a, b]\}.$$

This set is bounded and non-empty and thus has a supremum $M = \sup A$. Then for each positive integer n , $M - 1/n$ cannot be an upper bound for A . This implies that there is some $x_n \in [a, b]$ such that $M - 1/n < f(x_n) \leq M$.

By Bolzano–Weierstrass, x_n has a convergent subsequence $x_{n_j} \rightarrow x$. Since $a \leq x_n \leq b$, we know $a \leq x \leq b$. By the continuity of f , $f(x_{n_j}) \rightarrow f(x)$, but $f(x_{n_j}) \rightarrow M$ by construction. So $f(x) = M$. So $x_2 = x$. The minimum follows analogously. $\square$

Alternate Proof. As before, let $M = \sup A$ and suppose that there was no x_2 such

that $f(x_2) = M$. Then let $g(x) = \frac{1}{M-f(x)}$ for $x \in [a, b]$. This function is well defined and continuous. Now g must be bounded by the previous lemma, so $g(x) \leq K$ for all $x \in [a, b]$, for some K . This means that $f(x) \leq M - 1/k$ on $[a, b]$. This is contradiction since we set M as the supremum. $\square$

§1.4 Differentiability

You are likely familiar with differentiability (and particularly the computation of derivatives) from calculus. While this knowledge should certainly not be disregarded, we are going to go from the beginning, doing everything with a little more care than it got in calculus. Throughout this section we will deal with functions $f : A \subseteq \mathbb{R} \rightarrow \mathbb{R}$, though the basic definitions will apply to $\mathbb{C}$.⁴

Here's our basic definition:

Definition 1.4.1 (Differentiability)

Let $A \subseteq \mathbb{R}$ and $f : A \rightarrow \mathbb{R}$. Then if x is a limit point of A , we say that f is **differentiable at x** with derivative $f'(x)$ if

$$\lim_{h \rightarrow 0} \frac{f(x+h) - f(x)}{h} = f'(x).$$

We say that f is **differentiable** on A if f is differentiable at every $x \in A$.

Let's pause for a moment. The core idea of differentiation is we want to *approximate a function around some point using a linear map*⁵. Indeed, our definition of the derivative is directly equivalent to the following: f is differentiable at x if

$$f(x+h) = f(x) + f'(x)h + \varepsilon(h),$$

where $\lim_{h \rightarrow 0} \varepsilon(h)/h = 0$. That is, it is differentiable if we can approximate the function with some linear map where the error decreases faster than linearly.

§1.4.1 Properties of Differentiable Functions

With that spiel over, we can move on to some properties of differentiable functions. The first is that differentiability implies continuity.

Proposition 1.4.2 (Differentiability Implies Continuity)

If f is differentiable at x , then f is continuous at x .

Proof. Using the limit definition of continuity we have

$$\lim_{h \rightarrow 0} [f(x+h) - f(x)] = \lim_{h \rightarrow 0} \frac{f(x+h) - f(x)}{h} \cdot (h) = f'(x) \cdot 0 = 0,$$

thus $\lim_{h \rightarrow 0} f(x+h) = f(x)$, so f is continuous at x . □

Now we can prove some basic rules for computing derivatives.

⁴We will use differentiation over $\mathbb{C}$ in our discussion of power series though. One should also note that the other basic rules such as the sum, product and chain rules will also hold over $\mathbb{C}$, but being differentiable over $\mathbb{C}$ is a stronger condition than being differentiable over $\mathbb{R}$ or $\mathbb{R}^2$. For example, consider $f(z) = \bar{z}$, which is not complex differentiable.

⁵Indeed it is which this idea, not really that of 'the tangent to a curve' that is used to generalise the derivative to functions of multiple variables. Of course they are closely related.

Proposition 1.4.3 (Sum, Product & Quotient Rules)

Suppose that $f : \mathbb{R} \rightarrow \mathbb{R}$ and $g : \mathbb{R} \rightarrow \mathbb{R}$ are differentiable at x with derivatives $f'(x)$ and $g'(x)$. Then the following hold.

- (i) $f + g$ is differentiable at x , with $(f + g)'(x) = f'(x) + g'(x)$,
- (ii) fg is differentiable at x , with $(fg)'(x) = f'(x)g(x) + f(x)g'(x)$,
- (iii) If $g'(x) \neq 0$ then f/g is differentiable at x , with $(f/g)'(x) = \frac{g(x)f'(x) - g'(x)f(x)}{g^2(x)}$.

Proof. We prove each individually.

(i) This follows from the sum of limits.

(ii) We have by the continuity of f

$$\begin{aligned} & \lim_{h \rightarrow 0} \frac{f(x+h)g(x+h) - f(x)g(x)}{h} \\ &= \lim_{h \rightarrow 0} \left[f(x+h) \frac{g(x+h) - g(x)}{h} + g(x) \frac{f(x+h) - f(x)}{h} \right], \end{aligned}$$

and by the continuity of f and g at x we have $(fg)'(x) = f(x)g'(x) + f'(x)g(x)$.

(iii) Similarly we have

$$\begin{aligned} & \lim_{h \rightarrow 0} \frac{f(x+h)/g(x+h) - f(x)/g(x)}{h} \\ &= \lim_{h \rightarrow 0} \frac{1}{g(x)g(x+h)} \left[g(x) \frac{f(x+h) - f(x)}{h} - f(x) \frac{g(x+h) - g(x)}{h} \right], \end{aligned}$$

and by the continuity of f and g we have $(f/g)'(x) = \frac{g(x)f'(x) - g'(x)f(x)}{g^2(x)}$. $\square$

We will now prove the chain rule, which tells us how to compute the derivative of the composition of functions. Unfortunately this proof is quite ‘tricky’, and trying to do something like we did in the proof above will not work. Instead, we need to return to our equivalent definition of differentiability, with $f(x+h) = f(x) + f'(x)h + \varepsilon_f(h)$, where $\lim_{h \rightarrow 0} \varepsilon_f(h)/h = 0$.

Proposition 1.4.4 (Chain Rule)

Suppose $f : \mathbb{R} \rightarrow \mathbb{R}$ is differentiable at x and $g : \mathbb{R} \rightarrow \mathbb{R}$ is differentiable at $f(x)$. Then $g \circ f$ is differentiable at x with $(g \circ f)'(x) = g'(f(x)) \cdot f'(x)$.

Proof. We have

$$\begin{aligned} f(x+h) &= f(x) + f'(x)h + \varepsilon_f(h) \\ g(f(x) + h) &= g(f(x)) + g'(f(x))h + \varepsilon_g(h), \end{aligned}$$

where $\varepsilon_f(h)/h, \varepsilon_g(h)/h \rightarrow 0$ as $h \rightarrow 0$. From this we obtain

$$g(f(x+h)) = g(f(x) + f'(x)h + \varepsilon_f(h))$$

$$= g(f(x)) + g'(f(x))(f'(x)h + \varepsilon_f(h)) + \varepsilon_g(f'(x)h + \varepsilon_f(h)).$$

Rearranging we get

$$\begin{aligned} & \lim_{h \rightarrow 0} \frac{g(f(x+h)) - g(f(x))}{h} \\ &= \lim_{h \rightarrow 0} \frac{g'(f(x))(f'(x)h + \varepsilon_f(h)) + \varepsilon_g(f'(x)h + \varepsilon_f(h))}{h} \\ &= g'(f(x))f'(x) + \lim_{h \rightarrow 0} g'(f(x)) \frac{\varepsilon_f(h)}{h} + \lim_{h \rightarrow 0} \frac{\varepsilon_g(f'(x)h + \varepsilon_f(h))}{h}. \end{aligned}$$

Then as $h \rightarrow 0$ we have $\varepsilon_f(h)/h \rightarrow 0$ and $f'(x)h + \varepsilon_f(h) \rightarrow 0$ so $\varepsilon_g(f'(x)h + \varepsilon_f(h))/h \rightarrow 0$, and thus we have $(g \circ f)'(x) = g'(f(x))f'(x)$. $\square$

Example 1.4.5 (Using the Chain Rule)

Let $f(x) = \sin(x^2)$. Then since $(\sin x)' = \cos x$ we have $f'(x) = 2x \cos(x^2)$.

Example 1.4.6 (A Continuous Everywhere But Non-Differentiable Function)

Consider the function $f(x) = x \sin(1/x)$ when $x \neq 0$, and $f(0) = 0$. This function is continuous everywhere^a, but we will show that it is not differentiable at $x = 0$.

At $x \neq 0$ this is differentiable by the chain rule, but at $x = 0$ we would need the following limit to exist:

$$\lim_{h \rightarrow 0} \frac{(0+h) \sin\left(\frac{1}{x+h}\right) - 0 \sin\left(\frac{1}{x}\right)}{h} = \lim_{h \rightarrow 0} \sin\left(\frac{1}{h}\right),$$

but this limit does not exist (a similar construction to [Example 1.3.8](#) will show this), and thus f is not differentiable at $x = 0$.

^aFeel free to check this!

Now in the example above we have a continuous everywhere function that's not differentiable at 0. A related example is one of a function that is differentiable everywhere (and hence continuous), but whose derivative is discontinuous.

Example 1.4.7 (A Function with Discontinuous Derivative)

Consider the function $f(x) = x^2 \sin(1/x)$ when $x \neq 0$ and $f(0) = 0$.

For $x \neq 0$ we have that f is differentiable by the chain rule, and the derivative is given by

$$f'(x) = x \sin\left(\frac{1}{x}\right) + \cos\left(\frac{1}{x}\right).$$

For $x = 0$, we compute the derivative directly. We have

$$f'(0) = \lim_{h \rightarrow 0} \frac{f(0+h) - f(0)}{h} = \lim_{h \rightarrow 0} \frac{h^2 \sin\left(\frac{1}{h}\right)}{h} = 0.$$

Thus we can see that f' is not continuous, since $f'(x) \not\rightarrow 0$ as $x \rightarrow 0$ (as $\cos 1/x$ is not continuous).

There is however a limit as to how discontinuous a derivative can be. In particular the derivative of a differentiable function must have the intermediate value property.

Theorem 1.4.8 (Darboux's Theorem)

If $f : \mathbb{R} \rightarrow \mathbb{R}$ is differentiable then f' has the intermediate value property. That is to say, if $a < b$ and $f'(a) < z < f'(b)$ then there exists $c \in (a, b)$ with $f'(c) = z$.

Proof. Given $a < b$ and $z \in \mathbb{R}$ such that $f'(a) < z < f'(b)$, we wish to show there exists $c \in (a, b)$ such that $f'(c) = z$. We can rewrite the condition as $f'(a) - z < 0 < f'(b) - z$. Now define $g(x) = f(x) - zx$, and note that we have $g'(a) < 0 < g'(b)$.

We want to find $c \in (a, b)$ such that $g'(c) = 0$. Now, g is continuous (since f is continuous), and thus is bounded on $[a, b]$, and the minimum is attained say at some point k . We can't have $k = a$, as that would imply that $g'(a) \geq 0$, and we also can't have $k = b$ as that would imply $g'(b) \leq 0$. Thus $k \in (a, b)$, and we must then have $g'(k) = 0$, and we are done. $\square$

§1.4.2 Rolle's Theorem & The Mean Value Theorem

The sign of a function's derivative at a point can tell us quite a bit about the behaviour of that function near that point. In particular, knowing that the derivative at a point vanishes can be quite useful;

Definition 1.4.9 (Local Maxima & Minima)

Let $f : \mathbb{R} \rightarrow \mathbb{R}$. If there exists δ such that $|x - x_0| < \delta$ implies that $f(x_0) \geq f(x)$, then we call x a **local maximum**. Similarly if this implies that $f(x_0) \leq f(x)$, we call x a **local minimum**.

Our important result is as follows:

Lemma 1.4.10 (Derivative of Maxima)

Let $f : \mathbb{R} \rightarrow \mathbb{R}$. If x is a local maximum or minimum of f and f is differentiable at x then $f'(x) = 0$.

Proof. Without loss of generality, assume that x is a local maximum. Then there exists δ such that $|h| < \delta_1$ implies that $f(x + h) \leq f(x)$.

Then if $0 < h < \delta$ we have

$$\frac{f(x+h) - f(x)}{h} \geq 0,$$

and thus we have $f'(x) \geq 0$.

Similarly if $-\delta < h < 0$ we have

$$\frac{f(x+h) - f(x)}{h} \leq 0,$$

and thus we have $f'(x) \leq 0$. Hence $f'(x) = 0$. $\square$

When we combine this result with the boundedness theorem from our discussion about continuity, we end up with *Rolle's theorem*.

Theorem 1.4.11 (Rolle's Theorem)

Let $f : [a, b] \rightarrow \mathbb{R}$ be a continuous function which is differentiable on (a, b) . Then if $f(a) = f(b)$ then there exists $c \in (a, b)$ such that $f'(c) = 0$.

Proof. Since f is differentiable, it is also continuous and thus by the boundedness theorem f is bounded on $[a, b]$ and these bounds are achieved. Thus we can let $M = \max_{x \in [a, b]} f(x)$ and $m = \min_{x \in [a, b]} f(x)$.

If $M = m$, then f must be constant and $f'(x) = 0$ for all $x \in (a, b)$, so we are done. Otherwise $M > f(a)$ or $m < f(a)$. If $M > f(a)$ then since the bounds are attained there exists $c \in (a, b)$ such that $f(c) = M$. But then M is a maximum, so by our previous lemma we have $f'(c) = 0$. A similar argument works if $m < f(a)$. $\square$

A direct consequence of Rolle's theorem⁶ is another classic theorem of analysis, the *mean value theorem*, which is frequently abbreviated to MVT.

Theorem 1.4.12 (The Mean Value Theorem)

Let $f : [a, b] \rightarrow \mathbb{R}$ be a continuous function which is differentiable on (a, b) . Then there exists $c \in (a, b)$ such that $f(b) - f(a) = f'(c)(b - a)$.

Proof. Let $k = \frac{f(a) - f(b)}{a - b}$, and define $\phi(x) = f(x) - kx$. Note that $\phi(a) = \phi(b)$. Then by Rolle's theorem there exists $c \in (a, b)$ such that $\phi'(c) = 0$, that is $f'(c) = k$. $\square$

The mean value theorem says something notable: the size of the derivative controls the size of the function, or (in rougher terms) it puts a restriction on how 'badly behaved' the function can be. Also, if we appeal to geometric intuition (as we have tried not to, it's an easy way to go wrong) we can see that the mean value theorem says, as R. P. Burn wrote in *Numbers and functions*, "for the graph of a differentiable function, there is always a tangent parallel to the chord". Of course, we will quickly move on from geometrical thinking.⁷

⁶It's possible to establish this theorem without Rolle's theorem, and then Rolle's theorem pops out as a special case. The proof is (more or less) just what we did for Rolle's theorem laid out explicitly in the proof of this theorem.

⁷I guess here is a good place to mention how we can reason geometrically in analysis. Drawing pictures

Now let's think about applying the mean value theorem to two different functions. Suppose that $f, g : [a, b] \rightarrow \mathbb{R}$ is continuous and differentiable on (a, b) , and $g(a) \neq g(b)$. Then the mean value theorem gives us $s, t \in (a, b)$ such that

$$\frac{f(b) - f(a)}{g(b) - g(a)} = \frac{(b-a)f'(s)}{(b-a)g'(t)} = \frac{f'(s)}{g'(t)}.$$

A stronger version of the mean value theorem says that we can take $s = t$.

Theorem 1.4.13 (Cauchy's Mean Value Theorem)

Let $f, g : [a, b] \rightarrow \mathbb{R}$ be continuous functions which are differentiable on (a, b) . Then there exists $c \in (a, b)$ such that

$$(f(b) - f(a))g'(c) = f'(c)(g(b) - g(a)).$$

Proof. We define the function

$$\begin{aligned} \phi(x) &= \begin{vmatrix} 1 & 1 & 1 \\ f(a) & f(x) & f(b) \\ g(a) & g(x) & g(b) \end{vmatrix} \\ &= [f(x)g(b) - f(b)g(x)] - [f(a)g(b) - f(b)g(a)] + [f(a)g(x) - f(x)g(a)]. \end{aligned}$$

Then ϕ is continuous on $[a, b]$ and differentiable on (a, b) ^a. Also $\phi(a) = \phi(b) = 0$. Then by Rolle's theorem, there exists $c \in (a, b)$ such that $\phi'(c) = 0$.

Differentiating ϕ we then have

$$\phi'(x) = f'(x)[g(b) - g(a)] + g'(x)[f(a) - f(b)],$$

and thus $\phi'(c) = 0$ gives the desired result. $\square$

^aIf the use of determinants bothers you, then feel free to just look at the expansion. If also remember how integrals work, you can obtain ϕ from working backwards from what we need to arrive at.

Cauchy's mean value theorem has many applications. For example, we can use the mean value theorem to establish L'Hôpital's rule for evaluating limits.

Example 1.4.14 (L'Hôpital's Rule)

We wish to evaluate $\lim_{x \rightarrow 0} \frac{e^x - 1}{\sin x}$.

By Cauchy's mean value theorem, there exist $c \in (0, x)$ such that $\frac{e^x - e^0}{\sin x - \sin 0} = \frac{e^c}{\cos c}$. Then $c \rightarrow 0$ as $x \rightarrow 0$, and thus we get

$$\lim_{x \rightarrow 0} \frac{e^x - 1}{\sin x} = \lim_{c \rightarrow 0} \frac{e^c}{\cos c} = 1.$$

In more generality:

and thinking geometrically is a great way to understand how things work, to come up with counterexamples and much more. Still it is important to remember that *basically nothing in this course is provable by appealing to geometric intuition*. Instead this type of thinking should just inform the 'analysis' side of us how to approach things.

Theorem 1.4.15 (L'Hôpital's Rule)

Suppose $f, g : [a, b] \rightarrow \mathbb{R}$ are continuous and differentiable on (a, b) . Suppose that $f(a) = g(a) = 0$, that $g'(x)$ does not vanish near a and $f'(x)/g'(x) \rightarrow \ell$ as $x \rightarrow a$. Then $f(x)/g(x) \rightarrow \ell$ as $x \rightarrow a$.

Proof. Since $g'(x)$ does not vanish near a , we can suppose that $g'(x) \neq 0$ for $x \in (a, b)$, as otherwise we could just consider the subinterval (a, b') , defined so that this is the case.

By Cauchy's mean value theorem we have

$$\frac{f(x)}{g(x)} = \frac{f(x) - f(a)}{g(x) - g(a)} = \frac{f'(c)}{g'(c)}$$

where $c \in (a, x)$. Then $c \rightarrow a$ as $x \rightarrow a$, and hence $f(x)/g(x) \rightarrow \ell$ as $x \rightarrow a$. $\square$

The mean value theorem can also help us extend [Lemma 1.4.10](#). Knowing the sign of a derivative over some interval can tell us immediately if it is constant, increasing or decreasing.

Proposition 1.4.16 (Sign of the Derivative)

Let $f : [a, b] \rightarrow \mathbb{R}$ be differentiable on (a, b) . Then the following hold.

- (i) If $f'(x) \geq 0$ for all $x \in (a, b)$, then f is monotonically increasing.
- (ii) If $f'(x) = 0$ for all $x \in (a, b)$, then f is constant.
- (iii) If $f'(x) \leq 0$ for all $x \in (a, b)$, then f is monotonically decreasing.

Proof. By the mean value theorem we have $f(x_2) - f(x_1) = (x_2 - x_1)f'(x)$ where $a < x_1 < x < x_2 < b$. Then all of the results follow by considering the sign of $f'(x)$. $\square$

§1.4.3 Inverses of Functions

Before we move to slightly more exciting material, there's a few things about inverses of functions that we need to get out of the way. The proofs below are straightforward but require some care (by which I mean you have to avoid messing up which letter means what).

First of all, if we know that a continuous function is strictly increasing⁸ then we can deduce that the function has an inverse that is continuous and strictly increasing also. A similar result holds for strictly decreasing functions.

Theorem 1.4.17 (Continuous Inverse Theorem)

Let $f : [a, b] \rightarrow \mathbb{R}$ be a continuous and strictly increasing function. Then if $c = f(a)$ and $d = f(b)$, $f : [a, b] \rightarrow [c, d]$ is bijective and the inverse $f^{-1} : [c, d] \rightarrow [a, b]$ is

⁸If a continuous function was not strictly increasing or strictly decreasing then we couldn't have a unique inverse.

continuous and strictly increasing.

Proof. As f is strictly increasing, it is an injection. It is also a surjection since if $c < t < d$ then there exists $x \in (a, b)$ such that $f(x) = t$. Thus f is a bijection, and has an inverse f^{-1} .

Since f is strictly increasing, we can write this as $x_1 < x_2 \iff f(x_1) < f(x_2)$, so letting $f(x_1) = y_1$ and $f(x_2) = y_2$ we have $f^{-1}(y_1) < f^{-1}(y_2) \iff y_1 < y_2$. Thus f^{-1} is also strictly increasing.

Now we will show f^{-1} is continuous at some $y \in [c, d]$. Given $\epsilon > 0$, let $x = f^{-1}(y)$. If $x \neq a, b$, we can find δ such that

$$f(x - \epsilon) \leq f(x) - \delta < f(x) < f(x) + \delta \leq f(x + \epsilon).$$

But then $|z - y| < \delta$ implies that $x - \epsilon < f^{-1}(z) < x + \epsilon$, so $|f^{-1}(z) - f^{-1}(y)| < \epsilon$. Thus f^{-1} is continuous on (a, b)

Otherwise, if $x = a$ we have $f(x) < f(x + \epsilon)$. Then $|z - y| < f(x + \epsilon) - f(x)$ implies that $|f^{-1}(z) - f^{-1}(y)| < \epsilon$, so f^{-1} is continuous at c . A similar argument shows that it is continuous at d . $\square$

Now this *is* the differentiability section, so we can also describe what the derivative of a differentiable function's inverse is. This result is known as the one variable *inverse function theorem*.

Theorem 1.4.18 (Inverse Function Theorem)

Let $f : [a, b] \rightarrow \mathbb{R}$ be continuous, strictly increasing, and differentiable on (a, b) . Then let $f(a) = c$ and $f(b) = d$. Then $f : [a, b] \rightarrow [c, d]$ is a bijection, and f^{-1} is differentiable on (c, d) , with

$$(f^{-1})'(x) = \frac{1}{f'(f^{-1}(x))}.$$

Proof. By our previous theorem, f is a bijection and f^{-1} is a continuous and strictly increasing function. Let $y = f(x)$, with $x \in (a, b)$. We wish to show that $g'(y) = 1/f'(x)$.

Given $k \neq 0$, let h be given by $y + k = f(x + h)$, that is, $f^{-1}(y + k) = x + h$, where $h \neq 0$. Then

$$\frac{f^{-1}(y + k) - f^{-1}(y)}{k} = \frac{h}{f(x + h) - f(x)}.$$

Then since $f'(x) > 0$ and f^{-1} is continuous (so $h \rightarrow 0$ as $k \rightarrow 0$) we have $k \rightarrow 0$

$$\lim_{k \rightarrow 0} \frac{f^{-1}(y + k) - f^{-1}(y)}{k} = \lim_{h \rightarrow 0} \frac{x + h - x}{f(x + h) - f(x)} = \frac{1}{f'(x)},$$

as required. $\square$

§1.4.4 Taylor's Theorem

We are now going to think about functions where we can take derivatives a number of times (getting higher-order derivatives). We will begin by looking at how we can get an analogue of Rolle's theorem for higher-order derivatives. I will apologise in advance that this discussion is a bit long, so feel free to just skip to Taylor's theorem.

The following generalisation will come directly from Rolle's theorem.

Theorem 1.4.19 (Higher-Order Rolle's Theorem)

Let f be continuous and $n - 1$ -times differentiable on $[a, b]$ and also n -times differentiable on (a, b) . Then if $f(a) = f'(a) = f''(a) = \dots = f^{(n-1)}(a) = 0$ and $f(b) = 0$ then there is a $c \in (a, b)$ such that $f^{(n)}(c) = 0$.

Proof. Since $f(a) = f(b)$, by Rolle's theorem there exists $c_1 \in (a, b)$ such that $f'(c_1) = 0$. Then since $f'(a) = f'(c_1) = 0$, we can use Rolle's theorem again to obtain $c_2 \in (a, c_1)$ such that $f''(c_2) = 0$. Continuing on like this we obtain a $c_n \in (a, b)$ such that $f^{(n)}(c_n) = 0$, as required. $\square$

We can also attempt to get some sort of 'higher-order' mean value theorem. Recall that our proof of the mean value theorem was more or less as follows:

Define the function $\phi(x) = f(x) - kx$, where we choose k such that the conditions of Rolle's theorem are satisfied. Then apply Rolle's theorem to ϕ .

We can try and do the same with a more elaborate construction. We will do this in three steps.

1. Construct a polynomial $P(x)$ such that $P(a) = f(a)$, $P'(a) = f'(a)$, and so on until $P^{(n-1)}(a) = f^{(n-1)}(a)$.
2. Construct another polynomial⁹ $E(x)$ such that $E^{(r)}(a) = 0$ for $r = 0, 1, \dots, n - 1$, but with $E(b) = f(b) - P(b)$.
3. Take $\phi(x) = f(x) - P(x) - E(x)$.

If we construct $\phi(x)$ in this way, then we will have $\phi(a) = \phi'(a) = \dots = \phi^{(n-1)}(a) = 0$, and also $\phi(b) = 0$, so it will satisfy our higher-order Rolle's theorem.

Aside: Constructing Our Polynomials

While it is likely you have seen a construction for P before, I'd like to take a minute to spell it out in detail because it has some nice ideas.

To construct this polynomial, what we really need is some construction of a term which affects the value of the polynomial at a point a if and only if we are considering a certain derivative. We can do this as follows:

$$Q_k(x) = \frac{(x - a)^k}{k!}.$$

⁹We can think of this as the 'error correcting term', because it fixes the discrepancy between $f(b)$ and $P(b)$ while not ruining the previous construction.

We can then (by taking derivatives) find that the value of this term is

$$Q_k^{(j)}(a) = \begin{cases} 1 & \text{if } j = k, \\ 0 & \text{if } j \neq k \end{cases}$$

With this we can immediately write down an explicit construction for $P(x)$.

$$\begin{aligned} P(x) &= \sum_{k=0}^{n-1} f^{(k)}(a) Q_k(x) = \sum_{k=0}^{n-1} \frac{f^{(k)}(a)}{k!} (x-a)^k \\ &= f(a) + f'(a)(x-a) + \frac{f''(a)}{2}(x-a)^2 + \cdots + \frac{f^{(n-1)}(a)}{(n-1)!} (x-a)^{n-1}. \end{aligned}$$

This polynomial is known as the **Taylor polynomial** of degree $n-1$ for f about a .

We can use the exact same method to construct $E(x)$. We need to not affect the first $n-1$ derivatives at $x=a$, so we will need to add some multiple of $Q_n(x)$. However, this time we care about the value of the undifferentiated term at $x=b$:

$$Q_n(b) = \frac{(b-a)^n}{n!}.$$

Since we want $E(b) = f(b) - P(b)$, if we are going to have $E(x) = \lambda Q_n(x)$ we are going to need

$$\begin{aligned} \lambda Q_n(b) &= \lambda \frac{(b-a)^n}{n!} = f(b) - P(b) \\ \implies \lambda &= \frac{[f(b) - P(b)] \cdot n!}{(b-a)^n}. \end{aligned}$$

And thus we get

$$\begin{aligned} E(x) &= \frac{[f(b) - P(b)] \cdot n!}{(b-a)^n} Q_n(x) \\ &= [f(b) - P(b)] \left(\frac{x-a}{b-a} \right)^n. \end{aligned}$$

Now with the constructions as above, we can write down $\phi(x) = f(x) - P(x) - E(x)$. Then since $\phi(x)$ satisfies all of the conditions of our higher-order Rolle's theorem, there exists $c \in (a, b)$ such that $\phi^{(n)}(c) = 0$.

Taking the n th derivative, since P is a degree $n-1$ polynomial and thus has a zero derivative, we get

$$\begin{aligned} \phi^{(n)}(c) &= f^{(n)}(c) - [f(b) - P(b)] \cdot \frac{n!}{(b-a)^n} = 0 \\ \implies f(b) &= P(b) + \frac{f^{(n)}(c)}{n!} (b-a)^n. \end{aligned}$$

for some $c \in (a, b)$.

This result is Taylor's theorem, specially Taylor's theorem with the Lagrange form of the remainder. For completeness, this proof is given in a standalone form below.

Theorem 1.4.20 (Taylor's Theorem with Lagrange Remainder)

Let f be continuous and $(n-1)$ -times differentiable on $[a, b]$ and n -times differentiable on (a, b) . Then we have

$$f(b) = f(a) + f'(a)(b-a) + \cdots + \frac{f^{(n-1)}(a)}{(n-1)!}(b-a)^{n-1} + \frac{f^{(n)}(c)}{n!}(b-a)^n,$$

for some $c \in (a, b)$.

Proof. We define

$$\phi(x) = f(x) - \sum_{k=0}^{n-1} \frac{f^{(k)}(a)}{k!}(x-a)^k - M \left(\frac{x-a}{b-a} \right)^n,$$

where M is chosen such that $\phi(a) = \phi(b) = 0$. Then differentiating we have $\phi(a) = \phi'(a) = \cdots = \phi^{(n-1)}(a) = 0$.

Then since $\phi(a) = \phi(b)$, there exists $c_1 \in (a, b)$ such that $\phi'(c_1) = 0$. Similarly $\phi'(a) = \phi'(c_1) = 0$, and thus there exists $c_2 \in (a, c_1)$ such that $\phi''(c_2) = 0$. Continuing on in this way, we find a c_n such that $\phi^{(n)}(c_n) = 0$, where $c_n \in (a, b)$.

Then differentiating again we have

$$\phi^{(n)}(c) = f^{(n)}(c) - \frac{M \cdot n!}{(b-a)^n} = 0.$$

Now we know that M is such that $\phi(b) = 0$, so we get

$$M = f(b) - \sum_{k=0}^{n-1} \frac{f^{(k)}(a)}{k!}(b-a)^k.$$

Thus we have

$$\begin{aligned} f^{(n)}(c) &= \frac{M \cdot n!}{(b-a)^n} = \left(f(b) - \sum_{k=0}^{n-1} \frac{f^{(k)}(a)}{k!}(b-a)^k \right) \cdot \frac{n!}{(b-a)^n} \\ \implies f(b) &= f(a) + f'(a)(b-a) + \cdots + \frac{f^{(n-1)}(a)}{(n-1)!}(b-a)^{n-1} + \frac{f^{(n)}(c)}{n!}(b-a)^n, \end{aligned}$$

where $c \in (a, b)$ as required. □

So we have Taylor's theorem (which in this case can be thought of as a higher-order mean value theorem), let's try and do something with it. One of the main uses of Taylor's theorem is in giving us an infinite series which converges to the value of our function. This involves considering the terms of the degree n Taylor polynomial for increasing values of n , as we shall see.

Doing this type of problem has two main steps.

1. Write down Taylor's theorem for the case of the function being considered.
2. Show that the error term tends to zero as n goes to infinity.

We see how this is done using a Tripos question from 2010 (so eh spoilers I guess).

Example 1.4.21 (Using Taylor's Theorem – Part IA, 2010 Paper 1, Q10)

Problem. Suppose that $e : \mathbb{R} \rightarrow \mathbb{R}$ is a differentiable function such that $e(0) = 1$ and $e'(x) = e(x)$ for all $x \in \mathbb{R}$. Use Taylor's theorem with the remainder in Lagrange's form to prove that

$$e(x) = \sum_{n \geq 0} \frac{x^n}{n!} \quad \text{for all } x \in \mathbb{R}$$

[No property of the exponential function may be assumed.]

Solution. We begin by noting that $e(x)$ is infinitely differentiable, with $e^{(n)}(x) = e(x)$. Indeed this is true for $n = 1$, and then it follows by induction for all n . Thus Taylor's theorem with Lagrange Remainder holds for all $n \in \mathbb{N}$.

Thus for all $n \in \mathbb{N}$ we have (using $e^{(n)}(0) = 1$ and $e^{(n)}(c) = e(c)$)

$$e(x) = \sum_{k=0}^{n-1} \frac{x^k}{k!} + \frac{e(c)x^n}{n!}$$

for some $c \in (0, x)$. And thus it suffices to show that $\frac{e(c)x^n}{n!} \rightarrow 0$ as $n \rightarrow \infty$, since that would imply that $e(x) - \sum_{k=0}^{n-1} \frac{x^k}{k!} \rightarrow 0$ as $n \rightarrow \infty$. Now $e(t)$ is differentiable and hence continuous on $[0, x]$, and thus is bounded. So it suffices to show that $x^n/n! \rightarrow 0$, which holds.

Thus

$$e(x) = \sum_{n=0}^{\infty} \frac{x^n}{n!},$$

as required.

Now it is *not* the case that the remainder term always goes to zero. A common counterexample is $f(x) = \exp(-1/x^2)$ for $x \neq 0$ with $f(0) = 0$.

§1.5 Power Series

Following on from our discussion of infinite series in Chapter 2, we are going to discuss a particular type of infinite series known as a *power series*. Throughout this section, we are going to work mostly in $\mathbb{C}$.

Definition 1.5.1 (Complex Power Series)

A **complex power series** is an infinite series of the form

$$\sum_{n=0}^{\infty} a_n z^n,$$

where $z \in \mathbb{C}$ and $a_n \in \mathbb{C}$.

In this section we will look at some properties of power series, and we will use them to (finally) define some functions that we have alluded to quite a bit.

§1.5.1 Radius of Convergence

Before we develop the concept of the radius of convergence, we first need to develop a lemma about the convergence of power series.

Lemma 1.5.2 (Absolute Convergence of Power Series)

Suppose that $\sum_{n=0}^{\infty} a_n z_0^n$ converges for some $z_0 \in \mathbb{C}$. Then $\sum_{n=0}^{\infty} a_n z^n$ converges absolutely for all $z \in \mathbb{C}$ with $|z| < |z_0|$.

Proof. Since $\sum_{n=0}^{\infty} a_n z_1^n$ converges, we have $a_n z_1^n \rightarrow 0$, implying this sequence is bounded. Then there is some $K > 0$ such that $|a_n z_1^n| < K$ for all n .

So if $|z| < |z_0|$, we have $|a_n z^n| \leq K |z/z_1|^n$. Since the geometric series $\sum_{n=0}^{\infty} |z/z_1|^n$ converges, our result follows by comparison. $\square$

With this lemma we can prove one of our key results in the study of power series, the existence of the *radius of convergence*.

Theorem 1.5.3 (Radius of Convergence)

Suppose that $a_n \in \mathbb{C}$. Then either the power series $\sum_{n=0}^{\infty} a_n z^n$ converges for all $z \in \mathbb{C}$, or there exists a real number R with $R \geq 0$ such that

- (i) $\sum_{n=0}^{\infty} a_n z^n$ converges absolutely if $|z| < R$,
- (ii) $\sum_{n=0}^{\infty} a_n z^n$ diverges if $|z| > R$.

We say that R is the **radius of convergence** of the power series.

Proof. If $\sum_{n=0}^{\infty} a_n z^n$ converges for all $z \in \mathbb{C}$, then we are done. Otherwise, there must exist $z_1 \in \mathbb{C}$ such that $\sum_{n=0}^{\infty} a_n z_1^n$ diverges. Then by our previous lemma the power series must diverge for all $z \in \mathbb{C}$ where $|z| > |z_1|$.

Now define the set $S = \{|z| : \sum_{n=0}^{\infty} a_n z^n \text{ converges}\}$. This set is bounded above by $|z_1|$, and is non-empty since the power series converges for $z = 0$. Thus it has a supremum, say $R = \sup S$.

Then by definition $\sum_{n=0}^{\infty} a_n z^n$ diverges if $|z| > R$, and then suppose $|z| < R$. Then there must be some z_0 with $|z| < |z_0| < R$ such that the power series converges for z_0 (by the definition of the supremum again). Then by our previous lemma the power series converges absolutely for z . $\square$

What's quite lovely is that when we are inside the radius of convergence, the power series converges absolutely! This means that we can avoid all of those issues with rearranging series that show up when things don't converge absolutely. This can be quite helpful when actually working with power series.

What's also quite nice is that we can employ all of those lovely results we developed in [section 1.2](#) to find what the radius of convergence of a power series is. Let's look at two lemmas that come from the ratio and root tests, which can give the radius of convergence.

Lemma 1.5.4 (The Ratio Test for Radius of Convergence)

Let $\sum_{n=0}^{\infty} a_n z^n$ be a power series with radius of convergence R . Then if $|a_{n+1}/a_n| \rightarrow \ell$ as $n \rightarrow \infty$, we have $R = 1/\ell$ if $\ell \neq 0$, and convergence everywhere if $\ell = 0$.

Proof. By the ratio test, we have absolute convergence if

$$\lim_{n \rightarrow \infty} \left| \frac{a_{n+1}}{a_n} \cdot \frac{z^{n+1}}{z^n} \right| < 1.$$

So if $\ell = 0$, then we have convergence everywhere. Alternatively, if $|z| < 1/\ell$ we have absolute convergence, and if $|z| > 1/\ell$ the series diverges, again by the ratio test. $\square$

Lemma 1.5.5 (The Root Test for Radius of Convergence)

Let $\sum_{n=0}^{\infty} a_n z^n$ be a power series with radius of convergence R . Then if $|a_n|^{1/n} \rightarrow \ell$ as $n \rightarrow \infty$, we have $R = 1/\ell$.

Proof. By the root test, we have absolute convergence if

$$\lim_{n \rightarrow \infty} |a_n z^n|^{1/n} < 1.$$

So if $\ell = 0$, then we have convergence everywhere. Alternatively, if $|z| < 1/\ell$ we have absolute convergence, and if $|z| > 1/\ell$ the series diverges, again by the root test. $\square$

Now it is time for an important conceptual point: if we have a power series with radius of convergence R , then this only specifies the convergence/divergence inside or outside the circle $|z| = R$ (the *circle of convergence*). Specifically **it says nothing about the behaviour on the circle**. To see this, we will look at a few examples¹⁰.

¹⁰This should remind you of the deadly sin mentioned in [section 1.2](#), where the root or ratio test said nothing if the limit was 1.

Example 1.5.6 (Convergence on $|z| = R$)

Consider the following power series:

$$(i) \sum_{n=0}^{\infty} z^n, \quad (ii) \sum_{n=1}^{\infty} \frac{z^n}{n} \quad (iii) \sum_{n=1}^{\infty} \frac{z^n}{n^2}.$$

All of these have a radius of convergence $R = 1$, however for $|z| = 1$ for each power series we have:

1. Divergence if $|z| = 1$.
2. Convergence^a if $|z| = 1$ with $z \neq 1$, and divergence if $z = 1$.
3. Convergence if $|z| = 1$.

Thus we can't say anything about the case $|z| = R$ and each case really has to be treated separately.

^aHave a look at Example Sheet 1 for this result

§1.5.2 Differentiating Power Series

So things are generally quite nice inside the circle of convergence. One of the nice things we can do is differentiate! Even better, we can differentiate power series just like we do polynomials! The following results you need to know (including the lemmas), but the proofs are not examinable (feel free to skip them).

We are going to show that the power series $\sum_{n=0}^{\infty} a_n z^n$ with radius of convergence R has the derivative $\sum_{n=0}^{\infty} n a_n z^{n-1}$, whenever $|z| < R$. Before showing this, we will need a lemma which gives us that this second power series converges for $|z| < R$.

Lemma 1.5.7

Let $f(z) = \sum_{n=0}^{\infty} a_n z^n$ be a power series whose radius of convergence is R . Then if $0 < r < R$, the power series $\sum_{n=1}^{\infty} n |a_n| r^{n-1}$ converges.

Proof. Pick w such that $r < |w| < R$. Then the power series $\sum_{n=0}^{\infty} a_n w^n$ converges, so the terms $|a_n w^n|$ are bounded above by say M . Then we have

$$n |a_n| r^n = n |a_n w^n| \frac{r^n}{|w|^n} \leq M n \frac{r^n}{|w|^n}.$$

But then the series $\sum_{n=1}^{\infty} M n (r/|w|)^n$ converges by the ratio test, and thus by the comparison test $\sum_{n=1}^{\infty} n |a_n| r^{n-1}$ converges. $\square$

Applying this lemma twice also gives us that the power series $\sum_{n=2}^{\infty} n(n-1) |a_n| r^{n-2}$ converges. We are now ready to prove our theorem about differentiating power series.

Theorem 1.5.8 (Differentiating Power Series)

Let $f(z) = \sum_{n=0}^{\infty} a_n z^n$ be a power series whose radius of convergence is R . Then f is differentiable at all points with $|z| < R$, and $f'(z) = \sum_{n=0}^{\infty} n a_n z^{n-1}$.

Proof. Using the difference of powers factorisation, we have

$$\begin{aligned}\frac{f(z+h) - f(z)}{h} &= \sum_{n=0}^{\infty} a_n \frac{(z+h)^n - z^n}{h} \\ &= \sum_{n=1}^{\infty} a_n [(z+h)^{n-1} + (z+h)^{n-2}z + \cdots + z^{n-1}].\end{aligned}$$

Then, since $\sum_{n=1}^{\infty} na_n z^{n-1}$ converges by our lemma, we have

$$\begin{aligned}\frac{f(z+h) - f(z)}{h} - \sum_{n=1}^{\infty} na_n z^{n-1} &= \sum_{n=1}^{\infty} a_n \left(\sum_{j=0}^{n-1} z^j (z+h)^{n-1-j} - z^{n-1} \right) \\ &= \sum_{n=1}^{\infty} a_n \left(\sum_{j=0}^{n-1} z^j [(z+h)^{n-1-j} - z^{n-1-j}] \right).\end{aligned}$$

Now we want to bound the terms of this inside sum. Choose r such that $|z| < r < R$ and h such that $|z| + |h| < r$. Then employing the difference of powers factorisation again we get

$$\begin{aligned}|(z+h)^{n-1-j} - z^{n-1-j}| &= |h((z+h)^{n-2-j} + z(z+h)^{n-3-j} + \cdots + z^{n-2-j})| \\ &\leq |h|(n-1-j)r^{n-2-j}.\end{aligned}$$

Applying this bound, assuming the right hand sum converges we have

$$\begin{aligned}\left| \frac{f(z+h) - f(z)}{h} - \sum_{n=1}^{\infty} na_n z^{n-1} \right| &\leq \sum_{n=1}^{\infty} |a_n| \left(\sum_{j=0}^{n-1} r^j |h|(n-1-j)r^{n-2-j} \right) \\ &= |h| \sum_{n=1}^{\infty} |a_n| r^{n-2} \left(\sum_{j=0}^{n-1} j \right) \\ &= \frac{1}{2} |h| \sum_{n=2}^{\infty} |a_n| n(n-1) r^{n-2}.\end{aligned}$$

Using our previous lemma twice shows that the right hand sum converges, and thus

$$\frac{f(z+h) - f(z)}{h} - \sum_{n=1}^{\infty} na_n z^{n-1} \rightarrow 0 \quad \text{as } h \rightarrow 0,$$

that is, $f'(z) = \sum_{n=0}^{\infty} na_n z^{n-1}$. □

§1.5.3 Exponential, Trigonometric & Hyperbolic Functions

With all that out of the way, let's define some functions! You'll hopefully be familiar with all of these anyway, but we will now be able to define them properly.

We are going to need one little lemma before we proceed.

Lemma 1.5.9 (Constant Value Theorem Over $\mathbb{C}$)

If $F : \mathbb{C} \rightarrow \mathbb{C}$ has $F'(z) = 0$ for all $z \in \mathbb{C}$, then $F(z)$ is constant for all z .

Proof. For some $z \in \mathbb{C}$, we define the functions $u_z, v_z : \mathbb{R} \rightarrow \mathbb{R}$ such that $F(tz) = u_z(t) + iv_z(t)$. By the chain rule $F'(tz)z = u'_z(t) + iv'_z(t) = 0$ for any $t \in \mathbb{R}$. Then comparing real and imaginary parts, this implies $u'_z(t) = 0$ and $v'_z(t) = 0$, for all $t \in \mathbb{R}$. So u_z and v_z are constant.

Then for any $z \in \mathbb{C}$ we have $F(z) = u_z(1) + iv_z(1) = u_z(0) + iv_z(0) = F(0)$, so F is constant too. $\square$

The Exponential & Logarithm Function

We will begin with one of the most important functions, the exponential function.

Definition 1.5.10 (The Exponential Function)

We define the **exponential function** $\exp : \mathbb{C} \rightarrow \mathbb{C}$ by the power series

$$\exp(z) = \sum_{n=0}^{\infty} \frac{z^n}{n!}.$$

When we state a definition using power series, we pretty much always have to check convergence straight away so that we do not end up writing complete nonsense. For this power series, we can see by the ratio test that it converges for all $z \in \mathbb{C}$. By the result in the previous section, we can also see that it's differentiable.

Now we can prove all of the properties that you already are aware of.

Proposition 1.5.11 (Properties of the Exponential Function)

Let $z, w \in \mathbb{C}$. Then the following hold.

- (i) $\exp'(z) = \exp(z)$.
- (ii) $\exp(z) \exp(w) = \exp(z + w)$.
- (iii) $\exp(x) > 0$ for $x \in \mathbb{R}$.
- (iv) $\exp(x)$ is strictly increasing on $\mathbb{R}$.
- (v) $\exp(x) \rightarrow \infty$ as $x \rightarrow \infty$, $\exp(x) \rightarrow 0$ as $x \rightarrow -\infty$.
- (vi) $\exp : \mathbb{R} \rightarrow (0, \infty)$ is a bijection.

Proof. We prove each individually.

- (i) This follows from differentiating the power series.
- (ii) Let $a, b \in \mathbb{C}$ and define $F(z) = \exp(a + b - z) \exp(z)$. Then $F'(z) = -\exp(a + b - z) \exp(z) + \exp(a + b - z) \exp(z) = 0$, and thus by the constant value theorem, F is constant. So $\exp(a + b - z) \exp(z) = F(0) = \exp(a + b)$, and setting $z = b$ gives $\exp(a) \exp(b) = \exp(a + b)$.

- (iii) Clearly $\exp(x) > 0$ for all $x \geq 0$, and $\exp(0) = 1$. Then $\exp(0) = \exp(x - x) = \exp(x) \exp(-x) = 1$, and thus $\exp(-x) > 0$ for $x > 0$.
- (iv) Differentiating, $\exp'(x) = \exp(x) > 0$, and thus $\exp$ is strictly increasing on $\mathbb{R}$.
- (v) Truncating the power series, $\exp(x) > 1 + x$ for $x > 0$. Thus if $x \rightarrow \infty$, $\exp(x) \rightarrow \infty$. Then $\exp(-x) = 1/\exp(x)$, so $\exp(x) \rightarrow 0$ as $x \rightarrow -\infty$.
- (vi) Injectivity follows directly from $\exp$ being strictly increasing. For surjectivity, take $y > 0$. Then by (v) there exists $a, b \in \mathbb{R}$ such that $\exp(a) < y < \exp(b)$, and by the intermediate value theorem there is $c \in (a, b)$ such that $\exp(c) = y$. $\square$

Since the exponential function is a bijection $\mathbb{R} \rightarrow \mathbb{R}^+$, it also has a well defined inverse.

Definition 1.5.12 (The Logarithm Function)

We define the **logarithm function** $\log : (0, \infty) \rightarrow \mathbb{R}$ to be the inverse of $\exp$.

By the inverse function theorem, this is a differentiable function, and its derivative is given by $\log'(t) = 1/t$ for $t > 0$.

Remark. As defined here, the logarithm function is an inverse of $\exp : \mathbb{R} \rightarrow (0, \infty)$, not over the whole of $\mathbb{C}$. In general, $\exp$ is *not* a bijection, and thus it having an inverse doesn't make sense (with the tools we have developed, this is remedied in later courses).

Using both the exponential and logarithm functions, we can define powers in the general case. For $x > 0$ and $\alpha \in \mathbb{R}$, we define $x^\alpha = \exp(\alpha \log x)$. With this we get the normal 'rules of indices' being properties of the exponential function, and it is not hard to see that this definition matches how powers would be previously defined for $\alpha \in \mathbb{Q}$. This also gives us a new shorthand for the exponential function: $\exp(z) = e^z$.

Aside: Multiplying Infinite Series

In [Proposition 1.5.11](#) we proved a result involving multiplying two exponential functions together. We also managed to do this in a way that avoided using the power series definition of the function. Despite this, I think it's worth taking a moment to look properly at the multiplication of infinite series¹¹.

When we talk about trying multiplying infinite series, we are really talking about taking two infinite series so that they can be combined into a new infinite series¹², which hopefully converges to the product of the two original series.

So how can we do this? A natural approach would be to just 'expand everything', but unfortunately that's not really how infinite series work, so we can't do that. Still, we can use this idea as inspiration for a more mathematically sound approach.

Being quite informal and hand-wavy, let's consider two power series $\sum_{n=0}^{\infty} a_n z^n$ and $\sum_{n=0}^{\infty} b_n z^n$, multiply them term by term and then group by powers of z . Doing this, we

¹¹This section is completely not-examinable and the proofs are relatively long, so I suggest that you skip it if you are using these notes for revision.

¹²If we don't care about obtaining a new infinite series, this discussion can be completely ignored.

get something like

$$(a_0 + a_1z + a_2z^2 + a_3z^3 + \cdots) \cdot (b_0 + b_1z + b_2z^2 + b_3z^3 + \cdots) \\ = a_0b_0 + (a_0b_1 + a_1b_0)z + (a_0b_2 + a_1b_1 + a_2b_0)z^2 + (a_0b_3 + a_1b_2 + a_2b_1 + a_3b_0)z^3 + \cdots.$$

Taking inspiration from this, for two sequence a_n and b_n we can define their **convolution** to be the sequence c_n where

$$c_n = a_0b_n + a_1b_{n-1} + \cdots + a_nb_0.$$

It is this construction that will form the basis of our product of infinite series.

Definition (Cauchy Product)

Given two infinite series $\sum_{n=0}^{\infty} a_n$ and $\sum_{n=0}^{\infty} b_n$, their **Cauchy product** is the infinite series

$$\sum_{n=0}^{\infty} c_n,$$

where $c_n = a_0b_n + a_1b_{n-1} + \cdots + a_nb_0$.

The Cauchy product does give us a way to obtain a ‘product’ of infinite series, but before we go any further some important caveats need to be pointed out. The most notable is the following: the infinite series obtained with the Cauchy product *does not necessarily converge*¹³.

Example (Convergent Series Whose Cauchy Product Diverges)

Consider the convergent^a series $\sum_{n=0}^{\infty} \frac{(-1)^n}{\sqrt{n+1}}$. Then the Cauchy product of this series with itself is given by

$$\sum_{n=0}^{\infty} \sum_{k=0}^n \frac{(-1)^k}{\sqrt{k+1}} \frac{(-1)^{n-k}}{\sqrt{n-k+1}}.$$

But then since

$$(k+1)(n-k+1) \leq \left(\frac{n}{2} + 1\right)^2 - \left(\frac{n}{2} - k\right)^2 \leq \left(\frac{n}{2} + 1\right)^2,$$

the terms of the Cauchy product satisfy

$$\left| \sum_{k=0}^n \frac{(-1)^k}{\sqrt{k+1}} \frac{(-1)^{n-k}}{\sqrt{n-k+1}} \right| \geq \sum_{k=0}^n \frac{1}{n/2 + 1} = \frac{n+1}{n/2 + 1},$$

and thus they don’t tend to 0 so the series cannot converge. This implies that we have two convergent series whose Cauchy product does not converge.

^aExercise!

This is obviously not a very good thing to happen, and we will spend the rest of this aside trying to deal with this possible issue. Luckily enough, this issue can be completely avoided if we know that one of the series being ‘multiplied’ converges absolutely¹⁴.

¹³It’s also possible for two divergent series to have a convergent Cauchy product. Try coming up with an example as an exercise.

¹⁴This is another reason why absolute convergence is a great property to have.

Theorem (Mertens' Theorem)

Suppose that $\sum_{n=0}^{\infty} a_n = A$ converges absolutely, and $\sum_{n=0}^{\infty} b_n = B$ converges. Then their Cauchy product $\sum_{n=0}^{\infty} c_n$ converges, and

$$\sum_{n=0}^{\infty} c_n = AB.$$

Proof. Let the partial sums of the series be

$$A_n = \sum_{k=0}^n a_k, \quad B_n = \sum_{k=0}^n b_k, \quad C_n = \sum_{k=0}^n c_k.$$

Then we have

$$\begin{aligned} C_n &= a_0 b_0 + (a_0 b_1 + a_1 b_0) + (a_0 b_2 + a_1 b_1 + a_2 b_0) + \cdots + (a_0 b_n + \cdots + a_{n-1} b_n) \\ &= a_0 B_n + a_1 B_{n-1} + \cdots + a_n B_0 \\ &= (a_0 B + \cdots + a_n B) - (a_0 B + \cdots + a_n B) + a_0 B_n + a_1 B_{n-1} + \cdots + a_n B_0 \\ &= A_n B + a_0 (B_n - B) + a_1 (B_{n-1} - B) + \cdots + a_n (B_0 - B). \end{aligned}$$

We wish to show $C_n \rightarrow AB$, and we will do so using three bounds. Given $\epsilon > 0$, since $A_n \rightarrow A$, there is an integer L such that $n \geq L$ implies

$$|A_n - A| \leq \frac{\epsilon/3}{|B|}.$$

Then since $\sum_{k=0}^{\infty} |a_k|$ converges and $B_n \rightarrow B$, there is an integer M such that $n \geq M$ implies

$$|B_n - B| \leq \frac{\epsilon/3}{\sum_{k=0}^{\infty} |a_k|}.$$

Also, since $\sum_{k=0}^{\infty} a_k$ converges, $a_n \rightarrow 0$, and thus there is an integer N such that $n \geq N$ implies that

$$|a_n| \leq \frac{\epsilon/3}{\sum_{k=0}^{M-1} |B_k - B|}.$$

Combining these^a, for $N \geq \max\{L, M + N\}$ we obtain

$$\begin{aligned} |C_n - AB| &= \left| (A_n - A)B + \sum_{k=0}^n a_{n-k}(B_k - B) \right| \\ &\leq |A_n - A||B| + \sum_{k=0}^{M-1} |a_{n-k}||B_k - B| + \sum_{k=M}^n |a_{n-k}||B_k - B| \leq \epsilon \end{aligned}$$

Thus $\sum_{n=0}^{\infty} c_n = AB$. □

^aWe use $M + N$ because we will need $n - (M - 1) \geq N$ to make the bounds work.

We can apply this result to power series. Recalling that power series converge absolutely inside their circle of convergence, we can safely multiply power series using the Cauchy product.

Corollary (Multiplying Power Series)

Let $\sum_{n=0}^{\infty} a_n z^n$ and $\sum_{n=0}^{\infty} b_n z^n$ be power series with radius of convergence R_1 and R_2 respectively. Then if $|z| < \min\{R_1, R_2\}$ we have

$$\left(\sum_{n=0}^{\infty} a_n z^n\right) \cdot \left(\sum_{n=0}^{\infty} b_n z^n\right) = \left(\sum_{n=0}^{\infty} c_n z^n\right),$$

where $c_n = a_0 b_n + a_1 b_{n-1} + \cdots + a_n b_0$.

So to summarise: when inside the circle of convergence, we can multiply power series in the natural way, and the result will be as we expect. Using this corollary, we could prove $\exp(a+b) = \exp(a)\exp(b)$ directly (though admittedly the other proof is much faster).

The Trigonometric Functions

We can use the exponential function to define the familiar trigonometric functions.

Definition 1.5.13 (Sine & Cosine)

We define the **sine** and **cosine functions** by the power series

$$\begin{aligned}\sin z &= \frac{e^{iz} - e^{-iz}}{2i} = z - \frac{z^3}{3!} + \frac{z^5}{5!} - \frac{z^7}{7!} + \cdots \\ \cos z &= \frac{e^{iz} + e^{-iz}}{2} = 1 - \frac{z^2}{2} + \frac{z^4}{4!} - \frac{z^6}{6!} + \cdots\end{aligned}$$

where $z \in \mathbb{R}$.

Stating these definitions in terms of the exponential function make lots of identities quite easy to derive.

Proposition 1.5.14 (Properties of sin and cos)

Let $z, w \in \mathbb{R}$. Then the following hold.

- (i) $\sin' z = \cos z$, $\cos' z = -\sin z$.
- (ii) $\sin^2 z + \cos^2 z = 1$.
- (iii) $|\sin z|, |\cos z| \leq 1$.
- (iv) $\cos(z+w) = \cos z \cos w - \sin z \sin w$.
- (v) $\sin(z+w) = \sin z \cos w + \cos z \sin w$.

Proof. We prove each individually, mainly by computation.

- (i) For sin we have $\sin' z = [(e^{iz} - e^{-iz})/2i]' = (e^{iz} + e^{-iz})/2 = \cos z$, and for cos we have $\cos' z = [(e^{iz} + e^{-iz})/2]' = (e^{-iz} - e^{iz})/2i = -\sin z$.
- (ii) $\sin^2 z + \cos^2 z = -(e^{2iz} + e^{-2iz} + 2)/4 + (e^{2iz} + e^{-2iz} - 2)/4 = 1$, as required.
- (iii) This follows from the above result.

(iv) Expanding the right hand expression gives

$$\begin{aligned}
 & \cos z \cos w - \sin z \sin w \\
 &= \frac{(e^{iz} + e^{-iz})(e^{iw} + e^{-iw})}{4} + \frac{(e^{iz} - e^{-iz})(e^{iw} - e^{-iw})}{4} \\
 &= \frac{e^{i(z+w)} + e^{-i(z+w)}}{2} \\
 &= \cos(z + w).
 \end{aligned}$$

(v) Differentiating the above result with respect to z , we have $-\sin z \cos w - \cos z \sin w = -\sin(z + w)$, giving us our desired result. $\square$

One of the more notable properties of $\sin$ and $\cos$ is that they are periodic, which is what we are going to show next. To establish this, we can try evaluating one of them (say $\cos$) at some values near where we expect a root to be (guided by our previous knowledge of these functions).

Lemma 1.5.15 (Smallest Root of $\cos$)

There is a smallest positive x such that $\cos(x) = 0$.

Proof. We begin by computing the sign of the derivative over $(0, 2)$. Since $\cos'(x) = -\sin(x)$, we can use the inequality $\frac{x^{2n-1}}{(2n-1)!} > \frac{x^{2n+1}}{(2n+1)!}$ to bound

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots > 0,$$

so $\cos$ has a negative derivative and must be decreasing on $(0, 2)$.

Evaluating the power series for $\cos$ at $\sqrt{2}$ and $\sqrt{3}$, we can see that the function changes sign

$$\cos \sqrt{2} = 1 - \frac{2}{2} + \frac{2^2}{4!} - \frac{2^3}{6!} + \cdots > 0, \cos \sqrt{3} = 1 - \frac{3}{2} + \frac{3^2}{4!} - \frac{3^3}{6!} + \cdots < 0.$$

Then by the intermediate value theorem, there must be a root in the interval $(\sqrt{2}, \sqrt{3})$. Also since $\cos$ is decreasing on $(0, 2)$, this must also be the smallest positive root. $\square$

The existence of this root gives us a way to define π .

Definition 1.5.16 (π)

π is the smallest positive real number such that $\cos \pi/2 = 0$.

We can easily determine the value of $\sin \pi/2$ too. We have $\sin^2 \pi/2 + \cos^2 \pi/2 = 1$, so $\sin^2 \pi/2 = 1$, and knowing from the proof of [Lemma 1.5.15](#) that $\sin(x) > 0$ on $(0, 2)$, we can deduce that $\sin \pi/2 = 1$. These results are all we need to show that $\sin$ and $\cos$ are periodic, and also that the two functions are just translated versions of each-other.

Proposition 1.5.17 (Periodicity of sin and cos)

The functions sin and cos are periodic with a period of 2π , and are related as follows.

$$\begin{aligned}\sin(z + \pi/2) &= \cos z, & \cos(z + \pi/2) &= -\sin z, \\ \sin(z + \pi) &= -\sin z, & \cos(z + \pi) &= -\cos z, \\ \sin(z + 2\pi) &= \sin z, & \cos(z + 2\pi) &= \cos z.\end{aligned}$$

Proof. This follows directly from $\sin(\pi/2) = 1$, $\cos(\pi/2) = 0$ and the angle addition formulas. $\square$

Remark (Periodicity of exp). If we use the power series for sin and cos, we can write $\exp(iz) = \cos z + i \sin z$, from which the above result implies that exp is periodic with a period of 2π .

With sin and cos have been defined properly, we can then define tan, sec, csc and all of those fun functions in the normal way.

The Hyperbolic Functions

The last set of functions we will touch on is the (probably) slightly less familiar hyperbolic functions. As with the standard trigonometric functions, we can state the definitions using the exponential function.

Definition 1.5.18 (Hyperbolic Sine & Cosine)

We define the **hyperbolic sine** and **hyperbolic cosine functions** by the power series

$$\begin{aligned}\sinh z &= \frac{e^z - e^{-z}}{2} = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \cdots \\ \cosh z &= \frac{e^z + e^{-z}}{2} = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \cdots\end{aligned}$$

where $z \in \mathbb{R}$.

Remark. The basic hyperbolic and trigonometric functions are related by $\cosh z = \cos(iz)$ and $\sinh z = -i \sin(iz)$. Remembering this can allow you to adapt facts about sin and cos to facts about sinh and cosh.

We will state a few properties for convenience.

Proposition 1.5.19 (Properties of sinh & cosh)

Let $z, w \in \mathbb{R}$. Then the following hold.

- (i) $\sinh' z = \cosh z$, $\cosh' z = \sinh z$.
- (ii) $\cosh^2 z - \sinh^2 z = 1$.
- (iii) $\sinh(z + w) = \sinh z \cosh w + \cosh z \sinh w$.
- (iv) $\cosh(z + w) = \cosh z \cosh w + \sinh z \sinh w$.

Proof. We will use the observation made in the above remark.

- (i) For $\sinh$ we have $\sinh' z = [-i \sin(iz)]' = \cos(iz) = \cosh z$, and for $\cosh$ we have $\cosh' z = [\cos(iz)]' = -i \sin(iz) = \sinh z$.
- (ii) $\cosh^2 z - \sinh^2 z = \cos^2(iz) - (-i \sin(iz))^2 = \cos^2(iz) + \sin^2(iz) = 1$.
- (iii) $\sinh(z + w) = -i \sin(iz + iw) = \sinh(z) \cosh(w) + \cosh(z) \sinh(w)$.
- (iv) $\cosh(z + w) = \cos(iz + iw) = \cosh(z) \cosh(w) + \sinh(z) \sinh(w)$. □

§1.6 Integration

We are now prepared, both technically and emotionally, to talk about *integrals*. The idea behind integration is to assign some sort of ‘area’ to sets. The first issue we run into is that it is not quite clear what ‘area’ actually means (in mathematical terms), so to avoid this difficulty, we will instead define the notion of an integral (specifically the *Riemann integral*, there are other types) and we will use this as our definition of area (not vice versa).

Throughout this section, we will deal with the integration of bounded functions defined on bounded intervals, $f : [a, b] \rightarrow \mathbb{R}$. We will discuss a slight generalisation later on.

§1.6.1 Dissections, Upper & Lower Sums, and Riemann Integrals

As with most ideas in analysis, integration depends fundamentally on a ‘limiting process’. For Riemann integrals, this is conducted by considering *dissections* of the interval in which we will be integrating over.

Definition 1.6.1 (Dissection)

A **dissection** $\mathcal{D}$ of a finite interval $[a, b]$ is a finite subset of $[a, b]$ containing the endpoints. We typically write $\mathcal{D} = \{x_0, x_1, x_2, \dots, x_n\}$ with $a = x_0 \leq x_1 \leq \dots \leq x_n = b$.

For a given dissection, because we are dealing with bounded functions we can sensibly define the lower and upper sums of a function as follows.

Definition 1.6.2 (Upper & Lower Sums)

Let $f : [a, b] \rightarrow \mathbb{R}$ be a bounded function, and let $\mathcal{D}$ be a dissection of $[a, b]$. We define the **upper sum** $S_{\mathcal{D}}(f)$ and **lower sum** $s_{\mathcal{D}}(f)$ by

$$S_{\mathcal{D}}(f) = \sum_{j=1}^n (x_j - x_{j-1}) \sup_{x \in [x_{j-1}, x_j]} f(x),$$

$$s_{\mathcal{D}}(f) = \sum_{j=1}^n (x_j - x_{j-1}) \inf_{x \in [x_{j-1}, x_j]} f(x).$$

Let's make some observations. By construction we have $S_{\mathcal{D}}(f) \geq s_{\mathcal{D}}(f)$, and we can also see intuitively that replacing a dissection by a more elaborate one will decrease the upper

sum and increase the lower sum. Indeed, if we say that $\mathcal{D}'$ **refines** $\mathcal{D}$ when $\mathcal{D}' \supseteq \mathcal{D}$, then we can formalise this intuition as follows.

Lemma 1.6.3 (Refinement Lemma)

If $f : [a, b] \rightarrow \mathbb{R}$ is a bounded function and $\mathcal{D}, \mathcal{D}'$ are dissections of $[a, b]$ such that $\mathcal{D} \subseteq \mathcal{D}'$, then

$$s_{\mathcal{D}}(f) \leq s_{\mathcal{D}'}(f) \leq S_{\mathcal{D}'}(f) \leq S_{\mathcal{D}}(f).$$

Proof. It suffices to show that this holds when $\mathcal{D}'$ and $\mathcal{D}$ differ by a single element (since then we can just repeatedly apply this argument to obtain the general case). Suppose that $\mathcal{D}' = \{x_0, \dots, x_n\}$, and that $\mathcal{D} = \mathcal{D}' \setminus \{x_i\}$ where $i \neq 0, n$. Then let

$$A = \sup_{x \in [x_{i-1}, x_i]} f(x), \quad \text{and} \quad B = \sup_{x \in [x_i, x_{i+1}]} f(x).$$

We can then establish the right hand side of the inequality with

$$\begin{aligned} S_{\mathcal{D}}(f) - S_{\mathcal{D}'}(f) &= (x_{i+1} - x_{i-1}) \max\{A, B\} - (x_i - x_{i-1})A - (x_{i+1} - x_i)B \\ &\geq \max\{A, B\}[(x_{i+1} - x_{i-1}) - (x_i - x_{i-1}) - (x_{i+1} - x_i)] = 0. \end{aligned}$$

Then the left hand side of the inequality follows similarly (taking infima). $\square$

A direct consequence of this lemma is that lower sums can *never* exceed upper sums.

Lemma 1.6.4 (Key Integration Property)

If $f : [a, b] \rightarrow \mathbb{R}$ is a bounded function and $\mathcal{D}_1, \mathcal{D}_2$ are dissections of $[a, b]$ then

$$s_{\mathcal{D}_1}(f) \leq S_{\mathcal{D}_2}(f).$$

Proof. This follows from the previous lemma by noting that $s_{\mathcal{D}_1}(f) \leq s_{\mathcal{D}_1 \cup \mathcal{D}_2}(f)$, and $S_{\mathcal{D}_1 \cup \mathcal{D}_2}(f) \leq S_{\mathcal{D}_2}(f)$. $\square$

We are now (finally) ready to say what it means for a function to be Riemann integrable.

Definition 1.6.5 (Upper & Lower Integrals)

For a bounded function $f : [a, b] \rightarrow \mathbb{R}$ we define the **upper integral** as $I^*(f) = \inf_{\mathcal{D}} S_{\mathcal{D}}(f)$ and the **lower integral** as $I_*(f) = \sup_{\mathcal{D}} s_{\mathcal{D}}(f)$.

Note that [Lemma 1.6.4](#), along with the boundedness of the function, guarantees that the upper and lower integrals always exist.

Definition 1.6.6 (Riemann Integrable)

If $f : [a, b] \rightarrow \mathbb{R}$ is a bounded function and $I^*(f) = I_*(f)$, then we say f is **Riemann integrable** and write

$$\int_a^b f(x) \, dx = I^*(f).$$

So this is what it means for a function to be Riemann integrable¹⁵. In general using this definition directly on a function to show that it's integrable is quite tricky. As an example, we can attempt to show that $f(x) = x$ is integrable.

Example 1.6.7 ($f(x) = x$ is Integrable)

Consider the function $f(x) = x$ defined on the interval $[a, b]$. Then for any dissection $\mathcal{D} = \{x_0, x_1, \dots, x_n\}$ of $[a, b]$ we have the upper sum given by

$$\begin{aligned} S_{\mathcal{D}}(f) &= \sum_{j=1}^n (x_j - x_{j-1})x_j \\ &= \sum_{j=1}^n \left(\frac{x_j^2}{2} - \frac{x_{j-1}^2}{2} + \frac{x_j^2}{2} + \frac{x_{j-1}^2}{2} - x_{j-1}x_j \right) \\ &= \sum_{j=1}^n \left(\frac{x_j^2}{2} - \frac{x_{j-1}^2}{2} \right) + \frac{1}{2} \sum_{j=1}^n (x_j - x_{j-1})^2 \\ &= \left(\frac{b^2}{2} - \frac{a^2}{2} \right) + \frac{1}{2} \sum_{j=1}^n (x_j - x_{j-1})^2. \end{aligned}$$

If $x_j - x_{j-1} < \delta$ for all j , then we can obtain the upper bound

$$S_{\mathcal{D}}(f) \leq \left(\frac{b^2}{2} - \frac{a^2}{2} \right) + \frac{1}{2} \sum_{j=1}^n \delta (x_j - x_{j-1}) = \left(\frac{b^2}{2} - \frac{a^2}{2} \right) + \frac{\delta}{2} (b - a).$$

So given $\epsilon > 0$, there is some dissection $\mathcal{D}$ such that $S_{\mathcal{D}}(f) \leq (b^2 - a^2)/2 + \epsilon$, and a similar argument also gives $s_{\mathcal{D}}(f) \geq (b^2 - a^2)/2 - \epsilon$. So by our key integration property, we have

$$\frac{1}{2}(b^2 - a^2) - \epsilon \leq I^*(f), I_*(f) \leq \frac{1}{2}(b^2 - a^2) + \epsilon,$$

for any $\epsilon > 0$, and thus $I^*(f) = I_*(f) = (b^2 - a^2)/2$. This shows that $f(x) = x$ is integrable over $[a, b]$, with

$$\int_a^b x \, dx = \frac{b^2}{2} - \frac{a^2}{2}.$$

There are a few ways that we can streamline this argument. Later on we will develop more general integrability results, but the following criterion is also quite useful for showing particular functions are integrable.

Theorem 1.6.8 (Riemann's Integrability Criterion)

Let $f : [a, b] \rightarrow \mathbb{R}$ be a bounded function. Then f is Riemann integrable if and only if given any $\epsilon > 0$, we can find a dissection $\mathcal{D}$ with

$$S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) < \epsilon.$$

¹⁵We will regularly drop the 'Riemann', and when referring to 'integrability' we will always be talking only about Riemann integrability.

Proof. If f is Riemann integrable, then given $\epsilon > 0$ there must exist dissections $\mathcal{D}_1, \mathcal{D}_2$ such that

$$S_{\mathcal{D}_1}(f) < \int_a^b f(x) \, dx + \frac{\epsilon}{2} \quad \text{and} \quad s_{\mathcal{D}_2}(f) > \int_a^b f(x) \, dx - \frac{\epsilon}{2}.$$

Then taking $\mathcal{D} = \mathcal{D}_1 \cup \mathcal{D}_2$ we have $S_{\mathcal{D}}(f) \leq S_{\mathcal{D}_1}(f)$, and $s_{\mathcal{D}}(f) \geq s_{\mathcal{D}_2}(f)$, and thus

$$S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) \leq S_{\mathcal{D}_1}(f) - s_{\mathcal{D}_2}(f) < \epsilon.$$

Otherwise if for any $\epsilon > 0$ we can find a dissection $\mathcal{D}$ such that $S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) < \epsilon$, then we would have

$$\inf_{\mathcal{D}'} S_{\mathcal{D}'}(f) - \sup_{\mathcal{D}'} s_{\mathcal{D}'}(f) \leq S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) < \epsilon,$$

that is, $I^*(f) - I_*(f) < \epsilon$ for all $\epsilon > 0$. So we must have $I^*(f) = I_*(f)$, implying f is Riemann integrable. $\square$

§1.6.2 Properties of Integration

We now need to prove many of the properties of integrals that you are (most likely) already familiar with. The first result we would like to prove is that an arbitrary linear combination of integrable functions is integrable, but we will need to prove some smaller results first.

The proofs below are a little bit fiddly, but they all follow the same basic idea: simplify the problem as much as possible, think a bit about what's going on with the suprema/infima, and use our key property of integration, Riemann's criterion and so on.

Proposition 1.6.9 (Adding Integrable Functions)

If $f, g : [a, b] \rightarrow \mathbb{R}$ are Riemann integrable, then so is $f + g$ and

$$\int_a^b f(x) + g(x) \, dx = \int_a^b f(x) \, dx + \int_a^b g(x) \, dx.$$

Proof. We begin by noting the general fact

$$\sup_{x \in [x_{j-1}, x_j]} (f(x) + g(x)) \leq \sup_{x \in [x_{j-1}, x_j]} f(x) + \sup_{x \in [x_{j-1}, x_j]} g(x),$$

which directly implies that $S_{\mathcal{D}}(f + g) \leq S_{\mathcal{D}}(f) + S_{\mathcal{D}}(g)$. A similar fact about infima implies $s_{\mathcal{D}}(f + g) \geq s_{\mathcal{D}}(f) + s_{\mathcal{D}}(g)$.

Now let $\mathcal{D}_1$ and $\mathcal{D}_2$ be dissections, and let $\mathcal{D} = \mathcal{D}_1 \cup \mathcal{D}_2$. Then we have

$$S_{\mathcal{D}}(f + g) \leq S_{\mathcal{D}}(f) + S_{\mathcal{D}}(g) \leq S_{\mathcal{D}_1}(f) + S_{\mathcal{D}_2}(g),$$

which implies that $I^*(f + g) \leq I^*(f) + I^*(g)$. Similarly we have $I_*(f + g) \geq I_*(f) + I_*(g)$.

Since f and g are integrable, their upper and lower integrals are equal, so combining

the two previous inequalities gives

$$\int_a^b f(x) \, dx + \int_a^b g(x) \, dx \leq I_*(f+g) \leq I^*(f+g) \leq \int_a^b f(x) \, dx + \int_a^b g(x) \, dx,$$

so $I_*(f+g) = I^*(f+g)$, showing $f+g$ is integrable, with the integral given by $\int_a^b f(x) + g(x) \, dx = \int_a^b f(x) \, dx + \int_a^b g(x) \, dx$. $\square$

Proposition 1.6.10 (Negating Integrable Functions)

If $f : [a, b] \rightarrow \mathbb{R}$ is Riemann integrable, then so is $-f$, and

$$\int_a^b (-f(x)) \, dx = - \int_a^b f(x) \, dx.$$

Proof. Let $\mathcal{D}$ be a dissection of $[a, b]$. Then since $\sup_x -f(x) = -\inf_x f(x)$, we have

$$\begin{aligned} S_{\mathcal{D}}(-f) &= \sum_{j=1}^n (x_j - x_{j-1}) \sup_{x \in [x_{j-1}, x_j]} (-f(x)) \\ &= - \sum_{j=1}^n (x_j - x_{j-1}) \inf_{x \in [x_{j-1}, x_j]} f(x) \\ &= -s_{\mathcal{D}}(f). \end{aligned}$$

Similarly $s_{\mathcal{D}}(-f) = -S_{\mathcal{D}}(f)$. This then implies that $I^*(-f) = -I_*(f)$ and $I_*(-f) = -I^*(f)$. But then f is integrable, so $I^*(-f) = I_*(-f) = -I^*(f)$. Thus $-f$ is also integrable, and $\int_a^b (-f(x)) \, dx = - \int_a^b f(x) \, dx$. $\square$

Proposition 1.6.11 (Scaling Integrable Functions)

If $\lambda \in \mathbb{R}$ and $f : [a, b] \rightarrow \mathbb{R}$ is Riemann integrable, then so is λf and

$$\int_a^b \lambda f(x) \, dx = \lambda \int_a^b f(x) \, dx.$$

Proof. Without loss of generality^a, we may assume that $\lambda \geq 0$. Then if $\mathcal{D}$ is a dissection of $[a, b]$ we have

$$S_{\mathcal{D}}(\lambda f) = \sum_{j=1}^n (x_j - x_{j-1}) \sup_{x \in [x_{j-1}, x_j]} \lambda f(x) = \lambda S_{\mathcal{D}}(f),$$

and similarly $s_{\mathcal{D}}(\lambda f) = \lambda s_{\mathcal{D}}(f)$. Then $I^*(\lambda f) = \lambda I^*(f)$ and $I_*(\lambda f) = \lambda I_*(f)$. Since f is integrable, we then have $I^*(\lambda f) = I_*(\lambda f) = \lambda I^*(f)$, so λf is integrable and $\int_a^b \lambda f(x) \, dx = \lambda \int_a^b f(x) \, dx$. $\square$

^aIf $\lambda < 0$, we can consider $|\lambda|f$, then by the previous lemma $-|\lambda|f = \lambda f$ will be integrable.

To summarise these results, if $f, g : [a, b] \rightarrow \mathbb{R}$ are integrable and $\lambda, \mu \in \mathbb{R}$ then $\lambda f + \mu g$

is integrable and

$$\int_a^b \lambda f(x) + \mu g(x) \, dx = \lambda \int_a^b f(x) \, dx + \mu \int_a^b g(x) \, dx.$$

Let's now turn our attention¹⁶ to another set of integral properties which are still natural but probably ever-so-slightly less familiar: integral inequalities. The first result is one you'd expect to be true.

Proposition 1.6.12 (Basic Integral Inequality)

If $f, g : [a, b] \rightarrow \mathbb{R}$ are Riemann integrable and $f(x) \leq g(x)$ for all $x \in [a, b]$, then

$$\int_a^b f(x) \, dx \leq \int_a^b g(x) \, dx.$$

Proof. If $f \leq g$ then for all dissections $\mathcal{D}$ we have $S_{\mathcal{D}}(f) \leq S_{\mathcal{D}}(g)$, and hence $\int_a^b f(x) \, dx = \inf_{\mathcal{D}} S_{\mathcal{D}}(f) \leq \inf_{\mathcal{D}} S_{\mathcal{D}}(g) = \int_a^b g(x) \, dx$. $\square$

The next result shows that $|f|$ is integrable if f is, and also something like a triangle inequality for integrals.

Proposition 1.6.13 (Integral Triangle Inequality)

If $f : [a, b] \rightarrow \mathbb{R}$ is Riemann integrable, then so is $|f|$ and

$$\int_a^b |f(x)| \, dx \geq \left| \int_a^b f(x) \, dx \right|.$$

Proof. We define $f_+(x) = \max\{f(x), 0\}$. We will show that $f_+(x)$ is integrable. For some interval I we have

$$\sup_{x \in I} f_+(x) = \max \left\{ 0, \sup_{x \in I} f(x) \right\}, \quad \inf_{x \in I} f_+(x) = \max \left\{ 0, \inf_{x \in I} f(x) \right\},$$

and then considering the cases $\sup_{x \in I} f(x) \geq 0$ and $\sup_{x \in I} f(x) \leq 0$, we find that the following inequality holds:

$$\begin{aligned} \sup_{x \in I} f_+(x) - \inf_{x \in I} f_+(x) &= \max \left\{ 0, \sup_{x \in I} f(x) \right\} - \max \left\{ 0, \inf_{x \in I} f(x) \right\} \\ &\leq \sup_{x \in I} f(x) - \inf_{x \in I} f(x). \end{aligned}$$

Then since f is integrable, given $\epsilon > 0$ there is a dissection $\mathcal{D}$ such that

$$S_{\mathcal{D}}(f_+) - s_{\mathcal{D}}(f_+) \leq S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) < \epsilon,$$

and thus f_+ is integrable. We can write $|f| = 2f_+ - f$, and thus $|f|$ is also integrable.

¹⁶Don't get too sad – we still have to show that the product of integrable functions is integrable, but we will come back to that once we have shown $|f|$ is integrable

We also have $-|f| \leq f \leq |f|$, so $\left| \int_a^b f(x) dx \right| \leq \int_a^b |f(x)| dx$. $\square$

We can use this property to prove that the product of two integrable functions fg is integrable. To do this, the expansion $2fg = (f+g)^2 - f^2 - g^2$ can be used, so all we need to show is that f^2 is integrable if f is. Also since $f^2 = |f| \cdot |f|$, we can work only with the case that f is positive.

Unlike some of the previous results, we will not write down what the value of this integral will be (there's not really a nice rule). We will only be proving integrability.

Proposition 1.6.14 (Multiplying Integrable Functions)

If $f, g : [a, b] \rightarrow \mathbb{R}$ are Riemann integrable, then so is fg .

Proof. We will first show that if $f : [a, b] \rightarrow \mathbb{R}$ is an integrable function such that $f(x) \geq 0$ for all $x \in [a, b]$, then f^2 is integrable.

Since f is integrable (and hence bounded), we can choose some $K > 0$ such that $|f(x)| \leq K$ for all $x \in [a, b]$. Then given any $\epsilon > 0$, there exists some dissection $\mathcal{D}$ where $S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) < \epsilon/2K$.

Using $\mathcal{D}$, we define $M_j = \sup_{x \in [x_{j-1}, x_j]} f(x)$ and $m_j = \inf_{x \in [x_{j-1}, x_j]} f(x)$. Then we have

$$\begin{aligned} S_{\mathcal{D}}(f^2) - s_{\mathcal{D}}(f^2) &= \sum_{j=1}^n (x_j - x_{j-1})(M_j^2 - m_j^2) \\ &= \sum_{j=1}^n (x_j - x_{j-1})(M_j + m_j)(M_j - m_j) \\ &\leq 2K(S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f)) < \epsilon, \end{aligned}$$

showing that f^2 is integrable.

Since $f^2 = |f| \cdot |f|$, and $|f| \geq 0$, this argument shows that f^2 is integrable for any integrable function f . Using this and previous properties then shows that $[(f+g)^2 - f^2 - g^2]/2 = fg$ is integrable. $\square$

§1.6.3 Integrable Functions

At this point we have our definition of integrability, along with some basic properties of integrals. However, we have so far only really seen that $f(x) = x$ and $f(x) = |x|$ are integrable. In this section we will prove some results that will expand this list quite widely.

We have so only looked at bounded functions, and a natural question is whether bounded is a sufficient criterion for integrability. This sadly is not the case, and there is a standard counterexample due to Dirichlet.

Example 1.6.15 (A Bounded Non-Integrable Function)

The function $f : [0, 1] \rightarrow \mathbb{R}$ given by

$$f(x) = \begin{cases} 1 & \text{if } x \in \mathbb{Q}, \\ 0 & \text{if } x \notin \mathbb{Q}. \end{cases}$$

is not Riemann integrable.

To see this, note that for any dissection $\mathcal{D}$, since $\mathbb{Q}$ is dense in $\mathbb{R}$, we have $s_{\mathcal{D}}(f) = 0$ and $S_{\mathcal{D}}(f) = 1$.

So let's look at some types of integrable functions. The first is that monotonic functions are integrable, which can be shown by taking an evenly spaced dissection causing the sum to telescope.

Proposition 1.6.16 (Monotonic Functions are Integrable)

Let $f : [a, b] \rightarrow \mathbb{R}$ be monotonic. Then f is Riemann integrable.

Proof. Without loss of generality, assume that f is increasing. Then given $\epsilon > 0$, for any integer $n > [(b-a)(f(b)-f(a))]/\epsilon$ we can define the dissection $\mathcal{D} = \{x_0, x_1, \dots, x_n\}$ of $[a, b]$, where $x_0 = a$, and $x_j - x_{j-1} = (b-a)/n$. Then we have

$$\begin{aligned} S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) &= \sum_{j=1}^n (x_j - x_{j-1}) \left[\sup_{x \in [x_{j-1}, x_j]} f(x) - \inf_{x \in [x_{j-1}, x_j]} f(x) \right] \\ &= \sum_{j=1}^n \frac{b-a}{n} [f(x_j) - f(x_{j-1})] \\ &= \frac{(b-a)(f(b) - f(a))}{n} < \epsilon, \end{aligned}$$

and thus f is integrable. □

An interesting consequence of this is that if we can write $f(x) = f_1(x) - f_2(x)$ with f_1, f_2 are increasing, then f is integrable. Such functions are known as ‘functions of bounded variation’.

The next result we would like to show is that every continuous function is Riemann integrable on some bounded interval. Before jumping into the proof, let's take a moment to reflect on what might be needed¹⁷. For some continuous function, we want to get $S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) < \epsilon$ with some dissection. What this comes down to is finding some way to bound

$$\sup_{x \in I} f(x) - \inf_{x \in I} f(x),$$

under some sufficiently small interval I . Now we know that f is continuous, and continuity tells us that there if the interval is of size at most some δ (which can depend on where the interval is) then we can get $|f(x) - f(y)| < \epsilon$. This works for one interval, but we need to construct a dissection, so we would need to make this type of argument work for intervals which cover the whole of $[a, b]$.

What would be really nice is if we could find some δ that would work no matter where

¹⁷This is not the only possible proof! You can prove things without uniform continuity, but this is a more natural (and more slick) argument.

the sub-interval in $[a, b]$ is. If this was the case, then the dissection could just be made up of points which are about a distance of δ apart. It turns out that this is always possible, and gives us the notion of *uniform continuity*.¹⁸

Definition 1.6.17 (Uniform Continuity)

Let $A \subset \mathbb{R}$ and $f : A \rightarrow \mathbb{R}$. We say that f is **uniformly continuous** on A if given any $\epsilon > 0$ we can find a $\delta > 0$ such that for $x, y \in A$, whenever $|x - y| < \delta$ we have $|f(x) - f(y)| < \epsilon$.

Note that unlike the previous definition, we have no knowledge of where in the set A the points x and y are, just how far apart they are. It turns out that on closed bounded intervals (like what we have when we talk about integration, at least in this section), continuous functions are always uniformly continuous. The proof of this is quite natural – we use Bolzano-Weierstrass to show that a contradiction to uniform continuity is a contradiction to continuity.

Theorem 1.6.18 (Continuous Functions are Uniformly Continuous)

Let $f : [a, b] \rightarrow \mathbb{R}$ be continuous. Then f is uniformly continuous.

Proof. Suppose f was not uniformly continuous, that is, there exists some $\epsilon > 0$ such that for all $\delta > 0$ there is some x, y with $|x - y| < \delta$ such that $|f(x) - f(y)| \geq \epsilon$.

Taking $\delta = 1/n$, we can find some sequences $x_n, y_n \in [a, b]$ such that $|x_n - y_n| < 1/n$, and $|f(x_n) - f(y_n)| \geq \epsilon$. Then by Bolzano-Weierstrass, we can find some convergent subsequence $x_{n_j} \rightarrow x$ for some $x \in [a, b]$. But then $|x_{n_j} - y_{n_j}| < 1/n_j$ for all j , so we must have $y_{n_j} \rightarrow x$ also.

Then $|f(x_{n_j}) - f(y_{n_j})| \geq \epsilon$ for every j , which implies that $f(x_{n_j})$ and $f(y_{n_j})$ cannot converge to the same value. But then by continuity we have $f(x_{n_j}) \rightarrow f(x)$ and $f(y_{n_j}) \rightarrow f(x)$, which is a contradiction. Thus f must be uniformly continuous. $\square$

With this result, we can prove that continuous functions are integrable in the way we discussed previously.

Theorem 1.6.19 (Continuous Functions are Integrable)

Let $f : [a, b] \rightarrow \mathbb{R}$ be continuous. Then f is Riemann integrable.

Proof. Given $\epsilon > 0$, since f is uniformly continuous, there is some $\delta > 0$ such that $|f(x) - f(y)| < \epsilon/(b - a)$ whenever $|x - y| < \delta$ and $x, y \in [a, b]$.

Now choose some integer $n \geq (b - a)/\delta$, and define the dissection $\mathcal{D} = \{x_0, x_1, \dots, x_n\}$ with $x_j = a + j(b - a)/n$. Then we have

$$\sup_{x \in [x_{j-1}, x_j]} f(x) - \inf_{x \in [x_{j-1}, x_j]} f(x) \leq \frac{\epsilon}{(b - a)},$$

¹⁸The ‘uniform’ part of the definition is part of a larger class of definitions that you will come across in later analysis courses.

for all $1 \leq j \leq n$, and thus

$$\begin{aligned} S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) &= \sum_{j=1}^n (x_j - x_{j-1}) \left[\sup_{x \in [x_{j-1}, x_j]} f(x) - \inf_{x \in [x_{j-1}, x_j]} f(x) \right] \\ &\leq \sum_{j=1}^n \frac{b-a}{n} \cdot \frac{\epsilon}{b-a} = \epsilon, \end{aligned}$$

and thus f is Riemann integrable. $\square$

This theorem shows that most of the functions we deal with regularly (and all of the ones discussed in the previous chapter) are integrable as well as continuous.

Also, we have so far spent relatively little time on the ‘evaluating integrals’ side of things, but knowing a function is integrable can help in determining the actual value of the integral. A straightforward example is shown below.

Example 1.6.20 (Integral of $f(x) = 1$)

Consider the function $f : [a, b] \rightarrow \mathbb{R}$ defined by $f(x) = 1$. This function is continuous and hence integrable. Then taking the dissection $\mathcal{D} = \{a, b\}$, we have $S_{\mathcal{D}}(f) = s_{\mathcal{D}}(f) = b - a$, so the value of the integral is

$$\int_a^b 1 \, dx = b - a.$$

§1.6.4 The Fundamental Theorem of Calculus

With all of that out of the way, we can now prove a central result in the theory of integration: the fundamental theorem of calculus. The fundamental theorem of calculus connects the theory that we built up relating to differentiation and integration, showing that (in some sense) they are ‘inverses’.

Theorem 1.6.21 (Fundamental Theorem of Calculus)

Let $f : [a, b] \rightarrow \mathbb{R}$ be continuous. For $x \in [a, b]$, we define

$$F(x) = \int_a^x f(t) \, dt.$$

Then F is differentiable, with derivative $F'(x) = f(x)$ for every x .

Proof. For $|h| > 0$, we note that

$$\frac{F(x+h) - F(x)}{h} = \frac{1}{h} \int_x^{x+h} f(t) \, dt.$$

Now given $\epsilon > 0$, since f is continuous at x there is some $\delta > 0$ such that when

$|x - y| < \delta$ we have $|f(x) - f(y)| < \epsilon$. Hence if $0 < |h| < \delta$ we have

$$\begin{aligned} \left| \frac{1}{h} \int_x^{x+h} f(t) \, dt - f(x) \right| &= \left| \frac{1}{h} \int_x^{x+h} f(t) - f(x) \, dt \right| \\ &\leq \frac{1}{|h|} \left| \int_x^{x+h} |f(t) - f(x)| \, dt \right| \\ &\leq \frac{1}{|h|} \cdot \epsilon |h| = \epsilon, \end{aligned}$$

hence $\lim_{h \rightarrow 0} \frac{F(x+h) - F(x)}{h} = f(x)$, as required. $\square$

Another way to view this theorem (which is quite useful in evaluating integrals) is the corollary below.

Corollary 1.6.22 (Fundamental Theorem of Calculus – Again)

Suppose that $f : [a, b] \rightarrow \mathbb{R}$ has a continuous derivative. Then

$$\int_a^b f'(t) \, dt = f(b) - f(a).$$

Proof. Define $g(x) = \int_a^x f'(t) \, dt$. Then by the fundamental theorem of calculus, $g'(x) = f'(x)$. Also $g(a) = 0$.

Let $h(x) = g(x) - f(x)$. Then $h'(x) = 0$, so by the mean value theorem, $h(x)$ is constant. Taking the value at a , we then have $h(a) = -f(a) = g(a) - f(a) = -f(a)$ for all x . So if $x = b$, this becomes $g(b) = f(b) - f(a)$, which is our desired result. $\square$

One of the most useful applications of the fundamental theorem of calculus is that we can translate results about derivatives to results about integrals. This works in both coming up with the integrals of functions (by thinking about which functions result in a given function when differentiated), but also in the development of general methods for evaluating integrals. Two results we will look at are integration by parts, which comes from the product rule of differentiation, and integration by substitution, which comes from the chain rule.

Corollary 1.6.23 (Integration By Parts)

Suppose that the derivatives f' and g' exist and are continuous on $[a, b]$. Then

$$\int_a^b f'(x)g(x) \, dx = f(b)g(b) - f(a)g(a) - \int_a^b f(x)g'(x) \, dx.$$

Proof. By the product rule $(fg)' = f'g + fg'$. Then by the fundamental theorem of calculus we have $f(b)g(b) - f(a)g(a) = \int_a^b f'(x)g(x) \, dx + \int_a^b f(x)g'(x) \, dx$. $\square$

Corollary 1.6.24 (Integration By Substitution)

Let $g : [\alpha, \beta] \rightarrow [a, b]$ with $g(\alpha) = a$ and $g(\beta) = b$, let g' exist and be continuous on

$[\alpha, \beta]$. Also let $f : [a, b] \rightarrow \mathbb{R}$ be continuous. Then

$$\int_a^b f(x) \, dx = \int_\alpha^\beta f(g(t))g'(t) \, dt.$$

Proof. Set $F(x) = \int_a^x f(t) \, dt$, and let $h(t) = F(g(t))$, which is defined since g takes values in $[a, b]$. Then by the fundamental theorem of calculus we have

$$\int_\alpha^\beta f(g(t))g'(t) \, dt = \int_\alpha^\beta F'(g(t))g'(t) \, dt$$

Then by the chain rule, we have

$$\int_\alpha^\beta F'(g(t))g'(t) \, dt = \int_\alpha^\beta h'(t) \, dt = h(\beta) - h(\alpha) = F(b) - F(a) = \int_a^b f(x) \, dx.$$

□

§1.6.5 Taylor's Theorem Again

With some results now built up around integration, we are going to spend the next two sections discussing two applications of integration to topics we have discussed earlier. The first will be revisiting Taylor's theorem, and after that we will look back at the convergence of infinite series.

A nice application of integration by parts (and by extension the fundamental theorem of calculus) is in proving Taylor's theorem. You may recall from our discussion of differentiation that the proof of Taylor's theorem with Lagrange remainder was somewhat cumbersome. Using integration, we can derive another form of Taylor's theorem (this time with the 'integral remainder'). This other form can then even be used to obtain Lagrange's form of the remainder, under some slightly stronger assumptions about our function¹⁹.

Theorem 1.6.25 (Taylor's Theorem with Integral Remainder)

Let f be n -times continuously differentiable on $[a, b]$. Then we have

$$f(b) = f(a) + f'(a)(b-a) + \cdots + \frac{f^{(n-1)}(a)}{(n-1)!}(b-a)^{n-1} + \int_a^b \frac{f^{(n)}(t)}{(n-1)!}(b-t)^{n-1} \, dt$$

Proof. We do induction on n . For $n = 1$, the result becomes $f(b) - f(a) = \int_a^b f'(t) \, dt$, which is true by the fundamental theorem of calculus.

Now if f is $(n+1)$ -times continuously differentiable, integrating by parts we have

$$\int_a^b \frac{f^{(n)}(t)}{(n-1)!}(b-t)^{n-1} \, dt = \left[-\frac{f^{(n)}(t)}{n!}(b-t)^n \right]_a^b + \int_a^b \frac{f^{(n+1)}(t)}{n!}(b-t)^n \, dt$$

¹⁹This is why we don't just throw out the old proof! We need a stronger continuity condition than before - specifically $f^{(n)}$ being continuous, not just existing.

$$= \frac{f^{(n)}(a)}{n!}(b-a)^n + \int_a^b \frac{f^{(n+1)}(t)}{n!}(b-t)^n dt.$$

Thus if the result is true for n , it is also true for $n+1$, so we are done by induction. $\square$

With this result in hand, we can try and re-obtain the Lagrange form of the remainder. Looking back at the form of this, we really want to some way take the $f^{(n)}(t)$ term ‘out of the integral’, turning it into some scale factor $f^{(n)}(c)$, for some $c \in (a, b)$.

The way we worked with this type of idea before was using the mean value theorem, so we are going to prove an analogue of the mean value theorem for integrals. To do this we will (naturally) use the mean value theorem along with the fundamental theorem of calculus.

Lemma 1.6.26 (Integral Mean Value Theorem)

Let $f, g : [a, b] \rightarrow \mathbb{R}$ be continuous with $g(x) \neq 0$ for all $x \in (a, b)$. Then there exists $c \in (a, b)$ such that

$$\int_a^b f(x)g(x) dx = f(c) \int_a^b g(x) dx.$$

Proof. Let $F(x) = \int_a^x f(t)g(t) dt$ and $G(x) = \int_a^x g(t) dt$. By Cauchy’s mean value theorem, there exists some $c \in (a, b)$ such that

$$(F(b) - F(a))G'(c) = F'(c)(G(b) - G(a)),$$

which by the fundamental theorem of calculus implies

$$\left(\int_a^b f(t)g(t) dt \right) g(c) = f(c)g(c) \int_a^b g(t) dt.$$

Then since $g(c) \neq 0$, the result follows. $\square$

And now we can write down a weaker form of Taylor’s theorem with Lagrange remainder.

Theorem 1.6.27 (Taylor’s Theorem with Lagrange Remainder – Weaker)

Let f be n -times continuously differentiable on $[a, b]$. Then we have

$$f(b) = f(a) + f'(a)(b-a) + \cdots + \frac{f^{(n-1)}(a)}{(n-1)!}(b-a)^{n-1} + \frac{f^{(n)}(c)}{n!}(b-a)^n,$$

for some $c \in (a, b)$.

Proof. By Taylor’s theorem with integral remainder, we have

$$f(b) = f(a) + f'(a)(b-a) + \cdots + \frac{f^{(n-1)}(a)}{(n-1)!}(b-a)^{n-1} + \int_a^b \frac{f^{(n)}(t)}{(n-1)!}(b-t)^{n-1} dt.$$

Then the integral mean value theorem gives us that

$$\int_a^b \frac{f^{(n)}(t)}{(n-1)!} (b-t)^{n-1} dt = f^{(n)}(c) \int_a^b \frac{(b-t)^{n-1}}{(n-1)!} dt = \frac{f^{(n)}(c)}{n!} (b-a)^n,$$

for some $c \in (a, b)$, giving our result. $\square$

Now, to just emphasize one last time: this version of the result imposes *an extra continuity condition*, and *does not replace the result and proof we had earlier*. That said, it's still a perfectly good result on its own.

§1.6.6 Improper Integrals & The Integral Test

So far our definition of Riemann integration applies only to functions that are bounded over some closed interval. In this subsection we are going to try and extend this definition in a natural way to discuss the integration of functions that are not necessarily bounded and integration over an interval that may not be closed (and may be infinite).

Definition 1.6.28 (Improper Integrals)

Suppose $f : [a, b) \rightarrow \mathbb{R}$ is integrable (and bounded) on every interval $[a, R]$, where $b \in \mathbb{R} \cup \{\infty\}$, and

$$\int_a^R f(x) dx \rightarrow \ell \quad \text{as } R \rightarrow b.$$

Then we say that the **improper integral** $\int_a^b f(x) dx$ converges, and that its value is ℓ . Otherwise, we say that it diverges.

Let's have a look at some examples.

Example 1.6.29 (Integral of $1/x^k$ from 1 to ∞)

We will show that the improper integral $\int_1^\infty \frac{1}{x^k} dx$ converges if and only if $k > 1$.

If $k \neq 1$, then considering the integral of $1/x^k$ over $[1, R]$, we have

$$\begin{aligned} \int_1^R \frac{1}{x^k} dx &= \left. \frac{x^{1-k}}{1-k} \right|_1^R \\ &= \frac{R^{1-k} - 1}{1-k}, \end{aligned}$$

which tends to a finite limit as $R \rightarrow \infty$, namely $-1/(1-k)$, if and only if $k > 1$.

Otherwise, if $k = 1$, then over $[1, R]$ we have

$$\int_1^R \frac{1}{x} dx = \log R,$$

which does not tend to a finite limit as $R \rightarrow \infty$. Thus the integral converges if and only if $k > 1$.

Example 1.6.30 (Integral of $1/\sqrt{x}$ from 0 to 1)

We will show that the improper integral $\int_0^1 \frac{1}{\sqrt{x}} dx$ converges.

For any $\delta > 0$, we have

$$\int_{\delta}^1 \frac{1}{\sqrt{x}} dx = 2\sqrt{x} \Big|_{\delta}^1 = 2 - 2\sqrt{\delta} \rightarrow 2 \quad \text{as } \delta \rightarrow 0,$$

and thus the improper integral converges to 2.

Note the example above shows that it is possible to have an improper integral which converges when the function is not bounded on the interval being integrated over.²⁰

The definition of improper integrals also gives us a sensible way to say if $\int_{-\infty}^{\infty} f(x) dx$ converges. If for some a we have $\int_{-\infty}^a f(x) dx = \ell_1$ and $\int_a^{\infty} f(x) dx = \ell_2$, then we say that $\int_{-\infty}^{\infty} f(x) dx = \ell_1 + \ell_2$.

Remark (Warning). This is a strictly stronger notion than saying that $\int_{-R}^R f(x) dx$ converges to some limit as $R \rightarrow \infty$.

It is with improper integrals that we get the last application of integration to our previously discussed topics: infinite series.

Theorem 1.6.31 (The Integral Comparison Test)

If $f : [1, \infty) \rightarrow \mathbb{R}$ is a non-negative decreasing function with $f(x) \rightarrow 0$ as $x \rightarrow \infty$ then

$$\sum_1^{\infty} f(n) \quad \text{and} \quad \int_1^{\infty} f(x) dx$$

either both diverge or both converge.

Proof. Since f is decreasing and is non-negative, we have for $n \geq 2$ that

$$\int_n^{n+1} f(x) dx \leq f(n) \leq \int_{n-1}^n f(x) dx.$$

That is, since $\int_1^2 f(x) dx \leq f(1)$, we have

$$\int_1^{N+1} f(x) dx \leq \sum_{n=1}^N f(n) \leq \int_1^N f(x) dx + f(1),$$

and then our result follows as $N \rightarrow \infty$. □

The integral comparison test is useful because in many cases it is easier to evaluate an integral than it is to evaluate a sum (of course this isn't always true, and there's many examples in both directions). This test also gives us a way to determine the convergence of sums that previously required tools such as Cauchy's condensation test²¹. An example

²⁰It is also possible to have a function f that is unbounded on the interval $[1, \infty)$, and yet $\int_1^{\infty} f(x) dx$ converges. If you haven't seen this before, try coming up with an example (as a hint, one way to do it is by drawing triangles in a somewhat clever way).

²¹Though it can be rather cumbersome to evaluate the integrals in certain cases, in which case reaching

is shown below.

Example 1.6.32 (Using the Integral Test)

We will prove that $\sum_{n=2}^{\infty} \frac{\log n}{n^2}$ converges using the integral test.

We compute using integration by parts that

$$\begin{aligned}\int_2^R \frac{\log x}{x^2} dx &= -\frac{\log x}{x} \Big|_2^R + \int_2^R \frac{1}{x^2} dx \\ &= -\frac{\log R}{R} + \frac{\log 2}{2} - \frac{1}{R} + \frac{1}{2}.\end{aligned}$$

This converges to $(1+\log 2)/2$ as $R \rightarrow \infty$, and thus $\int_2^{\infty} \log x/x^2 dx$ and $\sum_{n=2}^{\infty} \log n/n^2$ both converge by the integral test.

for Cauchy's condensation test first might be still helpful. Using the integral test also is a straightforward way to derive Cauchy's condensation test

2 Differential Equations

A differential equation is an equation that relates a function to its derivatives. Such equations are the natural language in which much of science is written – whenever the rate at which something changes depends on its current state, a differential equation is lurking. This course is about developing a collection of techniques for solving (and, when solving is too hard, understanding the behaviour of) differential equations and their discrete cousins, difference equations.

This article constitutes my notes for the ‘Differential Equations’ course, held in Michaelmas 2020 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§2.1 A Revision of Calculus

This course leans heavily on the machinery of calculus, so we will begin with a quick (and informal) review of differentiation, along with some notation for describing the sizes of functions that will be used constantly in what follows. This section is not meant to be a first introduction to calculus¹, and the reader should feel free to skim it.

§2.1.1 Differentiation

We recall the basic definition of the derivative of a function.

Definition 2.1.1 (Derivative)

The **derivative** of a function $f(x)$ with respect to x is

$$\frac{df}{dx} = \lim_{h \rightarrow 0} \frac{f(x+h) - f(x)}{h},$$

when this limit exists. We say f is **differentiable** at x if the limit exists, which requires the limits from the left and from the right to exist and agree.

The derivative measures the instantaneous rate of change of f , and geometrically it is the slope of the graph of f . We will use the notations

$$\frac{df}{dx} = f'(x) = \frac{d}{dx}f(x)$$

interchangeably, and write f'' , f''' , $f^{(n)}$ and so on for higher derivatives. In this course we will also frequently use Newton’s notation $\dot{y}$, $\ddot{y}$ for derivatives with respect to time.

One thing worth being slightly careful about: the notation f' always denotes the derivative of f *with respect to its argument*. So $f'(2x)$ means the derivative of f evaluated at $2x$, not the derivative of the function $x \mapsto f(2x)$.

¹The reader who wants to see calculus done *properly*, with all of the analytic details filled in, should consult the ‘Analysis I’ course. In this course we take a rather more relaxed attitude towards questions of convergence and rigour.

Example 2.1.2 (A Function That is Not Differentiable)

The function $f(x) = |x|$ is not differentiable at $x = 0$, since

$$\lim_{h \rightarrow 0^+} \frac{|h| - |0|}{h} = 1, \quad \lim_{h \rightarrow 0^-} \frac{|h| - |0|}{h} = -1,$$

and these two one-sided limits disagree.

§2.1.2 Big- O and Little- o Notation

Throughout this course (and indeed throughout mathematics), it is useful to have a compact notation for comparing the sizes of functions near a point.

Definition 2.1.3 (Little- o)

We write $f(x) = o(g(x))$ as $x \rightarrow x_0$ if

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)} = 0.$$

Informally, ‘ f is much smaller than g near x_0 ’.

Definition 2.1.4 (Big- O)

We write $f(x) = O(g(x))$ as $x \rightarrow x_0$ if $f(x)/g(x)$ is bounded as $x \rightarrow x_0$. Informally, ‘ f is at most comparable in size to g near x_0 ’.

Usually x_0 will be 0 or ∞ , and often we will not say which explicitly when it is clear from context. Note that $f = o(g)$ implies $f = O(g)$, but not conversely. Also, for $f = O(g)$ we do *not* require that $\lim f/g$ exists – boundedness is enough.

There is a standard abuse of notation here that is worth pointing out. When we write $f(x) = o(g(x))$, we are not saying that $f(x)$ literally equals some function called ‘ $o(g(x))$ ’; rather, $o(g(x))$ stands for the *class* of functions small compared to g , and we are asserting that f belongs to it. In particular such ‘equations’ should only be read left to right.

Example 2.1.5

As illustrations of the notation:

- (i) $x = o(\sqrt{x})$ as $x \rightarrow 0$, while $\sqrt{x} = o(x)$ as $x \rightarrow \infty$.
- (ii) $\sin 2x = O(x)$ as $x \rightarrow 0$, since $\sin \theta \approx \theta$ for small θ .
- (iii) $\sin 2x = O(1)$ as $x \rightarrow \infty$, even though $\lim_{x \rightarrow \infty} \sin 2x$ does not exist.

The real utility of this notation is that it lets us do calculus ‘to leading order’, keeping track of the error terms without needing to write them down explicitly. As a first example of this, we can rephrase differentiability.

Proposition 2.1.6 (Derivative as Linear Approximation)

If f is differentiable at x_0 then

$$f(x_0 + h) = f(x_0) + f'(x_0)h + o(h) \quad \text{as } h \rightarrow 0.$$

Proof. By the definition of the derivative,

$$\frac{f(x_0 + h) - f(x_0)}{h} - f'(x_0) \rightarrow 0 \quad \text{as } h \rightarrow 0,$$

so the left-hand side is $o(h)/h$, that is, $f(x_0 + h) - f(x_0) - f'(x_0)h = o(h)$. $\square$

In other words – near x_0 , a differentiable function looks like a straight line, up to an error which is small compared to h . This point of view (functions being locally linear) is the correct way to think about differentiation, and it is the form of the definition which generalises to higher dimensions.

§2.1.3 Rules for Differentiation

The basic rules of differentiation can all be derived quite cleanly using the o notation. We will do the chain rule as an example.

Theorem 2.1.7 (Chain Rule)

If $f(x) = F(g(x))$, then

$$\frac{df}{dx} = \frac{dF}{dg} \frac{dg}{dx} = F'(g(x)) g'(x).$$

Proof. Assuming g is differentiable at x and F is differentiable at $g(x)$, we compute

$$\begin{aligned} \frac{df}{dx} &= \lim_{h \rightarrow 0} \frac{F(g(x+h)) - F(g(x))}{h} \\ &= \lim_{h \rightarrow 0} \frac{F(g(x) + hg'(x) + o(h)) - F(g(x))}{h} \\ &= \lim_{h \rightarrow 0} \frac{F(g(x)) + (hg'(x) + o(h))F'(g(x)) + o(hg'(x) + o(h)) - F(g(x))}{h} \\ &= \lim_{h \rightarrow 0} \left[g'(x)F'(g(x)) + \frac{o(h)}{h} \right] = g'(x)F'(g(x)). \square \end{aligned}$$

Theorem 2.1.8 (Product Rule)

If $f(x) = u(x)v(x)$, then $f'(x) = u'(x)v(x) + u(x)v'(x)$.

The product rule extends to higher derivatives in a way that looks suspiciously like the binomial theorem (and indeed the proof is an induction of exactly the same shape).

Theorem 2.1.9 (Leibniz's Rule)

If $f = uv$ then the n th derivative of f is

$$f^{(n)}(x) = \sum_{r=0}^n \binom{n}{r} u^{(r)}(x) v^{(n-r)}(x).$$

Example 2.1.10

Let's find the n th derivative of $f(x) = x^2 e^x$. Take $u = x^2$ and $v = e^x$. All derivatives of v are e^x , while $u' = 2x$, $u'' = 2$, and all higher derivatives of u vanish. So only three terms of the sum survive:

$$f^{(n)}(x) = \binom{n}{0} x^2 e^x + \binom{n}{1} \cdot 2x \cdot e^x + \binom{n}{2} \cdot 2 \cdot e^x = (x^2 + 2nx + n(n-1)) e^x.$$

Leibniz's rule is at its best in situations like this, where one factor is eventually annihilated by differentiation.

§2.1.4 Taylor Series

Linear approximation says a differentiable function looks like a line up to $o(h)$. If the function has more derivatives, we can do better.

Theorem 2.1.11 (Taylor's Theorem)

If f is n -times differentiable at x , then

$$f(x+h) = f(x) + hf'(x) + \frac{h^2}{2!} f''(x) + \cdots + \frac{h^n}{n!} f^{(n)}(x) + E_n,$$

where $E_n = o(h^n)$ as $h \rightarrow 0$. If additionally $f^{(n+1)}$ exists, then $E_n = O(h^{n+1})$.

It is sometimes convenient to relabel and write this as

$$f(x) = f(x_0) + (x - x_0)f'(x_0) + \cdots + \frac{(x - x_0)^n}{n!} f^{(n)}(x_0) + E_n,$$

an expansion of f *about the point* x_0 . Letting $n \rightarrow \infty$ (and not worrying too much about when this is valid) gives the **Taylor series** of f about x_0 .

We should stress that Taylor's theorem is a purely *local* statement: it describes the behaviour of f arbitrarily close to x_0 , and by itself says nothing about what f does far away.

Example 2.1.12 (Standard Taylor Series)

Some expansions about $x = 0$ that we will use freely throughout the course:

$$\begin{aligned} e^x &= 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots, \\ \sin x &= x - \frac{x^3}{3!} + \frac{x^5}{5!} - \cdots, \quad \cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \cdots, \\ \ln(1+x) &= x - \frac{x^2}{2} + \frac{x^3}{3} - \cdots \quad (|x| < 1), \end{aligned}$$

$$(1+x)^\alpha = 1 + \alpha x + \frac{\alpha(\alpha-1)}{2!}x^2 + \cdots \quad (|x| < 1).$$

Each follows by computing derivatives at 0 and applying the theorem. The most common use in this course is truncation: statements like $e^\varepsilon = 1 + \varepsilon + O(\varepsilon^2)$ or $\sin \varepsilon = \varepsilon + O(\varepsilon^3)$, valid for small ε , are the engine behind every ‘linearisation’ we will perform.

§2.1.5 L'Hôpital's Rule

A pleasant application of Taylor's theorem is a systematic way of evaluating limits of the form $0/0$.

Theorem 2.1.13 (L'Hôpital's Rule)

Let f and g be differentiable at x_0 , with $\lim_{x \rightarrow x_0} f(x) = \lim_{x \rightarrow x_0} g(x) = 0$. Then

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)} = \lim_{x \rightarrow x_0} \frac{f'(x)}{g'(x)},$$

provided the right-hand limit exists.

Proof. By Taylor's theorem, $f(x) = f(x_0) + (x - x_0)f'(x_0) + o(x - x_0)$, and similarly for g . Since $f(x_0) = g(x_0) = 0$,

$$\lim_{x \rightarrow x_0} \frac{f(x)}{g(x)} = \lim_{x \rightarrow x_0} \frac{(x - x_0)f'(x_0) + o(x - x_0)}{(x - x_0)g'(x_0) + o(x - x_0)} = \lim_{x \rightarrow x_0} \frac{f'(x_0) + \frac{o(x-x_0)}{x-x_0}}{g'(x_0) + \frac{o(x-x_0)}{x-x_0}} = \lim_{x \rightarrow x_0} \frac{f'(x)}{g'(x)}.$$

□

Example 2.1.14

Let's compute $\lim_{x \rightarrow 0} \frac{1 - \cos x}{x^2}$. Both numerator and denominator vanish at 0, so

$$\lim_{x \rightarrow 0} \frac{1 - \cos x}{x^2} = \lim_{x \rightarrow 0} \frac{\sin x}{2x} = \lim_{x \rightarrow 0} \frac{\cos x}{2} = \frac{1}{2},$$

applying the rule twice. (Alternatively, just expand $\cos x = 1 - x^2/2 + O(x^4)$ and read off the answer – Taylor series are frequently faster than repeated applications of L'Hôpital.)

Example 2.1.15

As another quick illustration,

$$\lim_{x \rightarrow 0} \frac{e^x - 1}{x} = \lim_{x \rightarrow 0} \frac{e^x}{1} = 1.$$

In fact, whenever $g(x) = x$ and $f(0) = 0$, L'Hôpital's rule simply restates the definition of $f'(0)$ as a limiting difference quotient – the rule is a generalisation of the derivative itself.

§2.1.6 Integration

We will also need integration, which we think of informally as computing the area under a graph: for a partition $a = x_0 < x_1 < \cdots < x_N = b$ with spacing Δx ,

$$\int_a^b f(x) \, dx = \lim_{\Delta x \rightarrow 0} \sum_n f(x_n) \Delta x.$$

The connection between integration and differentiation is the fundamental theorem of calculus.

Theorem 2.1.16 (Fundamental Theorem of Calculus)

Let $F(x) = \int_a^x f(t) \, dt$. Then $F'(x) = f(x)$.

Proof. We compute directly, using the fact that the integral from x to $x+h$ is an area of width h and height $f(x) + o(1)$:

$$F'(x) = \lim_{h \rightarrow 0} \frac{1}{h} \left[\int_a^{x+h} f(t) \, dt - \int_a^x f(t) \, dt \right] = \lim_{h \rightarrow 0} \frac{1}{h} \int_x^{x+h} f(t) \, dt = \lim_{h \rightarrow 0} \frac{f(x)h + o(h)}{h} = f(x). \quad \square$$

Some direct consequences worth recording: $\frac{d}{dx} \int_x^b f(t) \, dt = -f(x)$, and by the chain rule

$$\frac{d}{dx} \int_a^{g(x)} f(t) \, dt = f(g(x)) g'(x).$$

From the product rule we obtain the standard technique of **integration by parts**,

$$\int uv' \, dx = uv - \int u'v \, dx,$$

and from the chain rule we get **integration by substitution**. We will assume fluency with both.

Example 2.1.17 (Integration by Substitution)

Consider $\int \sqrt{2x - x^2} \, dx$. Completing the square, $2x - x^2 = 1 - (x - 1)^2$, which suggests the trigonometric substitution $x - 1 = \sin \theta$, $dx = \cos \theta \, d\theta$. The integral becomes

$$\begin{aligned} \int \cos^2 \theta \, d\theta &= \int \frac{1 + \cos 2\theta}{2} \, d\theta = \frac{\theta}{2} + \frac{\sin 2\theta}{4} + C \\ &= \frac{1}{2} \sin^{-1}(x - 1) + \frac{1}{2}(x - 1)\sqrt{2x - x^2} + C, \end{aligned}$$

undoing the substitution with $\sin 2\theta = 2 \sin \theta \cos \theta$ and $\cos \theta = \sqrt{2x - x^2}$.

Example 2.1.18 (Integration by Parts)

Consider $\int \log x \, dx$. Taking $u = \log x$ and $v' = 1$, we have $u' = 1/x$ and $v = x$, so

$$\int \log x \, dx = x \log x - \int dx = x \log x - x + C.$$

As another quick example, $\int_0^\infty x e^{-x} dx$: taking $u = x$ and $v' = e^{-x}$,

$$\int_0^\infty x e^{-x} dx = [-x e^{-x}]_0^\infty + \int_0^\infty e^{-x} dx = 0 + 1 = 1.$$

§2.2 Functions of Several Variables

Many of the differential equations we will meet involve functions of more than one variable, so before going any further we should establish the basics of multivariate calculus. We will return to this subject in more depth later in the course; for now we need just enough to get going.

§2.2.1 Partial Derivatives

If $f(x, y)$ is a function of two variables, we can differentiate it with respect to either one, holding the other fixed.

Definition 2.2.1 (Partial Derivative)

The **partial derivative** of $f(x, y)$ with respect to x is the rate of change of f as x varies with y held constant:

$$\left. \frac{\partial f}{\partial x} \right|_y = \lim_{\delta x \rightarrow 0} \frac{f(x + \delta x, y) - f(x, y)}{\delta x}.$$

In practice, computing a partial derivative is no harder than ordinary differentiation – we just treat the other variables as constants. When it is clear which variables are being held constant we drop the subscript and write $\partial f / \partial x$, and we will also use the compact notation

$$f_x = \frac{\partial f}{\partial x}, \quad f_{xy} = (f_x)_y = \frac{\partial^2 f}{\partial y \partial x}.$$

Example 2.2.2

Let $f(x, y) = x^2 + y^3 + e^{xy^2}$. Then

$$f_x = 2x + y^2 e^{xy^2}, \quad f_y = 3y^2 + 2xy e^{xy^2},$$

and differentiating again,

$$f_{xx} = 2 + y^4 e^{xy^2}, \quad f_{xy} = 2y e^{xy^2} + 2xy^3 e^{xy^2}.$$

The reader is invited to check that computing f_{yx} gives the same answer as f_{xy} .

That last observation is no coincidence.

Theorem 2.2.3 (Symmetry of Mixed Partial Derivatives)

If f has continuous second partial derivatives, then $f_{xy} = f_{yx}$.

We will not prove this (the proof belongs to an analysis course), but we will use it freely.

§2.2.2 The Multivariate Chain Rule and Differentials

Suppose we perturb both arguments of $f(x, y)$ at once, sending $(x, y) \mapsto (x + \delta x, y + \delta y)$. The change in f can be computed by moving one coordinate at a time:

$$\begin{aligned}\delta f &= f(x + \delta x, y + \delta y) - f(x, y) \\ &= [f(x + \delta x, y + \delta y) - f(x + \delta x, y)] + [f(x + \delta x, y) - f(x, y)] \\ &= f_y(x + \delta x, y) \delta y + o(\delta y) + f_x(x, y) \delta x + o(\delta x) \\ &= \frac{\partial f}{\partial x} \delta x + \frac{\partial f}{\partial y} \delta y + o(\delta x, \delta y).\end{aligned}$$

Taking the limit of small displacements, we write this relation between infinitesimals as follows.

Theorem 2.2.4 (Chain Rule for Partial Derivatives)

For $f = f(x, y)$,

$$df = \frac{\partial f}{\partial x} dx + \frac{\partial f}{\partial y} dy.$$

The expression on the right is called the **differential** of f . This one formula packages up every version of the chain rule we could want. For instance, if x and y are both functions of a parameter t , dividing by dt gives the derivative of f along the path $(x(t), y(t))$:

$$\frac{df}{dt} = \frac{\partial f}{\partial x} \frac{dx}{dt} + \frac{\partial f}{\partial y} \frac{dy}{dt}.$$

Similarly, if we move along a path given as a graph $y = y(x)$, then

$$\frac{df}{dx} = \frac{\partial f}{\partial x} \Big|_y + \frac{\partial f}{\partial y} \frac{dy}{dx},$$

and if we change to new independent variables, say polar coordinates $x = x(r, \theta)$, $y = y(r, \theta)$, then

$$\frac{\partial f}{\partial \theta} \Big|_r = \frac{\partial f}{\partial x} \Big|_y \frac{\partial x}{\partial \theta} \Big|_r + \frac{\partial f}{\partial y} \Big|_x \frac{\partial y}{\partial \theta} \Big|_r.$$

Example 2.2.5

Let $f(x, y) = x^2 + y^2$, and let's differentiate f along the circular path $x = \cos t$, $y = \sin t$:

$$\frac{df}{dt} = 2x \cdot (-\sin t) + 2y \cdot \cos t = -2 \cos t \sin t + 2 \sin t \cos t = 0,$$

as it should be – the path runs along a contour of f , so f doesn't change along it.

§2.2.3 Exact Differentials

A general expression of the form $P(x, y) dx + Q(x, y) dy$ is called a *differential form*. Sometimes such a form is the differential of some function, and sometimes it is not.

Definition 2.2.6 (Exact Differential)

The differential form $P(x, y) dx + Q(x, y) dy$ is **exact** if there is a function $f(x, y)$ such that

$$df = P(x, y) dx + Q(x, y) dy.$$

If the form is exact, then comparing with $df = f_x dx + f_y dy$ (and noting the displacements dx, dy are arbitrary) we must have

$$\frac{\partial f}{\partial x} = P, \quad \frac{\partial f}{\partial y} = Q.$$

Differentiating the first with respect to y and the second with respect to x , symmetry of mixed partials forces a necessary condition:

$$\frac{\partial P}{\partial y} = \frac{\partial Q}{\partial x}.$$

This condition is not quite sufficient in general, but it is if the domain we are working on has no ‘holes’.

Definition 2.2.7 (Simply Connected Domain)

A domain $\mathcal{D}$ is **simply connected** if it is connected and every closed curve in $\mathcal{D}$ can be continuously shrunk to a point without leaving $\mathcal{D}$.

For example, a disc is simply connected, but a disc with a point removed is not (a loop around the missing point cannot be shrunk down).

Theorem 2.2.8

If $\partial P/\partial y = \partial Q/\partial x$ everywhere on a simply connected domain $\mathcal{D}$, then $P dx + Q dy$ is the exact differential of some single-valued function on $\mathcal{D}$.

We won’t prove this, but we will make good use of it when we come to solve ‘exact’ differential equations shortly.

§2.2.4 Implicit Differentiation and Differentiating Integrals

Suppose a surface is given implicitly by $F(x, y, z) = c$ for a constant c . This implicitly defines z as a function $z(x, y)$, even when we cannot solve for z explicitly. We can still compute its partial derivatives: taking the differential of both sides,

$$dF = \frac{\partial F}{\partial x} dx + \frac{\partial F}{\partial y} dy + \frac{\partial F}{\partial z} dz = 0.$$

Holding y constant ($dy = 0$) and dividing by dx gives the following.

Proposition 2.2.9 (Implicit Differentiation)

If $F(x, y, z) = c$ defines $z = z(x, y)$, then

$$\left. \frac{\partial z}{\partial x} \right|_y = -\frac{\partial F / \partial x}{\partial F / \partial z}.$$

Example 2.2.10

Let $xy^2 + yz^2 + z^5x = 5$. Solving for $z(x, y)$ explicitly would require solving a quintic, which is hopeless, but differentiating with respect to x (holding y fixed) gives

$$y^2 + 2yz \frac{\partial z}{\partial x} + z^5 + 5z^4x \frac{\partial z}{\partial x} = 0 \implies \frac{\partial z}{\partial x} = -\frac{y^2 + z^5}{2yz + 5z^4x}.$$

One more tool in a similar spirit: differentiating an integral with respect to a parameter. If $I(b, c) = \int_0^b f(x, c) \, dx$, then $\partial I / \partial b = f(b, c)$ by the fundamental theorem of calculus, and (interchanging the limit and the integral, which we will do without comment)

$$\frac{\partial I}{\partial c} = \lim_{\delta c \rightarrow 0} \int_0^b \frac{f(x, c + \delta c) - f(x, c)}{\delta c} \, dx = \int_0^b \frac{\partial f}{\partial c} \, dx.$$

Combining these with the chain rule gives the general formula for differentiating an integral whose limit and integrand both depend on x .

Theorem 2.2.11 (Differentiation Under the Integral Sign)

$$\frac{d}{dx} \int_0^{b(x)} f(y, c(x)) \, dy = f(b, c) b'(x) + c'(x) \int_0^b \frac{\partial f}{\partial c} \, dy.$$

§2.3 First-Order Linear Differential Equations

We now begin the course proper. A *first-order* differential equation is one involving only first derivatives of the unknown function. In this section we deal with the linear ones, which we can solve completely.

Let's first fix some terminology, which applies to differential equations of any order.

Definition 2.3.1 (Linearity)

A differential equation for $y(x)$ is **linear** if the dependent variable y and its derivatives appear only linearly.

Definition 2.3.2 (Homogeneous Equation)

A linear differential equation is **homogeneous** if $y = 0$ is a solution.

Definition 2.3.3 (Constant Coefficients)

A linear differential equation has **constant coefficients** if the coefficients multiplying y and its derivatives do not depend on the independent variable.

So, for example, $5y' - 3y = 0$ is linear, homogeneous, and has constant coefficients; $y' + xy = x^2$ is linear with non-constant coefficients and is not homogeneous; and $yy' = 1$ is not linear.

§2.3.1 The Exponential Function

The solutions of linear differential equations are built almost entirely out of exponentials, so it is worth pausing to recall why the exponential function is so special.

Consider $f(x) = a^x$ for some constant $a > 0$. Then

$$\frac{df}{dx} = \lim_{h \rightarrow 0} \frac{a^{x+h} - a^x}{h} = a^x \lim_{h \rightarrow 0} \frac{a^h - 1}{h} = \lambda a^x,$$

where $\lambda = f'(0)$ is a constant depending only on a . So the derivative of an exponential is a *multiple of itself*. The natural choice of base is the one for which this multiple is exactly 1.

Definition 2.3.4 (Exponential Function)

The function $\exp(x) = e^x$ is the unique function f with $f'(x) = f(x)$ and $f(0) = 1$. Its inverse is written $\ln x$ or $\log x$.

With this in hand, if $y = a^x = e^{x \ln a}$ then $y' = a^x \ln a$, so the constant λ above is $\ln a$.

The reason exponentials matter so much for us is the following language.

Definition 2.3.5 (Eigenfunction)

A function f is an **eigenfunction** of the differential operator $\frac{d}{dx}$ if

$$\frac{df}{dx} = \lambda f$$

for some constant λ , the **eigenvalue**.

The functions e^{mx} are eigenfunctions of $\frac{d}{dx}$ with eigenvalue m , since $\frac{d}{dx}e^{mx} = me^{mx}$. Differentiation doesn't change the *shape* of an exponential, only its magnitude – and this is precisely why substituting exponentials into constant coefficient equations works so well, as we are about to see.

§2.3.2 Homogeneous Equations with Constant Coefficients

Everything in this section rests on the following observation about exponentials.

Proposition 2.3.6

Every linear, homogeneous ordinary differential equation with constant coefficients has solutions of the form e^{mx} .

Rather than proving this in general (the general statement will fall out of our later work), let's see the idea in action.

Example 2.3.7

Consider $5y' - 3y = 0$. Trying $y = e^{mx}$, we get

$$5me^{mx} - 3e^{mx} = 0.$$

Since e^{mx} is never zero we may divide by it, giving $5m - 3 = 0$, so $m = 3/5$ and $y = e^{3x/5}$ is a solution.

Because the equation is linear and homogeneous, any constant multiple of a solution is again a solution, so $y = Ae^{3x/5}$ solves the equation for any constant A . In fact this is the *general* solution: a first-order linear equation has exactly a one-parameter family of solutions^a, and we have found it. The constant A is then determined by an initial or boundary condition, such as the value $y(0)$. Here is the family of solutions $y = Ae^{3x/5}$, one curve for each value of A :

^aMore generally, an n th-order linear equation has an n -parameter family of solutions – the solution space of the homogeneous equation is a vector space of dimension n . We will see why when we discuss phase space in §2.6.4.

Comparison with a Discrete Equation

Before moving on, it is illuminating to see how the exponential arises as the limit of a *discrete* process. Suppose we wanted to solve $5y' - 3y = 0$ with $y(0) = y_0$ numerically. We could discretise: take small steps of size h , write y_n for our approximation to $y(x_n)$ where $x_n = nh$, and replace the derivative by a difference quotient:

$$5 \frac{y_{n+1} - y_n}{h} - 3y_n \approx 0.$$

Rearranging, $y_{n+1} = (1 + \frac{3}{5}h) y_n$, and applying this repeatedly,

$$y_n = \left(1 + \frac{3}{5}h\right)^n y_0.$$

Now fix a point x and let the step size shrink, taking $h = x/n$ with $n \rightarrow \infty$:

$$y(x) = \lim_{n \rightarrow \infty} y_0 \left(1 + \frac{3x/5}{n}\right)^n = y_0 e^{3x/5},$$

recovering exactly the solution of the differential equation, using the standard limit $e^t = \lim_{n \rightarrow \infty} (1 + t/n)^n$. The exponential is what compound growth becomes when the compounding is continuous.

Series Solution

There is yet a third way to solve $5y' - 3y = 0$, which foreshadows a technique we will use seriously later in the course: assume the solution has a power series expansion

$$y = \sum_{n=0}^{\infty} a_n x^n,$$

substitute it in, and see what the coefficients must be. We have $y' = \sum_n n a_n x^{n-1}$, so

$$5y' - 3y = \sum_n (5(n+1)a_{n+1} - 3a_n) x^n = 0.$$

For this to vanish identically, the coefficient of each power of x must vanish, so $a_{n+1} = \frac{3}{5(n+1)}a_n$ for all $n \geq 0$. Iterating this recurrence,

$$a_n = \frac{3}{5n} a_{n-1} = \frac{3^2}{5^2 n(n-1)} a_{n-2} = \cdots = \left(\frac{3}{5}\right)^n \frac{1}{n!} a_0,$$

with a_0 arbitrary (it is our constant of integration). Hence

$$y = a_0 \sum_{n=0}^{\infty} \frac{1}{n!} \left(\frac{3x}{5}\right)^n = a_0 e^{3x/5},$$

as expected.

§2.3.3 Forced Equations

An equation like $5y' - 3y = 10$ or $5y' - 3y = x^2$, with ‘extra’ terms not involving y , is called **forced** (or inhomogeneous), and the extra terms are **forcing terms**. The name comes from physics: such terms typically represent an external force being applied to a system.

The general strategy for solving forced linear equations is one we will use over and over again:

- (1) Find *any* single solution y_p of the forced equation, called a **particular integral**. This is often done by an educated guess.
- (2) Solve the associated homogeneous equation to find the general **complementary function** y_c .
- (3) The general solution is $y = y_p + y_c$.

Why does this work? If y is any solution of the forced equation, then $y - y_p$ solves the homogeneous equation by linearity, so $y - y_p$ is a complementary function. It is worth internalising this structure: the solutions of a forced linear equation form the translate of a vector space (the homogeneous solutions) by a particular solution.

Example 2.3.8 (Constant Forcing)

Consider $5y' - 3y = 10$. We spot the constant (equilibrium) solution $y_p = -10/3$. The complementary function satisfies $5y'_c - 3y_c = 0$, which we solved above. So the general solution is

$$y = -\frac{10}{3} + A e^{3x/5}.$$

A word of warning: any boundary condition must be applied to the *full* solution y ,

not just to the complementary function.

Eigenfunction Forcing

A particularly clean situation is when the forcing term is itself an eigenfunction of the differential operator. The natural guess for the particular integral is then a multiple of the forcing.

Example 2.3.9 (Radioactive Decay Chains)

In a radioactive rock, isotope A decays into isotope B at a rate proportional to the number a of remaining A nuclei, and B in turn decays at a rate proportional to the number b of B nuclei. We would like to determine $b(t)$.

The setup gives us the pair of equations

$$\frac{da}{dt} = -k_a a, \quad \frac{db}{dt} = k_a a - k_b b.$$

The first equation is homogeneous, with solution $a = a_0 e^{-k_a t}$. Substituting into the second,

$$\frac{db}{dt} + k_b b = k_a a_0 e^{-k_a t}.$$

The forcing term is an eigenfunction of d/dt , so we guess a particular integral $b_p = C e^{-k_a t}$. Substituting,

$$-k_a C + k_b C = k_a a_0 \implies C = \frac{k_a}{k_b - k_a} a_0.$$

The complementary function satisfies $b'_c + k_b b_c = 0$, so $b_c = D e^{-k_b t}$, and altogether

$$b = \frac{k_a}{k_b - k_a} a_0 e^{-k_a t} + D e^{-k_b t}.$$

With the natural initial condition $b(0) = 0$ we get $D = -\frac{k_a}{k_b - k_a} a_0$, so

$$b = \frac{k_a}{k_b - k_a} a_0 (e^{-k_a t} - e^{-k_b t}).$$

This little computation has a genuinely useful application: the isotope ratio is

$$\frac{b}{a} = \frac{k_a}{k_b - k_a} [1 - e^{(k_a - k_b)t}],$$

so measuring b/a in a rock sample today, with the decay rates k_a, k_b known from laboratory measurement, determines t – the age of the rock. This is (a simplified version of) how radiometric dating works.

Example 2.3.10 (Newton's Law of Cooling)

A cup of tea at temperature $T(t)$ sits in a room at constant ambient temperature T_a . Newton's law of cooling says the tea loses heat at a rate proportional to the

temperature difference:

$$\frac{dT}{dt} = -k(T - T_a), \quad k > 0.$$

This is a forced linear equation, $\dot{T} + kT = kT_a$, with constant forcing. The equilibrium (particular) solution is $T_p = T_a$, the complementary function is Ce^{-kt} , and with initial temperature $T(0) = T_0$,

$$T(t) = T_a + (T_0 - T_a)e^{-kt}.$$

The temperature difference decays exponentially with rate k ; after a few multiples of the timescale $1/k$, the tea is at room temperature. Note how the structure ‘particular + complementary’ matches the physics: the equilibrium is where the system ends up, and the complementary function describes the decaying transient.

§2.3.4 Non-Constant Coefficients: The Integrating Factor

Now we drop the assumption of constant coefficients and consider the general first-order linear equation

$$a(x)y' + b(x)y = c(x).$$

Dividing through by $a(x)$, we may as well consider the *standard form*

$$y' + p(x)y = f(x).$$

The trick to solving this is a clever piece of reverse-engineering. Multiply the whole equation by a yet-to-be-chosen function $\mu(x)$:

$$\mu y' + \mu p y = \mu f.$$

The left-hand side would be exactly $(\mu y)'$ – a perfect derivative – if only $\mu' = \mu p$. But we can simply *choose* μ to make that happen! Solving $\mu'/\mu = p$ by integrating,

$$\ln \mu = \int p \, dx \implies \mu(x) = \exp\left(\int p(x) \, dx\right).$$

This μ is called the **integrating factor**. With this choice, the equation reads $(\mu y)' = \mu f$, and integrating once,

$$y = \frac{1}{\mu} \int \mu f \, dx, \quad \mu = \exp\left(\int p \, dx\right),$$

where the constant of integration hiding in $\int \mu f \, dx$ supplies the expected one-parameter family.

Example 2.3.11

Let's solve $xy' + (1-x)y = 1$. In standard form this is

$$y' + \frac{1-x}{x}y = \frac{1}{x},$$

so the integrating factor is

$$\mu = \exp\left(\int \left(\frac{1}{x} - 1\right) dx\right) = e^{\ln x - x} = xe^{-x}.$$

Then $(xe^{-x}y)' = xe^{-x} \cdot \frac{1}{x} = e^{-x}$, so

$$xe^{-x}y = -e^{-x} + C \implies y = -\frac{1}{x} + \frac{C}{x}e^x.$$

Suppose we are told that y remains finite as $x \rightarrow 0$. Since $y = (Ce^x - 1)/x$, we need $Ce^x - 1 \rightarrow 0$ as $x \rightarrow 0$, forcing $C = 1$. Then by L'Hôpital's rule, $y \rightarrow 1$ as $x \rightarrow 0$ – so the boundary condition picks out the unique well-behaved solution.

§2.4 Nonlinear First-Order Equations

Life gets harder (and more interesting) when we allow nonlinearity. A reasonably general first-order equation has the form

$$Q(x, y) \frac{dy}{dx} + P(x, y) = 0.$$

There is no method that solves all such equations, but there are two important classes we *can* solve exactly, and for the rest we will develop graphical and qualitative techniques that are often more informative than an explicit formula anyway.

§2.4.1 Separable Equations

The simplest nonlinear equations we can hope to solve are those where the variables can be pried apart.

Definition 2.4.1 (Separable Equation)

A first-order equation is **separable** if it can be rearranged into the form

$$q(y) dy = p(x) dx,$$

with all the y dependence on one side and all the x dependence on the other. It can then be solved directly by integrating both sides:

$$\int q(y) dy = \int p(x) dx.$$

This is the easy kind, and there isn't much to say beyond doing an example.

Example 2.4.2

Consider $(x^2y - 3y) \frac{dy}{dx} - 2xy^2 = 4x$. Rearranging,

$$\frac{dy}{dx} = \frac{4x + 2xy^2}{x^2y - 3y} = \frac{2x(2 + y^2)}{y(x^2 - 3)},$$

and now the variables separate:

$$\int \frac{y}{2 + y^2} dy = \int \frac{2x}{x^2 - 3} dx.$$

Both sides are of the form $\int u'/u$, giving

$$\frac{1}{2} \ln(2 + y^2) = \ln(x^2 - 3) + C \implies \sqrt{y^2 + 2} = A(x^2 - 3),$$

where $A = e^C$. This is a perfectly good (implicit) description of the family of solution curves.

§2.4.2 Exact Equations

The second solvable class makes direct use of the exact differentials we studied in the previous section.

Definition 2.4.3 (Exact Equation)

The equation $Q(x, y) \frac{dy}{dx} + P(x, y) = 0$ is **exact** if the differential form $P dx + Q dy$ is exact, i.e. if there is a function $f(x, y)$ with

$$df = P dx + Q dy.$$

If the equation is exact, then along any solution curve we have $df = 0$, so the solutions are simply the level sets

$$f(x, y) = \text{constant}.$$

And we know from before how to detect exactness: check whether $\partial P/\partial y = \partial Q/\partial x$ (on a simply connected domain). To find f , integrate $f_x = P$ and $f_y = Q$.

Example 2.4.4

Consider

$$6y(y - x) \frac{dy}{dx} + (2x - 3y^2) = 0.$$

Here $P = 2x - 3y^2$ and $Q = 6y(y - x) = 6y^2 - 6xy$. We check:

$$\frac{\partial P}{\partial y} = -6y = \frac{\partial Q}{\partial x},$$

so the equation is exact. Now we hunt for f . Integrating $f_x = P$ with respect to x ,

$$f = x^2 - 3xy^2 + h(y),$$

where the ‘constant of integration’ h may depend on y (we were holding x fixed). Differentiating with respect to y and comparing with $f_y = Q$:

$$-6xy + h'(y) = 6y^2 - 6xy \implies h'(y) = 6y^2 \implies h(y) = 2y^3 + C.$$

So the solutions are the curves

$$x^2 - 3xy^2 + 2y^3 = \text{constant}.$$

Remark. If an equation fails the exactness test, all is not necessarily lost: multiplying through by a suitable function can sometimes *make* it exact. Indeed, the integrating factor μ for first-order linear equations is exactly this idea – multiplying $y' + py - f = 0$

by μ turned the left-hand side into the exact derivative $(\mu y)'$. Finding integrating factors for general nonlinear equations, however, is an art rather than an algorithm.

§2.4.3 Sketching Solution Curves

For equations we cannot solve explicitly – and even for ones we can – it is extremely useful to be able to *sketch* the family of solutions of

$$\frac{dy}{dt} = f(t, y)$$

directly from the equation. The equation tells us the slope of the solution curve through every point of the (t, y) plane, and we can piece together the qualitative picture from this slope field. The main tools are:

- *Constant solutions*: values $y = c$ with $f(t, c) = 0$ for all t . Solution curves cannot cross these horizontal lines, so they partition the plane into invariant strips.
- *Isoclines*: curves along which the slope $f(t, y)$ takes a constant value D . Marking a few isoclines (in particular the $D = 0$ isocline, where solutions have horizontal tangents) pins down the flow.
- *Signs*: in each region cut out by the isocline $f = 0$, the sign of f tells us whether solutions rise or fall.

Example 2.4.5

Consider

$$\frac{dy}{dt} = t(1 - y^2).$$

This is actually separable, and solving it (using partial fractions) gives

$$\int \frac{dy}{1 - y^2} = \int t \, dt \implies \frac{1}{2} \ln \frac{1 + y}{1 - y} = \frac{1}{2} t^2 + C \implies y = \frac{A - e^{-t^2}}{A + e^{-t^2}}.$$

But let's instead see how much we can say without solving. First, $y = 1$ and $y = -1$ are constant solutions. Second, $y' = 0$ whenever $t = 0$, so every solution crosses the y -axis horizontally. Third, for $t > 0$ we have $y' > 0$ when $-1 < y < 1$ and $y' < 0$ otherwise. So for $t > 0$, solutions in the strip between -1 and 1 climb towards $y = 1$; solutions above $y = 1$ descend towards it; and solutions below $y = -1$ plunge downwards. The isoclines $t(1 - y^2) = D$ can be sketched to refine the picture. All of this matches the exact solution above: as $t \rightarrow \infty$, every solution with $y(0) > -1$ tends to 1 .

Note the qualitative structure: $y = 1$ attracts nearby solutions, while $y = -1$ repels them.

Example 2.4.6 (Straight-Line Isoclines)

Consider $\frac{dy}{dx} = x - y$. The isoclines $x - y = D$ are parallel straight lines of unit slope, along which all solution curves have slope D . Something special happens on the isocline $x - y = 1$: the prescribed slope there is 1, which is exactly the slope of the isocline itself – so that line is *itself a solution*, $y = x - 1$.

Above this line ($y > x - 1$), slopes are less than 1; below it, greater than 1; and one can convince oneself from the slope field that all solutions converge towards the line $y = x - 1$ as $x \rightarrow \infty$. In the sketch below, the dashed lines are the isoclines $D = -1, 0, 2$ (with short strokes showing the prescribed slope on each), and the blue curves are solutions.

Since the equation is actually linear, we can confirm this: the integrating factor is e^x , giving $(e^x y)' = x e^x$, so $e^x y = (x - 1)e^x + C$ and

$$y = x - 1 + C e^{-x}.$$

Every solution is the special straight line plus an exponentially decaying correction – precisely the convergence the isoclines predicted.

§2.4.4 Equilibrium Points and Stability

The behaviour in the last example – solutions being attracted to or repelled from constant solutions – is so important that it deserves proper terminology.

Definition 2.4.7 (Equilibrium Point)

An **equilibrium point** (or **fixed point**) of a differential equation is a constant solution $y = c$, i.e. one with $\frac{dy}{dt} = 0$ for all t .

Equilibria are usually the easiest solutions to find: just set the right-hand side of the equation to zero and solve.

Definition 2.4.8 (Stability)

An equilibrium $y = c$ is **stable** if whenever y is perturbed slightly from c , we have $y \rightarrow c$ as $t \rightarrow \infty$. It is **unstable** if small perturbations grow.

Perturbation Analysis

To determine stability we use *perturbation analysis*, which is really just a Taylor expansion. Suppose $y = a$ is a fixed point of $\dot{y} = f(y, t)$, so $f(a, t) = 0$ for all t . Set

$$y(t) = a + \varepsilon(t),$$

where ε is a small perturbation. Substituting into the equation and Taylor expanding f in its first argument about a :

$$\dot{\varepsilon} = f(a + \varepsilon, t) = \underbrace{f(a, t)}_{=0} + \varepsilon \frac{\partial f}{\partial y}(a, t) + O(\varepsilon^2).$$

While ε remains small the $O(\varepsilon^2)$ term is negligible, and we are left with the **linearised equation**

$$\dot{\varepsilon} \simeq \varepsilon \frac{\partial f}{\partial y}(a, t),$$

a linear equation which we know how to solve. If the resulting ε decays, the equilibrium is stable; if it grows, unstable².

Example 2.4.9

Return to $\dot{y} = t(1 - y^2)$, with fixed points $y = \pm 1$. We have

$$\frac{\partial f}{\partial y} = -2yt = \begin{cases} -2t & \text{at } y = 1, \\ 2t & \text{at } y = -1. \end{cases}$$

At $y = 1$: $\dot{\varepsilon} = -2t\varepsilon$, so $\varepsilon = \varepsilon_0 e^{-t^2} \rightarrow 0$, and $y = 1$ is stable. At $y = -1$: $\dot{\varepsilon} = 2t\varepsilon$, so $\varepsilon = \varepsilon_0 e^{t^2}$ grows, and $y = -1$ is unstable – exactly as our sketch suggested.

Autonomous Equations and the Phase Line

Very often the physics of a system doesn't change with time, so that $\dot{y}$ depends only on y itself.

Definition 2.4.10 (Autonomous Equation)

An equation of the form $\dot{y} = f(y)$, with no explicit t dependence, is called **autonomous**.

For autonomous equations the perturbation analysis is particularly simple. Near a fixed point $y = a$ with $f(a) = 0$, the linearisation is

$$\dot{\varepsilon} = f'(a) \varepsilon = k\varepsilon \implies \varepsilon = \varepsilon_0 e^{kt},$$

with $k = f'(a)$ constant. So the rule is simply:

$$f'(a) < 0 \implies \text{stable}, \quad f'(a) > 0 \implies \text{unstable}.$$

²Strictly, once ε has grown large the linearisation is no longer valid, so we cannot conclude that $\varepsilon \rightarrow \infty$ – only that the perturbation initially grows and the solution moves away from the equilibrium. That is exactly what instability means.

Graphically, this is obvious: plot $f(y)$ against y . Where $f > 0$, y increases; where $f < 0$, y decreases. So y flows to the right where the graph is above the axis and to the left where it is below, and the fixed points where f crosses the axis *downwards* are the stable ones. Recording just the fixed points and flow directions on a copy of the y -axis gives the **phase portrait** (or phase line) of the equation, a diagram which captures the entire qualitative behaviour at a glance.

Example 2.4.11 (Chemical Kinetics)

Consider the reaction $\text{NaOH} + \text{HCl} \rightarrow \text{NaCl} + \text{H}_2\text{O}$, with a molecules of NaOH and b of HCl present, starting from a_0 and b_0 respectively, and c molecules of each product formed. In dilute solution the reaction rate is proportional to ab , so

$$\frac{dc}{dt} = \lambda ab = \lambda(a_0 - c)(b_0 - c) = f(c).$$

Suppose (without loss of generality) that $a_0 < b_0$. The graph of $f(c)$ is an upward parabola with roots at $c = a_0$ and $c = b_0$; between the roots $f > 0$, so c increases towards a_0 from below. Checking stability: $f'(c) = \lambda(2c - a_0 - b_0)$, so $f'(a_0) = \lambda(a_0 - b_0) < 0$ and $f'(b_0) = \lambda(b_0 - a_0) > 0$. Hence $c = a_0$ is stable and $c = b_0$ is unstable.

Physically, of course, only $0 \leq c \leq a_0$ makes sense (we cannot have a negative amount of NaOH!), and every physical solution tends to $c = a_0$: the reaction runs until the scarcer reagent is used up.

For completeness, the equation is separable and can be solved exactly:

$$c = \frac{a_0 b_0 [1 - e^{-(b_0 - a_0)\lambda t}]}{b_0 - a_0 e^{-(b_0 - a_0)\lambda t}},$$

which indeed tends to a_0 as $t \rightarrow \infty$ – but notice how much less work the phase portrait was.

§2.4.5 The Logistic Equation

The logistic equation is the classic model of a population limited by finite resources, and it makes a nice showcase for everything in this section.

Consider a population of size y with birth rate αy and death rate βy . Then $\dot{y} = (\alpha - \beta)y$, giving exponential growth or decay – fine for small populations, but unsustainable forever. To model competition for limited resources, note that the rate of pairwise encounters between individuals is proportional to y^2 , so fighting over scarce food contributes an extra death rate γy^2 . This gives

$$\frac{dy}{dt} = (\alpha - \beta)y - \gamma y^2 = ry \left(1 - \frac{y}{Y}\right),$$

where $r = \alpha - \beta$ and $Y = r/\gamma$. This is the **logistic equation**.

The equation is separable and can be solved explicitly, but the phase portrait tells the whole story with far less effort. Take $r > 0$. The graph of $f(y) = ry(1 - y/Y)$ is a

downward parabola with zeros at $y = 0$ and $y = Y$:

- $f'(0) = r > 0$, so $y = 0$ is unstable;
- $f'(Y) = -r < 0$, so $y = Y$ is stable.

For small populations $\dot{y} \simeq ry$ and growth is exponential; as y approaches the *carrying capacity* Y the growth saturates, and every positive solution tends to Y . The characteristic S-shaped (‘sigmoid’) solution curves interpolate between exponential growth at the bottom and saturation at the top.

For completeness, let’s also solve the equation exactly. Separating variables and using partial fractions,

$$\int \frac{dy}{y(1 - y/Y)} = \int \left(\frac{1}{y} + \frac{1/Y}{1 - y/Y} \right) dy = \ln \frac{y}{1 - y/Y} = rt + C,$$

so $\frac{y}{1 - y/Y} = Ae^{rt}$, and solving for y with $y(0) = y_0$:

$$y(t) = \frac{Y y_0 e^{rt}}{Y + y_0(e^{rt} - 1)}.$$

As a sanity check: for small t (while $y \ll Y$) this is approximately $y_0 e^{rt}$, and as $t \rightarrow \infty$ it tends to Y , from below if $y_0 < Y$ and from above if $y_0 > Y$ – exactly the picture the phase portrait predicted, with rather more algebra.

§2.5 First-Order Difference Equations

Differential equations describe quantities evolving continuously; but many systems evolve in discrete steps – populations with annual breeding seasons, and (importantly) any differential equation being solved numerically on a computer. The discrete analogue of a first-order ODE is a **difference equation** (or *recurrence*, or *map*)

$$x_{n+1} = f(x_n),$$

which generates a sequence from a starting value x_0 . The theory runs parallel to the continuous case, but with some genuine surprises.

§2.5.1 Fixed Points and Stability

As with differential equations, the natural starting point is to look for solutions that don't change at all.

Definition 2.5.1 (Fixed Point of a Map)

A **fixed point** of $x_{n+1} = f(x_n)$ is a value x^* with $f(x^*) = x^*$, so that the constant sequence $x_n = x^*$ is a solution.

To analyse stability we perturb, just as before. Write $x_n = x^* + \varepsilon_n$ and expand:

$$x^* + \varepsilon_{n+1} = f(x^* + \varepsilon_n) = f(x^*) + \varepsilon_n f'(x^*) + O(\varepsilon_n^2),$$

so to leading order $\varepsilon_{n+1} \simeq f'(x^*) \varepsilon_n$, giving $\varepsilon_n \simeq \varepsilon_0 [f'(x^*)]^n$. The perturbation shrinks precisely when the multiplier has modulus less than one:

$$|f'(x^*)| < 1 \implies \text{stable}, \quad |f'(x^*)| > 1 \implies \text{unstable}.$$

Note the contrast with the continuous case, where the criterion was on the *sign* of f' ; here it is on the *magnitude*. Note also that $f'(x^*)$ negative and small gives *oscillatory* convergence, with the iterates alternating sides of the fixed point.

Remark (Reconciling the Two Criteria). The discrete and continuous stability criteria fit together neatly. The Euler discretisation of $\dot{y} = f(y)$ with step h is the map $y_{n+1} = y_n + hf(y_n)$, whose fixed points coincide with the equilibria of the ODE, and whose multiplier there is

$$1 + hf'(a).$$

If $f'(a) < 0$ (stable for the ODE), then for small enough h we have $|1 + hf'(a)| < 1$ and the map is stable too, consistent with the ODE. But if $h > 2/|f'(a)|$, the multiplier drops below -1 and the discretisation is unstable even though the ODE is perfectly stable – a numerical instability caused purely by too large a time step. Numerical analysts spend a great deal of effort designing schemes that avoid this.

A useful way to visualise iteration is a **cobweb diagram**: draw the graphs of $x_{n+1} = f(x_n)$ and the diagonal $x_{n+1} = x_n$, then trace vertically to the curve and horizontally to the diagonal, repeatedly. Fixed points are where curve meets diagonal, and the stability criterion $|f'| < 1$ says the curve crosses the diagonal less steeply than 45° .

(The cobweb above shows convergence towards a stable fixed point where the blue curve cuts the diagonal.)

§2.5.2 The Logistic Map

Discretising the logistic equation with the Euler scheme (time step Δt):

$$\frac{y_{n+1} - y_n}{\Delta t} = r y_n \left(1 - \frac{y_n}{Y}\right),$$

and rescaling via $\lambda = 1 + r\Delta t$ and $x_n = \frac{r\Delta t}{1+r\Delta t} \cdot \frac{y_n}{Y}$, one arrives (after a little algebra) at the famous **logistic map**

$$x_{n+1} = \lambda x_n (1 - x_n).$$

Its fixed points satisfy $\lambda x(1 - x) = x$, giving

$$x^* = 0 \quad \text{or} \quad x^* = 1 - \frac{1}{\lambda},$$

and $f'(x) = \lambda(1 - 2x)$, so $f'(0) = \lambda$ and $f'(1 - 1/\lambda) = 2 - \lambda$. The stability analysis then predicts strikingly rich behaviour as λ increases:

- (i) For $0 < \lambda < 1$: only $x^* = 0$ is relevant, $|f'(0)| = \lambda < 1$, and the population dies out.
- (ii) For $1 < \lambda < 2$: $x^* = 0$ becomes unstable, and $x^* = 1 - 1/\lambda$ is stable with $0 < f' < 1$, so iterates converge to it monotonically.
- (iii) For $2 < \lambda < 3$: still stable, but now $-1 < f' < 0$, so the convergence is oscillatory, with iterates spiralling into the fixed point on the cobweb diagram.
- (iv) For $\lambda > 3$: $|f'(x^*)| > 1$, so *both* fixed points are unstable. The iterates settle instead into a *2-cycle*, oscillating between two values (a solution of $x_{n+2} = x_n$). As λ increases further to $1 + \sqrt{6} \approx 3.449$, the 2-cycle destabilises in favour of a 4-cycle, then an 8-cycle, and so on – a *period-doubling cascade* which accumulates at $\lambda \approx 3.57$, beyond which the dynamics become chaotic.

The moral is worth remembering: a discretisation can have wildly different behaviour from the differential equation it approximates. The continuous logistic equation is completely tame – every positive solution glides monotonically to the carrying capacity – while its discrete counterpart, for large enough λ (i.e. large enough time step), is chaotic.

§2.6 Second-Order Linear Differential Equations

We now move up an order. Second-order linear equations are probably the most important differential equations in all of physics – Newton's second law is one – and they will occupy us for a good while. Almost everything we do in this section extends routinely to higher-order linear equations, but second order is where all the ideas already appear.

§2.6.1 Constant Coefficients and the Characteristic Equation

The general second-order linear equation with constant coefficients is

$$ay'' + by' + cy = f(x).$$

Following the strategy from the first-order case, we solve this in two steps: find the general solution of the homogeneous equation $ay'' + by' + cy = 0$ (the complementary function), then find any one particular integral of the full equation, and add them.

For the complementary function, we again exploit the fact that $e^{\lambda x}$ is an eigenfunction of $\frac{d}{dx}$, and hence also of $\frac{d^2}{dx^2}$. Trying $y = e^{\lambda x}$ gives $a\lambda^2 e^{\lambda x} + b\lambda e^{\lambda x} + ce^{\lambda x} = 0$, and dividing by the (never-zero) exponential:

Definition 2.6.1 (Characteristic Equation)

The **characteristic equation** of $ay'' + by' + cy = 0$ is

$$a\lambda^2 + b\lambda + c = 0.$$

This is a quadratic with two roots λ_1, λ_2 . If they are distinct, we get two genuinely different solutions $e^{\lambda_1 x}$ and $e^{\lambda_2 x}$, and (as we will justify carefully in §2.6.4) the general complementary function is

$$y_c = Ae^{\lambda_1 x} + Be^{\lambda_2 x}.$$

Example 2.6.2

Consider $y'' - 5y' + 6y = 0$. The characteristic equation is $\lambda^2 - 5\lambda + 6 = 0$, with roots $\lambda = 2, 3$. So the general solution is

$$y = Ae^{2x} + Be^{3x}.$$

Example 2.6.3 (Simple Harmonic Motion)

Consider $y'' + 4y = 0$. The characteristic equation is $\lambda^2 + 4 = 0$, so $\lambda = \pm 2i$ and

$$y = Ae^{2ix} + Be^{-2ix}.$$

The constants A, B are allowed to be complex, but if this is modelling a physical oscillation we would like the answer to at least *look* real. Expanding with Euler's formula,

$$y = A(\cos 2x + i \sin 2x) + B(\cos 2x - i \sin 2x) = \alpha \cos 2x + \beta \sin 2x,$$

where $\alpha = A + B$ and $\beta = i(A - B)$. All we have done is change basis for the solution space, from $\{e^{2ix}, e^{-2ix}\}$ to $\{\cos 2x, \sin 2x\}$; whichever basis is more convenient may be used. More generally, complex roots $\lambda = \sigma \pm i\omega$ give solutions $e^{\sigma x}(\alpha \cos \omega x + \beta \sin \omega x)$ – oscillations with exponentially growing or decaying amplitude.

Remark (Higher-Order Equations). Everything here generalises immediately: an n th-order linear equation with constant coefficients has characteristic polynomial of degree n , and each distinct root λ contributes $e^{\lambda x}$ to the complementary function. For example, radioactive decay *sequences* $A \rightarrow B \rightarrow C \rightarrow \dots$, which we treated one step at a time in the previous section, can be packaged as a single higher-order equation whose characteristic roots are $-k_a, -k_b, -k_c, \dots$ – each isotope contributing its own decaying exponential to the mix.

§2.6.2 Degeneracy and Detuning

Something goes wrong when the characteristic equation has a repeated root: our method produces only *one* solution, but a second-order equation should have a two-parameter

family.

Example 2.6.4 (A Repeated Root)

Consider $y'' - 4y' + 4y = 0$. The characteristic equation is $(\lambda - 2)^2 = 0$, so $\lambda = 2$ twice, and we find only the single solution family Ae^{2x} . The solution space is two-dimensional, so we are missing a second, independent solution.

Here is a rather beautiful way of finding it, called **detuning**. The problem is that our two roots collided, so let's separate them slightly: perturb the equation to

$$y'' - 4y' + (4 - \varepsilon^2)y = 0,$$

which has roots $\lambda = 2 \pm \varepsilon$, and recovers our equation as $\varepsilon \rightarrow 0$. For $\varepsilon \neq 0$ the general solution is

$$y = Ae^{(2+\varepsilon)x} + Be^{(2-\varepsilon)x} = e^{2x} [Ae^{\varepsilon x} + Be^{-\varepsilon x}].$$

Now Taylor expand the small exponentials:

$$y = e^{2x} [(A + B) + \varepsilon x(A - B) + O(\varepsilon^2 A, \varepsilon^2 B)].$$

Fix constants α and β , and for each small ε choose $A = \frac{1}{2}(\alpha + \beta/\varepsilon)$ and $B = \frac{1}{2}(\alpha - \beta/\varepsilon)$, so that $A + B = \alpha$ and $\varepsilon(A - B) = \beta$. Since $A, B = O(1/\varepsilon)$, the error terms are $O(\varepsilon)$, and letting $\varepsilon \rightarrow 0$,

$$y \rightarrow e^{2x}(\alpha + \beta x).$$

So the missing second solution is xe^{2x} .

The pattern in this example is completely general, and worth committing to memory: *if the characteristic equation has a repeated root λ , the complementary function is $(A + Bx)e^{\lambda x}$.*

§2.6.3 Reduction of Order

Detuning relied on constant coefficients. There is a more robust technique for manufacturing a second solution out of a known one, which works for any linear second-order equation: look for a solution of the form

$$y_2(x) = v(x) y_1(x),$$

where y_1 is the solution we already have and v is to be found. The point is that substituting this in always produces a *first-order* equation for v' (the v terms cancel because y_1 is a solution) – hence the name **reduction of order**.

Example 2.6.5

Take $y'' - 4y' + 4y = 0$ again, with known solution $y_1 = e^{2x}$. Try $y_2 = ve^{2x}$. Then

$$y_2' = (v' + 2v)e^{2x}, \quad y_2'' = (v'' + 4v' + 4v)e^{2x},$$

and substituting in,

$$[(v'' + 4v' + 4v) - 4(v' + 2v) + 4v] e^{2x} = 0 \implies v'' = 0.$$

So $v = Ax + B$, and $y_2 = (Ax + B)e^{2x}$ – recovering the answer from detuning, this time with essentially no cleverness required.

§2.6.4 Phase Space, Linear Independence and the Wronskian

We have been asserting that a second-order linear equation has a two-parameter family of solutions, and that certain pairs of solutions are ‘independent’. Let’s now make this precise.

Consider a general n th-order linear equation. Its solution is not determined by the value $y(x_0)$ alone: we also need $y'(x_0)$, and so on up to $y^{(n-1)}(x_0)$. Once these n numbers are known, the equation itself determines $y^{(n)}(x_0)$, and by differentiating the equation, all higher derivatives too – so the entire Taylor series of the solution at x_0 is pinned down. This strongly suggests (and it is true, though a real proof needs the machinery of IB Analysis) that a solution is uniquely determined by the n initial conditions $y(x_0), y'(x_0), \dots, y^{(n-1)}(x_0)$.

This motivates packaging those numbers into a single object.

Definition 2.6.6 (Solution Vector and Phase Space)

The **solution vector** of a solution y of an n th-order differential equation is

$$\mathbf{Y}(x) = (y(x), y'(x), \dots, y^{(n-1)}(x)).$$

The n -dimensional space in which $\mathbf{Y}$ lives is called **phase space**. As x varies, $\mathbf{Y}(x)$ traces out a **trajectory** in phase space, and each point of phase space (viewed as an initial condition) has a unique trajectory through it.

Example 2.6.7

Consider $y'' + 4y = 0$. The initial condition $y(0) = 1, y'(0) = 0$ gives the solution $y_1 = \cos 2x$, with solution vector $\mathbf{Y}_1(x) = (\cos 2x, -2 \sin 2x)$ – which traces out an ellipse in phase space, traversed clockwise. The initial condition $y(0) = 0, y'(0) = 2$ gives $y_2 = \sin 2x$, with $\mathbf{Y}_2(x) = (\sin 2x, 2 \cos 2x)$.

Notice that the two initial vectors $(1, 0)$ and $(0, 2)$ are linearly independent, and one can check that $\mathbf{Y}_1(x)$ and $\mathbf{Y}_2(x)$ remain linearly independent for *every* x . This is not a coincidence, as we will now see.

For a second-order equation, phase space is a plane, and a natural question is whether two solutions y_1, y_2 give solution vectors forming a basis of that plane. The determinant testing this has a name.

Definition 2.6.8 (Wronskian)

The **Wronskian** of two solutions y_1, y_2 of a second-order differential equation is the determinant

$$W(x) = \begin{vmatrix} y_1 & y_2 \\ y_1' & y_2' \end{vmatrix} = y_1 y_2' - y_2 y_1'.$$

Definition 2.6.9 (Independent Solutions)

Solutions y_1 and y_2 are **independent** if their solution vectors $\mathbf{Y}_1(x), \mathbf{Y}_2(x)$ are linearly independent for some x – that is, if $W(x) \neq 0$ for some x .

Example 2.6.10

For $y'' + 4y = 0$ with $y_1 = \cos 2x$, $y_2 = \sin 2x$:

$$W = \cos 2x \cdot 2 \cos 2x - \sin 2x \cdot (-2 \sin 2x) = 2 \neq 0.$$

For $y'' - 4y' + 4y = 0$ with $y_1 = e^{2x}$, $y_2 = xe^{2x}$:

$$W = \begin{vmatrix} e^{2x} & xe^{2x} \\ 2e^{2x} & (1+2x)e^{2x} \end{vmatrix} = e^{4x}(1+2x-2x) = e^{4x} \neq 0.$$

In both examples the Wronskian was non-vanishing *everywhere*. Could the Wronskian vanish at some points but not others? Remarkably, no.

Theorem 2.6.11 (Abel's Theorem)

Let y_1, y_2 be solutions of $y'' + p(x)y' + q(x)y = 0$. Then either $W \equiv 0$, or $W(x) \neq 0$ for all x . In particular, if two solutions are independent at one point, they are independent everywhere.

Proof. Since y_1 and y_2 are both solutions,

$$\begin{aligned} y_2(y_1'' + py_1' + qy_1) &= 0, \\ y_1(y_2'' + py_2' + qy_2) &= 0. \end{aligned}$$

Subtracting the first from the second,

$$(y_1y_2'' - y_2y_1'') + p(y_1y_2' - y_2y_1') = 0.$$

Now observe that $W = y_1y_2' - y_2y_1'$ and, differentiating, $W' = y_1y_2'' - y_2y_1''$ (the cross terms cancel). So the equation above says precisely

$$W' + p(x)W = 0,$$

a first-order linear equation for W , with solution

$$W(x) = W_0 e^{-\int p \, dx}.$$

Since the exponential never vanishes, either $W_0 = 0$ and $W \equiv 0$, or W is nowhere zero. $\square$

Remark. Abel's theorem generalises: writing an n th-order homogeneous linear equation as a first-order system $\mathbf{Y}' = A\mathbf{Y}$ (as we will do in §2.11), one can show $W' + \text{tr}(A)W = 0$, so $W = W_0 e^{-\int \text{tr } A \, dx}$ and the same dichotomy holds.

§2.6.5 Particular Integrals

With the complementary function understood, we return to the forced equation

$$ay'' + by' + cy = f(x)$$

and the problem of finding a particular integral. The first method, as ever, is educated guessing: choose a trial form matching the forcing, with unknown coefficients, and substitute. The standard guesses are:

$f(x)$	trial $y_p(x)$
e^{mx}	Ae^{mx}
$\sin kx$ or $\cos kx$	$A \sin kx + B \cos kx$
polynomial of degree n	$a_n x^n + \cdots + a_1 x + a_0$

Note that for trigonometric forcing we must include *both* $\sin$ and $\cos$ in the guess (differentiation mixes them), and for polynomial forcing all lower-order terms. Since the equation is linear, a sum of forcing terms can be handled term by term and the particular integrals superposed.

Example 2.6.12

Consider $y'' - 5y' + 6y = 2x + e^{4x}$. We guess $y_p = ax + b + ce^{4x}$. Then $y'_p = a + 4ce^{4x}$ and $y''_p = 16ce^{4x}$, and substituting in:

$$16ce^{4x} - 5(a + 4ce^{4x}) + 6(ax + b + ce^{4x}) = 2x + e^{4x}.$$

Comparing coefficients of e^{4x} , x and 1 respectively:

$$\begin{aligned} 16c - 20c + 6c &= 1 \implies c = \frac{1}{2}, \\ 6a &= 2 \implies a = \frac{1}{3}, \\ -5a + 6b &= 0 \implies b = \frac{5}{18}. \end{aligned}$$

The complementary function was found earlier, so the general solution is

$$y = Ae^{3x} + Be^{2x} + \frac{1}{2}e^{4x} + \frac{1}{3}x + \frac{5}{18}.$$

§2.6.6 Resonance

The guessing procedure breaks down in one important situation: when the forcing is itself a complementary function.

Consider a simple harmonic oscillator forced at its own natural frequency:

$$\ddot{y} + \omega_0^2 y = \sin \omega_0 t.$$

The complementary function is $y_c = A \sin \omega_0 t + B \cos \omega_0 t$, and if we try $y_p = C \sin \omega_0 t + D \cos \omega_0 t$, we just get $\ddot{y}_p + \omega_0^2 y_p = 0$ – the guess is annihilated by the operator, and can never balance the forcing. This phenomenon is called **resonance**.

To understand what actually happens, we detune again: force at a nearby frequency $\omega \neq \omega_0$,

$$\ddot{y} + \omega_0^2 y = \sin \omega t,$$

and take the limit $\omega \rightarrow \omega_0$ at the end. Guessing the antisymmetric combination $y_p = C(\sin \omega t - \sin \omega_0 t)$ (chosen so that $y_p \rightarrow 0$ as $\omega \rightarrow \omega_0$, keeping the limit finite), we have

$$\ddot{y}_p = C(-\omega^2 \sin \omega t + \omega_0^2 \sin \omega_0 t),$$

and substituting in gives $C(\omega_0^2 - \omega^2) = 1$. So

$$y_p = \frac{\sin \omega t - \sin \omega_0 t}{\omega_0^2 - \omega^2} = \frac{2}{\omega_0^2 - \omega^2} \cos\left(\frac{\omega_0 + \omega}{2}t\right) \sin\left(\frac{\omega - \omega_0}{2}t\right),$$

using the sum-to-product formula. Writing $\Delta\omega = \omega_0 - \omega$, this is a fast oscillation at roughly the natural frequency, modulated by a slow envelope $\sin(\Delta\omega t/2)$ of amplitude $O(1/\Delta\omega)$ and period $O(1/\Delta\omega)$. This slow waxing and waning of amplitude, familiar from tuning musical instruments, is called **beating**: it occurs whenever a system is forced close to (but not exactly at) its natural frequency.

Now let $\Delta\omega \rightarrow 0$. The envelope's wavelength stretches to infinity, and using $\sin \theta \approx \theta$ for the slow factor,

$$y_p \rightarrow -\frac{t}{2\omega_0} \cos \omega_0 t.$$

So at exact resonance, the response is an oscillation whose amplitude *grows linearly in time* – the initial stretch of linear growth is all that remains of the beat envelope. This also tells us the correct guess to make at resonance, and the rule is general: *if the forcing is a complementary function, multiply the usual guess by the independent variable*. (If that is somehow still a complementary function, multiply by it again.)

Example 2.6.13

For $\ddot{y} + \omega_0^2 y = \sin \omega_0 t$, try $y_p = t(C \sin \omega_0 t + D \cos \omega_0 t)$. Substituting in, the t -proportional terms cancel (as they must – they are complementary functions) leaving

$$2C\omega_0 \cos \omega_0 t - 2D\omega_0 \sin \omega_0 t = \sin \omega_0 t,$$

so $C = 0$, $D = -1/(2\omega_0)$, and $y_p = -\frac{t}{2\omega_0} \cos \omega_0 t$, in agreement with the limit above.

The resonant response, with its linearly growing envelope, looks like this:

§2.6.7 Variation of Parameters

Guessing works when the forcing is simple. **Variation of parameters** is a systematic method that works for *any* forcing, provided we know the complementary functions. It is more work than guessing, so it should be a last resort – but it always succeeds.

Consider

$$y'' + p(x)y' + q(x)y = f(x),$$

with independent complementary functions y_1, y_2 . The idea comes from phase space: for each fixed x , the solution vectors $\mathbf{Y}_1(x)$ and $\mathbf{Y}_2(x)$ form a basis of the plane, so the particular solution vector we seek can be expanded in that basis, with coefficients that vary with x :

$$\mathbf{Y}_p(x) = u(x)\mathbf{Y}_1(x) + v(x)\mathbf{Y}_2(x).$$

Reading off the two components,

$$y_p = uy_1 + vy_2, \quad (\text{a})$$

$$y'_p = uy'_1 + vy'_2. \quad (\text{b})$$

These two equations carry a hidden constraint: differentiating (a) gives $y'_p = uy'_1 + vy'_2 + u'y_1 + v'y_2$, which is consistent with (b) only if

$$u'y_1 + v'y_2 = 0. \quad (\text{c})$$

Now differentiate (b):

$$y''_p = uy''_1 + vy''_2 + u'y'_1 + v'y'_2,$$

and substitute everything into the differential equation. The terms multiplying u and v vanish (since y_1, y_2 are complementary functions), leaving

$$u'y'_1 + v'y'_2 = f. \quad (\text{d})$$

Equations (c) and (d) are two linear equations for u' and v' :

$$\begin{pmatrix} y_1 & y_2 \\ y'_1 & y'_2 \end{pmatrix} \begin{pmatrix} u' \\ v' \end{pmatrix} = \begin{pmatrix} 0 \\ f \end{pmatrix},$$

and the matrix is invertible precisely because its determinant is the Wronskian $W \neq 0$. Inverting,

$$u' = -\frac{y_2 f}{W}, \quad v' = \frac{y_1 f}{W},$$

and integrating gives u and v , hence y_p . (It is far better to remember the derivation than the formula.)

Example 2.6.14

Let's redo resonance by this method: $y'' + 4y = \sin 2x$, with $y_1 = \sin 2x$, $y_2 = \cos 2x$ and $W = y_1 y'_2 - y_2 y'_1 = -2$. Then

$$u' = \frac{\cos 2x \sin 2x}{2} = \frac{\sin 4x}{4}, \quad v' = -\frac{\sin^2 2x}{2} = \frac{\cos 4x - 1}{4},$$

so

$$u = -\frac{\cos 4x}{16}, \quad v = \frac{\sin 4x}{16} - \frac{x}{4}.$$

Therefore

$$y_p = \frac{1}{16} (-\cos 4x \sin 2x + \sin 4x \cos 2x) - \frac{x}{4} \cos 2x = \frac{1}{16} \sin 2x - \frac{x}{4} \cos 2x.$$

The term $-\frac{x}{4} \cos 2x$ is the resonant response we found by detuning (here $\omega_0 = 2$), and $\frac{1}{16} \sin 2x$ is merely a complementary function, so the answers agree.

Example 2.6.15 (When Guessing is Hopeless)

Consider $y'' + y = \tan x$. No finite combination of elementary functions suggests itself as a guess – differentiating $\tan x$ generates ever more complicated expressions – so variation of parameters is the way forward. With $y_1 = \sin x$, $y_2 = \cos x$ and $W = \sin x \cdot (-\sin x) - \cos x \cdot \cos x = -1$:

$$u' = -\frac{y_2 f}{W} = \cos x \tan x = \sin x, \quad v' = \frac{y_1 f}{W} = -\sin x \tan x = \cos x - \sec x,$$

where we wrote $-\sin^2 x / \cos x = (\cos^2 x - 1) / \cos x$. Integrating,

$$u = -\cos x, \quad v = \sin x - \ln |\sec x + \tan x|,$$

so

$$y_p = uy_1 + vy_2 = -\cos x \sin x + \sin x \cos x - \cos x \ln |\sec x + \tan x| = -\cos x \ln |\sec x + \tan x|.$$

The general solution is $y = A \sin x + B \cos x - \cos x \ln |\sec x + \tan x|$ – involving a logarithm that no reasonable person would have guessed.

§2.6.8 Equidimensional Equations

There is one important class of *non*-constant coefficient equations that we can solve just as easily.

Definition 2.6.16 (Equidimensional Equation)

An equation is **equidimensional** if it has the form

$$ax^2y'' + bxy' + cy = f(x),$$

with a, b, c constants.

The name comes from dimensional analysis: if x carries some physical dimension, then each of x^2y'' , xy' and y has the same dimensions, so the equation is invariant under rescaling $x \mapsto \lambda x$. (These are often called ‘homogeneous’ equations, but that clashes horribly with our earlier usage, so we avoid it.)

Just as $e^{\lambda x}$ is the eigenfunction of $\frac{d}{dx}$, the powers x^k are eigenfunctions of the operator $x \frac{d}{dx}$, and this suggests trying $y = x^k$. Since $xy' = kx^k$ and $x^2y'' = k(k-1)x^k$, substituting into the homogeneous equation gives

$$ak(k-1) + bk + c = 0,$$

with roots k_1, k_2 , and complementary function $y_c = Ax^{k_1} + Bx^{k_2}$ when the roots are distinct.

Alternatively, substituting $z = \ln x$ transforms the equation into one with constant coefficients:

$$a \frac{d^2 y}{dz^2} + (b - a) \frac{dy}{dz} + cy = f(e^z),$$

whose characteristic equation $a\lambda(\lambda - 1) + b\lambda + c = 0$ is precisely the one above. This substitution is the easiest way to deal with the degenerate cases: a repeated root k gives $y_c = (A + B \ln x)x^k$ (from $(A + Bz)e^{kz}$), and resonant forcing proportional to x^{k_1} gives a particular integral proportional to $x^{k_1} \ln x$.

Example 2.6.17

Let's solve $x^2 y'' - 3xy' + 4y = x^2$ for $x > 0$. Trying $y = x^k$ in the homogeneous equation:

$$k(k - 1) - 3k + 4 = k^2 - 4k + 4 = (k - 2)^2 = 0,$$

a repeated root $k = 2$. So the complementary function is

$$y_c = (A + B \ln x) x^2.$$

The forcing x^2 is resonant (it is a complementary function!), so following the rule above we try $y_p = Cx^2(\ln x)^2$ – the usual resonant guess $x^2 \ln x$ is *also* a complementary function here, so we multiply by $\ln x$ once more. Substituting (a slightly tedious computation, best done via $z = \ln x$, where the equation becomes $\frac{d^2 y}{dz^2} - 4\frac{dy}{dz} + 4y = e^{2z}$ with double-resonant forcing and trial $Cz^2 e^{2z}$):

$$C(2 + 8z + 4z^2 - 8z - 8z^2 + 4z^2) e^{2z} = e^{2z} \implies 2C = 1,$$

so $C = \frac{1}{2}$ and the general solution is

$$y = (A + B \ln x + \frac{1}{2}(\ln x)^2) x^2.$$

§2.6.9 Transients and Damping

Let's use what we have built to study a genuinely physical system: a damped, forced oscillator. Consider a car of mass M riding on suspension; the springs supply a restoring force kx and the shock absorbers a friction force $l\dot{x}$ opposing motion, while $F(t)$ is an external vertical force. Newton's second law gives

$$M\ddot{x} = F(t) - kx - l\dot{x} \implies \ddot{x} + \frac{l}{M}\dot{x} + \frac{k}{M}x = \frac{F(t)}{M}.$$

Without damping and forcing this would be simple harmonic motion with angular frequency $\sqrt{k/M}$. It is illuminating to non-dimensionalise: measure time in units of $\sqrt{M/k}$ by setting $t = \tau \sqrt{M/k}$. The equation becomes

$$\ddot{x} + 2\kappa\dot{x} + x = f(\tau),$$

where now dots denote $d/d\tau$, and

$$\kappa = \frac{l}{2\sqrt{kM}}, \quad f = \frac{F}{k}.$$

The original three parameters M, l, k have collapsed into the single dimensionless damping parameter κ – this sort of reduction is one of the main payoffs of non-dimensionalisation.

Consider first the free response, $f = 0$. The characteristic equation $\lambda^2 + 2\kappa\lambda + 1 = 0$ has roots

$$\lambda = -\kappa \pm \sqrt{\kappa^2 - 1},$$

and the character of the motion depends entirely on where κ sits relative to 1.

- (i) *Underdamped* ($\kappa < 1$). The roots are complex, $\lambda = -\kappa \pm i\sqrt{1 - \kappa^2}$, and

$$x = e^{-\kappa\tau} \left(A \sin \sqrt{1 - \kappa^2} \tau + B \cos \sqrt{1 - \kappa^2} \tau \right).$$

The system oscillates with period $2\pi/\sqrt{1 - \kappa^2}$ – note that damping *lengthens* the period – inside an envelope decaying over a timescale $O(1/\kappa)$. As $\kappa \rightarrow 1$ the period tends to infinity.

- (ii) *Critically damped* ($\kappa = 1$). Repeated root $\lambda = -1$, so

$$x = (A + B\tau)e^{-\tau}.$$

The solution can rise at most once before decaying; both the rise and decay happen on the $O(1)$ timescale (i.e. $O(\sqrt{M/k})$ in dimensional terms).

- (iii) *Overdamped* ($\kappa > 1$). Two real negative roots $-\lambda_1 > -\lambda_2$, and

$$x = Ae^{-\lambda_1\tau} + Be^{-\lambda_2\tau}, \quad \lambda_{1,2} = \kappa \mp \sqrt{\kappa^2 - 1}.$$

The fast mode dies on a timescale $O(1/\lambda_2)$, and the solution then decays slowly, on the long timescale $O(1/\lambda_1)$. Heavy damping makes the system *slower* to settle.

The three regimes are compared below, each released from rest at $x = 1$: the underdamped solution overshoots and oscillates, the critically damped one settles fastest, and the overdamped one creeps home.

For car suspension we would tune κ close to critical damping: strong enough to kill oscillations, not so strong that the car takes forever to level out.

Example 2.6.18 (An Underdamped Oscillator)

Let's solve a concrete initial value problem:

$$\ddot{x} + 2\dot{x} + 5x = 0, \quad x(0) = 1, \quad \dot{x}(0) = 0.$$

The characteristic equation $\lambda^2 + 2\lambda + 5 = 0$ gives $\lambda = -1 \pm 2i$, so

$$x = e^{-t}(A \cos 2t + B \sin 2t).$$

The condition $x(0) = 1$ gives $A = 1$; then $\dot{x} = e^{-t}[(-A + 2B) \cos 2t + (-B - 2A) \sin 2t]$, and $\dot{x}(0) = 0$ gives $B = \frac{1}{2}$. So

$$x = e^{-t} \left(\cos 2t + \frac{1}{2} \sin 2t \right),$$

a decaying oscillation: the mass overshoots the origin, swings back, and each successive swing is smaller by a factor $e^{-\pi} \approx 0.04$ (one half-period is $\pi/2$, so a full period costs $e^{-\pi}$ in amplitude). Within a few swings the motion is imperceptible.

Now switch the forcing on, say $f(\tau) = \sin \tau$. In all three cases the roots of the characteristic equation have negative real part, so the complementary function decays exponentially: it is a **transient**, describing the system's short-time adjustment to its initial conditions. What survives at large times is the particular integral, the *steady-state response*. Guessing $x_p = C \sin \tau + D \cos \tau$ and substituting into $\ddot{x} + 2\kappa\dot{x} + x = \sin \tau$:

$$(-C - 2\kappa D + C) \sin \tau + (-D + 2\kappa C + D) \cos \tau = \sin \tau,$$

so $C = 0$ and $D = -1/(2\kappa)$, giving

$$x \sim -\frac{1}{2\kappa} \cos \tau \quad \text{as } \tau \rightarrow \infty.$$

Notice that the long-time response is 90° out of phase with the forcing (and its amplitude blows up as $\kappa \rightarrow 0$ – our old friend resonance, since the forcing here is at the natural frequency).

§2.7 Second-Order Difference Equations

Just as first-order ODEs had discrete analogues, so do second-order equations. Consider

$$a y_{n+2} + b y_{n+1} + c y_n = f_n.$$

The whole solution theory transfers almost verbatim from the continuous setting, because the same structural facts hold: the equation is linear, and we know an eigenfunction of the basic operator. Here the basic operator is the *shift* $D[y_n] = y_{n+1}$, and its eigenfunctions are the geometric sequences $y_n = k^n$, since $D[k^n] = k \cdot k^n$.

So, to solve the homogeneous equation $a y_{n+2} + b y_{n+1} + c y_n = 0$, we try $y_n = k^n$:

$$a k^{n+2} + b k^{n+1} + c k^n = 0 \implies a k^2 + b k + c = 0.$$

If the roots k_1, k_2 are distinct, the general complementary function is

$$y_n^{(c)} = A k_1^n + B k_2^n,$$

and if they coincide, $y_n^{(c)} = (A + Bn)k^n$ – multiplication by n playing exactly the role that multiplication by x played before.

For particular integrals we guess, following the same principles:

f_n	trial $y_n^{(p)}$
k^n ($k \neq k_1, k_2$)	Ak^n
k_1^n	Ank_1^n
n^p	$An^p + Bn^{p-1} + \dots + C$

with the resonant case again handled by an extra factor of n .

Example 2.7.1 (The Fibonacci Sequence)

The Fibonacci numbers satisfy

$$y_{n+2} - y_{n+1} - y_n = 0, \quad y_0 = y_1 = 1.$$

Trying $y_n = k^n$ gives $k^2 - k - 1 = 0$, so

$$k = \frac{1 \pm \sqrt{5}}{2}.$$

Write $\varphi_1 = \frac{1+\sqrt{5}}{2}$ (the golden ratio) and $\varphi_2 = \frac{1-\sqrt{5}}{2}$; note $\varphi_1\varphi_2 = -1$. The general solution is $y_n = A\varphi_1^n + B\varphi_2^n$, and the initial conditions give

$$A + B = 1, \quad A\varphi_1 + B\varphi_2 = 1,$$

from which $A = \varphi_1/\sqrt{5}$ and $B = -\varphi_2/\sqrt{5}$. Hence

$$y_n = \frac{\varphi_1^{n+1} - \varphi_2^{n+1}}{\sqrt{5}}.$$

Since $|\varphi_2| < 1$, the second term rapidly becomes negligible: the Fibonacci numbers grow like $\varphi_1^{n+1}/\sqrt{5}$, and the ratio of successive terms tends to the golden ratio. (It is mildly miraculous that this expression, stuffed full of $\sqrt{5}$'s, is an integer for every n – but of course it must be.)

Example 2.7.2 (A Forced Difference Equation)

Consider

$$y_{n+2} - 5y_{n+1} + 6y_n = 2^n.$$

The characteristic equation $k^2 - 5k + 6 = 0$ has roots $k = 2, 3$, so the complementary function is $A \cdot 2^n + B \cdot 3^n$. But the forcing 2^n is resonant with the root $k = 2$, so we try $y_n^{(p)} = Cn2^n$. Substituting:

$$C(n+2)2^{n+2} - 5C(n+1)2^{n+1} + 6Cn2^n = 2^n [4C(n+2) - 10C(n+1) + 6Cn] = -2C \cdot 2^n,$$

so $C = -\frac{1}{2}$, and the general solution is

$$y_n = A \cdot 2^n + B \cdot 3^n - \frac{n}{2} \cdot 2^n.$$

Everything about resonance transfers from the continuous world: the resonant response grows like n times the forcing, just as it grew like t times the forcing before.

§2.8 Impulses and Discontinuous Forcing

So far our forcing functions have been smooth. But many physical forces are not: a hammer blow, a ball bouncing, a switch being flicked. In this section we develop the (initially rather alarming) mathematical objects used to model instantaneous and switched-on forces.

§2.8.1 Impulses and the Dirac Delta Function

Consider a ball bouncing on the ground. When the ball hits the ground at time T , the ground exerts a large force $F(t)$ on it, but only during a very short interval $(T-\varepsilon, T+\varepsilon)$; at all other times $F(t) = 0$. Typically we neither know nor care about the detailed profile of F during the impact. What actually matters?

Newton's second law during the bounce reads $m\ddot{x} = F(t) - mg$. Integrating over the impact,

$$\int_{T-\varepsilon}^{T+\varepsilon} m\ddot{x} \, dt = \int_{T-\varepsilon}^{T+\varepsilon} F(t) \, dt - \int_{T-\varepsilon}^{T+\varepsilon} mg \, dt,$$

which is to say

$$\Delta p = I - O(\varepsilon), \quad I = \int_{T-\varepsilon}^{T+\varepsilon} F(t) \, dt,$$

where Δp is the change in momentum. The quantity I – the area under the force curve, called the **impulse** – is the *only* feature of F that affects the motion on macroscopic timescales. So for a short impact we may as well idealise: let $\varepsilon \rightarrow 0$ and imagine the force acting instantaneously, with the impulse held fixed.

To make this idealisation usable inside differential equations, consider (taking $T = 0$ for convenience) a family of functions $D(t; \varepsilon)$ that become taller and narrower as $\varepsilon \rightarrow 0$ while keeping unit area:

$$\lim_{\varepsilon \rightarrow 0} D(t; \varepsilon) = 0 \text{ for } t \neq 0, \quad \lim_{\varepsilon \rightarrow 0} \int_{-\infty}^{\infty} D(t; \varepsilon) \, dt = 1.$$

A standard choice is the Gaussian family

$$D(t; \varepsilon) = \frac{1}{\varepsilon\sqrt{\pi}} e^{-t^2/\varepsilon^2},$$

of height $O(1/\varepsilon)$ and width $O(\varepsilon)$. An idealised unit impulse at $t = 0$ is then modelled by the ‘limit’ of this family.

Definition 2.8.1 (Dirac Delta Function)

The **Dirac delta function** is defined by

$$\delta(x) = \lim_{\varepsilon \rightarrow 0} D(x; \varepsilon),$$

on the strict understanding that only its *integral* properties may ever be used: an expression $\int_{-\infty}^{\infty} g(x) \delta(x) dx$ means, by definition,

$$\lim_{\varepsilon \rightarrow 0} \int_{-\infty}^{\infty} g(x) D(x; \varepsilon) dx.$$

The delta function is not a function in any honest sense – the pointwise limit at 0 doesn't even exist – but the integrals it appears in are perfectly meaningful³. The key rule, obtained by noting that all the mass of $D(\cdot; \varepsilon)$ concentrates at the origin, is the **sampling property**:

$$\int_a^b g(x) \delta(x - c) dx = \begin{cases} g(c) & c \in (a, b), \\ 0 & c \notin [a, b], \end{cases}$$

for g continuous at c . Integrating against $\delta(x - c)$ simply evaluates at c .

With this notation, our bouncing ball obeys the single equation

$$m\ddot{x} = -mg + I\delta(t - T),$$

valid for all time, with the impact incorporated as a delta-function forcing.

Example 2.8.2 (Manipulating Delta Functions)

All computations with δ reduce to the sampling property, usually after a substitution. For instance, for a constant $a \neq 0$, substituting $u = ax$:

$$\int_{-\infty}^{\infty} g(x) \delta(ax) dx = \frac{1}{|a|} \int_{-\infty}^{\infty} g(u/a) \delta(u) du = \frac{g(0)}{|a|},$$

(the modulus appearing because $a < 0$ also reverses the limits). So, as distributions, $\delta(ax) = \delta(x)/|a|$. Similarly,

$$\int_0^5 (x^2 + 1) \delta(x - 2) dx = 5, \quad \int_3^5 (x^2 + 1) \delta(x - 2) dx = 0,$$

the second because the spike at $x = 2$ lies outside the range of integration.

§2.8.2 Delta-Function Forcing of Second-Order Equations

What does a delta-forced solution actually look like? The guiding principle is:

Differentiation makes functions less smooth, so the discontinuity in a delta-forced equation is always absorbed by the highest derivative present.

³The proper home for objects like δ is the theory of *distributions*, but the operational rules stated here are all we need.

For a second-order equation $y'' + py' + qy = \delta(x - c)$: the second derivative behaves like a delta function at $x = c$; hence y' has a finite jump there; and y itself is continuous. (If y itself jumped, y' would contain a delta and y'' something worse – which could not be balanced by the right-hand side.) The size of the jump in y' is found by integrating the equation across the singularity.

Example 2.8.3

Let's solve

$$y'' - y = 3\delta\left(x - \frac{\pi}{2}\right), \quad y(0) = y(\pi) = 0.$$

Away from $x = \pi/2$ the equation is just $y'' - y = 0$, with general solution built from $\sinh$ and $\cosh$. It is convenient to write the solutions in a form adapted to each boundary:

- On $0 \leq x < \pi/2$: $y = A \sinh x + B \cosh x$, and $y(0) = 0$ forces $B = 0$.
- On $\pi/2 < x \leq \pi$: $y = C \sinh(\pi - x) + D \cosh(\pi - x)$, and $y(\pi) = 0$ forces $D = 0$.

Now we join the pieces at $x = \pi/2$. First, continuity of y :

$$A \sinh \frac{\pi}{2} = C \sinh \frac{\pi}{2} \implies A = C.$$

Second, the jump condition. Integrating the equation from $\frac{\pi}{2}^-$ to $\frac{\pi}{2}^+$:

$$[y']_{\pi/2^-}^{\pi/2^+} - \int_{\pi/2^-}^{\pi/2^+} y \, dx = 3.$$

The integral of the (bounded, continuous) function y over a vanishing interval is zero, so the jump in y' is exactly 3:

$$-C \cosh \frac{\pi}{2} - A \cosh \frac{\pi}{2} = 3 \implies A = C = \frac{-3}{2 \cosh \frac{\pi}{2}}.$$

So the solution is

$$y = \begin{cases} \frac{-3 \sinh x}{2 \cosh \frac{\pi}{2}} & 0 \leq x \leq \frac{\pi}{2}, \\ \frac{-3 \sinh(\pi - x)}{2 \cosh \frac{\pi}{2}} & \frac{\pi}{2} \leq x \leq \pi, \end{cases}$$

a tent-like curve, continuous everywhere but with a corner (jump in y') at the point of impact.

§2.8.3 The Heaviside Step Function

Closely related to the delta function is the function that models a switch being flicked on.

Definition 2.8.4 (Heaviside Step Function)

The **Heaviside step function** is

$$H(x) = \int_{-\infty}^x \delta(t) dt = \begin{cases} 0 & x < 0, \\ 1 & x > 0, \end{cases}$$

with $H(0)$ left undefined.

By the fundamental theorem of calculus (applied, as always with these objects, in the sense of integrals),

$$\frac{dH}{dx} = \delta(x).$$

This gives a tidy hierarchy of smoothness: H has a jump, its derivative δ is an impulse, and going the other way, the integral of H is the continuous ‘ramp’ function $xH(x)$. Solving an equation with step-function forcing works just like the delta case, but one degree smoother: for $y'' + py' + qy = H(x - c)$, both y and y' are continuous at $x = c$, and it is y'' that jumps.

Example 2.8.5 (Switching On an Oscillator)

Consider an undamped oscillator, at rest, which at $t = 0$ has a constant force switched on:

$$\ddot{y} + y = H(t), \quad y = \dot{y} = 0 \text{ for } t < 0.$$

For $t < 0$ the solution is $y = 0$. For $t > 0$ the equation is $\ddot{y} + y = 1$, with particular integral $y_p = 1$ and general solution

$$y = 1 + A \cos t + B \sin t.$$

At $t = 0$ we require both y and $\dot{y}$ to be continuous (only $\ddot{y}$ may jump, matching the jump in H). So $y(0) = 0$ gives $A = -1$, and $\dot{y}(0) = 0$ gives $B = 0$:

$$y = \begin{cases} 0 & t < 0, \\ 1 - \cos t & t > 0. \end{cases}$$

The oscillator swings between 0 and 2 forever: switching on a constant force doesn’t move an undamped oscillator to its new equilibrium $y = 1$, but sets it oscillating about it – with, note, twice the amplitude one might naively expect. In a real system, damping would cause these oscillations to decay and the solution to settle at $y = 1$; the oscillation is the transient.

§2.9 Series Solutions

Many important second-order equations – Legendre’s, Bessel’s, and others that arise when PDEs are solved in special geometries – have non-constant coefficients and no closed-form solution in elementary functions. The method of this section constructs their solutions directly as power series.

We consider homogeneous equations of the form

$$p(x)y'' + q(x)y' + r(x)y = 0.$$

Prominent members of this family, which the reader will meet properly in IB, include *Legendre's equation* $(1 - x^2)y'' - 2xy' + \ell(\ell + 1)y = 0$ and *Bessel's equation* $x^2y'' + xy' + (x^2 - \nu^2)y = 0$; their series solutions (Legendre polynomials, Bessel functions) are among the standard 'special functions' of mathematical physics.

§2.9.1 Ordinary and Singular Points

The behaviour of series solutions about a point x_0 is governed by whether the leading coefficient vanishes there.

Definition 2.9.1 (Ordinary and Singular Points)

The point $x = x_0$ is an **ordinary point** of the equation if q/p and r/p have Taylor series about x_0 (i.e. are analytic there). Otherwise x_0 is a **singular point**.

A singular point x_0 is a **regular singular point** if the equation can be written as

$$P(x)(x - x_0)^2y'' + Q(x)(x - x_0)y' + R(x)y = 0$$

with Q/P and R/P analytic at x_0 .

Loosely: at a regular singular point the coefficients are allowed to blow up, but only as fast as the equidimensional equation's do.

Example 2.9.2

Some quick classifications:

- (i) $(1 - x^2)y'' - 2xy' + 2y = 0$ (Legendre's equation): $x = 0$ is ordinary; $x = \pm 1$ are regular singular points.
- (ii) $(\sin x)y'' + (\cos x)y' + 2y = 0$: the points $x = n\pi$ are regular singular points; all others are ordinary.
- (iii) $(1 + \sqrt{x})y'' - 2xy' + 2y = 0$: $x = 0$ is an *irregular* singular point, since $\sqrt{x}$ has no Taylor series at 0.

The fundamental facts – which we will use but not prove – are:

- (1) If x_0 is an *ordinary point*, the equation has two linearly independent solutions of Taylor form

$$y = \sum_{n=0}^{\infty} a_n(x - x_0)^n,$$

convergent in some neighbourhood of x_0 .

- (2) If x_0 is a *regular singular point*, there is at least one solution of the form

$$y = \sum_{n=0}^{\infty} a_n(x - x_0)^{n+\sigma}, \quad a_0 \neq 0,$$

a **Frobenius series**, where the **index** σ need not be an integer (nor even real). Requiring $a_0 \neq 0$ makes σ well defined. Equivalently, $y = (x - x_0)^\sigma f(x)$ with f analytic and $f(x_0) \neq 0$.

§2.9.2 Solutions About an Ordinary Point

The method is best introduced by simply watching it work on an important equation.

Example 2.9.3 (Legendre's Equation)

Let's find a series solution of

$$(1 - x^2)y'' - 2xy' + 2y = 0$$

about the ordinary point $x = 0$. Try $y = \sum_{n \geq 0} a_n x^n$. A small trick makes the bookkeeping cleaner: multiply the equation through by x^2 so that every term is a combination of the equidimensional building blocks $x^2 y''$, xy' and y (with polynomial coefficients), each of which acts diagonally on powers:

$$x^2 y'' = \sum_n n(n-1) a_n x^n, \quad xy' = \sum_n n a_n x^n.$$

We get

$$(1-x^2)(x^2 y'') - 2x^2(xy') + 2x^2 y = 0 \implies \sum_n a_n [n(n-1) + (-n^2 - n + 2)x^2] x^n = 0.$$

Setting the coefficient of x^n to zero gives the recurrence

$$n(n-1)a_n = [(n-2)^2 + (n-2) - 2] a_{n-2} = (n^2 - 3n) a_{n-2}.$$

We resist the urge to divide, because the prefactors may vanish – and indeed the cases $n = 0$ and $n = 1$ read $0 \cdot a_0 = 0$ and $0 \cdot a_1 = 0$, so a_0 and a_1 are both arbitrary: they are our two constants of integration. For $n \geq 2$ we may divide:

$$a_n = \frac{n-3}{n-1} a_{n-2}.$$

For odd n , the chain passes through $a_3 = 0 \cdot a_1 = 0$, so all odd coefficients beyond a_1 vanish. For even $n = 2k$, the product telescopes:

$$a_{2k} = \frac{2k-3}{2k-1} \cdot \frac{2k-5}{2k-3} \cdots \frac{-1}{1} a_0 = \frac{-1}{2k-1} a_0.$$

So the general solution is

$$y = a_0 \left[1 - x^2 - \frac{x^4}{3} - \frac{x^6}{5} - \cdots \right] + a_1 x = a_0 \left[1 - \frac{x}{2} \ln \left(\frac{1+x}{1-x} \right) \right] + a_1 x,$$

where the closed form of the even series can be checked by expanding the logarithm. Two things are worth noticing: the polynomial solution $y = x$ (Legendre equations always have one polynomial solution for the right parameter values), and the logarithmic divergence of the other solution at $x = \pm 1$ – precisely at the singular points of the equation. The series knows about the singularities.

The same happens for every parameter value $\ell(\ell+1)$ with ℓ a non-negative integer: one of the two series terminates, leaving a polynomial solution of degree ℓ . Normalised so that $y(1) = 1$, these are the **Legendre polynomials** $P_\ell(x)$; the first few are $P_0 = 1$, $P_1 = x$, $P_2 = \frac{1}{2}(3x^2 - 1)$ and $P_3 = \frac{1}{2}(5x^3 - 3x)$, sketched below on $[-1, 1]$.

§2.9.3 Solutions About a Regular Singular Point: Frobenius

To see why singular points demand something new, let's try our hand at an example.

Example 2.9.4

Consider

$$4xy'' + 2(1 - x^2)y' - xy = 0.$$

The point $x = 0$ is singular (the coefficient of y'' vanishes), but multiplying by x puts the equation in the form

$$4(x^2y'') + 2(1 - x^2)(xy') - x^2y = 0,$$

and comparing with the definition, $Q/P = (1 - x^2)/2$ and $R/P = -x^2/4$ are analytic, so $x = 0$ is a *regular* singular point. We therefore try a Frobenius series

$$y = \sum_{n=0}^{\infty} a_n x^{n+\sigma}, \quad a_0 \neq 0.$$

Using the diagonal action $x^2y'' = \sum a_n(n+\sigma)(n+\sigma-1)x^{n+\sigma}$ and $xy' = \sum a_n(n+\sigma)x^{n+\sigma}$:

$$\sum_n a_n x^{n+\sigma} [4(n+\sigma)(n+\sigma-1) + 2(n+\sigma)] - \sum_n a_n x^{n+\sigma+2} [2(n+\sigma) + 1] = 0.$$

The coefficient of $x^{n+\sigma}$ gives the recurrence

$$2(n+\sigma)(2n+2\sigma-1)a_n = (2n+2\sigma-3)a_{n-2}.$$

Now the crucial step: setting $n = 0$ (where $a_{-2} = 0$) gives

$$2\sigma(2\sigma-1)a_0 = 0,$$

and since $a_0 \neq 0$ by fiat, we obtain the **indicial equation** $2\sigma(2\sigma - 1) = 0$, so

$$\sigma = 0 \quad \text{or} \quad \sigma = \frac{1}{2}.$$

The index $\sigma = 0$ will give an analytic solution; $\sigma = \frac{1}{2}$ a genuinely non-analytic one (a series in x multiplied by $\sqrt{x}$).

Case $\sigma = 0$. The recurrence is $2n(2n - 1)a_n = (2n - 3)a_{n-2}$. Here a_0 is arbitrary, $n = 1$ gives $a_1 = 0$ (and hence all odd terms vanish), and for even n ,

$$a_n = \frac{2n - 3}{2n(2n - 1)} a_{n-2} \implies y_1 = a_0 \left[1 + \frac{1}{4 \cdot 3} x^2 + \frac{5}{8 \cdot 7 \cdot 4 \cdot 3} x^4 + \cdots \right].$$

Case $\sigma = \frac{1}{2}$. The recurrence is $(2n + 1)(2n)a_n = (2n - 2)a_{n-2}$. Again a_0 (call it b_0 to avoid confusion) is arbitrary and odd terms vanish, and for even n ,

$$a_n = \frac{n - 1}{n(2n + 1)} a_{n-2} \implies y_2 = b_0 x^{1/2} \left[1 + \frac{1}{2 \cdot 5} x^2 + \frac{3}{2 \cdot 5 \cdot 4 \cdot 9} x^4 + \cdots \right].$$

Together, $y = y_1 + y_2$ gives the general solution.

§2.9.4 When the Indices Differ by an Integer

The indicial equation is a quadratic with roots σ_1, σ_2 (say $\operatorname{Re} \sigma_1 \leq \operatorname{Re} \sigma_2$), and the structure of the solutions depends on the difference $\sigma_2 - \sigma_1$.

- (1) If $\sigma_2 - \sigma_1$ is *not* an integer, everything is pleasant: there are two independent Frobenius solutions, one for each index, and near x_0 the general solution behaves like $(x - x_0)^{\sigma_1}$.
- (2) If $\sigma_2 - \sigma_1$ *is* an integer (including the repeated case $\sigma_1 = \sigma_2$), the larger index σ_2 always yields a Frobenius solution y_1 , but the smaller one generally does not: the recurrence for $\sigma = \sigma_1$ breaks down when it reaches the offending coefficient. The second solution instead (usually) takes the logarithmic form

$$y_2 = \ln(x - x_0) y_1 + \sum_{n=0}^{\infty} b_n (x - x_0)^{n+\sigma_1},$$

with the coefficients b_n found by substituting this form into the equation. The appearance of the logarithm is a resonance phenomenon between the two solutions – entirely analogous to the resonant forcing we met earlier, where the natural guess had to be corrected by a factor breaking the degeneracy. (Occasionally the resonance ‘accidentally’ avoids itself and two ordinary Frobenius solutions exist after all.)

Example 2.9.5

Consider $x^2 y'' - xy = 0$, already in equidimensional form. Trying $y = \sum a_n x^{n+\sigma}$ with $a_0 \neq 0$:

$$\sum_n a_n x^{n+\sigma} (n + \sigma)(n + \sigma - 1) - \sum_n a_n x^{n+\sigma+1} = 0,$$

giving the recurrence

$$(n + \sigma)(n + \sigma - 1)a_n = a_{n-1}.$$

The indicial equation is $\sigma(\sigma - 1) = 0$, so $\sigma = 0, 1$ – differing by an integer, so we should brace ourselves.

Index $\sigma = 1$ (the larger). The recurrence is $(n + 1)n a_n = a_{n-1}$, so a_0 is arbitrary and for $n \geq 1$,

$$a_n = \frac{a_{n-1}}{n(n+1)} = \frac{a_0}{(n+1)(n!)^2},$$

giving

$$y_1 = a_0 x \left(1 + \frac{x}{2} + \frac{x^2}{12} + \frac{x^3}{144} + \cdots \right).$$

Index $\sigma = 0$. The recurrence is $n(n-1)a_n = a_{n-1}$. At $n = 1$ this reads $0 \cdot a_1 = a_0$, which is impossible since $a_0 \neq 0$. So there is *no* Frobenius solution with index 0, exactly as advertised, and the second solution has the logarithmic form

$$y_2 = y_1 \ln x + \sum_{n=0}^{\infty} b_n x^n,$$

whose coefficients could be ground out by substitution.

Remark. It is no accident that we saw logarithms appearing at singular points before – in the Legendre example, the second solution behaved like $\ln\left(\frac{1+x}{1-x}\right)$ near the regular singular points $x = \pm 1$. Singular points are exactly where solutions are allowed to misbehave, and the possible misbehaviours at a *regular* singular point are tightly controlled: a branch-point power $(x - x_0)^\sigma$, possibly decorated with a logarithm. Irregular singular points can do far wilder things (consider $e^{1/x}$ near 0), which is why the theory stops there.

§2.10 The Gradient and Stationary Points

We now return to functions of several variables, and develop the tools needed to do calculus in genuinely multi-dimensional settings: the gradient vector, Taylor series in $\mathbb{R}^n$, and the classification of stationary points. Beyond their intrinsic interest, these are exactly the tools we will need to analyse systems of differential equations in the next section.

§2.10.1 The Directional Derivative and the Gradient

Consider $f(x, y)$ and a small displacement $ds = (dx, dy)$ in the plane. The chain rule gives the change in f :

$$df = \frac{\partial f}{\partial x} dx + \frac{\partial f}{\partial y} dy = ds \cdot \left(\frac{\partial f}{\partial x}, \frac{\partial f}{\partial y} \right).$$

The vector appearing on the right is important enough to name. Writing $ds = \hat{s} ds$ with $|\hat{s}| = 1$:

Definition 2.10.1 (Directional Derivative and Gradient)

The **gradient** of f , written ∇f , is the vector such that for every unit vector $\hat{\mathbf{s}}$, the **directional derivative** of f in the direction $\hat{\mathbf{s}}$ is

$$\frac{df}{ds} = \hat{\mathbf{s}} \cdot \nabla f.$$

In Cartesian coordinates, $\nabla f = \left(\frac{\partial f}{\partial x}, \frac{\partial f}{\partial y} \right)$.

(One can take either statement as the definition; taking the coordinate-free one, the Cartesian formula becomes a small theorem, following from the chain rule computation above.)

Writing $\frac{df}{ds} = |\nabla f| \cos \theta$, where θ is the angle between $\hat{\mathbf{s}}$ and ∇f , we can read off the geometry of the gradient:

- (i) ∇f points in the direction in which f increases fastest;
- (ii) $|\nabla f|$ is that maximal rate of increase;
- (iii) if $\hat{\mathbf{s}}$ is tangent to a contour of f (a curve of constant f), then $\frac{df}{ds} = 0$, so ∇f is perpendicular to the contours.

These three facts are worth having thoroughly absorbed – they are used constantly, in this course and in Vector Calculus.

Example 2.10.2

Let $f(x, y) = x^2y$, and let's find the rate of change of f at the point $(1, 2)$ in the direction of the unit vector $\hat{\mathbf{s}} = \frac{1}{5}(3, 4)$. We have

$$\nabla f = (2xy, x^2), \quad \nabla f(1, 2) = (4, 1),$$

so

$$\frac{df}{ds} = \hat{\mathbf{s}} \cdot \nabla f = \frac{1}{5}(3 \cdot 4 + 4 \cdot 1) = \frac{16}{5}.$$

The maximum possible rate of change at this point is $|\nabla f| = \sqrt{17}$, attained in the direction $\frac{1}{\sqrt{17}}(4, 1)$, and the level curve of f through $(1, 2)$ has tangent perpendicular to this, i.e. along $(1, -4)$.

§2.10.2 Taylor Series in Several Variables

To classify stationary points we need the second-order Taylor expansion of a multivariate function. Let $\mathbf{x}_0$ be a point and $\delta \mathbf{x} = \mathbf{x} - \mathbf{x}_0$ a small displacement, along a straight line in the direction $\hat{\mathbf{s}}$, so $\delta \mathbf{x} = \hat{\mathbf{s}} \delta s$. Along that line, f is a function of the single variable s with $\frac{d}{ds} = \hat{\mathbf{s}} \cdot \nabla$, and the ordinary Taylor expansion gives

$$f = f(\mathbf{x}_0) + \delta s (\hat{\mathbf{s}} \cdot \nabla) f + \frac{1}{2} (\delta s)^2 (\hat{\mathbf{s}} \cdot \nabla)(\hat{\mathbf{s}} \cdot \nabla) f + \dots$$

The first-order term is $\delta \mathbf{x} \cdot \nabla f$. For the second-order term, expanding in coordinates,

$$(\delta \mathbf{x} \cdot \nabla)(\delta \mathbf{x} \cdot \nabla) f = (\delta x)^2 f_{xx} + 2 \delta x \delta y f_{xy} + (\delta y)^2 f_{yy} = \delta \mathbf{x}^T H \delta \mathbf{x},$$

where H is the following matrix of second derivatives.

Definition 2.10.3 (Hessian Matrix)

The **Hessian** of f is the matrix of second partial derivatives

$$H = \nabla \nabla f = \begin{pmatrix} f_{xx} & f_{xy} \\ f_{yx} & f_{yy} \end{pmatrix},$$

(and the analogous $n \times n$ matrix in n variables). By symmetry of mixed partials, H is a symmetric matrix.

So we have the coordinate-free second-order Taylor expansion

$$f(\mathbf{x}) = f(\mathbf{x}_0) + \delta \mathbf{x} \cdot \nabla f(\mathbf{x}_0) + \frac{1}{2} \delta \mathbf{x}^T H(\mathbf{x}_0) \delta \mathbf{x} + o(|\delta \mathbf{x}|^2),$$

which is the multivariate analogue of ‘constant + linear + quadratic’.

Example 2.10.4

Let’s expand $f(x, y) = e^{xy}$ to second order about $(0, 0)$. We have

$$f_x = ye^{xy}, \quad f_y = xe^{xy}, \quad f_{xx} = y^2 e^{xy}, \quad f_{xy} = (1 + xy)e^{xy}, \quad f_{yy} = x^2 e^{xy},$$

so at the origin $f = 1$, $\nabla f = (0, 0)$ and

$$H = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Hence

$$e^{xy} = 1 + \frac{1}{2} \begin{pmatrix} x & y \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} + \cdots = 1 + xy + \cdots,$$

which agrees, reassuringly, with substituting $u = xy$ into $e^u = 1 + u + \cdots$. Note in passing that the origin is a stationary point of e^{xy} , and the Hessian has eigenvalues ± 1 (eigenvectors $(1, \pm 1)$): a saddle, as a sketch of the function quickly confirms.

§2.10.3 Stationary Points and Their Classification

At any point there is always at least one direction with $df/ds = 0$, namely along the contour. A *stationary point* is where this happens in every direction.

Definition 2.10.5 (Stationary Point)

A **stationary point** of f is a point where $\nabla f = \mathbf{0}$, i.e. where all partial derivatives vanish.

In one variable, stationary points are maxima, minima or (rarely) inflections. In two or more variables there is a genuinely new type: the **saddle point**, where f increases in some directions and decreases in others (like the middle of a mountain pass – or a horse’s saddle). We define a saddle to be any stationary point that is neither a local maximum nor a local minimum.

Near a stationary point the Taylor expansion reads

$$f(\mathbf{x}) \approx f(\mathbf{x}_0) + \frac{1}{2} \delta \mathbf{x}^T H \delta \mathbf{x},$$

so the local behaviour is governed entirely by the sign of the quadratic form $\delta \mathbf{x}^T H \delta \mathbf{x}$:

- minimum: $\delta \mathbf{x}^T H \delta \mathbf{x} > 0$ for all $\delta \mathbf{x} \neq \mathbf{0}$ (H is *positive definite*);
- maximum: $\delta \mathbf{x}^T H \delta \mathbf{x} < 0$ for all $\delta \mathbf{x} \neq \mathbf{0}$ (H is *negative definite*);
- saddle: the form takes both signs (H is *indefinite*).

To determine which case we are in, we use the fact that H is symmetric, and hence diagonalisable with respect to orthogonal axes (its principal axes). In those axes,

$$\delta \mathbf{x}^T H \delta \mathbf{x} = \lambda_1(\delta x_1)^2 + \lambda_2(\delta x_2)^2 + \cdots + \lambda_n(\delta x_n)^2,$$

where λ_i are the eigenvalues of H . Reading off the signs:

Proposition 2.10.6 (Classification by Eigenvalues)

At a stationary point with Hessian H :

- (i) if all eigenvalues of H are positive, the point is a local minimum;
- (ii) if all are negative, a local maximum;
- (iii) if there are eigenvalues of both signs, a saddle;
- (iv) if some eigenvalue is zero (and the rest are of one sign), the quadratic term is degenerate and higher-order terms must be examined.

Computing eigenvalues can be tedious, and there is a shortcut using determinants.

Definition 2.10.7 (Signature)

The **signature** of H is the sequence of signs of the leading principal minors

$$|H_1| = f_{x_1 x_1}, \quad |H_2| = \begin{vmatrix} f_{x_1 x_1} & f_{x_1 x_2} \\ f_{x_2 x_1} & f_{x_2 x_2} \end{vmatrix}, \quad \dots, \quad |H_n| = |H|.$$

Proposition 2.10.8 (Sylvester's Criterion)

H is positive definite if and only if its signature is $+, +, \dots, +$, and negative definite if and only if its signature is $-, +, -, \dots, (-1)^n$ (alternating, starting negative).

In two dimensions this boils down to something very memorable: compute $\det H = f_{xx}f_{yy} - f_{xy}^2$. If $\det H < 0$, saddle. If $\det H > 0$, it is a max or min according to the sign of f_{xx} .

Example 2.10.9

Let's find and classify the stationary points of

$$f(x, y) = 4x^3 - 12xy + y^2 + 10y + 6.$$

The first derivatives are

$$f_x = 12x^2 - 12y, \quad f_y = -12x + 2y + 10.$$

Setting $f_x = 0$ gives $y = x^2$; substituting into $f_y = 0$ gives $-12x + 2x^2 + 10 = 0$, i.e. $x^2 - 6x + 5 = (x - 1)(x - 5) = 0$. So the stationary points are $(1, 1)$ and $(5, 25)$.

The second derivatives are $f_{xx} = 24x$, $f_{xy} = -12$, $f_{yy} = 2$.

- At $(1, 1)$: $H = \begin{pmatrix} 24 & -12 \\ -12 & 2 \end{pmatrix}$, with $|H_1| = 24 > 0$ and $|H_2| = 48 - 144 = -96 < 0$. Signature $+, -$: indefinite, so a *saddle point*.
- At $(5, 25)$: $H = \begin{pmatrix} 120 & -12 \\ -12 & 2 \end{pmatrix}$, with $|H_1| = 120 > 0$ and $|H_2| = 240 - 144 = 96 > 0$. Signature $+, +$: positive definite, so a *local minimum*.

A final remark on the geometry of contours. Near a maximum or minimum, in principal axes the contours $\lambda_1 X^2 + \lambda_2 Y^2 = \text{const}$ (with $\lambda_1 \lambda_2 > 0$) are locally *ellipses*; near a saddle ($\lambda_1 \lambda_2 < 0$) they are locally *hyperbolae*, and the two branches of the contour through the saddle itself cross there. Indeed, contour lines of a function can only cross at saddle points – a fact which makes sketching contour maps much easier: find and classify the stationary points, draw the local pictures, and join everything up consistently.

§2.11 Systems of Differential Equations

So far we have studied single equations for a single unknown function. But interesting systems usually involve several interacting quantities – predators and prey, coupled circuits, positions and momenta – each with its own differential equation, coupled together. In this section we solve linear systems using matrices and eigenvalues, and then use *linearisation* to understand nonlinear systems near their equilibria.

§2.11.1 Linear Systems and Matrix Methods

Consider two functions $y_1(t)$, $y_2(t)$ satisfying the coupled linear equations

$$\dot{y}_1 = ay_1 + by_2 + f_1(t), \quad \dot{y}_2 = cy_1 + dy_2 + f_2(t),$$

which we write in matrix form as

$$\dot{\mathbf{Y}} = M\mathbf{Y} + \mathbf{F}, \quad \mathbf{Y} = \begin{pmatrix} y_1 \\ y_2 \end{pmatrix}, \quad M = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \quad \mathbf{F} = \begin{pmatrix} f_1 \\ f_2 \end{pmatrix}.$$

First, let us note that first-order systems and higher-order scalar equations are two descriptions of the same thing. In one direction, differentiating the first equation and eliminating y_2 turns the system into a single second-order equation for y_1 :

$$\ddot{y}_1 - (a + d)\dot{y}_1 + (ad - bc)y_1 = bf_2 - df_1 + \dot{f}_1.$$

(Notice the trace and determinant of M appearing – this is no accident, as we will see in a moment.) In the other direction, given a second-order equation $\ddot{y} + a\dot{y} + by = f$, setting $y_1 = y$ and $y_2 = \dot{y}$ gives the first-order system

$$\dot{\mathbf{Y}} = \begin{pmatrix} 0 & 1 \\ -b & -a \end{pmatrix} \mathbf{Y} + \begin{pmatrix} 0 \\ f \end{pmatrix}.$$

This second direction is the more useful one: it says every ODE can be viewed as a first-order system, i.e. as a flow in phase space, and lets us bring linear algebra to bear.

To solve the homogeneous system $\dot{\mathbf{Y}} = M\mathbf{Y}$, we make the by-now-familiar exponential ansatz, but with a constant *vector* attached:

$$\mathbf{Y} = \mathbf{v} e^{\lambda t}.$$

Substituting in, $\lambda \mathbf{v} e^{\lambda t} = M\mathbf{v} e^{\lambda t}$, so

$$M\mathbf{v} = \lambda \mathbf{v}$$

– an eigenvalue problem! The exponents are the eigenvalues of M (roots of $\det(M - \lambda I) = 0$), and the directions are the corresponding eigenvectors. With two distinct eigenvalues, the general solution is

$$\mathbf{Y} = A\mathbf{v}_1 e^{\lambda_1 t} + B\mathbf{v}_2 e^{\lambda_2 t}.$$

For forced systems, we find a particular integral by guessing in the same spirit as before, now with vector-valued coefficients.

Example 2.11.1

Let's solve

$$\dot{\mathbf{Y}} = \begin{pmatrix} -4 & 24 \\ 1 & -2 \end{pmatrix} \mathbf{Y} + \begin{pmatrix} 4 \\ 1 \end{pmatrix} e^t.$$

Complementary function. The characteristic equation is

$$\begin{vmatrix} -4 - \lambda & 24 \\ 1 & -2 - \lambda \end{vmatrix} = \lambda^2 + 6\lambda - 16 = (\lambda + 8)(\lambda - 2) = 0,$$

so $\lambda = 2, -8$. For $\lambda = 2$, solving $(M - 2I)\mathbf{v} = \mathbf{0}$:

$$\begin{pmatrix} -6 & 24 \\ 1 & -4 \end{pmatrix} \begin{pmatrix} v_1 \\ v_2 \end{pmatrix} = \mathbf{0} \implies \mathbf{v}_1 = \begin{pmatrix} 4 \\ 1 \end{pmatrix}.$$

For $\lambda = -8$:

$$\begin{pmatrix} 4 & 24 \\ 1 & 6 \end{pmatrix} \begin{pmatrix} v_1 \\ v_2 \end{pmatrix} = \mathbf{0} \implies \mathbf{v}_2 = \begin{pmatrix} -6 \\ 1 \end{pmatrix}.$$

So the complementary function is

$$\mathbf{Y}_c = A \begin{pmatrix} 4 \\ 1 \end{pmatrix} e^{2t} + B \begin{pmatrix} -6 \\ 1 \end{pmatrix} e^{-8t}.$$

Particular integral. The forcing is e^t , not resonant with either eigenvalue, so try $\mathbf{Y}_p = \mathbf{u} e^t$. Substituting,

$$\mathbf{u} - M\mathbf{u} = \begin{pmatrix} 4 \\ 1 \end{pmatrix} \implies \begin{pmatrix} 5 & -24 \\ -1 & 3 \end{pmatrix} \mathbf{u} = \begin{pmatrix} 4 \\ 1 \end{pmatrix} \implies \mathbf{u} = \frac{1}{-9} \begin{pmatrix} 3 & 24 \\ 1 & 5 \end{pmatrix} \begin{pmatrix} 4 \\ 1 \end{pmatrix} = \begin{pmatrix} -4 \\ -1 \end{pmatrix}.$$

So the general solution is

$$\mathbf{Y} = A \begin{pmatrix} 4 \\ 1 \end{pmatrix} e^{2t} + B \begin{pmatrix} -6 \\ 1 \end{pmatrix} e^{-8t} - \begin{pmatrix} 4 \\ 1 \end{pmatrix} e^t.$$

§2.11.2 Phase Portraits in the Plane

For an autonomous planar system $\dot{\mathbf{Y}} = M\mathbf{Y}$, we can draw the trajectories $(y_1(t), y_2(t))$ in the (y_1, y_2) plane – the **phase portrait** of the system. The eigenvector directions

organise the entire picture: along an eigenvector $\mathbf{v}_i$, the trajectory stays on the line through the origin spanned by $\mathbf{v}_i$, moving outwards if $\lambda_i > 0$ and inwards if $\lambda_i < 0$. Every other trajectory is a combination of the two eigen-motions, dominated for large t by whichever mode grows fastest (and for large negative t by the other).

There are three main cases, according to the eigenvalues of M .

- (1) *Real eigenvalues of opposite sign* ($\lambda_1 > 0 > \lambda_2$): a **saddle point**. Trajectories come in along the stable (λ_2) direction and are flung out along the unstable (λ_1) direction, sweeping past the origin on hyperbola-like paths. (This is the shape of the example above, with $\lambda = 2, -8$.)
- (2) *Real eigenvalues of the same sign*: a **node**. All trajectories head into the origin (if both $\lambda_i < 0$: a *stable node*) or away from it (both positive: an *unstable node*). Trajectories are tangent to the ‘slow’ eigenvector direction (smaller $|\lambda|$) near the origin, and asymptotically parallel to the ‘fast’ one far away.
- (3) *Complex conjugate eigenvalues* $\lambda = \sigma \pm i\omega$: a **spiral** (or, if $\sigma = 0$, a family of concentric ellipses – a *centre*). The solutions are of the form $e^{\sigma t} \times (\text{oscillation})$, so trajectories spiral inwards if $\sigma < 0$ (*stable spiral*) and outwards if $\sigma > 0$ (*unstable spiral*). The sense of rotation can be found by evaluating $\dot{\mathbf{Y}} = M\mathbf{Y}$ at one convenient point, say $(1, 0)$, and seeing which way the flow points.

It is worth noting that everything here can be read off from just the trace and determinant of M , since $\lambda_1\lambda_2 = \det M$ and $\lambda_1 + \lambda_2 = \text{tr } M$: negative determinant means a saddle; positive determinant and negative trace a stable node or spiral (spiral if $(\text{tr } M)^2 < 4\det M$); and so on.

Example 2.11.2 (The Damped Oscillator, Revisited)

The damped oscillator $\ddot{x} + 2\kappa\dot{x} + x = 0$ from earlier becomes, upon setting $\mathbf{Y} = (x, \dot{x})$, the planar system

$$\dot{\mathbf{Y}} = \begin{pmatrix} 0 & 1 \\ -1 & -2\kappa \end{pmatrix} \mathbf{Y},$$

with $\text{tr } M = -2\kappa$ and $\det M = 1$, so the eigenvalues are our old friends $\lambda = -\kappa \pm \sqrt{\kappa^2 - 1}$. Reading off the classification:

- $\kappa = 0$ (undamped): purely imaginary eigenvalues, a *centre* – the closed ellipses of simple harmonic motion in phase space, energy conserved.
- $0 < \kappa < 1$ (underdamped): complex eigenvalues with negative real part, a *stable spiral* – the trajectory winds around the origin as the oscillator swings back and forth, spiralling inwards as the amplitude decays.
- $\kappa > 1$ (overdamped): two negative real eigenvalues, a *stable node* – no more

winding; trajectories slide into the origin, tangent to the slow eigenvector.

The transition through critical damping $\kappa = 1$ is precisely the moment the spiral degenerates into a node, i.e. the eigenvalues collide on the real axis. Phase-portrait language and the earlier time-domain analysis are two views of the same underlying picture.

Example 2.11.3 (An Initial Value Problem)

Continuing the earlier example, let's impose the initial condition $\mathbf{Y}(0) = (0, 0)$ on

$$\mathbf{Y} = A \begin{pmatrix} 4 \\ 1 \end{pmatrix} e^{2t} + B \begin{pmatrix} -6 \\ 1 \end{pmatrix} e^{-8t} - \begin{pmatrix} 4 \\ 1 \end{pmatrix} e^t.$$

At $t = 0$:

$$4A - 6B - 4 = 0, \quad A + B - 1 = 0,$$

so $B = 1 - A$ and $4A - 6 + 6A = 4$, giving $A = 1$, $B = 0$. The solution through the origin is

$$\mathbf{Y} = \begin{pmatrix} 4 \\ 1 \end{pmatrix} (e^{2t} - e^t) :$$

as it happens the e^{-8t} mode is not excited at all, and this particular trajectory runs along the fixed direction $(4, 1)$ for all time.

§2.11.3 Nonlinear Systems and Linearisation

Finally we come to nonlinear autonomous systems,

$$\dot{x} = f(x, y), \quad \dot{y} = g(x, y),$$

where f and g have no explicit time-dependence. Solving such systems exactly is usually hopeless, but – just as for single autonomous equations – we can understand the phase portrait by finding the equilibria and analysing the flow near each.

Definition 2.11.4 (Equilibrium Point of a System)

An **equilibrium point** of the system is a point (x_0, y_0) where $\dot{x} = \dot{y} = 0$, i.e. where $f(x_0, y_0) = g(x_0, y_0) = 0$ simultaneously.

Near an equilibrium, write $x = x_0 + \xi$, $y = y_0 + \eta$ for small perturbations ξ, η , and Taylor expand:

$$\dot{\xi} = f(x_0 + \xi, y_0 + \eta) = \underbrace{f(x_0, y_0)}_{=0} + \xi f_x + \eta f_y + O(\xi^2, \xi\eta, \eta^2),$$

and similarly for $\dot{\eta}$. Dropping the quadratic terms, we obtain the **linearised system**

$$\begin{pmatrix} \dot{\xi} \\ \dot{\eta} \end{pmatrix} = \begin{pmatrix} f_x & f_y \\ g_x & g_y \end{pmatrix} \begin{pmatrix} \xi \\ \eta \end{pmatrix},$$

where the matrix of partial derivatives (the *Jacobian*) is evaluated at the equilibrium. This is a linear system of exactly the type we have just classified, so near each equilibrium the phase portrait looks (in the non-degenerate cases) like a saddle, node or spiral, determined by the Jacobian's eigenvalues. The global phase portrait is then assembled by patching together these local pictures.

Example 2.11.5 (A Predator–Prey System)

Suppose $x(t)$ counts prey and $y(t)$ predators. A reasonable model:

$$\dot{x} = \underbrace{\alpha x}_{\text{births}} - \underbrace{\beta x^2}_{\text{competition}} - \underbrace{\gamma xy}_{\text{predation}}, \quad \dot{y} = \underbrace{\varepsilon xy}_{\text{food supply}} - \underbrace{\delta y}_{\text{deaths}}.$$

Take, concretely,

$$\dot{x} = 8x - 2x^2 - 2xy, \quad \dot{y} = xy - y.$$

Equilibria. We need $x(8 - 2x - 2y) = 0$ and $y(x - 1) = 0$. The first gives $x = 0$ or $y = 4 - x$; the second gives $y = 0$ or $x = 1$. Combining, the equilibria are

$$(0, 0), \quad (4, 0), \quad (1, 3).$$

Near (0, 0). The linearisation is

$$\begin{pmatrix} \dot{\xi} \\ \dot{\eta} \end{pmatrix} = \begin{pmatrix} 8 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} \xi \\ \eta \end{pmatrix},$$

with eigenvalues $8, -1$ along the coordinate axes: a *saddle*, unstable along the prey axis (a few prey with no predators multiply) and stable along the predator axis (predators with no prey starve).

Near (4, 0). Set $x = 4 + \xi$, $y = \eta$. Rather than computing the Jacobian abstractly, we can substitute directly and discard quadratic terms:

$$\begin{aligned} \dot{\xi} &= (4 + \xi)(8 - 8 - 2\xi - 2\eta) = -8\xi - 8\eta + O(2), \\ \dot{\eta} &= \eta(4 + \xi - 1) = 3\eta + O(2). \end{aligned}$$

The matrix $\begin{pmatrix} -8 & -8 \\ 0 & 3 \end{pmatrix}$ has eigenvalues -8 and 3 (it is triangular), with eigenvectors $(1, 0)$ and $(8, -11)$: another *saddle*. A prey-only population at carrying capacity is unstable to the introduction of predators.

Near (1, 3). Set $x = 1 + \xi$, $y = 3 + \eta$:

$$\begin{aligned} \dot{\xi} &= (1 + \xi)(8 - 2 - 2\xi - 6 - 2\eta) \approx -2\xi - 2\eta, \\ \dot{\eta} &= (3 + \eta)\xi \approx 3\xi. \end{aligned}$$

The matrix $\begin{pmatrix} -2 & -2 \\ 3 & 0 \end{pmatrix}$ has characteristic equation $\lambda^2 + 2\lambda + 6 = 0$, giving

$$\lambda = -1 \pm i\sqrt{5}.$$

Complex with negative real part: a *stable spiral*. To find the sense of rotation, perturb to the right, $(\xi, \eta) = (\xi, 0)$ with $\xi > 0$: then $(\dot{\xi}, \dot{\eta}) = (-2\xi, 3\xi)$, pointing up and to the left, so the spiral is anticlockwise.

The global picture. Patching the three local portraits together: trajectories leave the two saddles along their unstable directions and are drawn into the spiral. Almost every solution with $x, y > 0$ spirals in towards the coexistence state $(1, 3)$ – predators and prey settle down, through decaying oscillations, to stable coexistence.

§2.12 Partial Differential Equations

We end the course with a first look at *partial* differential equations – equations involving partial derivatives of a function of several variables. The subject is vast (much of IB and beyond is devoted to it), but even with the tools we already have, we can solve some of the most important examples: the wave equation and the diffusion equation.

§2.12.1 The First-Order Wave Equation

Consider, for a function $y(x, t)$ and a constant c , the equation

$$\frac{\partial y}{\partial t} = c \frac{\partial y}{\partial x},$$

known as the **first-order wave equation**. The key idea for solving it – the **method of characteristics** – is to stop thinking of y as a function on the whole (x, t) plane, and instead watch how y varies along well-chosen *paths* $x = x(t)$.

Along a path $x(t)$, the multivariate chain rule gives

$$\frac{d}{dt}y(x(t), t) = \frac{\partial y}{\partial t} + \frac{dx}{dt} \frac{\partial y}{\partial x} = \left(c + \frac{dx}{dt}\right) \frac{\partial y}{\partial x},$$

where we used the PDE in the last step. Now *choose* the paths to kill the right-hand side: along paths with

$$\frac{dx}{dt} = -c \quad \text{we have} \quad \frac{dy}{dt} = 0.$$

We have traded one PDE for a pair of ODEs. The chosen paths, called the **characteristics** of the equation, are the straight lines $x = x_0 - ct$, one for each constant $x_0 = x + ct$; and along each characteristic, y is constant. So the value of y at (x, t) depends only on which characteristic the point lies on – that is, only on $x + ct$:

$$y = f(x + ct)$$

for an arbitrary function f (one can check directly that any such y solves the equation). This is a *wave*: the profile f translates rigidly to the left with speed c , unchanged in shape. Note that in place of the arbitrary *constants* in the general solutions of ODEs, the general solution of a PDE contains an arbitrary *function*.

It is helpful to picture the characteristics in the (x, t) plane: a family of parallel lines of slope $-1/c$, each carrying a single constant value of y , transported up from its intersection with the x -axis.

The arbitrary function is pinned down by initial data. Given $y(x, 0)$, we have $f(x) = y(x, 0)$ and hence the full solution: to find y at (x, t) , follow the characteristic through that point back down to the x -axis and read off the initial value there.

Example 2.12.1

Solve $y_t = cy_x$ with $y(x, 0) = x^2 - 3$. Since $y = f(x + ct)$ with $f(x) = x^2 - 3$,

$$y = (x + ct)^2 - 3,$$

the initial parabola sliding left at speed c .

Forced versions succumb to the same method – along the characteristics, y is no longer constant, but satisfies an ODE we can solve.

Example 2.12.2

Solve

$$\frac{\partial y}{\partial t} + 5 \frac{\partial y}{\partial x} = e^{-t}, \quad y(x, 0) = e^{-x^2}.$$

The characteristics are now $\frac{dx}{dt} = 5$, i.e. the lines $x_0 = x - 5t$, and along them

$$\frac{dy}{dt} = e^{-t} \implies y = F(x_0) - e^{-t},$$

with a ‘constant of integration’ $F(x_0)$ that may differ from characteristic to characteristic. At $t = 0$ we have $x = x_0$ and $y = F(x_0) - 1 = e^{-x_0^2}$, so $F(x_0) = 1 + e^{-x_0^2}$, and

$$y = 1 + e^{-(x-5t)^2} - e^{-t}.$$

A rightward-travelling Gaussian pulse, riding on a background that relaxes from 0 up to 1.

§2.12.2 The Second-Order Wave Equation

The equation usually called *the* wave equation is second order:

$$\frac{\partial^2 y}{\partial t^2} = c^2 \frac{\partial^2 y}{\partial x^2}.$$

This models, for instance, small transverse vibrations of a taut string, with $y(x, t)$ the displacement at position x and time t : the acceleration of each element of string is proportional to the local *curvature* y_{xx} , since a straight (even sloped) string feels no net sideways force, while a curved one does.

To solve it, factorise the differential operator:

$$\frac{\partial^2}{\partial t^2} - c^2 \frac{\partial^2}{\partial x^2} = \left(\frac{\partial}{\partial t} - c \frac{\partial}{\partial x} \right) \left(\frac{\partial}{\partial t} + c \frac{\partial}{\partial x} \right),$$

where the two first-order factors commute. Anything annihilated by either factor is annihilated by the product, and each factor is a first-order wave equation, solved above. So $y = f(x + ct)$ and $y = g(x - ct)$ are both solutions, and by linearity so is their sum. In fact this is everything:

Proposition 2.12.3 (d’Alembert’s Solution)

The general solution of $y_{tt} = c^2 y_{xx}$ is

$$y = f(x + ct) + g(x - ct)$$

for arbitrary (twice-differentiable) functions f and g : a superposition of a leftward- and a rightward-travelling wave, each moving at speed c with fixed profile.

Proof. That these are solutions is a direct check. For the converse, change variables to $\xi = x + ct$ and $\eta = x - ct$; the chain rule turns the equation into

$$y_{tt} - c^2 y_{xx} = -4c^2 \frac{\partial^2 y}{\partial \xi \partial \eta} = 0,$$

and integrating once in each variable gives $y = f(\xi) + g(\eta)$. $\square$

Since the equation is second order in t (and in x), we expect to need two initial conditions and two boundary conditions to pin down a unique solution – one pair for each of the two arbitrary functions.

Example 2.12.4

Solve $y_{tt} = c^2 y_{xx}$ subject to

$$y(x, 0) = \frac{1}{1 + x^2}, \quad y_t(x, 0) = 0, \quad y \rightarrow 0 \text{ as } x \rightarrow \pm\infty.$$

Write $y = f(x + ct) + g(x - ct)$. The initial conditions give

$$f(x) + g(x) = \frac{1}{1 + x^2}, \quad cf'(x) - cg'(x) = 0.$$

The second says $f' = g'$, so $f = g + A$ for a constant A ; since only $f + g$ enters the solution, we may absorb the constant and take $f = g$, whence

$$f(x) = g(x) = \frac{1}{2(1 + x^2)},$$

and

$$y = \frac{1}{2} \left[\frac{1}{1 + (x + ct)^2} + \frac{1}{1 + (x - ct)^2} \right].$$

The initial hump splits into two half-height copies, travelling apart at speeds $\pm c$.

§2.12.3 The Diffusion Equation

Our final equation models heat conduction in one dimension. If $T(x, t)$ is the temperature in a solid bar, then

$$\frac{\partial T}{\partial t} = \kappa \frac{\partial^2 T}{\partial x^2},$$

where the constant $\kappa > 0$ is the **diffusivity**. This is the **diffusion equation** (or heat equation). Structurally it looks like the wave equation with one time derivative removed, and this changes the character of solutions completely: for the wave equation, curvature drives *acceleration* and disturbances propagate forever; here, curvature drives *velocity*, so bumps in the temperature profile simply flatten themselves out. Diffusion is dissipative, not oscillatory.

Remark (Nomenclature). Second-order linear PDEs are traditionally classified by loose analogy with conic sections: the wave equation $y_{tt} - c^2 y_{xx} = 0$ is called *hyperbolic* (compare $t^2 - c^2 x^2 = \text{const}$), the diffusion equation is *parabolic* ($t = x^2$ -like, one time derivative against two space derivatives), and Laplace's equation $y_{xx} + y_{yy} = 0$, which the reader will meet in Vector Calculus, is *elliptic*. The analogy is purely formal, but the classification is genuinely meaningful: hyperbolic equations propagate signals along characteristics, parabolic ones smooth and dissipate, and elliptic ones describe equilibrium states.

We will solve one classic problem, which also introduces the useful idea of a *similarity solution*.

Example 2.12.5 (Heating a Semi-Infinite Bar)

Consider an infinitely long bar occupying $x \geq 0$, initially cold, whose end $x = 0$ is abruptly heated to unit temperature at $t = 0$ and held there:

$$T(x, 0) = 0, \quad T(0, t) = H(t), \quad T(x, t) \rightarrow 0 \text{ as } x \rightarrow \infty,$$

where H is the Heaviside function.

The key observation is dimensional. The only parameter in the problem is κ , with dimensions $(\text{length})^2/(\text{time})$, and neither the initial nor boundary data introduces any length scale. So the only dimensionless combination of x and t available is

$$\eta = \frac{x}{2\sqrt{\kappa t}}$$

(the factor 2 is for later convenience), and it is natural to seek a **similarity solution** depending on x and t only through η :

$$T(x, t) = \theta(\eta).$$

The temperature profiles at different times should all be the same shape, stretched horizontally by $\sqrt{\kappa t}$. Let's compute the derivatives by the chain rule:

$$\begin{aligned} \frac{\partial T}{\partial x} &= \theta'(\eta) \frac{\partial \eta}{\partial x} = \frac{1}{2\sqrt{\kappa t}} \theta'(\eta), & \frac{\partial^2 T}{\partial x^2} &= \frac{1}{4\kappa t} \theta''(\eta), \\ \frac{\partial T}{\partial t} &= \theta'(\eta) \frac{\partial \eta}{\partial t} = -\frac{1}{2} \cdot \frac{x}{2\sqrt{\kappa} t^{3/2}} \theta'(\eta) = -\frac{\eta}{2t} \theta'(\eta). \end{aligned}$$

Substituting into the PDE:

$$-\frac{\eta}{2t}\theta' = \frac{1}{4t}\theta'' \implies \theta'' + 2\eta\theta' = 0.$$

All the x 's and t 's have vanished, leaving an ODE for $\theta(\eta)$ – the sign that our similarity guess was consistent. Moreover it is an ODE we can solve: it is first order in θ' , with integrating factor $\mu = \exp(\int 2\eta d\eta) = e^{\eta^2}$, so

$$(e^{\eta^2}\theta')' = 0 \implies \theta' = Ae^{-\eta^2} \implies \theta = A \int_0^\eta e^{-u^2} du + B.$$

This integral has a standard name: the *error function* $\text{erf}(\eta) = \frac{2}{\sqrt{\pi}} \int_0^\eta e^{-u^2} du$, normalised so that $\text{erf}(\eta) \rightarrow 1$ as $\eta \rightarrow \infty$. So $\theta = \alpha \text{erf}(\eta) + B$.

Now the boundary conditions, translated into η : the heated end $x = 0$ (with $t > 0$) corresponds to $\eta = 0$, so $\theta(0) = 1$, giving $B = 1$. The far field $x \rightarrow \infty$ (or the initial instant $t \rightarrow 0^+$) corresponds to $\eta \rightarrow \infty$, so $\theta(\infty) = 0$, giving $\alpha = -1$. Hence $\theta = 1 - \text{erf}(\eta)$, and

$$T(x, t) = \text{erfc}\left(\frac{x}{2\sqrt{\kappa t}}\right),$$

where $\text{erfc} = 1 - \text{erf}$ is the complementary error function. The temperature profiles at successive times are stretched copies of one another:

The physical picture: at each time t , the temperature falls smoothly from 1 at the hot end towards 0, over a penetration depth of order $\sqrt{\kappa t}$. Heat creeps into the bar with the characteristic square-root-of-time spreading of diffusion – to heat twice as deep takes four times as long. (This also tells us when a *finite* bar of length L can be treated as infinite: precisely when $\sqrt{\kappa t} \ll L$, i.e. $t \ll L^2/\kappa$.)

And that is where we stop. We have seen equations solved exactly, approximated, discretised, linearised and sketched; the recurring themes – eigenfunctions, linearity, superposition, equilibria, stability – will reappear throughout the rest of the Tripos, in Methods and Analysis and far beyond. Differential equations are never really finished; one simply stops.

3 Dynamics and Relativity

Dynamics and relativity sets the scene for studying the problems of Newtonian dynamics and, towards the end, Einstein's theory of special relativity.

The first part of this course develops *Newtonian mechanics* – a mathematical framework built around the notion of a force, which turns out to be capable of describing an astonishing range of physical phenomena: projectiles, oscillations, planetary orbits, spinning tops and much more. Along the way we will meet the great conserved quantities of physics (energy, momentum and angular momentum), and we will see how symmetry principles constrain what a physical law is allowed to look like. The second part of the course takes one such symmetry principle seriously enough to break Newtonian mechanics entirely: insisting that the speed of light is the same for all observers leads to *special relativity*, where space and time mix together, moving clocks run slow, and mass is just another form of energy.

This article constitutes my notes for the 'Dynamics and Relativity' course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§3.1 Newton's Laws and Forces

In Newtonian mechanics, we use the idea of a force to build up a mathematical framework in which we can describe the motion of objects, typically particles.

§3.1.1 Particles & Inertial Frames

Newtonian mechanics is at its cleanest when describing the motion of *particles*.

Definition 3.1.1 (Particle)

A **particle** is an idealised object of negligible size and no internal structure, to which we can assign physical properties such as mass $m > 0$ and electric charge q .

Real objects are, of course, not points. This idealisation is still tremendously useful for two reasons. First, an extended body can be treated as a particle whenever its size is irrelevant to the problem at hand – the Earth, viewed on the scale of the solar system, is quite point-like. Secondly, as we will see in Section 3.5, an extended body can be modelled as a large collection of particles, and its overall motion is then governed by the very same laws.

To describe the positions of particles over time, we use a *reference frame*, which consists of a choice of origin and some coordinate system which can be used to consistently describe position.

For a particle with position vector $\mathbf{x}(t)$, a displacement vector from the origin of our reference frame, we then define the following quantities.

- *Velocity.* The velocity $\mathbf{v}$ of the particle is $\mathbf{v} = \dot{\mathbf{x}} = d\mathbf{x}(t)/dt$. This vector is always tangent to the particle's trajectory. The speed is then $v = |\mathbf{v}|$.
- *Acceleration.* The acceleration $\mathbf{a}$ of a particle is $\mathbf{a} = \ddot{\mathbf{x}} = d^2\mathbf{x}(t)/dt^2$.
- *Momentum.* The momentum $\mathbf{p}$ is then $\mathbf{p} = m\mathbf{v} = m\dot{\mathbf{x}}$.

Throughout these notes, an overdot will always denote a derivative with respect to time.

§3.1.2 Newton's Laws

The whole of Newtonian mechanics rests on three laws, which we will treat as axioms of our theory.

- Law 3.1.2 (Newton's Laws of Motion)**
1. *Galileo's Law of Inertia.* There exist **inertial frames**, reference frames in which particles travel at constant velocity when the force acting on them vanishes.
 2. *Newton's Second Law.* If a force $\mathbf{F}$ acts on a particle with momentum $\mathbf{p}$, then $d\mathbf{p}/dt = \mathbf{F}$.
 3. *Newton's Third Law.* Every action has an equal and opposite reaction: if a particle A exerts a force $\mathbf{F}$ on a particle B , then B exerts a force $-\mathbf{F}$ on A .

All of these are tied together with the *principle of Galilean relativity*, which is that the laws of physics are the same in every inertial reference frame.

A few comments are in order. The first law looks at a glance like it is just a special case of the second (if $\mathbf{F} = \mathbf{0}$ then $\mathbf{p}$ is constant) – its actual content is the *existence* of inertial frames, which is what makes the second law meaningful at all. A frame fixed to a spinning roundabout is not inertial: a particle with no force on it will appear to accelerate. Throughout the Newtonian part of this course we will work in inertial frames unless stated otherwise (and we will study what happens in rotating, non-inertial frames in Section 3.4).

For a particle whose mass is constant, the second law reads

$$m\ddot{\mathbf{x}} = \mathbf{F}(\mathbf{x}, \dot{\mathbf{x}}, t),$$

which is a second order ordinary differential equation for the trajectory $\mathbf{x}(t)$. Assuming the force is well behaved, such an equation has a unique solution once we specify the initial position $\mathbf{x}(t_0)$ and initial velocity $\dot{\mathbf{x}}(t_0)$. This is worth dwelling on – it means Newtonian mechanics is *deterministic*: the position and velocity of a particle right now determine its entire future (and past) motion. Solving dynamics problems is therefore really the art of solving differential equations.

§3.1.3 Galilean Transformations

A natural question is how one can transform between different inertial frames. That is, under what transformations do the laws of physics remain unchanged. It is straightforward to see that if we have some $(\mathbf{x}, t)$ in an inertial frame $\mathcal{F}$, then we can construct another inertial frame $\mathcal{F}'$ by combining:

- *Translations.* $\mathbf{x}' = \mathbf{x} + \mathbf{a}$ for a constant vector $\mathbf{a}$, and $t' = t + t_0$ for a constant t_0 .

- *Rotations and Reflections.* $\mathbf{x}' = R\mathbf{x}$, where R is some orthogonal matrix.
- *Boosts.* $\mathbf{x}' = \mathbf{x} + \mathbf{v}t$, for a constant velocity vector $\mathbf{v}$.

This set of transformations forms the *Galilean group*, the group of symmetries of Newton's laws. Indeed, each of these transformations maps straight-line motion to straight-line motion, so each maps inertial frames to inertial frames, and the general element of the group is a composition of the above types.

The principle of Galilean relativity can then be restated as: *the laws of physics are invariant under Galilean transformations*. Note that any Galilean transformation has $\ddot{\mathbf{x}}' = R\ddot{\mathbf{x}}$, so a particle's acceleration is the same in all inertial frames (up to the fixed rotation of the axes). Since Newton's second law involves only acceleration, and not absolute position or absolute velocity, it is compatible with this principle – there is no mechanical experiment that can detect a state of 'absolute rest'. A passenger in a smoothly moving train can pour their tea exactly as if they were at rest.

When working with Newton's laws, we assume that there is some 'absolute time', with the times t, t' in two inertial frames differing by at most a constant¹. All inertial observers therefore agree on the time interval between two events. This seems so obvious as to not be worth stating, but it is really a physical assumption – and we will see in Section 3.7 that it is *false* when speeds involved approach the speed of light.

Example 3.1.3 (Projectiles on a Train)

Let's check covariance concretely. In the frame $\mathcal{F}$ of the ground, a projectile obeys $m\ddot{\mathbf{x}} = m\mathbf{g}$, giving parabolic trajectories. Now watch from the frame $\mathcal{F}'$ of a train moving at constant velocity $\mathbf{v}$, so $\mathbf{x}' = \mathbf{x} - \mathbf{v}t$. Then

$$\ddot{\mathbf{x}}' = \ddot{\mathbf{x}} = \mathbf{g},$$

so the equation of motion takes *exactly the same form* in the train frame, and the trajectory is again a parabola – just one with different initial conditions (the initial velocity is shifted by $-\mathbf{v}$). A ball tossed straight up on a smoothly moving train lands back in your hand, not behind you; no experiment with projectiles can reveal the train's motion. Contrast an *accelerating* train: then $\ddot{\mathbf{x}}' = \mathbf{g} - \mathbf{a}$, the form of the law changes, and the tossed ball drifts backwards – accelerated frames are detectably not inertial.

§3.1.4 Examples of Forces

Newton's laws tell us how a particle responds to a force, but they are silent on what forces actually arise in nature – that information must be supplied separately, by *force laws*. At the fundamental level, remarkably few are needed: gravity and electromagnetism account for essentially everything we will meet in this course (the strong and weak nuclear forces operate only at subatomic ranges). The everyday 'contact' forces – tension in strings, normal reactions from surfaces, friction – are all electromagnetic in origin, arising from the interactions of vast numbers of atoms, and we model them phenomenologically rather than from first principles.

The *Lorentz force* describes the force on a particle moving in an electromagnetic field. If a particle has position $\mathbf{x}$ and charge q , and it moves in an electric field $\mathbf{E}$ and magnetic

¹Once we fix the units, of course.

field $\mathbf{B}$, then the force on the particle is given by

$$\mathbf{F} = q(\mathbf{E} + \dot{\mathbf{x}} \times \mathbf{B}).$$

The *gravitational force* describes the force due to gravity on a particle. If two particles have masses m_1 and m_2 and positions $\mathbf{x}_1$ and $\mathbf{x}_2$, then the force of gravity between them is given by

$$\mathbf{F}_1 = -\frac{Gm_1m_2}{|\mathbf{x}_1 - \mathbf{x}_2|^3}(\mathbf{x}_1 - \mathbf{x}_2) = -\mathbf{F}_2,$$

where G is the **gravitational constant**.

§3.1.5 Potentials in One Dimension

Roughly, the framework of Newtonian mechanics takes in particles and forces, and from that we get the dynamics at play. However, in many cases we think of forces as coming from a more primitive idea, one of *potentials*. We will work in one dimension for the time being.

Definition 3.1.4 (Potential Energy)

For a force field $F(x)$, depending only on position, we define the **potential energy** to be a function $V(x)$ such that

$$F = -\frac{dV}{dx},$$

so $V = -\int F dx$, defined up to a constant.

With this, Newton's second law becomes $\dot{p} = -dV/dx$. The arbitrary constant is harmless: only differences in potential energy will ever matter physically, so we may fix the constant however is convenient.

With forces in one dimension depending on position only, we have a naturally conserved quantity. We define the *kinetic energy* of a particle to be $T = \frac{1}{2}m\dot{x}^2$.

Proposition 3.1.5 (Conservation of Energy)

Consider a particle of mass m moving under a force $F(x) = -dV/dx$. Then the **total energy**

$$E = T + V = \frac{1}{2}m\dot{x}^2 + V(x)$$

is conserved, that is, $\dot{E} = 0$.

Proof. Differentiating with respect to time, using the chain rule and then Newton's second law,

$$\frac{dE}{dt} = m\dot{x}\ddot{x} + \frac{dV}{dx}\dot{x} = \dot{x}(m\ddot{x} - F(x)) = 0,$$

as required. □

It is important in this proposition that F depends only on position – if F depends on, say, velocity (as friction does), the argument breaks down and energy is typically not conserved.

Remark. A theme worth watching throughout this course: conserved quantities are systematically tied to *symmetries*. Energy conservation will hold when the physics is unchanged by translation in time; momentum conservation when it is unchanged by translation in space; angular momentum conservation when it is unchanged by rotation. This correspondence is made precise by *Noether's theorem*, which appears properly in next year's 'Variational Principles' course – but you can already spot the pattern in every conservation law we derive.

One nice thing about having such a conserved quantity is that

$$E = \frac{1}{2}m\dot{x}^2 + V(x) \implies \dot{x} = \pm\sqrt{\frac{2}{m}(E - V(x))},$$

which gives us a *first order* differential equation for position, which we can (at least in principle) solve by separating variables. The conservation of energy has done one integration of Newton's second law for us. Let's see this in action.

Example 3.1.6 (The Harmonic Oscillator)

The **harmonic oscillator** is the system with quadratic potential

$$V(x) = \frac{1}{2}kx^2,$$

which describes, for example, a particle attached to a spring of stiffness k : the force $F = -dV/dx = -kx$ is a restoring force proportional to the displacement (this is 'Hooke's law'). The equation of motion

$$m\ddot{x} = -kx$$

is linear, and has general solution

$$x(t) = A \cos \omega t + B \sin \omega t, \quad \text{where } \omega = \sqrt{k/m}.$$

The motion is periodic with *angular frequency* ω , that is, with period $\tau = 2\pi/\omega$. Note that the period is independent of the amplitude of the oscillation. Substituting the solution back in, the energy is

$$E = \frac{1}{2}m\dot{x}^2 + \frac{1}{2}kx^2 = \frac{1}{2}k(A^2 + B^2),$$

which is indeed constant. Energy sloshes back and forth between kinetic and potential, twice per period.

The reason the harmonic oscillator is *the* single most important system in physics is that it approximates almost everything, as we are about to see.

We can also get a lot of qualitative information about the motion of a particle by sketching the graph of the potential V against position. Since $T = E - V(x) \geq 0$, the particle can only ever be found in regions where $V(x) \leq E$, and it is instantaneously at rest where $V(x) = E$. Thinking of the graph of V as a landscape in which a ball rolls with total energy E gives entirely correct intuition: a particle with energy E trapped between two points where $V = E$ oscillates back and forth between them, while a particle that never meets a point with $V = E$ runs away to infinity.

Points where the force vanishes are of particular interest.

Definition 3.1.7 (Equilibrium Point)

A point x_0 is an **equilibrium point** if $V'(x_0) = 0$, so that a particle placed at rest at x_0 remains there for all time.

To understand the behaviour *near* an equilibrium point, we Taylor expand the potential about x_0 . Using $V'(x_0) = 0$,

$$V(x) \approx V(x_0) + \frac{1}{2}V''(x_0)(x - x_0)^2 + \cdots,$$

and so the equation of motion is approximately

$$m\ddot{x} \approx -V''(x_0)(x - x_0).$$

There are two cases worth distinguishing.

- (i) If $V''(x_0) > 0$, so x_0 is a local minimum of the potential, then this is exactly the harmonic oscillator equation: the particle oscillates about x_0 with angular frequency

$$\omega = \sqrt{\frac{V''(x_0)}{m}}.$$

We call such an equilibrium point *stable*, and these oscillations *small oscillations* about equilibrium.

- (ii) If $V''(x_0) < 0$, so x_0 is a local maximum, then the solutions are $e^{\pm\gamma t}$ with $\gamma = \sqrt{-V''(x_0)/m}$, and a generic small displacement grows exponentially. The equilibrium is *unstable* – think of a ball balanced on the top of a hill.

Example 3.1.8 (Motion in a Cubic Potential)

Let's carry out this programme for a particle of mass m in the potential

$$V(x) = m(x^3 - 3x),$$

sketching-first. We have $V'(x) = 3m(x^2 - 1)$, so the equilibria are at $x = \pm 1$, and $V''(x) = 6mx$ tells us that $x = 1$ (where $V = -2m$) is a stable local minimum while $x = -1$ (where $V = 2m$) is an unstable local maximum. The graph falls away to $-\infty$ on the far left.

Now release the particle from rest at various starting points and read off the motion from the graph:

- (i) Released near $x = 1$, the particle oscillates in the potential well about the stable equilibrium; for small displacements the angular frequency is $\omega = \sqrt{V''(1)/m} = \sqrt{6}$.
- (ii) Released anywhere with total energy $E < 2m$ and to the right of the potential hill, the particle remains trapped in the well, oscillating between the two solutions of $V(x) = E$ flanking $x = 1$.
- (iii) Released with $E > 2m$, the particle clears the hill at $x = -1$ and escapes to $x \rightarrow -\infty$, never to return.
- (iv) The critical case $E = 2m$ is the interesting one: a particle heading leftward towards the hilltop slows down more and more, *approaching* the unstable equilibrium $x = -1$ but never reaching it in finite time (near the top, $\dot{x} \propto (x+1)$, giving exponential approach). The hilltop is reached only ‘after infinite time’.

All of this qualitative information came from a sketch and no integration whatsoever.

Example 3.1.9 (The Pendulum)

A pendulum consists of a mass m attached to a light rod of length ℓ , swinging from a fixed pivot.

If θ is the angle from the downward vertical, the equation of motion is (as can be derived by resolving forces, or by using the energy below)

$$m\ell\ddot{\theta} = -mg \sin \theta.$$

This is of our potential form with generalised coordinate $x = \ell\theta$, with energy

$$E = \frac{1}{2}m\ell^2\dot{\theta}^2 - mg\ell \cos \theta.$$

The equilibria are $\theta = 0$ (stable) and $\theta = \pi$ (unstable, the pendulum balanced upside-down). Near $\theta = 0$ we have $\sin \theta \approx \theta$, and we recover a harmonic oscillator with angular frequency $\omega = \sqrt{g/\ell}$, so the period of small oscillations is

$$\tau = 2\pi\sqrt{\frac{\ell}{g}},$$

independent of the amplitude and of the mass. For larger swings the period does depend on the amplitude: using conservation of energy, a pendulum released from rest at angle θ_0 has

$$\dot{\theta} = \pm \sqrt{\frac{2g}{\ell}(\cos \theta - \cos \theta_0)},$$

and separating variables gives the period as an integral,

$$\tau = 4\sqrt{\frac{\ell}{2g}} \int_0^{\theta_0} \frac{d\theta}{\sqrt{\cos \theta - \cos \theta_0}},$$

which cannot be evaluated in elementary terms (it is an *elliptic integral*), but which can happily be studied asymptotically or numerically.

§3.1.6 Potentials in Three Dimensions

The concept of potentials generalises into three dimensions, but there is some groundwork needed to be done first. We first will need to redefine kinetic energy to make sense in multiple dimensions. This is done naturally with

$$T = \frac{1}{2}m\dot{\mathbf{x}} \cdot \dot{\mathbf{x}}.$$

Differentiating and using Newton's second law, we get $\dot{T} = m\ddot{\mathbf{x}} \cdot \dot{\mathbf{x}} = \mathbf{F} \cdot \dot{\mathbf{x}}$, so the kinetic energy changes at a rate given by the component of force along the direction of motion. In particular, a force which is always perpendicular to the velocity does not change the particle's speed.

Now consider a force field $\mathbf{F}(\mathbf{x})$, depending only on position. If the force $\mathbf{F}$ acts on a particle, moving it from $\mathbf{x}(t_1)$ to $\mathbf{x}(t_2)$ along a trajectory $\mathcal{C}$, we define the *work done* W to be

$$W = \int_{\mathcal{C}} \mathbf{F} \cdot d\mathbf{x} = \int_{t_1}^{t_2} \mathbf{F} \cdot \frac{d\mathbf{x}}{dt} dt.$$

Note that if $\mathbf{F} = m\ddot{\mathbf{x}}$ (as in there is no change in mass), then integrating the expression for $\dot{T}$ above shows that the work done is

$$W = m \int_{t_1}^{t_2} \ddot{\mathbf{x}} \cdot \dot{\mathbf{x}} dt = T(t_2) - T(t_1),$$

so the work done by the force is the change in kinetic energy of the particle.

In one dimension, every force $F(x)$ had a potential – we just integrated. In three dimensions this is no longer true: the work done by a general force field can depend on the *path* taken between the endpoints, in which case there is no way to consistently assign a potential energy to positions. The forces for which this does work get a special name.

Definition 3.1.10 (Conservative Force)

A force field $\mathbf{F}(\mathbf{x})$ is **conservative** if it can be written as

$$\mathbf{F} = -\nabla V$$

for some scalar potential $V(\mathbf{x})$, or equivalently^a if the work done by $\mathbf{F}$ along a trajectory depends only on the endpoints of the trajectory.

^aThe equivalence of these conditions (on suitable domains), along with the equivalent statement $\nabla \times \mathbf{F} = \mathbf{0}$, is established properly in the ‘Vector Calculus’ course.

Proposition 3.1.11

If $\mathbf{F} = -\nabla V$, then the total energy

$$E = T + V(\mathbf{x}) = \frac{1}{2}m\dot{\mathbf{x}} \cdot \dot{\mathbf{x}} + V(\mathbf{x})$$

is conserved.

Proof. We differentiate, using the chain rule $\frac{d}{dt}V(\mathbf{x}(t)) = \nabla V \cdot \dot{\mathbf{x}}$:

$$\frac{dE}{dt} = m\ddot{\mathbf{x}} \cdot \dot{\mathbf{x}} + \nabla V \cdot \dot{\mathbf{x}} = (m\ddot{\mathbf{x}} - \mathbf{F}) \cdot \dot{\mathbf{x}} = 0. \quad \square$$

Conversely, if a force depending only on position conserves energy for every trajectory, it must be conservative in the above sense. Happily, the fundamental forces of nature that we will meet – gravity and (static) electromagnetism – are conservative.

§3.1.7 Gravity

Gravity is an example of a conserved force. For a particle of mass m , under the influence of gravity from a particle of mass M at the origin, we have the potential energy

$$V(r) = -\frac{GMm}{r}.$$

The force of gravity is then given by

$$\mathbf{F} = -\nabla V = -\frac{GMm}{r^2}\hat{\mathbf{r}},$$

with $\hat{\mathbf{r}}$ in the direction of the particle. Note that this force points towards the origin. It is sometimes convenient to remove the dependence on the mass of the particle m , which we do by defining the *gravitational potential* $\phi(r) = -GM/r$, with $V = \phi m$.

If there are many particles say of masses M_i and positions $\mathbf{r}_i$, the gravitational potential just adds, with

$$\begin{aligned} \phi(\mathbf{r}) &= -G \sum_i \frac{M_i}{|\mathbf{r} - \mathbf{r}_i|} \\ \Rightarrow \mathbf{F} &= -Gm \sum_i \frac{M_i}{|\mathbf{r} - \mathbf{r}_i|^3} (\mathbf{r} - \mathbf{r}_i). \end{aligned}$$

A remarkable fact (which we will take on trust – it is a pleasant exercise in vector calculus) is that the external gravitational potential of a spherically symmetric body of total mass M is exactly that of a point mass M at its centre. This is what lets us treat planets and stars as particles when studying orbits.

Example 3.1.12 (Gravity Near the Earth's Surface)

Consider a particle of mass m at height $z \ll R$ above the surface of the Earth, which has mass M and radius R . The potential energy is

$$V = -\frac{GMm}{R+z} = -\frac{GMm}{R} \left(1 - \frac{z}{R} + \dots\right) \approx \text{const} + mgz,$$

where we define

$$g = \frac{GM}{R^2} \approx 9.8 \text{ m s}^{-2}.$$

So near the surface of the Earth we may use the familiar uniform-gravity potential $V = mgz$, and every particle falls with the same acceleration g .

There is a genuinely deep assumption hiding in all of this. The mass appearing in Newton's second law (the *inertial mass*, measuring reluctance to accelerate) and the mass appearing in the law of gravitation (the *gravitational mass*, playing the role of a 'gravitational charge') have no a priori reason to be equal – yet experimentally they agree to extraordinary precision, which is why all bodies fall at the same rate. This equality, the *equivalence principle*, later became the starting point for Einstein's theory of general relativity.

§3.1.8 Electromagnetism

If we have time-independent electric and magnetic fields $\mathbf{E}$ and $\mathbf{B}$, then $\mathbf{E} = -\nabla\phi$ for some $\phi(\mathbf{x})$, the *electric potential*. We have conservation of energy for time-independent fields, with the total energy²

$$E = \frac{1}{2}m\dot{\mathbf{x}} \cdot \dot{\mathbf{x}} + q\phi(\mathbf{x}).$$

Just as objects with mass both feel the effect of and produce gravitational force, the same is true of objects with charge. At the origin, a particle of charge Q creates an electric field as

$$\mathbf{E} = -\nabla \left(\frac{Q}{4\pi\epsilon_0 r} \right) = \frac{Q}{4\pi\epsilon_0} \frac{\hat{\mathbf{r}}}{r^2},$$

where $r^2 = \mathbf{x} \cdot \mathbf{x}$. The force between objects of charge Q and q is $\mathbf{F} = q\mathbf{E}$, or

$$\mathbf{F} = \frac{Qq}{4\pi\epsilon_0} \frac{\hat{\mathbf{r}}}{r^2}.$$

This is the *Coulomb force*, and has the same form as gravity – an inverse square law – with one important difference: charges come in both signs, so the Coulomb force can be attractive (unlike charges) or repulsive (like charges).

The magnetic part of the Lorentz force is stranger, since it depends on velocity. Note however that the magnetic force $q\dot{\mathbf{x}} \times \mathbf{B}$ is always perpendicular to the velocity, so it does no work – a magnetic field can bend a particle's path, but never change its speed.

²Again, this can be checked by differentiating.

Example 3.1.13 (Motion in a Uniform Magnetic Field)

Consider a particle of charge q and mass m in a uniform magnetic field $\mathbf{B} = B\mathbf{e}_z$, with no electric field. The equation of motion $m\ddot{\mathbf{x}} = q\dot{\mathbf{x}} \times \mathbf{B}$ has components

$$m\ddot{x} = qB\dot{y}, \quad m\ddot{y} = -qB\dot{x}, \quad m\ddot{z} = 0.$$

The z motion is uniform. For the rest, write $\omega = qB/m$ and combine the first two equations using the complex variable $\zeta = x + iy$:

$$\ddot{\zeta} = \ddot{x} + i\ddot{y} = \omega\dot{y} - i\omega\dot{x} = -i\omega\dot{\zeta},$$

so $\dot{\zeta} = \dot{\zeta}_0 e^{-i\omega t}$ and hence $\zeta = \zeta_0 + \frac{i\dot{\zeta}_0}{\omega} e^{-i\omega t}$. In the (x, y) plane the particle therefore moves in a circle, traversed with constant angular speed

$$\omega = \frac{qB}{m},$$

called the **gyrofrequency** (or cyclotron frequency). Combined with the uniform drift in z , the general trajectory is a helix winding around the magnetic field lines. Note that, as promised, the speed of the particle never changes.

§3.1.9 Friction

In many physical scenarios we deal with forces that do not come from potentials. Friction is one such force, and it is a force that is used to approximate the complex relationship between objects in contact.

One common form of friction is *dry friction*, which acts when solid bodies are in contact. If N is the magnitude of the normal reaction force between the surfaces, then the frictional force acts tangentially to the surfaces, opposing relative motion, with magnitude

$$|\mathbf{F}| = \mu N$$

when the surfaces slide over each other, where μ is the *coefficient of friction* (which depends on the materials involved). When the surfaces are not sliding, the friction takes whatever magnitude is required to prevent slipping, up to a maximum of roughly μN . Note that friction opposes relative motion – it never causes it.

Another common type of friction is *fluid drag*, the resistance felt by a body moving through a fluid. Fluid drag is typically modelled as either

- *linear* drag, with $\mathbf{F} = -\gamma\mathbf{v}$, suitable for small, slow-moving objects in viscous fluids (for a sphere of radius R , Stokes' law gives $\gamma = 6\pi\eta R$ where η is the fluid's viscosity); or
- *quadratic* drag, with $\mathbf{F} = -\gamma|\mathbf{v}|\mathbf{v}$, suitable for larger, fast-moving objects in less viscous fluids such as air, where the resistance comes mostly from the momentum transferred to the fluid pushed out of the way.

In either case, the drag force does negative work $\mathbf{F} \cdot \mathbf{v} < 0$, so the particle continually loses energy to the fluid (where it ends up as heat).

Let's now put several of our forces together in a classic worked example – a projectile moving under gravity, experiencing linear drag.

Example 3.1.14 (Projectile with Linear Drag)

A projectile of mass m is launched from the origin with initial velocity $\mathbf{u}$, moving under uniform gravity and linear air resistance. The equation of motion is

$$m \frac{d\mathbf{v}}{dt} = m\mathbf{g} - \gamma\mathbf{v}.$$

This is a linear first order equation for $\mathbf{v}$, which we can solve with an integrating factor $e^{\gamma t/m}$:

$$\frac{d}{dt} (e^{\gamma t/m} \mathbf{v}) = e^{\gamma t/m} \mathbf{g} \implies \mathbf{v}(t) = \frac{m\mathbf{g}}{\gamma} + \left(\mathbf{u} - \frac{m\mathbf{g}}{\gamma} \right) e^{-\gamma t/m}.$$

As $t \rightarrow \infty$, the velocity tends to the **terminal velocity** $\mathbf{v}_\infty = m\mathbf{g}/\gamma$, in which the drag exactly balances gravity – and it does so exponentially quickly, on the timescale m/γ , regardless of the initial conditions.

Integrating once more gives the trajectory:

$$\mathbf{x}(t) = \frac{m\mathbf{g}}{\gamma} t + \frac{m}{\gamma} \left(\mathbf{u} - \frac{m\mathbf{g}}{\gamma} \right) (1 - e^{-\gamma t/m}).$$

Taking $\mathbf{g} = -g\mathbf{e}_z$ and $\mathbf{u} = (u \cos \theta, 0, u \sin \theta)$, the components read

$$x(t) = \frac{mu \cos \theta}{\gamma} (1 - e^{-\gamma t/m}), \quad z(t) = -\frac{mg}{\gamma} t + \frac{m}{\gamma} \left(u \sin \theta + \frac{mg}{\gamma} \right) (1 - e^{-\gamma t/m}).$$

Two sanity checks are worth performing. First, as $\gamma \rightarrow 0$ (expanding the exponentials to second order) we recover the familiar drag-free parabola $x = ut \cos \theta$, $z = ut \sin \theta - \frac{1}{2}gt^2$. Secondly, note that x is bounded: $x < mu \cos \theta/\gamma$ always, so unlike the parabola, the trajectory has a vertical asymptote – the projectile ends up falling essentially straight down at terminal velocity.

Example 3.1.15 (Falling Raindrop with Quadratic Drag)

For a raindrop falling vertically under quadratic drag, taking v to be the downward speed,

$$m \frac{dv}{dt} = mg - \gamma v^2 = \gamma (v_\infty^2 - v^2), \quad \text{where } v_\infty = \sqrt{\frac{mg}{\gamma}}.$$

Separating variables and using partial fractions,

$$\int \frac{dv}{v_\infty^2 - v^2} = \frac{\gamma}{m} t + \text{const} \implies v(t) = v_\infty \tanh \left(\frac{gt}{v_\infty} \right)$$

for a drop released from rest. Again the speed approaches the terminal velocity v_∞ , this time with the characteristic tanh profile.

§3.2 Dimensional Analysis

Before going any further with dynamics proper, we pause for a very useful tool. Physical quantities are not pure numbers – each carries a *dimension*, which is roughly the kind of thing that its units measure. Keeping track of dimensions is a powerful (and almost

free) source of information about physical problems.

§3.2.1 Dimensions of Physical Quantities

For the problems of dynamics, three basic dimensions suffice:

- length, L ;
- mass, M ;
- time, T .

The dimensions of any other physical quantity X in mechanics, written $[X]$, can then be expressed uniquely as a product of powers of L , M and T . For example, working directly from the definitions and from equations we know to be true,

$$\begin{aligned} [\text{area}] &= L^2, & [\text{velocity}] &= LT^{-1}, & [\text{acceleration}] &= LT^{-2}, \\ [\text{force}] &= MLT^{-2}, & [\text{energy}] &= ML^2T^{-2}, & [\text{angular momentum}] &= ML^2T^{-1}, \end{aligned}$$

where, say, the dimensions of force are read off from $F = ma$ and the dimensions of energy from $E = \frac{1}{2}mv^2$. Dimensionful physical constants are treated the same way: from $F = GMm/r^2$ we find $[G] = M^{-1}L^3T^{-2}$.

The key principle is that of *dimensional consistency*: in any meaningful physical equation, both sides must have the same dimensions, and we may only add or subtract terms of equal dimensions. Adding a length to an area is as meaningless as adding a vector to a matrix. Moreover, arguments of functions like $\exp$, $\sin$ or $\log$ must be *dimensionless*: if x had a dimension, the series $e^x = 1 + x + \frac{1}{2}x^2 + \dots$ would be a sum of terms of different dimensions. (It is a good check on our projectile-with-drag example above that $\gamma t/m$ is dimensionless, since $[\gamma] = [F]/[v] = MT^{-1}$.)

Units are conventional reference amounts of dimensional quantities – in the SI system, the metre, kilogram and second for L , M and T respectively. The choice is arbitrary and historical, and no law of physics can depend on it; dimensional consistency is exactly what guarantees that our equations hold in any consistent system of units.

§3.2.2 Scaling

These restrictions are not a hindrance – they are a gift. If we believe that some quantity Y depends only on the quantities X_1, X_2, X_3 , and the dependence is a power law

$$Y = CX_1^{p_1}X_2^{p_2}X_3^{p_3}$$

with C a dimensionless constant, then taking dimensions of both sides gives three linear equations for the three exponents p_1, p_2, p_3 (one for each of L, M, T). Provided the dimensions of X_1, X_2, X_3 are independent, these determine the exponents uniquely – so we learn the entire form of the physical law, up to the constant C , without solving any dynamics at all.

If there are more than three quantities involved, their dimensions can no longer be independent, and we can form dimensionless combinations $\lambda_1, \lambda_2, \dots$ of the variables. The most general relationship then takes the form

$$Y = f(\lambda_1, \lambda_2, \dots) X_1^{p_1} X_2^{p_2} X_3^{p_3},$$

where f is an undetermined dimensionless function³. Dimensional analysis cannot pin down f – but knowing the scaling structure is often most of the battle.

Example 3.2.1 (The Simple Pendulum, by Dimensional Analysis)

Consider again the pendulum: a mass m on a light rod of length ℓ , released from rest a horizontal distance d from the vertical through the pivot, swinging under gravity g . What can the period τ depend on? Our candidate variables have dimensions

$$[m] = M, \quad [\ell] = L, \quad [g] = LT^{-2}, \quad [d] = L,$$

and $[\tau] = T$. The first three have independent dimensions, and from the fourth we can form the dimensionless group d/ℓ . So the relationship must be of the form

$$\tau = f\left(\frac{d}{\ell}\right) m^{p_1} \ell^{p_2} g^{p_3},$$

and balancing dimensions,

$$T = M^{p_1} L^{p_2+p_3} T^{-2p_3} \implies p_1 = 0, \quad p_3 = -\frac{1}{2}, \quad p_2 = \frac{1}{2}.$$

Hence

$$\tau = f\left(\frac{d}{\ell}\right) \sqrt{\frac{\ell}{g}}.$$

Without solving any differential equation, we have learnt that the period is independent of the mass, and scales as $\sqrt{\ell/g}$: if ℓ and d are both quadrupled, the period doubles. Comparing with our earlier small-oscillation result $\tau = 2\pi\sqrt{\ell/g}$, we see that $f(x) \rightarrow 2\pi$ as $x \rightarrow 0$.

Example 3.2.2 (The Speed of Water Waves)

How fast do waves travel on deep water? Plausibly the wave speed v depends on the wavelength Λ , the water density ρ , and gravity g (which provides the restoring force). These three have independent dimensions, so we look for

$$v = C \Lambda^{p_1} \rho^{p_2} g^{p_3},$$

and balancing dimensions,

$$LT^{-1} = L^{p_1} (ML^{-3})^{p_2} (LT^{-2})^{p_3} \implies p_2 = 0, \quad p_3 = \frac{1}{2}, \quad p_1 = \frac{1}{2}.$$

So

$$v = C \sqrt{g\Lambda}.$$

The density drops out entirely, and long waves travel faster than short ones – which is why the long, slow swell from a distant storm arrives at the beach before the choppy short waves do. (A full fluid-dynamical calculation gives $C = 1/\sqrt{2\pi}$.)

³This is a special case of what is formally known as the *Buckingham Pi theorem*.

Example 3.2.3 (Taylor's Estimate of a Blast Energy)

A famous (and true) story: in 1950, G. I. Taylor estimated the (then classified) energy yield of the first atomic bomb from declassified photographs of the fireball, using nothing but dimensional analysis. Suppose the radius R of the blast wave at time t after the explosion depends only on t , the energy released E , and the density ρ of the surrounding air:

$$R = CE^{p_1} \rho^{p_2} t^{p_3}.$$

Balancing dimensions with $[E] = ML^2T^{-2}$ and $[\rho] = ML^{-3}$,

$$L = M^{p_1+p_2} L^{2p_1-3p_2} T^{-2p_1+p_3} \implies p_1 = \frac{1}{5}, \quad p_2 = -\frac{1}{5}, \quad p_3 = \frac{2}{5}.$$

So

$$R = C \left(\frac{Et^2}{\rho} \right)^{1/5} \implies E \sim \frac{\rho R^5}{t^2},$$

taking the undetermined constant C to be of order 1. Reading off R at known times t from the photographs gave Taylor an estimate of about 20 kilotons of TNT – embarrassingly close to the classified value.

Dimensional analysis is not magic, and it is worth being honest about its limits: it cannot produce dimensionless constants (the 2π in the pendulum period), it cannot help if we have misidentified which quantities are relevant, and when there are many dimensionless groups it constrains the answer only loosely. But as a first line of attack on any physical problem – and as an ever-present check on the sanity of our formulae – it is hard to beat.

§3.3 Orbits

We now turn to one of the triumphs of Newtonian mechanics – the description of the motion of planets, comets, moons and satellites. The key structural feature of all of these problems is that the force always points towards a fixed centre, and we will see that this alone constrains the motion enormously.

§3.3.1 Central Forces

If a force is given by a potential V , depending only on the distance from the origin, then

$$\mathbf{F}(\mathbf{x}) = -\nabla V(|\mathbf{x}|) = -\frac{dV}{dr} \hat{\mathbf{r}},$$

where $\hat{\mathbf{r}} = \mathbf{x}/|\mathbf{x}|$. Such forces are known as **central forces** – the force is always parallel to the position vector. Gravity due to a mass fixed at the origin and the Coulomb force due to a fixed charge are the standard examples.

§3.3.2 Angular Momentum

An important result when dealing with central forces is the existence of another conserved quantity, *angular momentum*.

Definition 3.3.1 (Angular Momentum)

The **angular momentum** of a particle about the origin is

$$\mathbf{L} = \mathbf{x} \times \mathbf{p} = m\mathbf{x} \times \dot{\mathbf{x}}.$$

Note that, unlike momentum, angular momentum depends on the choice of origin – it measures something like ‘the amount of rotation about the origin’. Let’s see how it changes in time. With a general force $\mathbf{F}$,

$$\frac{d\mathbf{L}}{dt} = m\dot{\mathbf{x}} \times \dot{\mathbf{x}} + m\mathbf{x} \times \ddot{\mathbf{x}} = \mathbf{x} \times \mathbf{F} = \boldsymbol{\tau},$$

a quantity named *torque* (about the origin). This is the rotational analogue of Newton’s second law: torque is the rate of change of angular momentum.

Proposition 3.3.2

For motion in a central force, angular momentum is conserved.

Proof. If the force is central, then $\mathbf{F} \parallel \mathbf{x}$, so $\boldsymbol{\tau} = \mathbf{x} \times \mathbf{F} = \mathbf{0}$, and thus $\dot{\mathbf{L}} = \mathbf{0}$. $\square$

This conservation law has an immediate geometric consequence. Since $\mathbf{L} = m\mathbf{x} \times \dot{\mathbf{x}}$ is a constant vector and $\mathbf{x} \cdot \mathbf{L} = 0$ always, the position vector is confined to the plane through the origin perpendicular to $\mathbf{L}$.⁴ So *motion in a central force is planar*, and a problem that started in three dimensions is now a problem in two. We will shortly reduce it to one.

§3.3.3 Polar Coordinates in the Plane

Since the motion is planar, it makes sense to use coordinates adapted to the geometry: plane polar coordinates (r, θ) , with $x = r \cos \theta$ and $y = r \sin \theta$. We use the orthonormal basis vectors

$$\hat{\mathbf{r}} = \begin{pmatrix} \cos \theta \\ \sin \theta \end{pmatrix}, \quad \hat{\boldsymbol{\theta}} = \begin{pmatrix} -\sin \theta \\ \cos \theta \end{pmatrix},$$

pointing in the directions of increasing r and θ respectively.

The subtlety, and the entire content of what follows, is that these basis vectors *depend on the position of the particle*, so they change as the particle moves. Differentiating the expressions above with respect to θ ,

$$\frac{d\hat{\mathbf{r}}}{d\theta} = \hat{\boldsymbol{\theta}}, \quad \frac{d\hat{\boldsymbol{\theta}}}{d\theta} = -\hat{\mathbf{r}}.$$

⁴If $\mathbf{L} = \mathbf{0}$, then $\mathbf{x}$ and $\dot{\mathbf{x}}$ are always parallel, and the motion takes place on a straight line through the origin – which is certainly also planar.

Proposition 3.3.3 (Velocity and Acceleration in Polar Coordinates)

For a particle with position $\mathbf{x} = r\hat{\mathbf{r}}$,

$$\begin{aligned}\dot{\mathbf{x}} &= \dot{r}\hat{\mathbf{r}} + r\dot{\theta}\hat{\theta}, \\ \ddot{\mathbf{x}} &= (\ddot{r} - r\dot{\theta}^2)\hat{\mathbf{r}} + (r\ddot{\theta} + 2\dot{r}\dot{\theta})\hat{\theta}.\end{aligned}$$

Proof. By the chain rule, $\dot{\hat{\mathbf{r}}} = \dot{\theta}\hat{\theta}$ and $\dot{\hat{\theta}} = -\dot{\theta}\hat{\mathbf{r}}$. So differentiating $\mathbf{x} = r\hat{\mathbf{r}}$,

$$\dot{\mathbf{x}} = \dot{r}\hat{\mathbf{r}} + r\dot{\hat{\mathbf{r}}} = \dot{r}\hat{\mathbf{r}} + r\dot{\theta}\hat{\theta},$$

and differentiating again,

$$\ddot{\mathbf{x}} = \ddot{r}\hat{\mathbf{r}} + \dot{r}\dot{\hat{\mathbf{r}}} + \dot{r}\dot{\hat{\theta}} + r\ddot{\hat{\theta}} - r\dot{\theta}^2\hat{\mathbf{r}} = (\ddot{r} - r\dot{\theta}^2)\hat{\mathbf{r}} + (r\ddot{\theta} + 2\dot{r}\dot{\theta})\hat{\theta}. \quad \square$$

The term $-r\dot{\theta}^2\hat{\mathbf{r}}$ should be familiar: for a particle moving on a *circle* of constant radius r with angular speed $\omega = \dot{\theta}$, the acceleration is $-r\omega^2\hat{\mathbf{r}}$, of magnitude $r\omega^2 = v^2/r$ directed towards the centre – the *centripetal acceleration*. Some force must supply this if a particle is to move in a circle.

Example 3.3.4 (Circular Orbit Speed)

For a satellite in a circular orbit of radius r about the Earth, gravity supplies the centripetal force:

$$\frac{mv^2}{r} = \frac{GMm}{r^2} \implies v = \sqrt{\frac{GM}{r}}.$$

The period is then $\tau = 2\pi r/v = 2\pi r^{3/2}/\sqrt{GM}$ – a first glimpse of Kepler's third law, to which we will return.

§3.3.4 Reduction to One Dimension

Suppose we had a potential $V(r)$, with $\mathbf{F} = -\nabla V = -\frac{dV}{dr}\hat{\mathbf{r}}$. Newton's second law in the plane with plane polar coordinates (r, θ) is (for constant mass)

$$\begin{aligned}m\ddot{\mathbf{x}} &= -\frac{dV}{dr}\hat{\mathbf{r}} \\ \implies m(\ddot{r} - r\dot{\theta}^2)\hat{\mathbf{r}} + m(r\ddot{\theta} + 2\dot{r}\dot{\theta})\hat{\theta} &= -\frac{dV}{dr}\hat{\mathbf{r}}.\end{aligned}$$

Then since the components are orthogonal, we can then obtain two separate equations. The first (taking the $\hat{\theta}$ component) is

$$r\ddot{\theta} + 2\dot{r}\dot{\theta} = 0 \implies \frac{1}{r} \frac{d}{dt}(r^2\dot{\theta}) = 0.$$

This is not a surprise but a consistency check: the angular momentum of the system is $\mathbf{L} = \mathbf{x} \times m\dot{\mathbf{x}} = mr^2\dot{\theta}(\hat{\mathbf{r}} \times \hat{\theta})$, and thus $|\mathbf{L}| = mr^2\dot{\theta} = m\ell$, where $\ell = r^2\dot{\theta}$ is the angular momentum per unit mass. So this equation just says that angular momentum is conserved, which we already knew.

The other component then gives us the equation

$$m(\ddot{r} - r\dot{\theta}^2) = -\frac{dV}{dr} \implies m\ddot{r} = -\frac{dV}{dr} + mr\dot{\theta}^2 = -\frac{dV}{dr} + \frac{m\ell^2}{r^3},$$

where in the last step we eliminated $\dot{\theta}$ using $\dot{\theta} = \ell/r^2$. Thus we have reduced our three dimensional problem of a central force into a one dimensional problem involving the radial component only – the price being an extra, angular-momentum-dependent term in the force.

§3.3.5 The Effective Potential

Using our reduced problem, we can ‘forget’ about the θ component, and consider a one dimensional system, under the influence of the *effective potential*

$$V_{\text{eff}}(r) = V(r) + \frac{m\ell^2}{2r^2}.$$

The rightmost term is the *angular momentum barrier*, and it stops the particle from getting too close to the origin: as $r \rightarrow 0$ it blows up like $1/r^2$, which (for potentials less singular than this, such as gravity) dominates and repels the particle.

We can even use this viewpoint in energy conservation, as

$$E = \frac{1}{2}m\dot{\mathbf{x}} \cdot \dot{\mathbf{x}} + V(r) = \frac{1}{2}m\dot{r}^2 + V_{\text{eff}}(r),$$

using $|\dot{\mathbf{x}}|^2 = \dot{r}^2 + r^2\dot{\theta}^2$ and $\dot{\theta} = \ell/r^2$. So all our one dimensional technology – sketching the potential, classifying allowed regions by energy, finding equilibria – applies directly to the radial motion.

Example 3.3.5 (Orbits in an Inverse Square Law Potential)

For gravity, $V(r) = -GMm/r$, the effective potential

$$V_{\text{eff}}(r) = -\frac{GMm}{r} + \frac{m\ell^2}{2r^2}$$

tends to $+\infty$ as $r \rightarrow 0$ (the angular momentum barrier wins), and tends to 0^- as $r \rightarrow \infty$, with a single minimum in between at $r_* = \ell^2/GM$.

Reading off the qualitative motion from the graph:

- (i) If $E = V_{\text{eff}}(r_*)$, then $r = r_*$ is constant, and the orbit is a *circle*.
- (ii) If $V_{\text{eff}}(r_*) < E < 0$, the radius oscillates between two values $r_{\min} \leq r \leq r_{\max}$ (the *perihelion* and *aphelion*) – the orbit is bounded.
- (iii) If $E \geq 0$, the particle can escape to $r \rightarrow \infty$ – the orbit is unbounded, and the particle approaches, swings past, and leaves, never to return.

We will see shortly that the bounded orbits are precisely ellipses, and the unbounded ones hyperbolae (or, in the marginal case $E = 0$, parabolae).

Example 3.3.6 (Finding the Turning Points)

The perihelion and aphelion distances can be computed directly from the conserved quantities. At a turning point of the radial motion, $\dot{r} = 0$, so $E = V_{\text{eff}}(r)$:

$$E = -\frac{GMm}{r} + \frac{m\ell^2}{2r^2} \implies Er^2 + GMmr - \frac{m\ell^2}{2} = 0,$$

a quadratic in r . For bound orbits ($E < 0$) it has two positive roots, $r_{\min}$ and $r_{\max}$, and by the standard formulae for the sum and product of roots,

$$r_{\min} + r_{\max} = -\frac{GMm}{E} \quad (= 2a), \quad r_{\min} r_{\max} = -\frac{m\ell^2}{2E} \quad (= b^2),$$

which the reader may enjoy checking against the geometry of the ellipse. For $E \geq 0$ there is a single positive root – the distance of closest approach of an unbound trajectory.

§3.3.6 Stability of Circular Orbits

A circular orbit at radius r_* exists whenever $V'_{\text{eff}}(r_*) = 0$, and just as for one dimensional potentials, the orbit is *stable* (small perturbations of the radius oscillate rather than grow) precisely when r_* is a minimum of the effective potential, that is when $V''_{\text{eff}}(r_*) > 0$. In that case a slightly perturbed orbit has radius oscillating about r_* with angular frequency ω_r given by $m\omega_r^2 = V''_{\text{eff}}(r_*)$.

Example 3.3.7 (Stability for Power Law Forces)

Suppose the force is attractive with $F(r) = -mk/r^n$ for some n , so $V(r) = -\frac{mk}{(n-1)r^{n-1}}$ for $n \neq 1$. Then

$$V_{\text{eff}}(r) = -\frac{mk}{(n-1)r^{n-1}} + \frac{m\ell^2}{2r^2},$$

and circular orbits satisfy $V'_{\text{eff}}(r_*) = 0$, giving $\ell^2 = kr_*^{3-n}$. Computing the second derivative and substituting this in,

$$V''_{\text{eff}}(r_*) = -\frac{nmk}{r_*^{n+1}} + \frac{3m\ell^2}{r_*^4} = \frac{mk}{r_*^{n+1}} (3-n).$$

So circular orbits are stable if and only if $n < 3$. In particular the inverse square law $n = 2$ gives stable circular orbits (reassuring, given that we live on a planet in a nearly circular orbit), while an inverse cube force $n = 3$ or stronger cannot support stable circles – a slight nudge sends the particle spiralling inwards or outwards.

§3.3.7 Escape Velocity

Consider a projectile launched from the surface of a planet of mass M and radius R . Ignoring air resistance, when can it escape the planet's gravity entirely? By conservation

of energy,

$$E = \frac{1}{2}mv^2 - \frac{GMm}{r},$$

and (as we saw from the effective potential) the projectile can reach $r \rightarrow \infty$ precisely when $E \geq 0$. Launching from $r = R$, this requires

$$v \geq v_{\text{esc}} = \sqrt{\frac{2GM}{R}},$$

the **escape velocity** of the planet. For the Earth, $v_{\text{esc}} \approx 11.2 \text{ km s}^{-1}$. Note that v_{esc} is independent of the mass of the projectile, and (perhaps surprisingly) of the direction of launch: energy conservation cares only about speed. A particle launched at exactly v_{esc} reaches infinity with nothing to spare, arriving with zero speed.

§3.3.8 The $u(\theta)$ Equation

We now want the *shape* of a general orbit, that is, r as a function of θ rather than of t . It turns out that the substitution $u = 1/r$ just seems to work really well when dealing with the system we have set up. Using the chain rule with $\dot{\theta} = \ell u^2$, we have

$$\begin{aligned}\dot{r} &= \frac{dr}{d\theta} \dot{\theta} = \frac{dr}{d\theta} \ell = -\ell \frac{du}{d\theta}, \\ \ddot{r} &= \frac{d}{dt} \left(-\ell \frac{du}{d\theta} \right) = -\ell \frac{d^2u}{d\theta^2} \dot{\theta} = -\ell^2 u^2 \frac{d^2u}{d\theta^2}.\end{aligned}$$

Then our equation of motion goes from $m\ddot{r} - m\ell^2/r^3 = F(r)$ to *Binet's equation*:

$$-m\ell^2 u^2 \left(\frac{d^2u}{d\theta^2} + u \right) = F\left(\frac{1}{u}\right).$$

This is generally still nonlinear – but for inverse square laws (such as gravity), where $F(1/u) \propto u^2$, the factor of u^2 on the left cancels, and it becomes a *linear* equation, one we know exactly how to solve. After it is solved, we can get back the time dependence with $\dot{\theta} = \ell u^2$.

§3.3.9 The Kepler Problem

Binet's equation can be used to find the shapes of orbits under an inverse square law. Let

$$V(r) = -\frac{mk}{r}, \quad F(r) = -\frac{mk}{r^2},$$

where $k = GM$ for gravity due to a mass M fixed at the origin. Then Binet's equation is

$$\frac{d^2u}{d\theta^2} + u = \frac{k}{\ell^2}.$$

This is the harmonic oscillator equation (in the variable θ !) with a constant forcing term, so the general solution is

$$u = \frac{k}{\ell^2} + A \cos(\theta - \theta_0).$$

Taking $\theta_0 = 0$ (which we can arrange by rotating our coordinates) and $A \geq 0$, we conclude that for a planet in orbit about the origin, the shape of the orbit is given by

$$r = \frac{p}{1 + e \cos \theta},$$

with $p = \ell^2/k$ and $e = A\ell^2/k \geq 0$. This is the polar-coordinate equation of a *conic section* with a focus at the origin, where e is the **eccentricity**. Notice that r is minimised at $\theta = 0$ (the closest approach, or *perihelion* for orbits about the Sun) and, when the orbit is bounded, maximised at $\theta = \pi$ (*aphelion*). The nature of the conic depends on the eccentricity:

- (i) If $e = 0$ then $r = p$ is constant, and the orbit is a *circle*.
- (ii) If $0 < e < 1$, the denominator is always positive, so r is bounded with $\frac{p}{1+e} \leq r \leq \frac{p}{1-e}$, and the orbit is an *ellipse* with the origin at one focus. In Cartesian coordinates centred appropriately, it has semi-major and semi-minor axes

$$a = \frac{p}{1-e^2}, \quad b = \frac{p}{\sqrt{1-e^2}}.$$

- (iii) If $e = 1$, then $r \rightarrow \infty$ as $\theta \rightarrow \pm\pi$: the orbit is an unbounded *parabola*.
- (iv) If $e > 1$, then $r \rightarrow \infty$ as $\theta \rightarrow \pm\alpha$ where $\alpha = \cos^{-1}(1/e) \in (\pi/2, \pi)$: the orbit is one branch of a *hyperbola*, with asymptotes at angles $\pm\alpha$.

The bounded case is the one Kepler cared about – an ellipse with the attracting body at a focus:

Example 3.3.8 (Determining an Orbit from Initial Conditions)

A satellite is at distance r_0 from the Earth's centre, moving with speed v_0 *perpendicular* to its position vector. What orbit does it follow? Since $\dot{\mathbf{x}} \perp \mathbf{x}$, the angular momentum per unit mass is $\ell = r_0 v_0$, and this point is an apse of the orbit (a maximum or minimum of r), so it lies at $\theta = 0$ or $\theta = \pi$ in our standard form. Comparing r_0 with the orbit equation at $\theta = 0$,

$$r_0 = \frac{p}{1+e} = \frac{r_0^2 v_0^2}{GM(1+e)} \implies e = \frac{r_0 v_0^2}{GM} - 1.$$

Reading off the cases:

- (i) If $v_0^2 = GM/r_0$, then $e = 0$ – the circular orbit speed we found before.
- (ii) If $GM/r_0 < v_0^2 < 2GM/r_0$, then $0 < e < 1$: an ellipse with the launch point as perihelion.
- (iii) If $v_0^2 < GM/r_0$, the formula gives $e < 0$, which just means the launch point is the *aphelion* instead (replace $\theta \mapsto \theta + \pi$): the satellite falls inwards on an ellipse.
- (iv) If $v_0^2 \geq 2GM/r_0$, then $e \geq 1$ and the satellite escapes on a parabola or hyper-

bola – and indeed $v_0 = \sqrt{2GM/r_0}$ is precisely the escape velocity from radius r_0 that we found earlier.

§3.3.10 Energy and Eccentricity

Which orbit we get is determined by the energy. Evaluating the conserved energy at perihelion (where $\dot{r} = 0$, $r = p/(1+e)$ and so $\dot{\mathbf{x}} = r\dot{\theta}\hat{\theta}$ has magnitude ℓ/r),

$$E = \frac{1}{2} \frac{m\ell^2}{r^2} - \frac{mk}{r} \Big|_{r=p/(1+e)} = \frac{mk^2}{2\ell^2} (e^2 - 1).$$

So the classification by eccentricity is exactly the classification by energy that we sketched using the effective potential:

$$\begin{aligned} e < 1 &\iff E < 0 && \text{(ellipse),} \\ e = 1 &\iff E = 0 && \text{(parabola),} \\ e > 1 &\iff E > 0 && \text{(hyperbola).} \end{aligned}$$

Bound orbits are precisely those with negative total energy – the particle does not have enough kinetic energy to climb out of the potential well.

For an elliptical orbit there is a particularly clean way to package the energy. Using $\ell^2 = pk$ and $p = a(1 - e^2)$,

$$E = \frac{mk^2(e^2 - 1)}{2\ell^2} = \frac{mk^2(e^2 - 1)}{2a(1 - e^2)k} = -\frac{mk}{2a},$$

so the energy of an orbit depends only on its *semi-major axis*, not on its eccentricity – a circle of radius a and a wildly elongated ellipse of semi-major axis a have exactly the same energy. Writing out $E = \frac{1}{2}mv^2 - mk/r$ and rearranging gives the handy *vis-viva equation*,

$$v^2 = GM \left(\frac{2}{r} - \frac{1}{a} \right),$$

which gives the speed at any point of the orbit. Sanity checks: for a circle ($r = a$) it reduces to $v^2 = GM/r$, and letting $a \rightarrow \infty$ (the parabolic, marginally-escaping orbit) recovers $v^2 = 2GM/r$, the escape velocity.

§3.3.11 Kepler's Laws

Long before Newton, Kepler had extracted three empirical laws of planetary motion from Tycho Brahe's astronomical observations.

Law 3.3.9 (Kepler's Laws of Planetary Motion)

1. The orbit of a planet is an ellipse, with the Sun at one focus.
2. The line between the planet and the Sun sweeps out equal areas in equal times.
3. The square of the orbital period is proportional to the cube of the semi-major axis, $\tau^2 \propto a^3$.

Newton's great achievement was to show that all three follow from his laws of motion together with the inverse square law of gravitation – and we have now assembled everything needed to check this ourselves.

The first law follows from our discussion of the Kepler problem: bounded orbits under an inverse square law are ellipses with a focus at the origin.

The second law is just conservation of angular momentum in geometric clothing, and in fact holds for *any* central force. When the position vector sweeps through a small angle $d\theta$, the area swept out is that of a thin triangle, $dA = \frac{1}{2}r \cdot r d\theta$, so

$$\frac{dA}{dt} = \frac{1}{2}r^2\dot{\theta} = \frac{\ell}{2},$$

which is constant. A planet therefore moves fastest at perihelion and slowest at aphelion.

Example 3.3.10

Conservation of angular momentum relates the extreme speeds directly: at perihelion and aphelion the velocity is purely tangential, so $\ell = r_{\min}v_{\max} = r_{\max}v_{\min}$, giving

$$\frac{v_{\max}}{v_{\min}} = \frac{r_{\max}}{r_{\min}} = \frac{1+e}{1-e}.$$

The Earth's orbital eccentricity is a modest $e \approx 0.017$, so its speed varies by only about 3.4% over the year (roughly 30.3 versus 29.3 km s⁻¹). Halley's comet, with $e \approx 0.97$, moves about 66 times faster at perihelion than at aphelion – it spends decades dawdling in the outer solar system and mere months whipping around the Sun.

For the third law, integrate the second law over a full orbit: the area of an ellipse is $A = \pi ab$, so

$$\pi ab = \frac{\ell}{2}\tau.$$

Now using $b^2 = a^2(1 - e^2)$ and $\ell^2 = pk = a(1 - e^2)k$,

$$\tau^2 = \frac{4\pi^2 a^2 b^2}{\ell^2} = \frac{4\pi^2 a^4 (1 - e^2)}{a(1 - e^2)k} = \frac{4\pi^2}{GM} a^3,$$

recalling that $k = GM$. So $\tau^2 \propto a^3$, with a constant of proportionality depending only on the mass of the Sun – which is why the same law holds for every planet in the solar system.

Example 3.3.11 (Geostationary Orbit)

At what radius does a satellite orbit the Earth once per day, so as to hover over a fixed point on the equator? Rearranging the third law (for a circular orbit, $a = r$),

$$r = \left(\frac{GM\tau^2}{4\pi^2} \right)^{1/3},$$

and inserting $GM \approx 4.0 \times 10^{14} \text{ m}^3 \text{ s}^{-2}$ for the Earth and $\tau = 86\,400 \text{ s}$ gives $r \approx 4.2 \times 10^7 \text{ m}$, i.e. about 42 000 km from the Earth's centre, or some 36 000 km above the surface. This is where communications and weather satellites live.

Example 3.3.12 (Halley's Comet)

The third law works just as well in reverse. Halley's comet returns every 76 years; measuring in years and astronomical units (in which the Earth's orbit has $\tau = 1$ and $a = 1$, conveniently normalising the constant of proportionality), its semi-major axis is

$$a = \tau^{2/3} = 76^{2/3} \approx 17.9 \text{ AU.}$$

Since the comet's orbit is highly eccentric ($e \approx 0.97$), its distances of closest and furthest approach are $a(1 - e) \approx 0.6 \text{ AU}$ (inside Venus's orbit) and $a(1 + e) \approx 35 \text{ AU}$ (out past Neptune) – all deduced from its period and one observation of its perihelion.

§3.3.12 Rutherford Scattering

Finally, let's consider what happens when the inverse square force is *repulsive*, so

$$V(r) = +\frac{mk}{r}, \quad F(r) = +\frac{mk}{r^2}, \quad k > 0.$$

The classic physical setting is Rutherford's famous experiment: alpha particles (charge q) fired at gold atoms are repelled by the nucleus (charge Q), with $k = Qq/4\pi\epsilon_0 m > 0$ by the Coulomb force law.

Binet's equation now reads $u'' + u = -k/\ell^2$, with general solution

$$u = -\frac{k}{\ell^2} + A \cos(\theta - \theta_0),$$

and taking $\theta_0 = 0$, $A \geq 0$ as usual we get

$$r = \frac{p}{e \cos \theta - 1}, \quad p = \frac{\ell^2}{k}, \quad e = \frac{A\ell^2}{k}.$$

For r to be positive we need $e > 1$: *every* orbit in a repulsive inverse square force is a hyperbola (which makes sense – there can be no bound orbits when the force pushes you away). The particle comes in from infinity, reaches a closest approach at $\theta = 0$, and escapes to infinity again, with $r \rightarrow \infty$ as $\theta \rightarrow \pm\alpha$ where $\alpha = \cos^{-1}(1/e)$. This time the trajectory is the branch of the hyperbola on the *far side* from the focus, curving away from the origin.

The interesting physical question is: by what angle is the particle deflected? Characterise the incoming trajectory by its speed v at infinity, and its **impact parameter** b – the perpendicular distance between the incoming asymptote and the origin. Evaluating the conserved quantities far away, the angular momentum per unit mass is $\ell = bv$.

The two asymptotes make angles $\pm\alpha$ with the axis of the hyperbola, so the total *scattering angle* (between the incoming and outgoing directions) is $\beta = \pi - 2\alpha$. Then

$$\frac{1}{e} = \cos \alpha = \cos \left(\frac{\pi}{2} - \frac{\beta}{2} \right) = \sin \frac{\beta}{2}.$$

A little algebra with the geometry of the hyperbola shows that the impact parameter is $b = p/\sqrt{e^2 - 1}$, so

$$b = \frac{\ell^2}{k} \frac{1}{\sqrt{e^2 - 1}} = \frac{(bv)^2}{k} \tan \frac{\beta}{2},$$

and rearranging,

$$\beta = 2 \tan^{-1} \left(\frac{k}{bv^2} \right).$$

Small impact parameters $b \ll k/v^2$ (nearly head-on collisions) give scattering angles approaching π – the particle bounces almost straight back. It was precisely the observation of such large-angle scattering of alpha particles that led Rutherford to conclude that an atom's positive charge is concentrated in a tiny nucleus, rather than being smeared throughout the atom: as he put it, “it was almost as incredible as if you fired a 15-inch shell at a piece of tissue paper and it came back and hit you.”

§3.4 Rotating Frames

Newton's laws hold in inertial frames – but many frames we care about are not inertial. The most important example is right beneath our feet: the Earth rotates once a day, so a laboratory fixed to its surface is a rotating frame. In this section we work out what Newton's second law looks like to an observer in a rotating frame, and find that they can continue to use it, provided they are willing to admit some additional ‘fictitious’ forces into their bookkeeping.

§3.4.1 Motion in Rotating Frames

Suppose that $\mathcal{F}$ is an inertial frame, and $\mathcal{F}'$ is rotating about the z axis with angular velocity $\omega = \omega \mathbf{e}_z$ with respect to $\mathcal{F}$.

Suppose we have basis vectors $\{\mathbf{e}_i\}$ and $\{\mathbf{e}'_i\}$ in $\mathcal{F}$ and $\mathcal{F}'$ respectively. If a particle is at rest in $\mathcal{F}'$, then in $\mathcal{F}$ its velocity is given by

$$\left(\frac{d\mathbf{r}}{dt} \right)_{\mathcal{F}} = \omega \times \mathbf{r}.$$

Of course, this also applies to the basis vectors in $\mathcal{F}'$, with

$$\left(\frac{d\mathbf{e}'_i}{dt} \right)_{\mathcal{F}} = \omega \times \mathbf{e}'_i.$$

Now for some vector $\mathbf{a}$, we can write it in the $\{\mathbf{e}'_i\}$ basis as

$$\mathbf{a} = \sum_i a'_i(t) \mathbf{e}'_i.$$

In the frame $\mathcal{F}'$, the basis vectors $\mathbf{e}'_i$ are constant, and thus the derivative of $\mathbf{a}$ is given by

$$\left(\frac{d\mathbf{a}}{dt}\right)_{\mathcal{F}'} = \sum_i \frac{da'_i(t)}{dt} \mathbf{e}'_i.$$

In the frame $\mathcal{F}$ however, the basis vectors $\{\mathbf{e}'_i\}$ are not constant, and we have

$$\left(\frac{d\mathbf{a}}{dt}\right)_{\mathcal{F}} = \sum_i \frac{da'_i(t)}{dt} \mathbf{e}'_i + \sum_i a'_i(t) \boldsymbol{\omega} \times \mathbf{e}'_i = \left(\frac{d\mathbf{a}}{dt}\right)_{\mathcal{F}'} + \boldsymbol{\omega} \times \mathbf{a}$$

§3.4.2 Change of Frame Operator

Let $\mathcal{F}$ be an inertial frame, and $\mathcal{F}'$ be rotating relative to $\mathcal{F}$ with angular velocity $\boldsymbol{\omega}$. Then we have

$$\left(\frac{d}{dt}\right)_{\mathcal{F}} = \left(\frac{d}{dt}\right)_{\mathcal{F}'} + \boldsymbol{\omega} \times$$

§3.4.3 Velocity and Acceleration

Using the change of frame operator, we can see that

$$\left(\frac{d\mathbf{r}}{dt}\right)_{\mathcal{F}} = \left(\frac{d\mathbf{r}}{dt}\right)_{\mathcal{F}'} + \boldsymbol{\omega} \times \mathbf{r},$$

and applying the operator again (and noting that $\dot{\boldsymbol{\omega}}$ is the same in both frames), we have

$$\left(\frac{d^2\mathbf{r}}{dt^2}\right)_{\mathcal{F}} = \left(\frac{d^2\mathbf{r}}{dt^2}\right)_{\mathcal{F}'} + 2\boldsymbol{\omega} \times \left(\frac{d\mathbf{r}}{dt}\right)_{\mathcal{F}'} + \dot{\boldsymbol{\omega}} \times \mathbf{r} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r}).$$

§3.4.4 Force in the Rotating Frame

Since $\mathcal{F}$ is an inertial frame, we have $m \left(\frac{d^2\mathbf{r}}{dt^2} \right)_{\mathcal{F}} = \mathbf{F}$ by Newton's laws. This allows us to write down what the force appears to be in the frame $\mathcal{F}'$ (as if the observer in the frame was trying to apply Newton's laws).

$$m \left(\frac{d^2\mathbf{r}}{dt^2}\right)_{\mathcal{F}'} = \mathbf{F} - 2m\boldsymbol{\omega} \times \left(\frac{d\mathbf{r}}{dt}\right)_{\mathcal{F}'} - m\dot{\boldsymbol{\omega}} \times \mathbf{r} - m\boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r}).$$

The additional terms on the right are known as *fictitious forces*, each with a different name.

1. *Coriolis force*. $-2m\boldsymbol{\omega} \times \left(\frac{d\mathbf{r}}{dt}\right)_{\mathcal{F}'}$.
2. *Euler force*. $-m\dot{\boldsymbol{\omega}} \times \mathbf{r}$.
3. *Centrifugal force*. $-m\boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r})$.

These are not forces in the sense of Newton's laws – nothing exerts them, and they have no third-law reaction partners. They are artefacts of insisting on doing mechanics in a non-inertial frame. Still, to an observer in the rotating frame they feel perfectly real, as anyone who has stood on a spinning roundabout can attest. For a frame rotating at constant angular velocity (such as the Earth, to good approximation) the Euler force vanishes, and we are left with the centrifugal and Coriolis forces, which we now examine in turn.

§3.4.5 The Centrifugal Force

Let's look more closely at the centrifugal force, $-m\boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r})$. Using the vector triple product identity $\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = (\mathbf{a} \cdot \mathbf{c})\mathbf{b} - (\mathbf{a} \cdot \mathbf{b})\mathbf{c}$,

$$-m\boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r}) = -m((\boldsymbol{\omega} \cdot \mathbf{r})\boldsymbol{\omega} - |\boldsymbol{\omega}|^2\mathbf{r}) = m\omega^2\mathbf{r}_\perp,$$

where $\mathbf{r}_\perp = \mathbf{r} - (\hat{\boldsymbol{\omega}} \cdot \mathbf{r})\hat{\boldsymbol{\omega}}$ is the component of $\mathbf{r}$ perpendicular to the rotation axis. So the centrifugal force has magnitude $m\omega^2 d$, where $d = |\mathbf{r}_\perp|$ is the distance from the axis, and points *directly away from the axis of rotation*. It is also conservative: we can write it as

$$-\nabla \left(-\frac{1}{2}m\omega^2|\mathbf{r}_\perp|^2 \right),$$

so it can be absorbed into an effective potential.

Example 3.4.1 (Apparent Gravity on the Earth)

For a particle at rest on the surface of the rotating Earth at latitude λ , the effective gravitational acceleration measured in the rotating frame is

$$\mathbf{g}_{\text{eff}} = \mathbf{g} - \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r}),$$

the sum of true gravity (pointing to the Earth's centre) and the centrifugal term (pointing away from the rotation axis, with magnitude $\omega^2 R \cos \lambda$). With $\omega = 2\pi/86400 \text{ s} \approx 7.3 \times 10^{-5} \text{ s}^{-1}$ and $R \approx 6400 \text{ km}$, the centrifugal term has magnitude at most $\omega^2 R \approx 0.03 \text{ m s}^{-2}$ – about 0.3% of g , largest at the equator and vanishing at the poles. Two consequences: the measured g is slightly smaller at the equator than at the poles, and a plumb line does not point exactly towards the centre of the Earth except at the poles and equator. (For the same reason the Earth itself is not quite spherical, but bulges at the equator.)

Example 3.4.2 (The Rotating Bucket)

Spin a bucket of water about its vertical axis at constant angular speed ω , and wait for the water to rotate with it. What shape is the surface? In the rotating frame the water is at rest, subject to gravity, the centrifugal force, and pressure forces. Since the centrifugal force is conservative, each fluid element sits in the effective potential (per unit mass)

$$\Phi_{\text{eff}} = gz - \frac{1}{2}\omega^2 r^2,$$

where r is the distance from the axis. The free surface of a fluid at rest is a surface of constant potential, so on the surface

$$gz - \frac{1}{2}\omega^2 r^2 = \text{const} \implies z = z_0 + \frac{\omega^2 r^2}{2g}.$$

The surface is a *paraboloid*, climbing up the sides of the bucket – as you can verify by stirring your tea. (Liquid mirror telescopes exploit exactly this: a slowly rotating dish of mercury forms a perfect parabolic mirror.)

§3.4.6 The Coriolis Force

The Coriolis force

$$\mathbf{F}_{\text{cor}} = -2m\boldsymbol{\omega} \times \mathbf{v}, \quad \text{where } \mathbf{v} = \left(\frac{d\mathbf{r}}{dt} \right)_{\mathcal{F}'},$$

is stranger: it depends on the particle's velocity *in the rotating frame*, and vanishes for objects at rest in that frame. Since $\mathbf{F}_{\text{cor}}$ is always perpendicular to $\mathbf{v}$, it does no work – like a magnetic force, it deflects motion sideways without changing speed.

To get oriented, consider the Northern hemisphere and motion in a horizontal plane. The locally vertical component of $\boldsymbol{\omega}$ points up out of the ground, and one can check from the cross product that the Coriolis force then deflects a moving object *to the right* of its velocity (in the Southern hemisphere, to the left). This is the origin of the rotation of weather systems: air being drawn towards a low pressure region is deflected rightwards as it flows, and the result is that cyclones in the Northern hemisphere rotate anticlockwise. On everyday scales the effect is tiny – it does *not* determine which way your bathtub drains, despite the folklore – but over the scale of an atmosphere it dominates.

In the diagram (drawn for the Northern hemisphere, viewed from above, with $\boldsymbol{\omega}$ pointing out of the page), a particle moving with velocity $\mathbf{v}$ feels a Coriolis force at right angles to its motion, and its trajectory (dashed) is continually deflected to the right.

Let's do a genuine calculation.

Example 3.4.3 (Dropping a Particle from a Tower)

Stand at the equator, and drop a particle from a tower of height h . Where does it land? In the rotating frame of the Earth, working to first order in the small quantity ω (so ignoring the centrifugal force, which is order ω^2),

$$\ddot{\mathbf{r}} = \mathbf{g} - 2\boldsymbol{\omega} \times \dot{\mathbf{r}}.$$

We solve perturbatively. At zeroth order, $\dot{\mathbf{r}}_0 = \mathbf{g}t$, and substituting this into the Coriolis term,

$$\ddot{\mathbf{r}} \approx \mathbf{g} - 2\boldsymbol{\omega} \times \mathbf{g}t \implies \mathbf{r}(t) \approx \mathbf{r}_0 + \frac{1}{2}\mathbf{g}t^2 - \frac{1}{3}\boldsymbol{\omega} \times \mathbf{g}t^3.$$

At the equator, $\boldsymbol{\omega}$ points north and $\mathbf{g}$ points down, so $-\boldsymbol{\omega} \times \mathbf{g}$ points *east*, with magnitude ωg . The particle hits the ground at time $t = \sqrt{2h/g}$, displaced eastward by

$$d = \frac{1}{3}\omega g \left(\frac{2h}{g} \right)^{3/2}.$$

For $h = 100$ m, this is about 2 cm – small, but measurable, and it was one of the early direct demonstrations of the Earth's rotation. Intuitively, the top of the tower moves faster eastward than its base, and the particle keeps its excess eastward velocity as it falls.

Example 3.4.4 (The Foucault Pendulum)

A related and more famous demonstration: suspend a long pendulum at latitude λ and let it swing freely for hours. Set up local axes with x pointing east, y north and z up. At latitude λ , the Earth's angular velocity in these axes is

$$\boldsymbol{\omega} = \omega(0, \cos \lambda, \sin \lambda).$$

For small swings of a pendulum of length ℓ , the bob moves essentially horizontally, with displacement (x, y) and a restoring force $-(g/\ell)(x, y)$ per unit mass, plus the Coriolis force. Computing $-2\boldsymbol{\omega} \times \mathbf{v}$ with $\mathbf{v} \approx (\dot{x}, \dot{y}, 0)$ and keeping the horizontal components, the equations of motion are

$$\ddot{x} = -\frac{g}{\ell}x + 2\Omega\dot{y}, \quad \ddot{y} = -\frac{g}{\ell}y - 2\Omega\dot{x}, \quad \text{where } \Omega = \omega \sin \lambda$$

is the locally vertical component of the Earth's rotation. The two equations beg to be combined into one complex variable $\zeta = x + iy$:

$$\ddot{\zeta} + 2i\Omega\dot{\zeta} + \omega_0^2\zeta = 0, \quad \omega_0^2 = \frac{g}{\ell}.$$

Seeking solutions $e^{i\alpha t}$ gives $\alpha = -\Omega \pm \sqrt{\omega_0^2 + \Omega^2} \approx -\Omega \pm \omega_0$, since $\Omega \ll \omega_0$. So

$$\zeta(t) \approx e^{-i\Omega t} (Ae^{i\omega_0 t} + Be^{-i\omega_0 t}).$$

The bracket is an ordinary pendulum oscillation; the prefactor $e^{-i\Omega t}$ slowly *rotates* the whole pattern. The plane of swing therefore precesses (clockwise viewed from above, in the Northern hemisphere) at angular rate $\Omega = \omega \sin \lambda$, completing a full turn in

$$T = \frac{24 \text{ h}}{\sin \lambda}.$$

At the poles this is exactly one day – the pendulum swings in a fixed inertial plane while the Earth turns beneath it, which is a helpful way to see the result must be true. At the latitude of Cambridge the period is around 30 hours, and at the equator there is no precession at all. Foucault's original 1851 demonstration in the Panthéon in Paris was the first direct mechanical evidence of the Earth's rotation.

§3.5 Systems of Particles

So far we have described the dynamics of single particles. Now let's have a look at systems involving multiple particles, and see how much of the single-particle story – momentum, angular momentum, energy – survives. The punchline is that a composite system behaves, in aggregate, remarkably like a single particle located at its centre of mass; this is precisely why we could get away with treating planets as points for so long.

§3.5.1 Centre of Mass & Conservation of Momentum

Suppose we have N particles, where particle i has position $\mathbf{x}_i$, mass m_i , and momentum $\mathbf{p}_i = m_i \dot{\mathbf{x}}_i$. Newton's second law for each particle becomes

$$\dot{\mathbf{p}}_i = \mathbf{F}_i,$$

and we can helpfully split the force on particle i as

$$\mathbf{F}_i = \mathbf{F}_i^{\text{ext}} + \sum_{j \neq i} \mathbf{F}_{ij},$$

where $\mathbf{F}_i^{\text{ext}}$ is the external force on particle i (from outside the system) and $\mathbf{F}_{ij}$ is the internal force on particle i from particle j . By Newton's third law, we have $\mathbf{F}_{ij} = -\mathbf{F}_{ji}$.

Definition 3.5.1 (Centre of Mass)

The **centre of mass** of the system is the mass-weighted average position

$$\mathbf{R} = \frac{1}{M} \sum_i m_i \mathbf{x}_i, \quad \text{where } M = \sum_i m_i \text{ is the total mass.}$$

The total momentum of the system is then $\mathbf{P} = \sum_i \mathbf{p}_i = M\dot{\mathbf{R}}$ – exactly the momentum of a single particle of mass M moving with the centre of mass.

Proposition 3.5.2 (Motion of the Centre of Mass)

$$M\ddot{\mathbf{R}} = \dot{\mathbf{P}} = \sum_i \mathbf{F}_i^{\text{ext}}.$$

Proof. Summing Newton's second law over the particles,

$$\dot{\mathbf{P}} = \sum_i \dot{\mathbf{p}}_i = \sum_i \mathbf{F}_i^{\text{ext}} + \sum_i \sum_{j \neq i} \mathbf{F}_{ij} = \sum_i \mathbf{F}_i^{\text{ext}} + \frac{1}{2} \sum_{i \neq j} (\mathbf{F}_{ij} + \mathbf{F}_{ji}) = \sum_i \mathbf{F}_i^{\text{ext}},$$

where the internal forces cancel in pairs by Newton's third law. $\square$

Thus the motion of the centre of mass is not influenced by internal forces at all – when a firework explodes, its centre of mass continues serenely along a parabola. This proposition is also what justifies treating extended bodies as particles: as far as its total momentum is concerned, a body *is* a particle of mass M at $\mathbf{R}$. If there is no external force, we then have *conservation of momentum*, $\dot{\mathbf{P}} = \mathbf{0}$. In this case the centre of mass moves uniformly, and it is often convenient to change to an inertial frame in which $\mathbf{R}$ is at rest at the origin – the **centre of mass frame**.

Example 3.5.3 (An Exploding Shell)

A shell is launched from the origin and, at the top of its parabolic flight, moving horizontally with speed v , explodes into two equal fragments. One fragment is observed to be momentarily at rest just after the explosion. Where does the other one go? Conservation of momentum across the explosion (the explosive forces are internal, and gravity's impulse during the brief explosion is negligible) gives

$$mv = \frac{m}{2} \cdot 0 + \frac{m}{2} v_2 \implies v_2 = 2v.$$

The second fragment moves off horizontally at double the speed. Both fragments then fall freely, and – as the proposition guarantees – the centre of mass of the pair continues along the *original* parabola exactly as if nothing had happened, with the

stationary fragment dropping straight down and the fast one landing correspondingly further along.

§3.5.2 Angular Momentum of a System

We define the total angular momentum of the system about the origin as

$$\mathbf{L} = \sum_i \mathbf{x}_i \times \mathbf{p}_i.$$

Differentiating, and using Newton's second and third laws as before,

$$\dot{\mathbf{L}} = \sum_i \mathbf{x}_i \times \dot{\mathbf{p}}_i = \sum_i \mathbf{x}_i \times \mathbf{F}_i^{\text{ext}} + \frac{1}{2} \sum_{i \neq j} (\mathbf{x}_i - \mathbf{x}_j) \times \mathbf{F}_{ij}.$$

To make the final sum vanish we need slightly more than Newton's third law: we need the internal forces to be *central*, that is $\mathbf{F}_{ij} \parallel (\mathbf{x}_i - \mathbf{x}_j)$, so that each term of the sum is zero. This is true of gravity and of electrostatic forces, so we will assume it. Then

$$\dot{\mathbf{L}} = \sum_i \mathbf{x}_i \times \mathbf{F}_i^{\text{ext}} = \boldsymbol{\tau}^{\text{ext}},$$

the total *external* torque. So, just as internal forces cannot change the total momentum, (central) internal forces cannot change the total angular momentum, and if the total external torque vanishes then $\mathbf{L}$ is conserved.

§3.5.3 Motion Relative to the Centre of Mass

Externally, then, a system of particles behaves like a point mass at $\mathbf{R}$. What about the internal motion? Write

$$\mathbf{x}_i = \mathbf{R} + \mathbf{y}_i,$$

where $\mathbf{y}_i$ is the position of particle i *relative to the centre of mass*. Directly from the definition of $\mathbf{R}$ we get the two useful identities

$$\sum_i m_i \mathbf{y}_i = \mathbf{0}, \quad \sum_i m_i \dot{\mathbf{y}}_i = \mathbf{0}.$$

Substituting into the angular momentum and expanding, the cross terms vanish by these identities, leaving

$$\mathbf{L} = M\mathbf{R} \times \dot{\mathbf{R}} + \sum_i m_i \mathbf{y}_i \times \dot{\mathbf{y}}_i.$$

Similarly for the kinetic energy:

$$T = \frac{1}{2} \sum_i m_i |\dot{\mathbf{x}}_i|^2 = \underbrace{\frac{1}{2} M |\dot{\mathbf{R}}|^2}_{\text{motion of the CoM}} + \underbrace{\frac{1}{2} \sum_i m_i |\dot{\mathbf{y}}_i|^2}_{\text{motion about the CoM}}.$$

Both quantities split cleanly into a 'centre of mass part' plus an 'internal part', with no interference between the two. These decompositions will be the key to understanding rigid bodies in Section 3.6.

Finally, energy. If the external forces are conservative with $\mathbf{F}_i^{\text{ext}} = -\nabla_i V_i(\mathbf{x}_i)$, and the internal forces are conservative with potentials depending on separations only, $\mathbf{F}_{ij} = -\nabla_i V_{ij}(\mathbf{x}_i - \mathbf{x}_j)$, then the total energy

$$E = T + \sum_i V_i(\mathbf{x}_i) + \frac{1}{2} \sum_{i \neq j} V_{ij}(\mathbf{x}_i - \mathbf{x}_j)$$

is conserved – the proof is the same differentiate-and-cancel argument as ever.

§3.5.4 The Two-Body Problem

The simplest multi-particle system has just two particles, interacting through a force obeying Newton's third law – say two bodies moving under mutual gravity. This is the *two-body problem*, and it can be solved completely by a change of variables.

Let the particles have masses m_1, m_2 and positions $\mathbf{x}_1, \mathbf{x}_2$. The clever move is to trade $\mathbf{x}_1, \mathbf{x}_2$ for the centre of mass and the *separation vector*:

$$\mathbf{R} = \frac{m_1 \mathbf{x}_1 + m_2 \mathbf{x}_2}{M}, \quad \mathbf{r} = \mathbf{x}_1 - \mathbf{x}_2,$$

where $M = m_1 + m_2$, so that

$$\mathbf{x}_1 = \mathbf{R} + \frac{m_2}{M} \mathbf{r}, \quad \mathbf{x}_2 = \mathbf{R} - \frac{m_1}{M} \mathbf{r}.$$

With no external forces, we know $\ddot{\mathbf{R}} = \mathbf{0}$, so the centre of mass moves uniformly and can be taken as the origin of an inertial frame. Meanwhile,

$$\ddot{\mathbf{r}} = \ddot{\mathbf{x}}_1 - \ddot{\mathbf{x}}_2 = \frac{\mathbf{F}_{12}}{m_1} - \frac{\mathbf{F}_{21}}{m_2} = \left(\frac{1}{m_1} + \frac{1}{m_2} \right) \mathbf{F}_{12},$$

which we can rewrite as

$$\mu \ddot{\mathbf{r}} = \mathbf{F}_{12}(\mathbf{r}), \quad \text{where } \mu = \frac{m_1 m_2}{m_1 + m_2}$$

is called the **reduced mass**. This is exactly the equation for a *single* particle of mass μ at position $\mathbf{r}$ moving about a fixed centre of force – which is the problem we solved in the orbits section! The two-body problem thus reduces entirely to the one-body Kepler problem, and one can check that the angular momentum and kinetic energy also split accordingly:

$$\mathbf{L} = M \mathbf{R} \times \dot{\mathbf{R}} + \mu \mathbf{r} \times \dot{\mathbf{r}}, \quad T = \frac{1}{2} M |\dot{\mathbf{R}}|^2 + \frac{1}{2} \mu |\dot{\mathbf{r}}|^2.$$

Example 3.5.4 (Binary Orbits)

For two bodies under mutual gravity, $\mathbf{F}_{12} = -Gm_1m_2\hat{\mathbf{r}}/|\mathbf{r}|^2$, so

$$\mu\ddot{\mathbf{r}} = -\frac{Gm_1m_2}{|\mathbf{r}|^2}\hat{\mathbf{r}} \implies \ddot{\mathbf{r}} = -\frac{GM}{|\mathbf{r}|^2}\hat{\mathbf{r}}.$$

So the *separation* traces out a conic exactly as before, but with the total mass M appearing in the force law. In the centre of mass frame, each body individually moves in an ellipse about the (fixed) centre of mass, with

$$\mathbf{x}_1 = \frac{m_2}{M}\mathbf{r}, \quad \mathbf{x}_2 = -\frac{m_1}{M}\mathbf{r},$$

so the two ellipses are similar, scaled by the mass ratio, with the bodies always on opposite sides of the centre of mass. When $m_1 \ll m_2$ (a planet and the Sun), $\mu \approx m_1$ and the centre of mass sits essentially at the heavier body – recovering our fixed-Sun approximation, with a small correction: the Sun itself executes a miniature ellipse. It is exactly this tiny stellar ‘wobble’ that provided some of the first detections of planets around other stars.

§3.5.5 Collisions

A *collision* is an interaction between two bodies which is brief and localised: before and after, the bodies move freely. Whatever complicated internal forces act during the collision, they are internal, so the *total momentum is always conserved*:

$$m_1\mathbf{u}_1 + m_2\mathbf{u}_2 = m_1\mathbf{v}_1 + m_2\mathbf{v}_2,$$

where $\mathbf{u}_i$ are velocities before and $\mathbf{v}_i$ after. Kinetic energy is a different matter – it may be transferred into heat, sound or deformation. We distinguish:

- *Elastic collisions*, in which the total kinetic energy is also conserved;
- *Inelastic collisions*, in which some kinetic energy is lost (a *totally* inelastic collision being one in which the bodies coalesce).

Example 3.5.5 (Elastic Collision in One Dimension)

Let a particle of mass m_1 and velocity u strike a stationary particle of mass m_2 , elastically, in one dimension.

Conservation of momentum and energy give

$$m_1u = m_1v_1 + m_2v_2, \quad \frac{1}{2}m_1u^2 = \frac{1}{2}m_1v_1^2 + \frac{1}{2}m_2v_2^2.$$

Rearranging the first as $m_1(u - v_1) = m_2v_2$ and the second as $m_1(u - v_1)(u + v_1) = m_2v_2^2$, then dividing (assuming a genuine collision, $v_2 \neq 0$), we get $u + v_1 = v_2$, and

hence

$$v_1 = \frac{m_1 - m_2}{m_1 + m_2}u, \quad v_2 = \frac{2m_1}{m_1 + m_2}u.$$

The limiting cases are instructive. If $m_1 = m_2$, then $v_1 = 0$ and $v_2 = u$: the particles simply exchange velocities, as anyone who has played snooker knows. If $m_2 \gg m_1$ (a ball bouncing off a wall), $v_1 \approx -u$: the light particle bounces straight back. If $m_1 \gg m_2$, the heavy particle barrels on essentially unaffected, and the light one is flung ahead at $v_2 \approx 2u$.

Example 3.5.6 (Totally Inelastic Collision)

If instead the two particles coalesce, momentum conservation alone determines the outcome:

$$v = \frac{m_1 u}{m_1 + m_2}.$$

The kinetic energy lost is

$$\Delta T = \frac{1}{2}m_1 u^2 - \frac{1}{2}(m_1 + m_2)v^2 = \frac{1}{2}\mu u^2,$$

where μ is the reduced mass – precisely the kinetic energy of the *relative* motion. This makes sense: the centre of mass motion cannot be destroyed (momentum conservation), so the most energy a collision can possibly dissipate is the internal part, and a totally inelastic collision dissipates exactly that.

In higher dimensions, the same conservation laws apply, but they no longer determine the outcome uniquely – the scattering angle remains free. A classic result: for an elastic collision between *equal* masses, one initially at rest, conservation of momentum gives $\mathbf{u}_1 = \mathbf{v}_1 + \mathbf{v}_2$, and conservation of energy gives $|\mathbf{u}_1|^2 = |\mathbf{v}_1|^2 + |\mathbf{v}_2|^2$. Squaring the first equation and comparing, $\mathbf{v}_1 \cdot \mathbf{v}_2 = 0$: the particles move off *at right angles* (unless one of them is at rest). We will revisit this in special relativity, where the right angle closes up.

Remark. Real collisions sit between the elastic and totally inelastic extremes. A common phenomenological model (‘Newton’s experimental law’) assigns a collision a *coefficient of restitution* $e \in [0, 1]$: the relative velocity of separation is e times the relative velocity of approach. Then $e = 1$ is the elastic case, $e = 0$ the totally inelastic one, and one can check that the kinetic energy lost is $\frac{1}{2}\mu(1 - e^2)|\mathbf{u}_1 - \mathbf{u}_2|^2$, interpolating between our two examples.

§3.5.6 Variable Mass Problems & The Rocket Equation

Newton’s second law reads $\dot{\mathbf{p}} = \mathbf{F}$ with $\mathbf{p} = m\mathbf{v}$ – and nothing in it requires m to be constant. Systems that gain or lose mass are everywhere: rockets burning fuel, raindrops accreting from a cloud, snowballs rolling downhill. The subtlety is that the mass that leaves (or joins) carries momentum with it, so we must be careful to apply the second law to a fixed collection of matter.

Consider the classic case: a rocket of mass $m(t)$ moving in a straight line with velocity $v(t)$, propelling itself by ejecting exhaust backwards with speed u *relative to the rocket*.

Consider the total system of rocket plus exhaust between times t and $t + \delta t$. At time t , the momentum is $m(t)v(t)$. At time $t + \delta t$, the rocket has mass $m(t + \delta t)$ and velocity $v(t + \delta t)$, and the mass $m(t) - m(t + \delta t)$ of ejected exhaust travels with velocity $v(t) - u + O(\delta t)$. So the change in total momentum is

$$\begin{aligned}\delta p &= m(t + \delta t)v(t + \delta t) + [m(t) - m(t + \delta t)][v(t) - u] - m(t)v(t) + O(\delta t^2) \\ &= (m + \dot{m}\delta t)(v + \dot{v}\delta t) - \dot{m}\delta t(v - u) - mv + O(\delta t^2) \\ &= (m\dot{v} + \dot{m}u)\delta t + O(\delta t^2).\end{aligned}$$

Newton's second law applied to the whole system (whose total mass *is* constant) says $\delta p / \delta t \rightarrow F$, the external force on the rocket. We obtain:

Proposition 3.5.7 (The Rocket Equation)

$$m \frac{dv}{dt} + u \frac{dm}{dt} = F.$$

Note $\dot{m} < 0$ for a rocket, so the second term acts as a forward thrust of magnitude $u|\dot{m}|$.

Example 3.5.8 (Rocket in Free Space)

In deep space, $F = 0$, and taking the exhaust speed u constant,

$$m \frac{dv}{dt} = -u \frac{dm}{dt} \implies \frac{dv}{dm} = -\frac{u}{m} \implies v = v_0 + u \log \left(\frac{m_0}{m} \right),$$

the *Tsiolkovsky rocket equation*. Two features deserve comment. First, the final velocity depends only on the exhaust speed and the fraction of mass burnt – not on *how fast* the fuel is burnt. Second, the dependence on the mass ratio is only logarithmic, which is the tyranny of rocketry: to gain speed $u \log 10 \approx 2.3u$, ninety percent of your initial mass must be fuel. This is why real rockets are almost entirely fuel tank, and why they shed stages as they climb – dropping an empty tank of mass m_{tank} improves every subsequent burn's mass ratio, and multi-stage rockets squeeze substantially more final velocity out of the same fuel.

Example 3.5.9 (A Falling Raindrop)

For a raindrop falling through a stationary cloud and accreting mass, the accreted mass is at rest, so relative to the drop it arrives with speed $u = v$ (opposing the motion). With gravity as the external force, the rocket equation gives

$$m \frac{dv}{dt} + v \frac{dm}{dt} = \frac{d}{dt}(mv) = mg,$$

that is, the momentum mv grows at rate mg . To go further we need a model for the accretion rate; for instance, if $\dot{m} = kmv$ (sweeping up mass in proportion to the volume swept out), one can show the drop approaches a constant terminal *acceleration* of $g/7$ – a fun exercise.

§3.6 Rigid Bodies

In many cases, we want to study a system of particles such that the particles are constrained such that their relative positions are fixed. Such systems correspond to solid objects that cannot deform, break or bend. Such systems are called *rigid bodies*. Everything we established for general systems of particles – the motion of the centre of mass, $\dot{\mathbf{P}} = \mathbf{F}^{\text{ext}}$ and $\dot{\mathbf{L}} = \boldsymbol{\tau}^{\text{ext}}$, the decompositions of energy and angular momentum – applies verbatim; what the rigidity constraint buys us is that the internal motion is always a *rotation*, so the whole configuration is captured by just a position and an orientation.

§3.6.1 Angular Velocity

Suppose a rigid body $\mathcal{B}$ is rotating about a fixed axis with angular speed ω . If $\hat{\mathbf{n}}$ is the unit vector parallel to the rotation axis, we define the *vector angular velocity* of $\mathcal{B}$ to be

$$\boldsymbol{\omega} = \omega \hat{\mathbf{n}},$$

where we choose the sign such that a positive ω corresponds to a right-handed rotation about the axis in the direction $\hat{\mathbf{n}}$.

If P is a particle in the rigid body $\mathcal{B}$, then its velocity due to the rotation of the body is given by

$$\mathbf{v} = \boldsymbol{\omega} \times (\mathbf{r} - \mathbf{b}),$$

where $\mathbf{b}$ is the position vector corresponding to any fixed point B on the rotation axis.

§3.6.2 Moment of Inertia

Now suppose we have a rigid body made up of N particles, rotating with angular velocity $\boldsymbol{\omega}$. Then we could write down the kinetic energy for the rigid body as

$$T = \frac{1}{2} \sum_i m_i \dot{\mathbf{x}}_i \cdot \dot{\mathbf{x}}_i = \frac{1}{2} I \omega^2,$$

where

$$I = \sum_{i=1}^N m_i d_i^2$$

is the **moment of inertia**, and d_i is the perpendicular distance from particle i to the axis of rotation.

The intuition behind moments of inertia is that they are to rotations what mass is to translations: the larger I is, the more energy you need to supply to the body to make it spin.

§3.6.3 Angular Momentum and Moments of Inertia

Recall that the angular momentum of a body is

$$\mathbf{L} = \sum_i m_i \mathbf{x}_i \times \dot{\mathbf{x}}_i.$$

Suppose that the body is rotating with angular velocity $\omega \hat{\mathbf{n}}$ about an axis through the origin. Then the component of angular momentum in the $\hat{\mathbf{n}}$ direction is given by

$$\begin{aligned}\mathbf{L} \cdot \hat{\mathbf{n}} &= \sum_i m_i \mathbf{x}_i \times (\omega \times \mathbf{x}_i) \cdot \hat{\mathbf{n}} \\ &= \omega \sum_i m_i (\mathbf{x}_i \times \hat{\mathbf{n}}) \cdot (\mathbf{x}_i \times \hat{\mathbf{n}}) \\ &= I\omega,\end{aligned}$$

since $|\mathbf{x}_i \times \hat{\mathbf{n}}| = d_i$, the perpendicular distance of particle i from the axis. (The components of $\mathbf{L}$ perpendicular to $\hat{\mathbf{n}}$ need not vanish, and in general $\mathbf{L}$ is *not* parallel to ω – but we will not need this complication in this course.) If there's a torque τ acting on the rigid body in the same direction as the angular velocity, so $\tau = \tau \hat{\mathbf{n}}$, then $I\dot{\omega} = \tau$.

§3.6.4 Calculating Moments of Inertia

If we consider the rigid body as a continuous object with density distribution $\rho(\mathbf{x})$, then the sums of the previous section become integrals, and the moment of inertia is given by

$$I = \int \rho(\mathbf{x}) x_{\perp}^2 dV,$$

where $x_{\perp}$ is the perpendicular distance from $\mathbf{x}$ to the axis of rotation. Let's compute a few of the standard examples properly.

Example 3.6.1 (Thin Rod)

Take a uniform thin rod of mass M and length $2a$, rotating about an axis through its centre, perpendicular to the rod.

The mass per unit length is $\rho = M/2a$, and a point at position $x \in [-a, a]$ along the rod is at distance $|x|$ from the axis. So

$$I = \int_{-a}^a \frac{M}{2a} x^2 dx = \frac{M}{2a} \cdot \frac{2a^3}{3} = \frac{1}{3}Ma^2.$$

Example 3.6.2 (Circular Hoop and Disc)

For a hoop of mass M and radius a , about the axis through its centre perpendicular to its plane, every point is at distance exactly a from the axis, so immediately $I = Ma^2$.

For a uniform disc of mass M and radius a about the same axis, the surface density is $\rho = M/\pi a^2$, and working in plane polar coordinates with area element $r dr d\theta$,

$$I = \int_0^{2\pi} \int_0^a \frac{M}{\pi a^2} r^2 \cdot r dr d\theta = \frac{M}{\pi a^2} \cdot 2\pi \cdot \frac{a^4}{4} = \frac{1}{2}Ma^2.$$

Here we have summed over rings of radius r and thickness dr (shaded), each of which contributes mass at a common distance r from the axis.

Example 3.6.3 (Solid Sphere)

For a uniform solid sphere of mass M and radius a about an axis through its centre, take the axis to be the z -axis and use the density $\rho = 3M/4\pi a^3$. Slicing the sphere into discs of thickness dz at height z , each of radius $\sqrt{a^2 - z^2}$, and using the disc result,

$$I = \int_{-a}^a \frac{1}{2} (\rho\pi(a^2 - z^2)) (a^2 - z^2) dz = \frac{\rho\pi}{2} \int_{-a}^a (a^2 - z^2)^2 dz = \frac{\rho\pi}{2} \cdot \frac{16a^5}{15} = \frac{2}{5}Ma^2.$$

Collecting these (all worth remembering):

1. *Thin Rod.* With mass M and length $2a$, about an axis perpendicular to the rod through its centre: $I = \frac{1}{3}Ma^2$.
2. *Circular Hoop.* With mass M and radius a , about an axis perpendicular to the plane of the hoop through its centre: $I = Ma^2$.
3. *Circular Disc.* With mass M and radius a , about an axis perpendicular to the plane of the disc through its centre: $I = \frac{1}{2}Ma^2$.
4. *Solid Sphere.* With mass M and radius a , about an axis through its centre: $I = \frac{2}{5}Ma^2$.

Two general theorems let us transport these results to other axes without redoing any integrals.

Theorem 3.6.4 (Parallel Axis Theorem)

If a rigid body of mass M has moment of inertia I_G about an axis through its centre of mass, then its moment of inertia about a parallel axis a distance d away is

$$I = I_G + Md^2.$$

Proof. Set up coordinates with origin at the centre of mass and the first axis along $\mathbf{e}_z$, and let the parallel axis pass through the point $d\mathbf{e}_x$. Writing $\mathbf{x}_i = (x_i, y_i, z_i)$ for the particles of the body, the perpendicular distance from particle i to the new axis satisfies $d_i'^2 = (x_i - d)^2 + y_i^2$. So

$$I = \sum_i m_i ((x_i - d)^2 + y_i^2) = \sum_i m_i (x_i^2 + y_i^2) - 2d \sum_i m_i x_i + d^2 \sum_i m_i = I_G + Md^2,$$

where the middle sum vanishes because the centre of mass is at the origin. $\square$

Note in particular that $I \geq I_G$: of all axes in a given direction, the one through the centre of mass gives the smallest moment of inertia.

Theorem 3.6.5 (Perpendicular Axis Theorem)

For a two dimensional body (a *lamina*) lying in the (x, y) plane, the moments of inertia about the coordinate axes satisfy

$$I_z = I_x + I_y.$$

Proof. Since $z_i = 0$ for every particle, we have $I_x = \sum m_i y_i^2$ and $I_y = \sum m_i x_i^2$, while $I_z = \sum m_i (x_i^2 + y_i^2) = I_x + I_y$. $\square$

Example 3.6.6

For the uniform disc, by symmetry $I_x = I_y$, and $I_z = \frac{1}{2}Ma^2$ from before. So the moment of inertia of a disc about one of its *diameters* is $I_x = \frac{1}{4}Ma^2$ – no integration required. Similarly, using the parallel axis theorem, a rod of length $2a$ spun about one of its *ends* has $I = \frac{1}{3}Ma^2 + Ma^2 = \frac{4}{3}Ma^2$.

Example 3.6.7 (Rectangular Lamina)

For a uniform rectangular plate of mass M with sides $2a$ and $2b$, the moment of inertia about the in-plane axis through the centre parallel to the side of length $2b$ only ‘sees’ the x -extent of the mass, so it equals that of a rod: $I_y = \frac{1}{3}Ma^2$, and likewise $I_x = \frac{1}{3}Mb^2$. The perpendicular axis theorem then gives, for the axis through the centre perpendicular to the plate,

$$I_z = I_x + I_y = \frac{1}{3}M(a^2 + b^2),$$

with all three answers obtained from a single one dimensional integral.

§3.6.5 Motion of Rigid Bodies

The general motion of a rigid body is a translation of its centre of mass along some trajectory $\mathbf{R}(t)$, together with a rotation about an axis through the centre of mass. Writing $\mathbf{x}_i = \mathbf{R} + \mathbf{y}_i$ as in Section 3.5, the rigidity constraint means the relative positions $\mathbf{y}_i$ evolve by pure rotation, so

$$\dot{\mathbf{x}}_i = \dot{\mathbf{R}} + \boldsymbol{\omega} \times \mathbf{y}_i$$

for some angular velocity $\boldsymbol{\omega}(t)$. Our kinetic energy decomposition then becomes

$$T = \frac{1}{2}M|\dot{\mathbf{R}}|^2 + \frac{1}{2}\sum_i m_i |\boldsymbol{\omega} \times \mathbf{y}_i|^2 = \underbrace{\frac{1}{2}M|\dot{\mathbf{R}}|^2}_{\text{translational}} + \underbrace{\frac{1}{2}I_G \omega^2}_{\text{rotational}},$$

where I_G is the moment of inertia about the axis through the centre of mass in the direction of $\boldsymbol{\omega}$. The motion is governed by our two equations for systems of particles,

$$\dot{\mathbf{P}} = \mathbf{F}^{\text{ext}}, \quad \dot{\mathbf{L}} = \boldsymbol{\tau}^{\text{ext}},$$

where the angular momentum and torque may be taken about any fixed point of an inertial frame, *or* about the centre of mass – the latter works even when the centre of mass is accelerating, since the fictitious forces this introduces have zero net torque about the centre of mass.⁵

In a *uniform* gravitational field, the external force and torque take a particularly nice form:

$$\mathbf{F} = \sum_i m_i \mathbf{g} = M \mathbf{g}, \quad \boldsymbol{\tau} = \sum_i \mathbf{x}_i \times m_i \mathbf{g} = M \mathbf{R} \times \mathbf{g}.$$

Both are exactly what would act on a single particle of mass M at the centre of mass. In particular, the gravitational torque *about* the centre of mass vanishes.

Example 3.6.8 (A Thrown Stick)

Throw a uniform stick spinning through the air (ignoring air resistance). The centre of mass traces a parabola, exactly as a point particle would. Meanwhile, since gravity exerts no torque about the centre of mass, $\dot{\mathbf{L}}^{\text{CoM}} = \mathbf{0}$, and the stick rotates with constant angular velocity about its centre as it flies.

§3.6.6 The Compound Pendulum

Our equation for rotation about a fixed axis is already enough to handle a classic example – a pendulum made from an arbitrary rigid body.

Example 3.6.9 (The Compound Pendulum)

A rigid body is free to swing under gravity in a vertical plane about a fixed horizontal axis through a point P , which is a distance d from the centre of mass G . Let θ be the angle of PG from the downward vertical, and let I be the moment of inertia of the body about the axis through P (computable via the parallel axis theorem: $I = I_G + Md^2$).

The body rotates about the fixed point P , so $L = I\dot{\theta}$, and the torque about P is due to gravity acting at the centre of mass:

$$I\ddot{\theta} = -Mgd \sin \theta.$$

This is exactly the simple pendulum equation, so all our pendulum analysis applies:

⁵In the accelerating centre of mass frame, each particle feels a fictitious force $-m_i \ddot{\mathbf{R}}$, and the total torque of these about the centre of mass is $-(\sum_i m_i \mathbf{y}_i) \times \ddot{\mathbf{R}} = \mathbf{0}$.

small oscillations have angular frequency

$$\omega = \sqrt{\frac{Mgd}{I}},$$

i.e. the body behaves as a simple pendulum of *effective length* $\ell_{\text{eff}} = I/Md$.

For instance, for a uniform rod of length ℓ pivoted at one end, we have $d = \ell/2$ and (from our earlier example, with $2a = \ell$) $I = \frac{1}{3}M\ell^2$, so

$$\ddot{\theta} = -\frac{3g}{2\ell} \sin \theta,$$

and the rod swings like a simple pendulum of length $2\ell/3$. The same equation drops out of energy conservation: differentiating $E = \frac{1}{2}I\dot{\theta}^2 - Mgd\cos\theta$ with respect to time and cancelling $\dot{\theta}$ recovers the equation of motion.

Example 3.6.10 (The Centre of Percussion)

Here is a question every cricketer cares about: where should the ball strike the bat so that your hands feel no jarring? Model the bat as a uniform rod of mass M and length ℓ , held (pivoted) at one end, and suppose the ball delivers a sharp horizontal impulse J at a distance b from the pivot. During the blow, the pivot exerts some impulsive reaction R on the rod.

Take angular impulse about the pivot (about which $I = \frac{1}{3}M\ell^2$): the reaction has no moment there, so

$$I \Delta\omega = Jb \implies \Delta\omega = \frac{Jb}{I}.$$

Meanwhile the linear impulse determines the change in velocity of the centre of mass, which sits at $d = \ell/2$ from the pivot and moves with velocity $d \Delta\omega$ after the blow:

$$J + R = Md \Delta\omega = \frac{MdJb}{I} \implies R = J \left(\frac{Mdb}{I} - 1 \right).$$

The reaction at the hands vanishes exactly when

$$b = \frac{I}{Md} = \frac{\frac{1}{3}M\ell^2}{M\ell/2} = \frac{2\ell}{3}.$$

This point is called the **centre of percussion** – strike there and the bat pivots cleanly about your hands with no sting; strike elsewhere and $R \neq 0$, which your palms report immediately. Note it is the same point $2\ell/3$ that appeared as the ‘effective length’ of the swinging rod, which is no coincidence: both are the point where the rod behaves like an equivalent simple pendulum.

§3.6.7 Rolling Without Slipping

Consider a circular object – a cylinder, hoop or sphere – of radius a , moving along a surface, with its centre moving at speed v and the body rotating at angular speed ω about its centre. The velocity of the material point of the body instantaneously in contact with the surface is

$$v_{\text{slip}} = v - a\omega.$$

There are two qualitatively different regimes:

- *Sliding*: $v_{\text{slip}} \neq 0$. The contact point scrapes along the surface, kinetic friction μN acts to oppose the slipping, and mechanical energy is dissipated.
- *Rolling*: $v_{\text{slip}} = 0$, i.e. $v = a\omega$. This is the **rolling without slipping** condition. The contact point is instantaneously stationary – so although friction may act (and is often what *enforces* rolling), it acts at a point moving with zero velocity, and hence *does no work*. Energy is conserved for rolling bodies.

A rolling body can equivalently be viewed as rotating with angular speed ω about the (instantaneously stationary) contact point.

Example 3.6.11 (Rolling Down a Slope)

A uniform cylinder or sphere of mass M , radius a and moment of inertia I (about its axis through the centre of mass) rolls without slipping down a plane inclined at angle α . Let x be the distance travelled down the slope, so the rolling condition gives $\omega = \dot{x}/a$. The energy

$$E = \frac{1}{2}M\dot{x}^2 + \frac{1}{2}I\omega^2 - Mgx \sin \alpha = \frac{1}{2} \left(M + \frac{I}{a^2} \right) \dot{x}^2 - Mgx \sin \alpha$$

is conserved (friction does no work while rolling), so differentiating and cancelling $\dot{x}$,

$$\ddot{x} = \frac{g \sin \alpha}{1 + I/Ma^2}.$$

The body accelerates more slowly than the sliding value $g \sin \alpha$, because some of the released potential energy must be spent spinning it up. The acceleration depends only on the *shape* through the ratio I/Ma^2 : a solid sphere ($I = \frac{2}{5}Ma^2$) has $\ddot{x} = \frac{5}{7}g \sin \alpha$, a solid cylinder ($\frac{1}{2}Ma^2$) has $\frac{2}{3}g \sin \alpha$, and a hoop (Ma^2) has $\frac{1}{2}g \sin \alpha$. So in a race down a hill, the sphere beats the cylinder, which beats the hoop, with the masses and radii entirely irrelevant. The same result follows from the force/torque equations $M\dot{v} = Mg \sin \alpha - F$ and $I\dot{\omega} = aF$, where F is the friction force enforcing the rolling.

Example 3.6.12 (The Struck Snooker Ball)

A snooker ball (a uniform sphere, $I = \frac{2}{5}Ma^2$) is struck centrally, so it initially translates with speed v_0 but does not spin: $v = v_0$, $\omega = 0$, and so $v_{\text{slip}} = v_0 > 0$. The ball is sliding, so kinetic friction $F = \mu_k Mg$ acts backwards at the contact point, and

$$M\dot{v} = -\mu_k Mg, \quad I\dot{\omega} = a\mu_k Mg.$$

So the ball slows down while spinning up:

$$v(t) = v_0 - \mu_k g t, \quad a\omega(t) = \frac{5}{2} \mu_k g t,$$

and the slip velocity $v_{\text{slip}} = v_0 - \frac{7}{2} \mu_k g t$ decreases to zero at time $t_{\text{roll}} = \frac{2v_0}{7\mu_k g}$. At that moment $v = a\omega = \frac{5}{7}v_0$, rolling begins, friction ceases to act (no applied force, no tendency to slip), and the ball rolls on at constant speed $\frac{5}{7}v_0$. The kinetic energy at this point is

$$\frac{1}{2} \left(M + \frac{I}{a^2} \right) v^2 = \frac{7}{10} M \cdot \frac{25}{49} v_0^2 = \frac{5}{14} M v_0^2 < \frac{1}{2} M v_0^2,$$

the difference having been dissipated by friction during the sliding phase.

Example 3.6.13 (When Does Rolling Fail?)

Return to the body on the inclined plane, and ask: how steep can the slope be before rolling becomes impossible? While rolling, the friction force required to sustain the motion is, from the equations $M\dot{v} = Mg \sin \alpha - F$ and $I\dot{\omega} = aF$ with $\dot{v} = a\dot{\omega}$,

$$F = \frac{I/a^2}{M + I/a^2} Mg \sin \alpha.$$

But static friction can supply at most $\mu N = \mu Mg \cos \alpha$. So rolling is sustainable only if

$$\tan \alpha \leq \mu \left(1 + \frac{Ma^2}{I} \right).$$

On steeper slopes the contact point must slip, and the body slides as it spins. Note the shape-dependence again: a hoop ($I = Ma^2$) demands the most friction and starts slipping first, while a solid sphere holds on to steeper slopes.

§3.7 Special Relativity

We now leave Newtonian mechanics behind. The trouble began with electromagnetism: Maxwell's equations predict that light travels at a definite speed $c \approx 3 \times 10^8 \text{ m s}^{-1}$ – but a speed relative to *what*? Under Galilean transformations, velocities simply add, so different inertial observers should measure different speeds of light, and experiments (most famously that of Michelson and Morley) resolutely failed to detect any such difference. Einstein's 1905 resolution was radical: keep the principle of relativity, keep the constancy of the speed of light, and let our assumptions about space and time – including Galilean transformations and absolute time itself – fall where they may.

§3.7.1 Axioms of Special Relativity

The whole of special relativity is built upon two deceptively simple postulates.

Axiom 3.7.1 (Postulates of Special Relativity) 1. *Principle of relativity.* The laws of physics are the same in all inertial reference frames.

2. *Constancy of the speed of light.* The speed of light in a vacuum is the same in all inertial reference frames.

The first postulate is just Galilean relativity as before. The second sounds innocuous but is flatly incompatible with the Galilean transformations: if a light ray passes you at speed c , and I chase after it at speed $c/2$, the second postulate insists that I *also* measure the light receding at speed c , not $c/2$. Clearly velocity addition – and with it, our notions of time and length – must be rebuilt from scratch.

Aside: The Michelson–Morley Experiment

Nineteenth-century physics held that light waves, like all other waves, must propagate in *some* medium – the ‘luminiferous ether’ – and that Maxwell’s c was the speed of light relative to it. The Earth, orbiting the Sun at about 30 km s^{-1} , ought then to be moving through the ether, and light should travel at measurably different speeds in different directions.

In 1887, Michelson and Morley set out to detect this using an interferometer: a light beam is split, sent down two perpendicular arms, reflected back, and recombined, with any difference in travel times showing up as a shift in the interference fringes as the apparatus is rotated. The expected effect was well within their sensitivity. They found *nothing* – no fringe shift, in any season, in any orientation. It is one of the most famous null results in the history of science.

Various rescues were attempted, most notably by FitzGerald and Lorentz, who observed that the null result could be explained if objects moving through the ether contracted by a factor $\sqrt{1 - v^2/c^2}$ in their direction of motion – the right formula, proposed as a mysterious dynamical accident. Einstein’s 1905 insight was that no ether and no accident are needed: if the speed of light is simply the same in every inertial frame, the contraction (and much else) follows from the geometry of space and time itself. That is the theory we now develop.

§3.7.2 Lorentz Transformations

In special relativity we think in terms of **events**: instantaneous, point-like occurrences. These are specified by four coordinates, one of time and three of position, like (t, x, y, z) . These coordinates will be measured differently in different inertial frames, and to make our axioms hold we need to use a new set of transformation laws.

Let $\mathcal{F}$ and $\mathcal{F}'$ be inertial frames, with $\mathcal{F}'$ moving at speed v relative to $\mathcal{F}$ in the x direction, in a *standard configuration*: axes aligned, origins coinciding at $t = t' = 0$. What could the transformation between them look like? We will sketch how the axioms pin it down. First, the transformation must map unaccelerated motion to unaccelerated motion (both frames are inertial), and this forces it to be *linear* in (t, x) . Motion transverse to the boost cannot be affected (by symmetry of the setup) so $y' = y$ and $z' = z$, and the origin of $\mathcal{F}'$ (i.e. $x' = 0$) must move along $x = vt$, so

$$x' = \gamma(x - vt)$$

for some factor $\gamma(v)$. By the principle of relativity, the inverse transformation must take the same form with $v \mapsto -v$ (and the same γ , which can depend only on $|v|$, again by symmetry):

$$x = \gamma(x' + vt').$$

Now impose the second postulate: a light ray through the origin has $x = ct$ in $\mathcal{F}$, and must also have $x' = ct'$ in $\mathcal{F}'$. Substituting both into the two equations above,

$$ct' = \gamma t(c - v), \quad ct = \gamma t'(c + v),$$

and multiplying these together gives $c^2 = \gamma^2(c - v)(c + v)$, so

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}},$$

the famous **Lorentz factor**. Eliminating x' between the two boxed-style relations then yields the transformation of time. The result is the **Lorentz transformation**:

$$\begin{aligned} ct' &= \gamma \left(ct - \frac{v}{c}x \right) \\ x' &= \gamma \left(x - \frac{v}{c}ct \right) \\ y' &= y \\ z' &= z. \end{aligned}$$

A few observations to orient ourselves.

- (i) *Time transforms.* The first line is the revolution: t' depends on x as well as t . Different frames genuinely disagree about time, and the disagreement grows with separation in space. Absolute time is gone.
- (ii) *The Newtonian limit.* When v/c is very small, $\gamma \approx 1$ and the transformations reduce to $x' = x - vt$, $t' = t$: the Galilean boost. All of Newtonian mechanics survives as the low-speed approximation, which is why it took humanity so long to notice anything was wrong.
- (iii) *The speed limit.* The factor γ is real only for $|v| < c$, and $\gamma \rightarrow \infty$ as $|v| \rightarrow c$. The speed of light is built into the geometry as a limiting speed for frames (and, as we will see, for particles).
- (iv) *Symmetry.* The map treats ct and x almost symmetrically, mixing them rather like a rotation mixes coordinates – a hint we will make precise when we study rapidity.

§3.7.3 Spacetime Diagrams

Relativity problems reward drawing pictures. A **spacetime diagram** plots position x horizontally against time *scaled as* ct vertically (so that both axes carry dimensions of length). A point on the diagram is an event; the history of a particle traces out a curve called its **world line**. A particle at rest has a vertical world line; a particle in uniform motion has a straight world line tilted from the vertical; and a light ray has a world line at exactly 45° , since it satisfies $x = \pm ct$.

Now the crucial construction: how do the axes of a moving frame $\mathcal{F}'$ appear on the diagram of $\mathcal{F}$? The ct' axis is the set of events with $x' = 0$, which is the line $x = vt$ – a line through the origin with gradient $c/v > 1$, i.e. tilted from the vertical. The x' axis is the set of events with $t' = 0$, which by the Lorentz transformation is the line $ct = \frac{v}{c}x$ – tilted *up* from the horizontal by the same angle. So the primed axes close in symmetrically, like a pair of scissors, about the 45° light ray:

The primed axes are *not* orthogonal on the page – but both frames agree on the world lines of light rays, which bisect the axes in each frame. Almost every counterintuitive result of the subject (the relativity of simultaneity, time dilation, length contraction) becomes nearly obvious once drawn on such a diagram, so we will use them liberally in what follows.

§3.7.4 Simultaneity

We say two events P_1 and P_2 are *simultaneous* in the frame $\mathcal{F}$ if they have the same time coordinate t . On a spacetime diagram, the events simultaneous with a given event form a horizontal line – a *line of simultaneity* of $\mathcal{F}$.

But the lines of simultaneity of $\mathcal{F}'$ are the lines of constant t' , which by the Lorentz transformation are the lines

$$ct - \frac{v}{c}x = \text{const},$$

which are *tilted* lines parallel to the x' axis. Events with the same t no longer correspond to events with equal t' , so what is simultaneous in one frame is not necessarily simultaneous in another.

In the diagram, P_1 and P_2 are simultaneous in $\mathcal{F}$ (they lie on a horizontal dashed line), but the tilted line of simultaneity of $\mathcal{F}'$ through P_1 passes *above* P_2 – so in $\mathcal{F}'$, the event P_2 happens first. This is a genuine disagreement, not an artefact of light taking time to reach anyone's eyes: the coordinates already account for all such delays.

§3.7.5 Causality & Light Cones

If observers can disagree about the order of events, should we worry about effects preceding their causes? Consider an event P , which we may as well place at the origin. The light rays through P divide spacetime into regions, and this division is *frame independent*, since all observers agree on the speed of light:

The region $|x| \leq ct$ (shaded) is the **light cone** of P : the *future light cone* consists of all events reachable from P by influences travelling at up to the speed of light, and the *past light cone* of all events that can influence P . For an event Q inside the future light cone of P , one can check from the Lorentz transformation that *every* inertial frame agrees that Q occurs after P – so cause and effect are never inverted. For an event R *outside* the light cone, frames can disagree about the order of P and R (and there is even a frame in which they are simultaneous) – but no signal travelling at speed at most c can connect them, so neither can influence the other, and no causal paradox arises. Causality survives, provided nothing travels faster than light.

§3.7.6 Time Dilation

Consider a clock sitting stationary at the origin of the frame $\mathcal{F}'$, ticking at intervals of T' . The tick events in frame $\mathcal{F}'$ occur at $(ct'_1, 0), (c(t'_1 + T'), 0), \dots$, all with $x' = 0$. Using the inverse Lorentz transformation $t = \gamma(t' + vx'/c^2)$ with $x' = 0$, the interval between ticks observed in $\mathcal{F}$ is

$$T = \gamma T' > T'.$$

So the interval between ticks is longer in the frame in which the clock moves: *moving clocks run slowly*. The effect is mutual – a clock at rest in $\mathcal{F}$ runs slowly as measured

in $\mathcal{F}'$ – which sounds paradoxical, but the two statements compare different pairs of measurements, made along different lines of simultaneity, and no contradiction can be manufactured (as the twin ‘paradox’ below illustrates).

Example 3.7.2 (Muons in the Atmosphere)

Muons are unstable particles with a lifetime of about $2.2\ \mu\text{s}$, created by cosmic rays striking the upper atmosphere, around 10 km up. Even travelling at essentially the speed of light, a muon should manage only about $c \times 2.2\ \mu\text{s} \approx 660\text{ m}$ before decaying – yet muons are detected in abundance at sea level. The resolution is time dilation: for a muon with $\gamma \approx 20$, its internal clock ticks 20 times slower as observed from the ground, giving it ample time to complete the journey. (From the muon’s own point of view, its clock runs normally – but, as we will see next, the atmosphere is length-contracted to a twentieth of its height.)

Nor is time dilation exotic: the clocks on GPS satellites, orbiting at about 3.9 km s^{-1} , run slow relative to the ground by around 7 microseconds per day due to time dilation (partially offset by a general-relativistic effect of the weaker gravity up there). Uncorrected, the resulting positioning error would accumulate at kilometres per day – your phone does relativity every time it finds you on a map.

Example 3.7.3 (The Twin Paradox)

Consider twins Alice and Bob. Bob stays at home (an inertial frame). Alice travels at constant speed v to a distant star, a distance d away in Bob’s frame, then immediately turns around and returns at the same speed. In Bob’s frame the journey takes $T = d/v$ each way, so Bob ages $2T$. Alice’s clock, moving throughout, runs slow by a factor γ , so she ages only $2T/\gamma$: Alice returns *genuinely younger* than her twin.

The apparent paradox: from Alice’s point of view, isn’t it Bob who moves, so shouldn’t Bob be younger? The asymmetry is that Bob remains inertial throughout while Alice does not – she turns around, and the situation is not symmetric. The spacetime diagram makes it precise:

On the outward leg, Alice’s line of simultaneity through the turnaround event A meets Bob’s world line at X – at that moment (by her reckoning) Bob has aged only T/γ^2 , and indeed each twin considers the other’s clock slow, symmetrically. But the moment Alice turns around, her frame changes, and her new line of simultaneity through A meets Bob’s world line at Z . From Alice’s perspective, Bob ages abruptly from X to Z during her turnaround. Adding up the pieces, both twins agree at the

reunion: Bob has aged $2T$, and Alice $2T/\gamma$. There is no paradox – only the (false) assumption that Alice’s viewpoint is that of a single inertial frame.

§3.7.7 Length Contraction

Consider a rod of length L' , stationary in the frame $\mathcal{F}'$. What is its length measured in $\mathcal{F}$? Some care is needed: the length of a moving object means the distance between its two ends *measured at the same time* – and we now know that ‘at the same time’ is a frame-dependent notion, which is exactly where the interesting physics hides.

The world lines of the endpoints of the rod are given by $x' = 0$ and $x' = L'$, which map under the Lorentz transformation into $x = vt$ and $x = vt + L'/\gamma$. So in $\mathcal{F}$, measuring at a fixed time t , the length of the rod is

$$L = \frac{L'}{\gamma} < L',$$

and thus lengths of moving objects are *contracted* in the direction of motion. (Lengths perpendicular to the motion are unaffected.) To deal with this, we define the **proper length** to be the length measured in an object’s rest frame; it is the longest length any inertial observer measures.

On the spacetime diagram, $\mathcal{F}$ measures the rod along a horizontal line of simultaneity, while $\mathcal{F}'$ measures it along the tilted x' axis – they are simply measuring *different* pairs of events, which is how both can be right.

Example 3.7.4 (The Train in the Station)

A train of proper length $2L$ travels at speed v , with $\gamma = 2$, through a station whose platform has length L . For observers on the platform, the train is contracted to length $2L/\gamma = L$, so for one instant it fits perfectly alongside the platform. But for observers on the train, it is the *platform* that is contracted, to $L/2$, and the train (length $2L$) never comes close to fitting!

Who is right? Both. ‘The train fits’ means ‘both ends of the train are alongside the platform *simultaneously*’ – and simultaneity is frame-dependent. The two events ‘front of train reaches far end of platform’ and ‘back of train passes near end of platform’ are simultaneous in the platform frame, but occur in a different order in the train frame. Once stated carefully, there is no contradiction, and the spacetime diagram of the two pairs of world lines shows exactly how the frames disagree.

§3.7.8 Composition of Velocities

Suppose a particle moves with constant velocity u' in frame $\mathcal{F}'$, which moves with velocity v relative to $\mathcal{F}$. We want to find its velocity u in the frame $\mathcal{F}$.

In $\mathcal{F}'$, the world line of the particle is $x' = u't'$. Substituting this into the (inverse) Lorentz transformation laws, we have

$$u = \frac{x}{t} = \frac{\gamma(x' + vt')}{\gamma(t' + vx'/c^2)} = \frac{u' + v}{1 + u'v/c^2}.$$

This is the relativistic law for the **composition of velocities**, replacing the Galilean $u = u' + v$. Some features worth noting:

- (i) When $u'v \ll c^2$, the denominator is close to 1 and we recover the Galilean answer – velocities approximately add at everyday speeds.
- (ii) If $u' = c$ then $u = (c+v)/(1+v/c) = c$, for *any* v : composing any velocity with the speed of light gives the speed of light, exactly as the second postulate demands.
- (iii) If $|u'| < c$ and $|v| < c$, then $|u| < c$. Try as we might, we cannot boost a particle past the speed of light by chaining together boosts – the speed of light is unreachable, not merely unreachd.

Example 3.7.5

A ship recedes from Earth at $\frac{1}{2}c$ and fires a probe forwards at $\frac{1}{2}c$ relative to itself. Galileo would have the probe moving at c ; instead,

$$u = \frac{\frac{1}{2}c + \frac{1}{2}c}{1 + \frac{1}{4}} = \frac{4}{5}c.$$

If the probe in turn launches its own sub-probe at $\frac{1}{2}c$, the Earth measures $\frac{(4/5+1/2)c}{1+2/5} = \frac{13}{14}c$ – each stage claws closer to c , with ever diminishing returns.

§3.7.9 Geometry of Minkowski Space

Consider two events P_1 and P_2 have coordinates (t_1, x_1) and (t_2, x_2) in the frame $\mathcal{F}$. These events are separated by $\Delta t = t_1 - t_2$ in time and $\Delta x = x_1 - x_2$.

We define the *invariant interval* between P_1 and P_2 to be

$$\Delta s^2 = c^2 \Delta t^2 - \Delta x^2.$$

We say it is invariant because it is the same in all inertial reference frames, that is, it is invariant under Lorentz transformations. This is a direct computation:

$$\begin{aligned} c^2 \Delta t'^2 - \Delta x'^2 &= \gamma^2 \left(c \Delta t - \frac{v}{c} \Delta x \right)^2 - \gamma^2 \left(\Delta x - \frac{v}{c} c \Delta t \right)^2 \\ &= \gamma^2 \left(1 - \frac{v^2}{c^2} \right) (c^2 \Delta t^2 - \Delta x^2) = c^2 \Delta t^2 - \Delta x^2, \end{aligned}$$

where the cross terms cancel. (In more than one spatial dimension, the interval is $\Delta s^2 = c^2 \Delta t^2 - \Delta x^2 - \Delta y^2 - \Delta z^2$, and the transverse coordinates are untouched by the boost.) The invariant interval plays the role in spacetime that squared distance plays in Euclidean geometry: it is the quantity that all observers agree on, even as they disagree about times and lengths separately.

Example 3.7.6

In the frame $\mathcal{F}$, two events are separated by $\Delta x = 3$ light-years and $c\Delta t = 5$ light-years. What does a ship travelling at $v = \frac{3}{5}c$ (so $\gamma = \frac{5}{4}$) between the two events make of them? Applying the Lorentz transformation to the separations,

$$\Delta x' = \gamma \left(\Delta x - \frac{v}{c} c\Delta t \right) = \frac{5}{4}(3-3) = 0, \quad c\Delta t' = \gamma \left(c\Delta t - \frac{v}{c} \Delta x \right) = \frac{5}{4} \left(5 - \frac{9}{5} \right) = 4.$$

In the ship's frame the two events happen at the *same place* (of course – the ship is present at both), separated by 4 years of ship time. And indeed the invariant interval agrees in both frames:

$$\Delta s^2 = 5^2 - 3^2 = 16 = 4^2 - 0^2,$$

with $\Delta s/c = 4$ years being precisely the time experienced aboard – the *proper time* between the events, computed without ever leaving the frame $\mathcal{F}$.

It is possible for Δs^2 to be either positive or negative. If it is positive, we say the events are *timelike* separated, and if it is negative we say they are *spacelike* separated, and if it is zero, we say they are *lightlike* (or *null*) separated. This classification is exactly the light cone structure from before: timelike separated events are in each other's light cones and can influence one another, spacelike separated events cannot, and lightlike separated events can be joined only by a light ray.

Each case has a natural interpretation. For timelike separated events, there is a frame in which the two events happen at the same place, and $\Delta s/c$ is the time between them in that frame – the *proper time*, of which much more shortly. For spacelike separated events, there is a frame in which they are simultaneous, and $\sqrt{-\Delta s^2}$ is their separation in that frame (the *proper distance*).

There is a nice picture of all this. On a spacetime diagram, the events at fixed invariant interval from the origin form *hyperbolae* $c^2t^2 - x^2 = \text{const}$, with the light cone $x = \pm ct$ as their asymptotes:

Lorentz transformations preserve the interval, so they slide events *along* these hyperbolae – just as rotations of the plane slide points along circles. This is the precise sense in which Lorentz transformations are the ‘rotations’ of spacetime geometry, and we will shortly make the analogy exact using rapidities.

§3.7.10 4-Vectors

We can view Minkowski space as a vector space equipped with the *Minkowski inner product*⁶. The coordinates of some event P in the frame $\mathcal{F}$ can be written as a *4-vector*

$$X = \begin{pmatrix} ct \\ x \\ y \\ z \end{pmatrix},$$

and then the Minkowski inner product is given by

$$X \cdot Y = X^T \eta Y, \quad \text{where} \quad \eta = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}.$$

Taking $X \cdot X$ gives the invariant interval between the origin and P , and is known as the *Minkowski metric*⁷.

More generally, a **4-vector** is any four-component quantity that transforms under a change of inertial frame in the same way that X does (via the Lorentz transformation matrices of the next subsection). The point of the definition is that the Minkowski inner product of any two 4-vectors is then automatically frame independent – so building physics out of 4-vectors and their inner products is a machine for generating statements that all inertial observers agree on. We will exploit this repeatedly in the final section.

A quick note on notation, for compatibility with the wider world: the components of a 4-vector are commonly written with a Greek superscript, X^μ for $\mu = 0, 1, 2, 3$, with $X^0 = ct$ the time component. We will not need the index machinery in this course (it comes into its own in the Part IB ‘Electromagnetism’ and Part II relativity courses), but it is useful to recognise it.

§3.7.11 The Lorentz Group

Using 4-vectors, we can view Lorentz transformations as linear transformations from the coordinates of one inertial frame $\mathcal{F}$ to another $\mathcal{F}'$. This would be represented by a 4×4 matrix Λ , with

$$X' = \Lambda X.$$

Since such transformations must preserve the invariant interval, they must preserve the Minkowski inner product⁸ and hence satisfy

$$\Lambda^T \eta \Lambda = \eta.$$

The group of all such matrices is the *Lorentz group*, and is generated by

$$\left(\begin{array}{c|ccc} 1 & 0 & 0 & 0 \\ \hline 0 & & & \\ 0 & & R & \\ 0 & & & \end{array} \right) \quad \text{and} \quad \left(\begin{array}{cc|cc} \gamma & -\gamma v/c & 0 & 0 \\ -\gamma v/c & \gamma & 0 & 0 \\ \hline 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{array} \right),$$

where the first corresponds to a rotation of space, leaving time intact (so we need R to be orthogonal), and the second corresponds to a Lorentz boost along the x direction.

⁶This is not an inner product in the normal sense since it's not positive definite

⁷Again, this isn't actually a metric in the normal sense since it's not positive definite

⁸These are the analogue of orthogonal matrices for Minkowski space

Remark. Taking determinants of $\Lambda^T \eta \Lambda = \eta$ gives $(\det \Lambda)^2 = 1$, so $\det \Lambda = \pm 1$, and one can also show $|\Lambda_0^0| \geq 1$. The physically relevant transformations – those continuously connected to the identity – have $\det \Lambda = +1$ and $\Lambda_0^0 \geq 1$: they preserve both spatial orientation and the direction of time. The remaining components of the group involve spatial reflections or time reversal.

§3.7.12 Rapidities

Consider a 2×2 matrix corresponding to a Lorentz boost by v in the x direction. Then if $\beta = v/c$, we have

$$\Lambda[\beta] = \begin{pmatrix} \gamma & -\gamma\beta \\ -\gamma\beta & \gamma \end{pmatrix}$$

and the composition law $\Lambda[\beta_1]\Lambda[\beta_2] = \Lambda\left[\frac{\beta_1 + \beta_2}{1 + \beta_1\beta_2}\right]$, which is exactly our composition law from before.

A slightly nicer way to deal with this is with *rapidities*. We define the *rapidity* of a Lorentz boost ϕ such that

$$\beta = \tanh \phi, \quad \gamma = \cosh \phi, \quad \gamma\beta = \sinh \phi.$$

Then

$$\Lambda[\beta] = \begin{pmatrix} \cosh \phi & -\sinh \phi \\ -\sinh \phi & \cosh \phi \end{pmatrix} = \Lambda(\phi),$$

and also

$$\Lambda(\phi_1)\Lambda(\phi_2) = \Lambda(\phi_1 + \phi_2),$$

which is much nicer. This also shows that Lorentz boosts correspond to hyperbolic rotations in spacetime, just as the rotation matrices (with $\cos$ and $\sin$) represent ordinary rotations of space. The trigonometry of Minkowski space is hyperbolic trigonometry.

Rapidities also give the slickest possible derivation of the composition of velocities: composing boosts of rapidities ϕ_1 and ϕ_2 gives a boost of rapidity $\phi_1 + \phi_2$, whose velocity is

$$\frac{u}{c} = \tanh(\phi_1 + \phi_2) = \frac{\tanh \phi_1 + \tanh \phi_2}{1 + \tanh \phi_1 \tanh \phi_2} = \frac{v_1/c + v_2/c}{1 + v_1 v_2 / c^2},$$

by the addition formula for $\tanh$ – our composition law falls straight out. And since $\tanh$ maps $\mathbb{R}$ to $(-1, 1)$, no amount of adding rapidities ever reaches the speed of light: on the rapidity scale, velocities add plainly, and c sits at infinity.

§3.8 Relativistic Physics

Having rebuilt the geometry of space and time, we now rebuild *dynamics*: velocity, momentum, energy and force, all in a form that respects Lorentz transformations. The guiding principle is to phrase everything in terms of 4-vectors and Lorentz invariants, so that the physics manifestly takes the same form in every inertial frame. The payoff comes at the end of the section, where conservation of 4-momentum will let us analyse particle collisions, decays and creation processes with remarkable ease.

§3.8.1 Proper Time

To do kinematics, it helps to have a notion of time that all observers can agree on. We do this by defining **proper time** τ , which is the time experienced by a particle in its own reference frame. It is given by

$$\Delta\tau = \frac{\Delta s}{c}$$

along the particle's world line, in all reference frames – this is well defined precisely because Δs is Lorentz invariant. (For a massive particle, successive events on the world line are timelike separated, so $\Delta s^2 > 0$ and the proper time is real.)

We can relate proper time to the time measured in any particular frame by considering small changes. If $\mathbf{u}$ is the velocity of the particle in the frame $\mathcal{F}$, we get

$$d\tau = \frac{1}{c} ds = \frac{1}{c} \sqrt{c^2 dt^2 - |\mathbf{dx}|^2} = \sqrt{1 - u^2/c^2} dt,$$

so

$$\frac{dt}{d\tau} = \gamma_u, \quad \text{where } \gamma_u = \frac{1}{\sqrt{1 - u^2/c^2}}.$$

Note that γ_u here is built from the *particle's* speed in $\mathcal{F}$, which need not be constant. We can then get the total time experienced by a particle along a segment of its world line as

$$T = \int d\tau = \int \frac{1}{\gamma_u} dt \leq \int dt.$$

So of all observers passing through the same two events, the one who experiences the most time is the one moving inertially – a restatement of the twin paradox.

Example 3.8.1

An astronaut spends six months on the International Space Station, orbiting at about 7.7 km s^{-1} . Over the mission, the proper time deficit relative to mission control is

$$\Delta t - \Delta\tau = \left(1 - \frac{1}{\gamma}\right) \Delta t \approx \frac{v^2}{2c^2} \Delta t \approx \frac{(7.7 \times 10^3)^2}{2(3 \times 10^8)^2} \times 1.6 \times 10^7 \text{ s} \approx 5 \text{ ms}.$$

The astronaut returns five milliseconds younger than if they had stayed home – a small effect, but one routinely confirmed by flying atomic clocks around the world.

§3.8.2 4-Velocity

Using proper time, we can parametrise the trajectory of a particle using a 4-vector

$$X(\tau) = \begin{pmatrix} ct(\tau) \\ \mathbf{x}(\tau) \end{pmatrix},$$

the *4-position*, and then define the **4-velocity** as its derivative with respect to proper time:

$$U = \frac{dX}{d\tau} = \begin{pmatrix} c dt/d\tau \\ d\mathbf{x}/d\tau \end{pmatrix} = \frac{dt}{d\tau} \begin{pmatrix} c \\ \mathbf{u} \end{pmatrix} = \gamma_u \begin{pmatrix} c \\ \mathbf{u} \end{pmatrix},$$

where $\mathbf{u} = d\mathbf{x}/dt$ is the ordinary velocity in the frame. The reason to differentiate with respect to τ rather than t is that τ is an invariant: since $X' = \Lambda X$ and τ is frame

independent, the 4-velocity genuinely transforms as a 4-vector, $U' = \Lambda U$. (The naive candidate dX/dt transforms in no nice way at all.)

Like any 4-vector, U has an invariant inner product with itself. Easiest computed in the particle's rest frame, where $U = (c, \mathbf{0})$:

$$U \cdot U = c^2,$$

and indeed in a general frame $U \cdot U = \gamma_u^2(c^2 - |\mathbf{u}|^2) = c^2$. Every particle traverses spacetime with '4-speed' c .

§3.8.3 Transforming Velocities & Aberration

Since $U' = \Lambda U$, transforming velocities between frames is now just linear algebra – which lets us generalise our composition law to velocities in arbitrary directions. Suppose in frame $\mathcal{F}$ a particle moves with speed u at angle θ to the x -axis, in the (x, y) plane, and let $\mathcal{F}'$ move at speed v in the x direction as usual. Applying the boost matrix to $U = \gamma_u(c, u \cos \theta, u \sin \theta, 0)^T$:

$$\begin{pmatrix} \gamma_{u'} c \\ \gamma_{u'} u' \cos \theta' \\ \gamma_{u'} u' \sin \theta' \\ 0 \end{pmatrix} = \begin{pmatrix} \gamma_v & -\gamma_v v/c & 0 & 0 \\ -\gamma_v v/c & \gamma_v & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \gamma_u c \\ \gamma_u u \cos \theta \\ \gamma_u u \sin \theta \\ 0 \end{pmatrix}.$$

Dividing the second row by the first eliminates the γ factors and gives

$$u' \cos \theta' = \frac{u \cos \theta - v}{1 - \frac{uv}{c^2} \cos \theta},$$

the familiar composition law applied to the parallel component. Dividing the third row by the second gives

$$\tan \theta' = \frac{u \sin \theta}{\gamma_v (u \cos \theta - v)},$$

which describes **aberration**: the direction of motion of a particle depends on the motion of the observer. There is a Newtonian part to this effect – walk through vertical rain and it appears to slant towards you – but the γ_v factor is genuinely relativistic. For light ($u = c$), aberration causes the apparent positions of stars to shift annually as the Earth swings around its orbit, an effect measured long before relativity explained it correctly.

§3.8.4 4-Momentum & Relativistic Energy

With the 4-velocity in hand, we can define the relativistic analogue of momentum.

Definition 3.8.2 (4-Momentum)

For a particle of mass m , the **4-momentum** is

$$P = mU = \begin{pmatrix} mc\gamma_u \\ m\gamma_u \mathbf{u} \end{pmatrix}.$$

The spatial components of P give us the *relativistic 3-momentum*, $\mathbf{p} = m\gamma_u \mathbf{u}$, which is the Newtonian momentum corrected by a factor of γ_u – note that $|\mathbf{p}| \rightarrow \infty$ as $|\mathbf{u}| \rightarrow c$.

The fundamental law of relativistic dynamics is that *4-momentum is conserved*: for a system of particles the total 4-momentum (the sum of the individual 4-momenta) is unchanged by collisions and interactions, in the absence of external forces. This single conservation law packages together the conservation of momentum *and* of energy, as we now see by interpreting the time component.

Expanding P^0 for speeds small compared to c ,

$$P^0 = m\gamma_u c = \frac{1}{c} \left(mc^2 + \frac{1}{2}m|\mathbf{u}|^2 + \dots \right).$$

The second term is the Newtonian kinetic energy, so we recognise $P^0 c$ as an energy.

Definition 3.8.3 (Relativistic Energy)

The **relativistic energy** of a particle is $E = P^0 c = m\gamma_u c^2$, so that

$$P = \begin{pmatrix} E/c \\ \mathbf{p} \end{pmatrix}, \quad \text{and} \quad E = mc^2 + \underbrace{(\gamma_u - 1)mc^2}_{\text{kinetic energy}}.$$

For a stationary particle we have the most famous equation in physics:

$$E = mc^2.$$

Mass is a form of energy – and an enormously concentrated one, with $c^2 \approx 9 \times 10^{16} \text{ J kg}^{-1}$ as the exchange rate. In relativity, mass is *not* separately conserved: it can be converted to kinetic energy and back, as happens in nuclear reactions and particle colliders, and only the total energy (including mass energy) is conserved.

Since we can calculate the Lorentz invariant quantity $P \cdot P$ in the particle's rest frame, we have

$$P \cdot P = \frac{E^2}{c^2} - |\mathbf{p}|^2 = m^2 c^2,$$

so generally we have the **energy-momentum relation**

$$E^2 = |\mathbf{p}|^2 c^2 + m^2 c^4.$$

This invariant is the workhorse of collision problems: given any 4-momentum (perhaps a sum over several particles), dotting it with itself produces frame-independent information.

Massless particles. For particles that have zero mass (like photons), we cannot define proper time or 4-velocity – but we can still perfectly well assign them a 4-momentum, with $P \cdot P = 0$. Such particles travel at the speed of light, along lightlike trajectories, and can still carry momentum and energy, related by $E = |\mathbf{p}|c$. Thus

$$P = \frac{E}{c} \begin{pmatrix} 1 \\ \mathbf{n} \end{pmatrix},$$

where $\mathbf{n}$ is a unit vector in the direction of propagation. Quantum mechanics supplies the energy in terms of the light's frequency f (or wavelength $\lambda = c/f$) via the *Planck relation* $E = hf = hc/\lambda$, where h is Planck's constant.

§3.8.5 The Relativistic Doppler Effect

Suppose a source of light recedes from an observer at speed v , emitting light of frequency f' (as measured in the source's own rest frame). What frequency does the observer measure? Two effects stack: successive wave crests are emitted at intervals lengthened by time dilation, *and* each crest is emitted from further away than the last, adding travel time.

Quantitatively: in the observer's frame, the source's clock ticks slowly, so crests are emitted at intervals $\gamma T'$, where $T' = 1/f'$. Between successive emissions the source recedes a further distance $v\gamma T'$, delaying the later crest's arrival by $v\gamma T'/c$. So crests arrive separated by

$$T = \gamma T' + \frac{v\gamma T'}{c} = T' \gamma \left(1 + \frac{v}{c}\right) = T' \sqrt{\frac{1 + v/c}{1 - v/c}},$$

and hence the observed frequency is

$$f = f' \sqrt{\frac{1 - v/c}{1 + v/c}}.$$

For a receding source, $f < f'$: the light is shifted towards the red end of the spectrum (*redshift*). For an approaching source, replace v with $-v$ to get a *blueshift*. An elegant alternative derivation: apply a Lorentz boost to the photon's 4-momentum, $E = \gamma(E' - vE'/c \cdot 1)$ for a photon emitted backwards, and use $E = hf$ – the same factor drops out.

Note that even the *transverse* Doppler effect (source moving perpendicular to the line of sight) is nontrivial in relativity, giving $f = f'/\gamma$ purely from time dilation, with no Newtonian counterpart.

The Doppler effect is a workhorse of astronomy: the redshifts of spectral lines tell us how fast stars and galaxies move along our line of sight, and the systematic redshift of distant galaxies – Hubble's observation that essentially everything is receding from us – is the observational cornerstone of the expanding universe.

It also gives a satisfying second look at the twin paradox. Suppose the travelling twin Alice sends Bob a light pulse every year of *her* time. On the outward leg, Bob receives the pulses at the slowed rate $\sqrt{(1 - \beta)/(1 + \beta)}$ per year; after her turnaround, at the sped-up rate $\sqrt{(1 + \beta)/(1 - \beta)}$. But here is the asymmetry: Alice's turnaround changes what she *sends* at her half-way point, while Bob only starts *receiving* the sped-up pulses late in the trip, when the last outbound pulse finally crawls to him. Counting the pulses each twin receives over the whole journey (a pleasant exercise) reproduces exactly the asymmetric ageing – no frames or lines of simultaneity required, just counting flashes of light.

§3.8.6 4-Force

We can now write down the relativistic version of Newton's second law. The natural formulation uses proper time and 4-vectors throughout.

Definition 3.8.4 (4-Force)

The **4-force** on a particle with 4-momentum P is

$$F = \frac{dP}{d\tau}.$$

Since P is a 4-vector and τ is invariant, F is a genuine 4-vector, transforming as $F' = \Lambda F$ – so if this law holds in one inertial frame, it holds in all of them, exactly as the principle of relativity requires. Writing out the components in a frame where the particle has velocity $\mathbf{u}$, and comparing with $P = (E/c, \mathbf{p})$, we can express the 4-force in terms of the ordinary 3-force $\mathbf{F} = d\mathbf{p}/dt$:

$$F = \gamma_u \begin{pmatrix} \mathbf{F} \cdot \mathbf{u}/c \\ \mathbf{F} \end{pmatrix},$$

where the factors of γ_u come from $dt/d\tau = \gamma_u$. The two components carry familiar content:

$$\frac{dE}{dt} = \mathbf{F} \cdot \mathbf{u}, \quad \frac{d\mathbf{p}}{dt} = \mathbf{F},$$

that is, the rate of working of the force equals the rate of change of (relativistic) energy, and force is the rate of change of (relativistic) momentum – Newtonian mechanics upgraded, with γ factors hiding inside E and $\mathbf{p}$.

For a particle of constant mass we can also write $F = mA$, where

$$A = \frac{dU}{d\tau}$$

is the *4-acceleration*. Differentiating the identity $U \cdot U = c^2$ with respect to τ gives

$$U \cdot A = 0,$$

so the 4-acceleration is always Minkowski-orthogonal to the 4-velocity. In the instantaneous rest frame, $U = (c, \mathbf{0})$ and $A = (0, \mathbf{a})$, making the orthogonality manifest.

Example 3.8.5 (Motion Under a Constant Force)

Push a particle of mass m with a constant 3-force F (in one dimension) forever. Newtonian mechanics says $v = Ft/m$ grows without bound; what does relativity say? We have $dp/dt = F$, so starting from rest,

$$p = m\gamma_u u = Ft \implies u = \frac{Ft/m}{\sqrt{1 + (Ft/mc)^2}},$$

solving for u . At early times ($Ft \ll mc$) this is the Newtonian $u \approx Ft/m$; at late times $u \rightarrow c$ but never reaches it – the momentum grows linearly forever, but ever more of the ‘push’ goes into the γ factor rather than into speed. Constant proper acceleration traces out a *hyperbola* on the spacetime diagram, asymptotic to a light ray: one more instance of hyperbolae being relativity’s circles.

§3.8.7 Particle Collisions & Decays

We finish the course with relativistic particle physics – the study of collisions, decays and creation of particles, where conservation of total 4-momentum

$$P = \begin{pmatrix} E/c \\ \mathbf{p} \end{pmatrix}$$

does essentially all of the work. A frame that makes calculations dramatically easier:

Definition 3.8.6 (Centre of Momentum Frame)

The **centre of momentum frame** of a system of particles is an inertial frame in which the total 3-momentum vanishes, $\sum_i \mathbf{p}_i = \mathbf{0}$.

Such a frame exists for any system except one consisting entirely of massless particles moving in a single direction. It is the relativistic analogue of the centre of mass frame from Newtonian collisions.

Remark. A closely related tool: for any system with total 4-momentum P_{tot} , the quantity

$$M_{\text{inv}}^2 c^2 = P_{\text{tot}} \cdot P_{\text{tot}}$$

defines the *invariant mass* of the system – it is frame independent, equal to the total energy in the centre of momentum frame divided by c^2 , and (because 4-momentum is conserved) unchanged by any decay or collision the system undergoes. Note that the invariant mass of a system is generally *greater* than the sum of the rest masses of its constituents, the excess being internal kinetic energy. Reconstructing invariant masses from measured decay products is how new particles are actually discovered.

Particle Decay

Suppose a particle of mass m_1 decays into two particles of masses m_2 and m_3 . Conservation of 4-momentum reads

$$P_1 = P_2 + P_3,$$

which contains both $E_1 = E_2 + E_3$ and $\mathbf{p}_1 = \mathbf{p}_2 + \mathbf{p}_3$. Work in the rest frame of the decaying particle (its own centre of momentum frame). There, $E_1 = m_1 c^2$, and using the energy-momentum relation for the products,

$$m_1 c^2 = \sqrt{|\mathbf{p}_2|^2 c^2 + m_2^2 c^4} + \sqrt{|\mathbf{p}_3|^2 c^2 + m_3^2 c^4} \geq m_2 c^2 + m_3 c^2.$$

So decay is possible only if

$$m_1 \geq m_2 + m_3$$

– a particle can only decay into products whose total mass does not exceed its own, with the excess mass converted into the kinetic energy of the products. (Mass is not conserved!)

Example 3.8.7 (Higgs Decay to Photons)

One of the decay channels in which the Higgs boson was discovered at the LHC is a decay into two photons, $h \rightarrow \gamma\gamma$ (allowed, since $m_\gamma = 0$). In the Higgs rest frame,

$$P_h = \begin{pmatrix} m_h c \\ \mathbf{0} \end{pmatrix} = P_{\gamma_1} + P_{\gamma_2}.$$

The spatial components force $\mathbf{p}_{\gamma_1} = -\mathbf{p}_{\gamma_2}$: the photons fly off back-to-back. Since $E_\gamma = |\mathbf{p}_\gamma|c$ for each photon, the two photons have equal energies, and the time component then gives

$$E_{\gamma_1} = E_{\gamma_2} = \frac{1}{2} m_h c^2.$$

All of the Higgs mass is converted into electromagnetic energy. Experimentally one runs this backwards: measuring the photon pair and reconstructing the invariant

$(P_{\gamma_1} + P_{\gamma_2}) \cdot (P_{\gamma_1} + P_{\gamma_2}) = m_h^2 c^2$ reveals the mass of the particle that decayed.

Example 3.8.8 (Photon Emission & Recoil)

An atom of mass m , at rest, drops to a lower energy state of mass $m' < m$ (the internal energy released being $\Delta E = (m - m')c^2$), emitting a single photon. Naively the photon should carry energy ΔE – but the atom must recoil to conserve momentum, and the recoil steals some energy. Conservation of 4-momentum gives $P_{\text{atom}} = P_\gamma + P'_{\text{atom}}$, so isolating and squaring the final atom's 4-momentum,

$$m'^2 c^2 = (P_{\text{atom}} - P_\gamma) \cdot (P_{\text{atom}} - P_\gamma) = m^2 c^2 - 2P_{\text{atom}} \cdot P_\gamma = m^2 c^2 - 2mE_\gamma,$$

using $P_\gamma \cdot P_\gamma = 0$ and evaluating $P_{\text{atom}} \cdot P_\gamma = mE_\gamma$ in the rest frame. Hence

$$E_\gamma = \frac{(m^2 - m'^2)c^2}{2m} = \Delta E \left(1 - \frac{\Delta E}{2mc^2} \right).$$

The photon carries slightly *less* than the transition energy, the deficit being carried off as the atom's recoil kinetic energy. For optical transitions the correction is minuscule ($\Delta E/mc^2 \sim 10^{-10}$), but for gamma-ray emission from nuclei it matters enormously – and clever ways around the recoil (the Mössbauer effect) enabled some of the most precise tests of relativity ever performed.

Particle Scattering

Next, consider an *elastic* collision: two identical particles of mass m collide and retain their identities, so

$$P_1 + P_2 = P_3 + P_4.$$

Set up the standard experiment in the lab frame $\mathcal{F}$: particle 1 moves with speed u along the x -axis and strikes particle 2 at rest, after which the particles move off at angles θ and ϕ to the axis.

The trick is to analyse the collision in the centre of momentum frame $\mathcal{F}'$, which moves at some speed v along the x -axis relative to the lab. In $\mathcal{F}'$, the two particles approach head-on with equal and opposite momenta, and (comparing the time components of 4-momentum before and after) they must also *recede* with equal and opposite momenta of the same magnitude, each with the same speed v as before. The only freedom is the scattering angle θ' :

$$P'_3 = \begin{pmatrix} m\gamma_v c \\ m\gamma_v v \cos \theta' \\ m\gamma_v v \sin \theta' \\ 0 \end{pmatrix}, \quad P'_4 = \begin{pmatrix} m\gamma_v c \\ -m\gamma_v v \cos \theta' \\ -m\gamma_v v \sin \theta' \\ 0 \end{pmatrix}.$$

Now boost back to the lab frame with the inverse Lorentz transformation. The incoming particle's speed matches the collision setup provided

$$u = \frac{2v}{1 + v^2/c^2}$$

(the composition of v with v , naturally, since the target is at rest in the lab and moves at v in $\mathcal{F}'$). Transforming P'_3 and P'_4 and taking ratios of components to extract the

angles, the half-angle formulae give

$$\tan \theta = \frac{\sin \theta'}{\gamma_v(1 + \cos \theta')} = \frac{1}{\gamma_v} \tan \frac{\theta'}{2}, \quad \tan \phi = \frac{\sin \theta'}{\gamma_v(1 - \cos \theta')} = \frac{1}{\gamma_v} \cot \frac{\theta'}{2}.$$

The individual angles depend on θ' , which is not determined by conservation laws alone – but their product is universal:

$$\tan \theta \tan \phi = \frac{1}{\gamma_v^2}.$$

In the Newtonian limit $\gamma_v \rightarrow 1$ we recover $\tan \theta \tan \phi = 1$, i.e. $\theta + \phi = \pi/2$: the equal-mass particles separate at right angles, exactly as we found in Section 3.5. Relativistically, $\tan \theta \tan \phi < 1$, so the opening angle between the outgoing particles is *less* than a right angle – fast collisions throw both products forward, and measuring this closing-up of the angle is a direct test of special relativity.

Example 3.8.9 (Compton Scattering)

A lovely application of 4-momentum bookkeeping: scatter a photon off an electron (mass m) at rest, and ask how the photon's wavelength changes. Let the incoming photon have energy E , the outgoing photon energy E' at angle θ to the incident direction, and let the electron recoil with 4-momentum P'_e . Conservation says

$$P_\gamma + P_e = P'_\gamma + P'_e.$$

We don't care about the electron's recoil, so isolate it and take the invariant square:

$$P'_e \cdot P'_e = (P_\gamma + P_e - P'_\gamma) \cdot (P_\gamma + P_e - P'_\gamma).$$

The left side is $m^2 c^2$. Expanding the right side using $P_\gamma \cdot P_\gamma = P'_\gamma \cdot P'_\gamma = 0$ and $P_e \cdot P_e = m^2 c^2$,

$$m^2 c^2 = m^2 c^2 + 2P_\gamma \cdot P_e - 2P'_\gamma \cdot P_e - 2P_\gamma \cdot P'_\gamma,$$

and computing each inner product in the lab frame (where $P_e = (mc, \mathbf{0})$):

$$P_\gamma \cdot P_e = mE, \quad P'_\gamma \cdot P_e = mE', \quad P_\gamma \cdot P'_\gamma = \frac{EE'}{c^2}(1 - \cos \theta).$$

Substituting and tidying up,

$$\frac{1}{E'} - \frac{1}{E} = \frac{1 - \cos \theta}{mc^2},$$

or, in terms of wavelengths via the Planck relation $E = hc/\lambda$,

$$\lambda' - \lambda = \frac{h}{mc}(1 - \cos \theta).$$

The scattered light is shifted to longer wavelengths, by an amount depending only on the scattering angle and the universal length h/mc (the *Compton wavelength* of the electron). Compton's measurement of exactly this shift in 1923 was decisive evidence that light really does carry momentum in particle-like quanta.

Particle Creation & Threshold Energies

Finally, creation of new particles: collide two particles of mass m fast enough, and the excess kinetic energy can be converted into the mass of a new particle:

$$P_1 + P_2 = P_3 + P_4 + P_5,$$

where particles 3 and 4 have mass m and the newly created particle 5 has mass M .

Work in the centre of momentum frame, where the two initial particles approach with equal speeds v . The total 4-momentum is

$$P_1 + P_2 = \begin{pmatrix} 2m\gamma_v c \\ \mathbf{0} \end{pmatrix},$$

and after the collision, the total energy is $E_3 + E_4 + E_5 \geq (2m + M)c^2$, with equality when all three products are at rest. So creation is possible only if

$$2m\gamma_v c^2 \geq (2m + M)c^2, \quad \text{i.e.} \quad \gamma_v \geq 1 + \frac{M}{2m},$$

or in terms of kinetic energy: the initial kinetic energy in the centre of momentum frame must be at least Mc^2 . This is the **threshold energy** for the process – entirely reasonable: every joule of kinetic energy in this frame is available for making mass.

The situation is dramatically different in a *fixed-target* experiment, where one initial particle is at rest in the lab. The lab frame moves at speed v relative to the centre of momentum frame, so the moving particle has speed $u = 2v/(1 + v^2/c^2)$, for which one can check the useful identity

$$\gamma_u = 2\gamma_v^2 - 1.$$

At threshold, $\gamma_v = 1 + M/2m$, so we require

$$\gamma_u \geq 2 \left(1 + \frac{M}{2m}\right)^2 - 1 = 1 + \frac{2M}{m} + \frac{M^2}{2m^2},$$

that is, an initial kinetic energy of

$$m(\gamma_u - 1)c^2 \geq \left(2 + \frac{M}{2m}\right) Mc^2.$$

This is far more than Mc^2 when $M \gg m$: most of the beam's energy is wasted on the kinetic energy that the products are forced to carry (the total momentum is nonzero and must be conserved). This is precisely why modern particle physics is done with *colliders*, smashing two beams together head-on – the lab *is* the centre of momentum frame, and every unit of beam energy is available for creating new particles. To create a Higgs boson ($M \approx 130$ proton masses) with a fixed-target proton experiment would require a beam energy hundreds of times larger than the LHC's colliding beams need.

And that – from Newton's laws to the design principles of the Large Hadron Collider – is where we end the course.

4 Groups

Informally, group theory is the study of certain structures that occur when we think about symmetries in a mathematical way. In this course, we will look at what groups are, their basic properties – with lots of examples.

This article constitutes my notes for the ‘Groups’ course, held in Michaelmas 2020 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas.

§4.1 Groups

‘Groups’ is a course which introduces you to the subject of *Abstract Algebra*. Indeed, while groups are one of the simplest and most basic of all the algebraic structures, they are immensely useful and appear in almost every area of mathematics.

§4.1.1 Definition of a Group

We will begin our study of the subject by defining formally what a group is.

Definition 4.1.1 (Group)

A **group** is a set G with a binary operation^a $*$ which satisfies the axioms:

- *Identity*. There is an element $e \in G$ such that $g * e = e * g = g$ for every $g \in G$.
- *Inverses*. For every element $g \in G$, there is an element $g^{-1} \in G$ such that $g * g^{-1} = g^{-1} * g = e$.
- *Associativity*. The operation $*$ is associative.

^aSome texts include an additional *closure* axiom, but this is implied by $*$ being a binary operation on G .

We typically refer to a group as defined above by $(G, *)$, which explicitly states that $*$ is the group operation. When the operation being used is clear, we can refer to the group by just G . We will also be omitting the group’s operation symbol quite often, for example writing $gh = g * h$. If G is finite, we call $|G|$ the **order** of the group.

In a later section, we will look at some non-trivial examples of groups.

Elementary Properties of Groups

With the notion of a group now defined, we can now consider some basic facts that follow directly from the definition of a group. We will first address whether it is possible for a group to have multiple identity elements, or for an element to have multiple inverses (no).

Proposition 4.1.2 (Uniqueness of the Identity and Inverse)

Let $(G, *)$ be a group. Then there is a unique identity element, and for every $g \in G$, g^{-1} is unique.

Proof. To prove that the identity element is unique, let e and e' be identity elements of G . Then $e * e' = e$ and $e * e' = e'$ by definition, giving $e = e'$.

To prove that the inverses are unique, suppose that for some $g, h, k \in G$ we have $g * h = g * k = e$. Then $g^{-1} * g * h = g^{-1} * g * k$, implying $h = k$. The case of $h * g = k * g = e$ follows analogously. $\square$

The next useful fact is the *cancellation law*, whose proof bears a large resemblance to the proof that inverses are unique.

Proposition 4.1.3 (Cancellation Law)

If $(G, *)$ is a group, and $a, b, c \in G$, then $a * b = a * c$ and $b * a = c * a$ both imply $b = c$.

Proof. Taking $a * b = a * c$ and left-multiplying by a^{-1} we have $a^{-1} * a * b = a^{-1} * a * c$, that is, $b = c$. The other case follows analogously. $\square$

The last proposition we will prove in this section gives us a useful result about computing inverses.

Proposition 4.1.4 (Computing Inverses)

Let $(G, *)$ be a group, and let $g, h \in G$. Then the following hold:

- (i) $(g * h)^{-1} = h^{-1} * g^{-1}$.
- (ii) $(g^{-1})^{-1} = g$.

Proof.

- (i) We have $(g * h) * (h^{-1} * g^{-1}) = g * (h * h^{-1}) * g^{-1} = g * g^{-1} = e$, so $(g * h)^{-1} = h^{-1} * g^{-1}$.
- (ii) Similarly, $g^{-1} * g = e$, so $(g^{-1})^{-1} = g$. $\square$

Examples of Groups

It's probably of some use to have concrete examples of groups in your head, so you can get a feel for what they are. In this section we will present some non-trivial examples of groups (and some examples of non-groups).

It should be recognized that commutativity is *not* a group axiom, and the majority of groups are not commutative. We do have a name for groups where the binary operation is commutative though.

Definition 4.1.5 (Abelian Groups)

We say a group $(G, *)$ is **abelian** if $*$ is commutative, that is, if for any $g, h \in G$, $g * h = h * g$.

In this section, we will consider examples of both abelian and non-abelian groups¹. In the first few cases, the reasons why they are a group are stated. For the others, you should consider how they satisfy the group axioms yourself.

Example 4.1.6 (The Trivial Group)

The **trivial group** is a group whose only element is the identity, $\{e\}$.

Example 4.1.7 (Additive Group of Integers)

$(\mathbb{Z}, +)$ is an group. We have

- The identity element $0 \in \mathbb{Z}$, as $a + 0 = 0 + a = a$ for any $a \in \mathbb{Z}$
- The inverse of $a \in \mathbb{Z}$ being $-a$, as $a + (-a) = (-a) + a = 0$.
- The operation $+$ is associative and commutative.

We also have the additive group of rationals $(\mathbb{Q}, +)$, of reals $(\mathbb{R}, +)$, and of complex numbers $(\mathbb{C}, +)$ for the same reasons.

Example 4.1.8 (Addition Modulo n)

Let $n \in \mathbb{N}$, and let $\mathbb{Z}/n\mathbb{Z} = \{0, 1, \dots, n-1\}$ denote the set of residues modulo n . Then $(\mathbb{Z}/n\mathbb{Z}, +)$ is a group (where addition is done modulo n). We have

- The identity element is $0 \pmod{n}$, as $a + 0 \equiv 0 + a \equiv a \pmod{n}$.
- The inverse of $a \in \mathbb{Z}/n\mathbb{Z}$ is $-a$, as $a + (-a) \equiv 0 \pmod{n}$.
- Addition modulo n is associative.

Example 4.1.9 (Non-Zero Rationals)

Let $\mathbb{Q}^\times$ denote the set of non-zero rationals. Then $(\mathbb{Q}^\times, \times)$ is a group.

Similarly, we also have the groups $(\mathbb{R}^\times, \times)$ and $(\mathbb{C}^\times, \times)$.

Example 4.1.10 (Multiplication Modulo p)

Let p be a prime, and let $(\mathbb{Z}/p\mathbb{Z})^\times$ denote the set of non-zero residues modulo p . Then $((\mathbb{Z}/p\mathbb{Z})^\times, \times)$ is a group (where multiplication is done modulo p).

Example 4.1.11 (General Linear Group)

Let $\text{GL}_n(\mathbb{R})$ be the set of $n \times n$ matrices with non-zero determinant. Then $(\text{GL}_n(\mathbb{R}), \times)$ is the **general linear group**^a.

^aUsing matrix multiplication

¹If you are not familiar with some of the concepts used, such as matrices or modular arithmetic, feel free to ignore those examples.

Example 4.1.12 (Special Linear Group)

Let $\text{SL}_n(\mathbb{R})$ be the set of $n \times n$ matrices with determinant 1. Then $(\text{SL}_n(\mathbb{R}), \times)$ is the **special linear group**.

Non-Examples of Groups

We will now give some examples of sets with operations that are not groups. It should be useful to think about why each example does not satisfy the group axioms.

Example 4.1.13 (Non-Examples of Groups)

The following are all *not* groups.

- $(\mathbb{Z}, \times)$
- $(\mathbb{Q}, \times)$
- The set of 2×2 matrices with matrix multiplication.
- $(\mathbb{R}, *)$ where $r * s = r \times r \times s$
- $(\mathbb{N}, *)$ where $n * m = |n - m|$.

§4.1.2 Subgroups

Given any mathematical structure, it can be useful to know about its *substructure*. In the case of a group $(G, *)$, one might ask the question is there some subset $H \subseteq G$ that still acts like a group? This motivates the introduction of *subgroups*.

Definition 4.1.14 (Subgroups)

Let $(G, *)$ be a group. A subset $H \subseteq G$ is a **subgroup** of G if $(H, *)$ is also a group. If H is a subgroup of G , we will write $H \leq G$.

Example 4.1.15 (Examples of Subgroups)

The following are subgroups.

- For any group G , we have the **trivial subgroups** $\{e\} \leq G$ and $G \leq G$.
- $\mathbb{Z} \leq \mathbb{Q} \leq \mathbb{R} \leq \mathbb{C}$ with addition.
- $\{0, 2, 4, \dots\} \leq \mathbb{Z}$ with addition.
- $\text{SL}_n(\mathbb{R}) \leq \text{GL}_n(\mathbb{R})$ with matrix multiplication.

Checking whether something is a subgroup is easier than checking if something is a group, since we already know about the structure of the group. To check whether H is a subgroup of $(G, *)$, we can just check the following hold:

- *Closure.* $*$ is closed in H .
- *Identity.* $e \in H$.
- *Inverses.* For $h \in H$, we also have $h^{-1} \in H$.

These can all be combined into a single test, that is sometimes known as the ‘subgroup checking lemma’.

Lemma 4.1.16 (Subgroup Criterion)

A subset H of a set G is a subgroup of $(G, *)$ if and only if H is non-empty and $x * y^{-1} \in H$ for all $x, y \in H$.

Proof Sketch. First check that the conditions of H being non-empty and $x * y^{-1} \in H$ imply that it’s a subgroup. Then, show that if H is not a subgroup, then either H is empty or $x * y^{-1} \notin H$ for some $x, y \in H$. $\square$

As an example of using subgroups, let’s try to characterize all of the subgroups of $(\mathbb{Z}, +)$.

Theorem 4.1.17 (Subgroups of $\mathbb{Z}$)

The subgroups of $(\mathbb{Z}, +)$ are precisely the subsets of the form $n\mathbb{Z}$ for $n \in \mathbb{N}$, where $n\mathbb{Z} = \{nk : k \in \mathbb{Z}\}$.

Proof. First, we prove that $n\mathbb{Z}$ is a subgroup. Fix $n \in \mathbb{N}$.

- *Closure.* Given $nk_1, nk_2 \in n\mathbb{Z}$, then $nk_1 + nk_2 = n(k_1 + k_2) \in n\mathbb{Z}$.
- *Identity.* $0 = n \cdot 0 \in n\mathbb{Z}$.
- *Inverses.* The inverse of nk is $-nk = n(-k) \in n\mathbb{Z}$.

Thus each is subgroup. Now we prove that there is no other subgroups.

Let $H \leq \mathbb{Z}$. If $H = \{0\}$, then $H \equiv 0\mathbb{Z}$. If not, then take the smallest positive element in H (namely n). Since H is a subgroup, it’s closed and contains inverses, so $n + n + \cdots + n \in H$ and $-n - n - n - \cdots - n \in H$, so $n\mathbb{Z} \subseteq H$.

Suppose, for a contradiction, there is some $k \in H$ such that $k \notin n\mathbb{Z}$. So, there is some integer m such that $nm < k < n(m + 1)$. But then $0 \leq k - nm < n$, and $k - nm \in H$ which is a contradiction, so $H = n\mathbb{Z}$. $\square$

We can use the definition of a subgroup to prove some elementary facts.

Proposition 4.1.18 (Elementary Properties of Subgroups)

Let G be a group.

- (i) Let H and K be subgroups of G . Then $H \cap K \leq G$.
- (ii) If $K \leq H$ and $H \leq G$ then $K \leq G$ (being a subgroup is transitive).
- (iii) If $K \subset H$, $H \leq G$ and $K \leq G$, then $K \leq H$.

Proof. There is multiple ways to prove these, but we will use the subgroup criterion as an example of it being used.

- (i) Note that $H \cap K$ is not empty as $e \in H$ and $e \in K$. Then, for any $x, y \in H \cap K$, it suffices to show that $x * y^{-1} \in H$. By the subgroup criterion, we have

$x * y^{-1} \in H$ and $x * y^{-1} \in K$, thus $x * y^{-1} \in H \cap K$, and we are done.

- (ii) If $K \leq H$, then for any $x, y \in K$, we have $x * y^{-1} \in K$. Then as $K \subset H \subset G$, we must have $x * y^{-1} \in G$, and thus $K \leq G$.
- (iii) As $K \leq G$, we know K is non-empty. Thus it suffices to show that $x * y^{-1} \in K$ for any $x, y \in H$. But this is implied by $K \leq G$ and the subgroup criterion, and thus as $K \subset H$, $K \leq H$. $\square$

Generators

We will now consider a certain kind of subgroup, which is specified by some of the elements it contains.

Definition 4.1.19 (Subgroup Generated By A Subset)

For some set $X \subseteq G$, we define the **subgroup generated by X** , $\langle X \rangle$, to be the smallest subgroup of G which contains X .

From this definition, we can see that we must have $e \in \langle X \rangle$ and $X \subseteq \langle X \rangle$. Also, $\langle X \rangle$ must contain all products of elements in X and their inverses. We can put this in a more useful form with the following proposition.

Proposition 4.1.20

Let X be a non-empty subset of G . Then $\langle X \rangle$ is the set of elements of G of the form $x_1^{\alpha_1} x_2^{\alpha_2} \cdots x_k^{\alpha_k}$ where $x_i \in X$ (not necessarily distinct), $\alpha_i = \pm 1$ and $k \geq 0$ (For $k = 0$, we say the element is e).

Proof. Let T be the set of such elements. Clearly $T \subseteq \langle X \rangle$, and also clearly T is a subgroup of G . We also have that $X \subseteq T$ so $\langle X \rangle \subseteq T$. Thus $T = \langle X \rangle$. $\square$

Example 4.1.21

We have $(\mathbb{Z}, +) = \langle 1 \rangle = \langle 2, 3 \rangle^a$, and $\mathbb{Z}/5\mathbb{Z} = \langle 1 \rangle = \langle 3 \rangle$.

^aNote that we write $\langle 2, 3 \rangle$ instead of $\langle \{2, 3\} \rangle$.

In the above examples, we found that there was some subset of the elements in each of the group where if we considered the subgroup generated by those elements, we get the entire group. There is a special name for such subsets.

Definition 4.1.22 (Generators)

If X is a subset of G such that $\langle X \rangle = G$, then we call X a **generating set** of G .

Notably, these generators are not necessarily unique, as can be seen in the example above.

§4.1.3 Homomorphisms

Imagine you had two groups, G and H and you wanted to think of a function from H to G that preserved some of the structure of the group. Let's say the function was

$\phi : H \rightarrow G$. We could take any two elements $h_1, h_2 \in H$, and we could find $h_1 h_2$, and then apply ϕ to get $\phi(h_1 h_2)$. Alternatively, we could try and find $\phi(h_1)$ and $\phi(h_2)$, and then get $\phi(h_1)\phi(h_2)$. If these were the same, then the function ϕ would indeed preserve some of the structure of the group. This motivates the introduction of *homomorphisms*.

Definition 4.1.23 (Homomorphism)

Let $(G, *_G)$ and $(H, *_H)$ be groups. A function $\phi : H \rightarrow G$ is a **group homomorphism** if for all $a, b \in H$,

$$\phi(a *_H b) = \phi(a) *_G \phi(b).$$

Example 4.1.24 (Inclusion Function)

If $H \leq G$, then the function $\iota : H \rightarrow G$ that has $\iota(h) = h$ for $h \in H$ is a homomorphism. It is also injective.

Example 4.1.25

The function $\phi : \mathbb{Z} \rightarrow \mathbb{Z}/n\mathbb{Z}$ with $\phi(k) = k \pmod{n}$ is a homomorphism, since for $k, l \in \mathbb{Z}$,

$$\phi(k + l) = (k + l) \pmod{n} = (k \pmod{n}) + (l \pmod{n}) = \phi(k) + \phi(l).$$

ϕ is also surjective, since $\{0, 1, \dots, n-1\}$ are all the possible residues modulo n .

Example 4.1.26

The function $\phi : (\mathbb{R}, +) \rightarrow (\mathbb{R}^*, \cdot)$ where $x \mapsto e^x$ is a homomorphism. We have

$$\phi(x + y) = e^{x+y} = e^x \cdot e^y = \phi(x) \cdot \phi(y).$$

It is injective, as $e^x = e^y$ implies $x = y$ using logarithms, and surjective, as given $a \in \mathbb{R}^*$, $\phi(\log a) = e^{\log a} = a$.

We can see some natural consequences of this definition of a homomorphism, which shows how well it preserves the group's structure.

Proposition 4.1.27 (Properties of Homomorphisms)

Let $\phi : H \rightarrow G$ be a homomorphism.

- (i) $\phi(e_H) = e_G$.
- (ii) $\phi(h^{-1}) = \phi(h)^{-1}$ for all $h \in H$.
- (iii) If $\psi : G \rightarrow K$ is another homomorphism, then $\psi \circ \phi : H \rightarrow K$ is also a homomorphism.

Proof.

- (i) We have $e_H *_H e_H = e_H$, so $\phi(e_H *_H e_H) = \phi(e_H) *_G \phi(e_H) = \phi(e_H)$, so by the

cancellation law, $\phi(e_H) = e_G$.

(ii) Consider $\phi(h) *_{\mathcal{G}} \phi(h^{-1}) = \phi(h *_{\mathcal{H}} h^{-1}) = \phi(e_H) = e_G$, by (i). So $\phi(h) *_{\mathcal{G}} \phi(h^{-1}) = e_G$ which is the defining property of an inverse, so $\phi(h^{-1}) = \phi(h)^{-1}$.

(iii) We have

$$\begin{aligned} (\psi \circ \phi)(a *_{\mathcal{H}} b) &= \psi(\phi(a *_{\mathcal{H}} b)) \\ &= \psi(\phi(a) *_{\mathcal{G}} \phi(b)) \\ &= \psi(\phi(a)) *_{\mathcal{K}} \psi(\phi(b)) \\ &= (\psi \circ \phi)(a) *_{\mathcal{K}} (\psi \circ \phi)(b), \end{aligned}$$

so $\psi \circ \phi$ is a homomorphism from $H \rightarrow K$. □

There is a special case of homomorphism, which we can use to define when two groups ‘are the same’.

Definition 4.1.28 (Isomorphism)

If a function $\phi : H \rightarrow G$ is bijection, and ϕ is also a homomorphism from $H \rightarrow G$, then we say it is an **isomorphism**. We say two groups H, G are **isomorphic**, written $H \cong G$ if there is an isomorphism from $H \rightarrow G$.

Having an isomorphism between two groups can be thought of in a few ways. Because we have a bijection function between the two groups, the groups must have the same order. But also, because a homomorphism preserves the structure of the group, we must also have the same group-structure within each group. Thus, when we have two isomorphic groups, we can think of them as two different descriptions of the same group.

For example, we might claim that ‘there is exactly one group of order 2’, and what we mean is that for any group of order 2, we can find an isomorphism to any other group of order 2.

Example 4.1.29

Consider the group $G = \{1, i, -1, -i\}$ with complex multiplication. Then $G \cong \mathbb{Z}/4\mathbb{Z}$. This is isomorphic with the isomorphism $\phi : G \rightarrow \mathbb{Z}/4\mathbb{Z}$, where

$$\begin{aligned} \phi(1) &= 0, \\ \phi(i) &= 1, \\ \phi(-1) &= 2, \\ \phi(-i) &= 3 \end{aligned}$$

The general case is true too, where the group $H = \{e^{2\pi i k/n} : 0 \leq k \leq n-1\}$ with complex multiplication is isomorphic to $\mathbb{Z}/n\mathbb{Z}$.

Example 4.1.30 ($\mathbb{Z}$ ’s subgroups are isomorphic)

$\mathbb{Z} \cong n\mathbb{Z}$ for $n \in \mathbb{Z}$, as defined in [Theorem 4.1.17](#).

It’s worth noting that because isomorphisms are bijective, we have the following result.

Proposition 4.1.31 (Inverses of isomorphisms are isomorphisms)

Let $\phi : H \rightarrow G$ be an isomorphism. Then $\phi^{-1} : G \rightarrow H$ is also an isomorphism.

Proof Sketch. Check that ϕ^{-1} is a homomorphism. □

Kernels

When dealing with homomorphisms, say $\phi : H \rightarrow G$, it is useful to be able to think about what elements in H our homomorphism ‘reaches’. Another useful idea is thinking about what elements in H get mapped to the identity of G . To think about these questions, we use concepts of a homomorphism’s *image* and *kernel*.

Definition 4.1.32 (Image)

Let $\phi : H \rightarrow G$ be a homomorphism. We define the **image** of ϕ to be the set

$$\text{img}(\phi) = \{g \in G : g = \phi(h) \text{ for some } h \in H\}.$$

Definition 4.1.33 (Kernel)

Let $\phi : H \rightarrow G$ be a homomorphism. We define the **kernel** of ϕ to be the set

$$\ker(\phi) = \{h \in H : \phi(h) = e_G\}.$$

Indeed, while both of these are subsets of G and G respectively, they are also subgroups.

Proposition 4.1.34 (The Image and Kernel are Subgroups)

Let H and G be groups and let $\phi : H \rightarrow G$ be a homomorphism. Then $\text{img}(\phi)$ is a subgroup of G , and $\ker(\phi)$ is a subgroup of H .

Proof. We consider the two sets separately.

1. We will show $\text{img}(\phi) \leq G$. For any $x, y \in \text{img}(\phi)$, let $x = \phi(x')$ and $y = \phi(y')$ for $x', y' \in H$. Then

$$\phi(x'y'^{-1}) = \phi(x')\phi(y')^{-1} = xy^{-1} \in \text{img}(\phi),$$

thus by the subgroup criterion $\text{img}(\phi) \leq G$.

2. Now we show $\ker(\phi) \leq H$. For $x, y \in \ker(\phi)$, we have $xy^{-1} \in \ker(\phi)$, as

$$\phi(xy^{-1}) = \phi(x)\phi(y)^{-1} = \phi(x)\phi(y)^{-1} = e_G,$$

so again using the subgroup criterion, $\ker(\phi) \leq H$. □

Example 4.1.35

$\phi : \mathbb{Z} \rightarrow \mathbb{Z}/n\mathbb{Z}$, where $\phi(k) = k \pmod{n}$ has $\text{img}(\phi) = \mathbb{Z}/n\mathbb{Z}$ and $\ker(\phi) = n\mathbb{Z}$.

One of the beauties of introducing the kernel and image is that it allows us to easily see whether a homomorphism is surjective or injective.

Proposition 4.1.36 (Surjectivity and Injectivity Criterion)

Let $\phi : H \rightarrow G$ be a homomorphism.

- (i) ϕ is surjective iff $\text{img}(\phi) = G$.
- (ii) ϕ is injective iff $\ker(\phi) = \{e\}$.

Proof. The first is true by definition, so we prove (ii). Suppose ϕ is injective, then as we have $\phi(e_H) = e_G$, so e_H must be the only element sent to e_G (by the definition of injectivity), which implies that $\ker(\phi) = \{e_H\}$. Now suppose that $\ker(\phi) = \{e_H\}$. Then if $\phi(a) = \phi(b)$ for some $a, b \in H$, we have $\phi(ab^{-1}) = \phi(a)\phi(b)^{-1} = \phi(b)\phi(b)^{-1} = e_G$. However, this implies $ab^{-1} = e_H$, so $a = b$, and ϕ is injective. $\square$

Direct Products

How can we easily find a group that will have two given groups G, H as subgroups? With the aim of getting the simplest construction possible, we can ‘stick them together’: by defining a group operation on the product $G \times H = \{(g, h) : g \in G, h \in H\}$ (a set of ordered pairs).

Definition 4.1.37 (Direct Product)

The **direct product** of two groups G, H is the set $G \times H$ with the operation of component-wise composition,

$$(g_1, h_1) * (g_2, h_2) = (g_1 *_G g_2, h_1 *_H h_2).$$

Proposition 4.1.38

The direct product of two groups G and H is a group.

Proof Sketch. Check everything component-wise. $\square$

This group contains subgroups isomorphic to G and H , taking $G \times \{e_H\}$ and $\{e_G\} \times H$.

A useful idea might be to try and recognize when a group is a direct product of two groups. This can be done with the following theorem.

Theorem 4.1.39 (Direct Product Theorem)

Let $H, K \leq G$ such that

- (i) $H \cap K = \{e\}$
- (ii) $\forall h \in H$ and $k \in K$, we have $hk = kh$
- (iii) $\forall g \in G$, there exists $h \in H, k \in K$ such that $g = hk$

then $G \cong H \times K$.

Proof. Consider the function $\phi : H \times K \rightarrow G$, where $\phi(h, k) = hk$. ϕ is a homomorphism, as

$$\phi((h_1, k_1) \cdot (h_2, k_2)) = \phi(h_1 h_2, k_1 k_2) = h_1 h_2 k_1 k_2 = h_1 k_1 h_2 k_2 = \phi(h_1, k_1) \phi(h_2, k_2).$$

ϕ is surjective by (ii), and now we will show ϕ is injective. Suppose that $(h, k) \in \ker \phi$. Then $h = k^{-1}$, which implies that $h, k \in H \cap K$ by (i), and thus $(h, k) = (e_H, e_K)$. Thus $\ker \phi = \{(e_H, e_K)\}$, so ϕ is injective by the injectivity criterion. $\square$

We now have two ways to think about the direct product.

- If we have two groups H, K , we can form their direct product $H \times K$, and view H and K as subgroups, namely $H \times \{e_K\}$ and $\{e_H\} \times K$.
- Given a group with subgroups H and K , which satisfy the conditions of the direct product theorem, then we know that we are really dealing with $H \times K$.

Indeed these are just two descriptions of the same thing. The convention is often to refer to $H \times \{e_K\}$ and $\{e_H\} \times K$ as just H and K respectively.

§4.2 Important Groups

Now that we have seen some properties of groups, we will now consider some important examples of groups.

§4.2.1 Cyclic Groups

Recall the notion of a generator from [Definition 4.1.22](#).

Definition 4.2.1 (Cyclic)

If G is a group and there is some $a \in G$ such that $\langle a \rangle = G$, then we say G is **cyclic**.

Notably, if this is the case, for all $b \in G$, there exists $k \in \mathbb{Z}$ such that $b = a^k$.

Example 4.2.2 (Examples of Cyclic Groups)

The following groups are all cyclic.

- $(\mathbb{Z}, +)$, which is generated by $\langle 1 \rangle$ or $\langle -1 \rangle$.
- $(\mathbb{Z}/n\mathbb{Z}, +)$, generated by $\langle 1 \rangle$. Indeed, any k coprime to n will satisfy $\langle k \rangle = \mathbb{Z}/n\mathbb{Z}$.
- Let $G = \{e^{2\pi i k/n} : 0 \leq k \leq n-1\}$. Then $(G, \cdot)$ is generated by $\langle e^{2\pi i/n} \rangle$ where k is coprime to n .

These groups all have the same ‘feel’ to them, and indeed they are all isomorphic to the following group.

Definition 4.2.3 (Cyclic Group C_n)

Let C_n be the group of elements $\{e = a^0, a, a^2, \dots, a^{n-1}\}$, where $a^k * a^j = a^{k+j \pmod n}$.

Then $(C_n, *)$ is the **cyclic group of order n** .

Theorem 4.2.4 (Cyclic Groups are Isomorphic)

A cyclic group G is isomorphic to $\mathbb{Z}$ or to C_n for some $n \in \mathbb{N}$.

Proof. As G is cyclic, we have $\langle b \rangle = G$, for some $b \in G$. Now let's suppose that there's some n such that $b^n = e$. Then define $\phi : C_n \rightarrow G$ by $\phi(a^k) = b^k$ for $0 \leq k \leq n-1$. Then for any a^j and $a^k \in C_n$, we trivially have that $\phi(a^j a^k) = \phi(a^{j+k}) = b^{j+k} = b^j b^k = \phi(a^j) \phi(a^k)$. Thus ϕ is a homomorphism. ϕ is also surjective as all elements in G can be written as b^k , $0 \leq k < n$. It is also injective, since $\phi(a^k) = e \implies b^k = e$ and so $k = 0$ (otherwise it contradicts the minimality of n). So ϕ is an isomorphism, and $G \cong C_n$.

If there is no such n , then we define $\phi : \mathbb{Z} \rightarrow G$ by $\phi(k) = b^k$. Then $\phi(k+m) = b^{k+m} = b^k b^m = \phi(k) \phi(m)$, so ϕ is a homomorphism. It is also clearly surjective. Now suppose $m \in \ker(\phi)$. Then $\phi(m) = b^m = e$, and $\phi(-m) = b^{-m} = e$, so if $m \neq 0$, we would get a contradiction to the fact that there is no $n > 0$ with $b^n = e$. So $m = 0$, $\ker(\phi) = \{0\}$ and ϕ must be an isomorphism. Thus $G \cong \mathbb{Z}$. $\square$

Because of this theorem, we will often just write C_n or $\mathbb{Z}$ for a cyclic group, regardless of its description.

Proposition 4.2.5

Cyclic groups are abelian.

Proof Sketch. Check definitions. $\square$

The idea of there being some k such that $g^k = e$ for some g is a frequently occurring concept.

Definition 4.2.6 (Order of an Element)

The **order of an element** $g \in G$ is the smallest $n \in \mathbb{N}$ such that $g^n = e$. This is sometimes written $\text{ord}_G(g) = n$. If there is no such n , we say g has **infinite order**.

Theorem 4.2.7 (Fundamental Theorem of Orders)

Let G be a group, and let $g \in G$ have finite order n . Then if $g^k = 1$, we have $n \mid k$.

Proof. By the division algorithm, we can write $k = qn + r$ uniquely with $q, r \in \mathbb{Z}$ and $0 \leq r < n$. Then we have

$$g^k = g^{qn+r} = g^{qn} g^r = (g^n)^q g^r = g^r = e.$$

But we defined n to be the smallest positive power for which $g^n = e$, and as $r < n$, we must have $r = 0$, otherwise we contradict the minimality of n . Thus $k = qn$, that is, $n \mid k$. $\square$

§4.2.2 Dihedral Group

Group theory is frequently thought of as the ‘algebraic study of symmetry’. With this rather vague claim in mind, we will now look at some groups related to geometry – the symmetries of a regular n -gon. Let’s define what we mean by a ‘symmetry’ of a regular polygon.

Definition 4.2.8

A **symmetry** of a regular n -gon is a transformation of the n -gon, so that when the transformed n -gon is placed on the original n -gon, it exactly covers it.

Definition 4.2.9

The **dihedral group** D_{2n} is the group of symmetries of a regular n -gon, where the group operation is the composition of symmetries.

Clearly in this group, we will have n rotations (clockwise) of the angle $\frac{2\pi k}{n}$, $0 \leq k < n$ ($k = 0$ gives the identity or ‘do nothing’ symmetry). There is also n reflections.

When n is odd, the n reflections are in axis through the center and each of the vertices. For even n , we have $n/2$ reflections in axis through pairs of opposite vertices, and $n/2$ reflections in axes through pairs of opposite midpoints of edges.

From this you should count $2n$ elements, and we will now see that there is no other elements.

Proposition 4.2.10

A regular n -gon has $2n$ symmetries.

Proof. Let $g \in D_{2n}$. Since g is a symmetry of our n -gon, it must send vertices to vertices and edges to edges. So if v_1 is a vertex who’s adjacent vertices are v_2 and v_n and we have $g(v_1) = v_i$, then we must know $g(v_2)$ and $g(v_n)$, so we must know exactly what g . Since there is n possibilities for where v_1 is sent, and 2 possibilities for where v_2 is sent, there must be $2n$ elements in total. $\square$

Proposition 4.2.11

D_{2n} is a group.

Proof. We have closure by ‘composition of symmetries are also symmetries’, identity with the ‘do nothing’ symmetry and also inverses, as a rotation by $\frac{2\pi k}{n}$ has an inverse of a $\frac{2\pi(n-k)}{n}$ rotation, and reflections are self inverse. We also have associativity, as

the composition of functions is associative. Thus D_{2n} is a group. $\square$

It's possible to generate every element in the group with just a single rotation and a reflection. Let r be the rotation by $\frac{2\pi}{n}$, and let s be the reflection about the axis through v_1 and the center. Then r^k gives the rotation by $\frac{2\pi k}{n}$ and we can perform any reflection by first rotating the n -gon, then applying the reflection, and then rotating back.

D_{2n} is also not abelian, and indeed we have $rs = sr^{-1}$.

Aside: Group Presentations

One way to write groups is with a **presentation**. This is an expression of the form

$$\langle \text{generators} \mid \text{relations between generators} \rangle.$$

As an example, we can express the cyclic and dihedral groups using generators as follows

$$\begin{aligned} C_n &= \langle a \mid a^n = e \rangle \\ D_{2n} &= \langle r, s \mid r^n = e, s^2 = e, rs = sr^{-1} \rangle \end{aligned}$$

You should be able to deduce all things that are true in the group from the relations in the presentation. However, you should be aware that there are some 'caveats', for example if we wrote down

$$\langle r, s \mid r^n = e, s^2 = e \rangle \neq D_{2n}.$$

It is, in general, quite hard to write down a presentation for a given group, or even to determine the group from a given presentation. In this course, we will not look at the 'mathematical tools' which allow us to discuss presentations in a rigorous way.

Example 4.2.12

The group

$$\langle a, b, c \mid aba^{-1}b^{-1} = b, bcb^{-1}c^{-1} = c, cac^{-1}a^{-1} = a \rangle = \{e\},$$

but the group

$$\langle a, b, c, d \mid aba^{-1}b^{-1} = b, bcb^{-1}c^{-1} = c, cdc^{-1}d^{-1} = d, dad^{-1}a^{-1} = a \rangle$$

is the **Higman group**, and it is infinite. It should be clear from this example that it is quite hard to determine a group from just its presentation.

§4.2.3 Permutation Groups

We are now going to discuss groups made up of *permutations*.

Definition 4.2.13 (Permutations)

Given a set X , a **permutation** of X is a bijective function $\sigma : X \rightarrow X$. The set of

all permutations of X is denoted $\text{Sym } X$.

Theorem 4.2.14

For any set X , $\text{Sym } X$ is a group with respect to composition.

Proof. We check the group axioms individually.

- *Closure.* The composition of two bijective functions from $X \rightarrow X$ is a bijective function from $X \rightarrow X$.
- *Associativity.* Composition of functions is associative.
- *Identity.* The identity function $\text{id}(x) = x$ is bijective.
- *Inverses.* Every bijective function has a bijective inverse.

Thus $\text{Sym } X$ is a group. □

Definition 4.2.15 (Symmetric Group)

If $|X| = n$, we write S_n for (the isomorphism class of) $\text{Sym } X$. S_n is the **symmetric group** on n elements.

It should be reasonably clear that $|S_n| = n(n-1) \cdots 1 = n!$. We will also normally use $X = \{1, 2, 3, \dots, n\}$ when we study S_n . When dealing with permutation groups, it's helpful to have some notation to express permutations. For a general $\sigma \in S_n$, we write

$$\sigma = \begin{pmatrix} 1 & 2 & 3 & \cdots & n \\ \sigma(1) & \sigma(2) & \sigma(3) & \cdots & \sigma(n) \end{pmatrix}.$$

Example 4.2.16

If we had some $\sigma \in S_3$ such that $\sigma(1) = 2$, $\sigma(2) = 3$, and $\sigma(3) = 1$, we would write

$$\sigma = \begin{pmatrix} 1 & 2 & 3 \\ 2 & 3 & 1 \end{pmatrix}.$$

A slightly better notation for when we have a permutation that ‘cycles’ some elements $a_1, \dots, a_k \in \{1, 2, \dots, n\}$ and leaves the other elements unchanged, we can write

$$\sigma = (a_1 \ a_2 \ \cdots \ a_k)$$

which denotes the permutation mapping the elements as follows

The cyclic nature of this notation also implies that the two permutations $(a_1 \ a_2 \ \cdots \ a_k) =$

$(a_2 \ a_3 \ \cdots \ a_k \ a_1)$. To define this notation slightly more formally, we have

$$(a_1 \ a_2 \ \cdots \ a_k)(x) = \begin{cases} a_{i+1} & \text{if } x = a_i, (i < k) \\ a_1 & \text{if } x = a_k \\ x & \text{if } x \notin \{a_1, a_2, \dots, a_k\}. \end{cases}$$

We distinguish between permutations that can be written directly in this form in the following way.

Definition 4.2.17 (Cycles and Transpositions)

A permutation of the form $\sigma = (a_1 \ a_2 \ \cdots \ a_k)$ is a **k -cycle**. If $k = 2$ then we call it a **transposition**.

As cycles are permutations, we can compose them.

Example 4.2.18 (Composing Cycles)

If we consider the composition of two cycles $(1 \ 2 \ 3 \ 4)(3 \ 2 \ 4)$, this should be a permutation in S_4 . Indeed we have

$$\begin{aligned} 1 &\mapsto 1 \mapsto 2 \\ 2 &\mapsto 4 \mapsto 1 \\ 3 &\mapsto 2 \mapsto 3 \\ 4 &\mapsto 3 \mapsto 4 \end{aligned}$$

So we actually have that the composition of these cycles is also a cycle^a, namely $(1 \ 2 \ 3 \ 4)(3 \ 2 \ 4) = (1 \ 2)$.

^aThis is, in general, not the case

In the example above, the two cycles involved elements that were in both cycles. We have a specific term for when this is not the case.

Definition 4.2.19 (Disjoint Cycles)

We say that two cycles are **disjoint** if no number appears in both cycles.

Lemma 4.2.20

Disjoint cycles commute.

Proof. Let $\sigma, \tau \in S_n$ be two disjoint cycles. We want to show that $\sigma\tau = \tau\sigma$, that is, for any $x \in \{1, 2, \dots, n\}$, we have $\sigma(\tau(x)) = \tau(\sigma(x))$. We have two cases.

If x is in neither σ or τ , then $\sigma(x) = \tau(x) = x$, and thus $\sigma(\tau(x)) = \tau(\sigma(x)) = x$.

Otherwise x is in exactly one of σ or τ . WLOG let it be in σ . Then $\sigma(x)$ is also in σ (and hence not τ), so $\tau(x) = x$ and $\tau(\sigma(x)) = \sigma(x)$. Thus $\sigma(\tau(x)) = \sigma(x)$, so they commute. $\square$

Slightly more surprising is the following theorem

Theorem 4.2.21 (Writing Permutations with Cycles)

Any $\sigma \in S_n$ can be written uniquely^a as the composition of disjoint cycles.

^aUp to the order of the cycles in the composition

Proof. First we show that any permutation can be written as the composition of cycles. Take $\sigma \in S_n$, and consider $1, \sigma(1), \sigma^2(1), \dots$. Since $\{1, 2, \dots, n\}$ is finite, there must exist $a > b$ such that $\sigma^a(1) = \sigma^b(1)$. So $\sigma^{a-b}(1) = 1$. Now let $k > 0$ be the smallest integer such that $\sigma^k(1) = 1$, which must exist by the previous argument. Then for $0 \leq l < m < k$, if $\sigma^m(1) = \sigma^l(1)$, then $\sigma^{m-l}(1) = 1$, which contradicts the minimality of k . So all of $1, \sigma(1), \sigma^2(1), \dots, \sigma^{k-1}(1)$ are distinct. This gives us our first cycle $(1 \ \sigma(1) \ \sigma^2(1) \ \dots \ \sigma^{k-1}(1))$. We can repeat this process for the next number in $\{1, 2, \dots, n\}$ that has not already appeared, until eventually every element has appeared. As σ is a bijection, no element can reappear.

We now show that this composition of cycles is unique up to the order of composition. Suppose we have two such decompositions

$$\begin{aligned} \sigma &= (a_1 \ \dots \ a_{k_1})(a_{k_1+1} \ \dots \ a_{k_2}) \dots (a_{k_{m-1}+1} \ \dots \ a_{k_m}) \\ &= (b_1 \ \dots \ b_{k_1})(b_{k_1+1} \ \dots \ b_{k_2}) \dots (b_{k_{m-1}+1} \ \dots \ b_{k_m}) \end{aligned}$$

and each $j \in \{1, 2, \dots, n\}$ appears exactly once in both. Then we have $a_1 = b_t$ for some t , and the other numbers in the cycle are uniquely determined by $\sigma(a_1), \sigma^2(a_1), \dots$. So we have

$$(a_1 \ \dots \ a_{k_1})(\dots) = (b_t \ \dots)(\dots),$$

since disjoint cycles commute and we can ‘cycle’ the elements in cycles. If we continue this, we will find that all other cycles match too. $\square$

Now let’s consider an element $\sigma \in S_n$, and specifically we will look at the order of σ .

Definition 4.2.22

The set of cycle lengths of the disjoint cycle decomposition of a permutation σ is its **cycle type**.

Example 4.2.23

$(1 \ 2 \ 3)(5 \ 6)$ has a cycle type of 3, 2 (or 2, 3).

Theorem 4.2.24

The order of $\sigma \in S_n$ is the least common multiple of the cycle lengths in its cycle type.

Proof. First note that the order of a k -cycle is k . Suppose that $\sigma = \tau_1 \tau_2 \dots \tau_r$, where τ_i is a cycle disjoint to the others. Then we have $\sigma^m = \tau_1^m \tau_2^m \dots \tau_r^m$, since disjoint cycles commute. Let each τ_i be a k_i -cycle, then if $\sigma^m = e$, we have $\tau_1^m \tau_2^m \dots \tau_r^m = e$,

and thus $\tau_i^m = e$ for all i as they are disjoint. By the fundamental theorem of orders, we must have $k_i \mid m$, and thus $m = \text{lcm}(k_1, k_2, \dots, k_r)$ by minimality. $\square$

This theorem gives us an easy way to find the order of the elements in S_n : write them in cycle notation.

Disjoint cycle notation is a useful way to express elements of S_n . Another useful notation is writing elements as the product of transpositions.

Theorem 4.2.25 (Writing Permutations with Transpositions)

Let $\sigma \in S_n$. Then σ is a product of transpositions.

Proof. It suffices to show that we can write any cycle as a product of transpositions. We observe that

$$(a_1 \ a_2 \ \cdots \ a_k) = (a_1 \ a_2)(a_2 \ a_3) \cdots (a_{k-1} \ a_k).$$

$\square$

Unlike the disjoint cycle decomposition, this isn't unique. For example, $(1 \ 2 \ 3 \ 4) = (1 \ 2)(2 \ 3)(3 \ 4) = (1 \ 2)(2 \ 3)(1 \ 2)(3 \ 4)(1 \ 2)$. However, the parity of the number of transpositions *is* invariant among decompositions.

Theorem 4.2.26 (Parity of Transpositions)

Writing $\sigma \in S_n$ as a product of transpositions in different ways, the number of transpositions used is always either even or odd, that is, the parity is invariant with respect to σ .

Proof. Let's write $\chi(\sigma)$ for the number of cycles in σ in its disjoint cycle decomposition, including any 1-cycles. We will consider what happens to $\chi(\sigma)$ when we multiply σ by a transposition $\tau = (c \ d)$.

- If a cycle does not contain c or d , it will not be affected.
- If c and d are in the same cycle, say $(c \ a_2 \ a_3 \ \cdots \ a_{k-1} \ d \ a_{k+1} \ \cdots \ a_l)$, then composing with $(c \ d)$ gives $(c \ a_{k+1} \ \cdots \ a_l)(d \ a_2 \ \cdots \ a_{k-1})$. So $\chi(\sigma\tau) = \chi(\sigma) + 1$.
- If c and d are in different cycles, we have

$$(c \ a_2 \ \cdots \ a_k)(d \ b_2 \ \cdots \ b_l)(c \ d) = (c \ b_2 \ \cdots \ b_l \ d \ a_2 \ \cdots \ a_k).$$

$$\text{So } \chi(\sigma\tau) = \chi(\sigma) - 1.$$

Thus for any σ and any transposition τ , $\chi(\sigma) \equiv \chi(\sigma\tau) + 1 \pmod{2}$. We know that $\chi(\sigma)$ is uniquely determined by σ , and if we write

$$\sigma = e\tau_1 \cdots \tau_k = e\tau'_1 \cdots \tau'_l,$$

we can use our result to get

$$\begin{aligned}\chi(\sigma) &\equiv \chi(e) + k \equiv n + k \pmod{2} \\ \chi(\sigma) &\equiv \chi(e) + l \equiv n + l \pmod{2},\end{aligned}$$

and thus $k \equiv l \pmod{2}$. □

Because of this invariance, we can distinguish between odd and even permutations.

Definition 4.2.27 (Sign of a Permutation)

Writing $\sigma \in S_n$ as a product of transpositions $\sigma = \tau_1 \tau_2 \cdots \tau_k$, the **sign** of σ is defined as $\text{sign}(\sigma) = (-1)^k$. If k is even, we say that σ is **even**, and if k is odd, we say that σ is **odd**.

Proposition 4.2.28

For $n \geq 2$, $\text{sign} : S_n \rightarrow \{\pm 1\}$ is a surjective homomorphism.

Proof. We already know that sign is well defined, and if $\chi(\sigma) = k$ and $\chi(\sigma') = l$ for $\sigma, \sigma' \in S_n$, then $\sigma\sigma'$ can be written with $k + l$ transpositions, so $\text{sign}(\sigma\sigma') = (-1)^{k+l} = (-1)^k(-1)^l = \text{sign}(\sigma)\text{sign}(\sigma')$, so sign is a homomorphism. It is also surjective since $\text{sign}(e) = 1$ and $\text{sign}(1\ 2) = -1$. □

There is an important group that comes from sign being a homomorphism.

Definition 4.2.29 (Alternating Group)

The **alternating group** A_n is the kernel of the homomorphism $\text{sign} : S_n \rightarrow \{\pm 1\}$, that is, it's the group of even permutations.

§4.2.4 Möbius Groups

In the previous section we discussed many of the properties of permutations of a finite set. In this section, we will look at some permutations of an infinite set. We will be looking at functions $\mathbb{C} \rightarrow \mathbb{C}$ - but since $\mathbb{C}$ has some intrinsic geometric properties (lines, circles, etc) unlike $\{1, 2, \dots, n\}$, we will restrict ourselves to functions that interact well with its geometry.

More precisely, we will be looking at functions of the form $f : \mathbb{C} \rightarrow \mathbb{C}$, where

$$f(z) = \frac{az + b}{cz + d},$$

with $a, b, c, d \in \mathbb{C}$ and $ad - bc \neq 0$. We have this condition because

$$f(z) - f(w) = \frac{az + b}{cz + d} - \frac{aw + b}{cw + d} = \frac{(ad - bc)(z - w)}{(cw + d)(cz + d)},$$

so if $ad - bc = 0$, we would have $f(z) = f(w)$ and f would be constant. We want to avoid this case as we wish to somehow form a group from these functions.

We also have another point which could cause some trouble, namely when $z = -d/c$, and the denominator of f is 0. To fix this, we are going to introduce a new point ' ∞ '

to $\mathbb{C}$ to form the **extended complex plane**, $\hat{\mathbb{C}} = \mathbb{C} \cup \{\infty\}$. This can be visualized through ‘stereographic projection’.

Consider a sphere with the complex plane cutting it at the equator.

We get a correspondence between points on the sphere and points in $\mathbb{C}$ by drawing a line from the north pole to a point on the sphere, and seeing where it intersects the plane as shown. The north pole corresponds to ∞ in $\hat{\mathbb{C}}$.

Definition 4.2.30 (Möbius Maps)

A **Möbius map** is a function $f : \hat{\mathbb{C}} \rightarrow \hat{\mathbb{C}}$ of the form

$$f(z) = \frac{az + b}{cz + d},$$

with $a, b, c, d \in \mathbb{C}$ and $ad - bc \neq 0$, and with $f(-d/c) = \infty$ and

$$f(\infty) = \begin{cases} \frac{a}{c} & \text{if } c \neq 0 \\ \infty & \text{if } c = 0 \end{cases}.$$

Let's look at some properties of Möbius maps.

Proposition 4.2.31

Möbius maps are bijections $\hat{\mathbb{C}} \rightarrow \hat{\mathbb{C}}$.

Proof Sketch. Define $f^{-1}(z) = \frac{dz-b}{-cz+a}$, and check that $f^{-1}(f(z)) = z$. □

We now have the main result of this section.

Theorem 4.2.32 (Möbius Group)

The set of Möbius maps forms a group $\mathcal{M}$ under composition.

Proof.

- *Closure.* Let $f_1(z) = \frac{a_1z+b_1}{c_1z+d_1}$ and $f_2(z) = \frac{a_2z+b_2}{c_2z+d_2}$. Then

$$f_2(f_1(z)) = \frac{(a_1a_2 + b_2c_1)z + (a_2b_1 + b_2d_1)}{(c_2a_1 + d_2c_1)z + (c_2b_1 + d_2d_1)} = \frac{a'z + b'}{c'z + d'},$$

and $a'd' - b'c' \neq 0$.

- *Identity.* Letting $a = 1, b = 0, c = 0$ and $d = 1$ gives $f(z) = z$.

- *Inverses.* For $f(z) = \frac{az+b}{cz+d}$, we have $f^{-1}(z) = \frac{dz-b}{-cz+a}$.

Thus the set of Möbius maps form a group. $\square$

Remark. When working with Möbius maps in $\hat{\mathbb{C}}$, we will (somewhat improperly) use the notation ' $\frac{1}{\infty} = 0$ ', ' $\frac{1}{0} = \infty$ ' and ' $\frac{a\infty}{c\infty} = \frac{a}{c}$ ' – but take care not to use this notation accidentally in other circumstances.

This group has an interesting set of generators, which provide some insight as to what Möbius maps do to the extended complex plane.

Theorem 4.2.33 (Generators of $\mathcal{M}$)

Every Möbius map can be written as a composition of maps of the following forms:

1. $f(z) = az$, $a \neq 0$ – dilation/rotation;
2. $f(z) = z + b$ – translation;
3. $f(z) = \frac{1}{z}$ – inversion;

Proof. Let $f(z) = \frac{az+b}{cz+d}$. Then if $c \neq 0$, $f(z)$ is the composition

$$\begin{aligned} z &\mapsto z + \frac{d}{c} \mapsto \frac{1}{z + \frac{d}{c}} \mapsto \frac{(-ad + bc)c^{-2}}{z + \frac{d}{c}} \\ &\mapsto \frac{a}{c} + \frac{(-ad + bc)c^{-2}}{z + \frac{d}{c}} = \frac{az + b}{cz + d}. \end{aligned}$$

If $c = 0$, then $z \mapsto \frac{a}{d}z \mapsto \frac{a}{d}z + \frac{b}{d}$. $\square$

§4.3 Lagrange's Theorem

We will now begin to add to our algebraic toolkit by developing some results that will shed some light on the internal structure of a group with respect to a subgroup. We will begin by defining the notion of a *coset*, which will be used frequently throughout the rest of the course.

Definition 4.3.1 (Coset)

Let G be a group and H a subgroup of G . For any element $g \in G$, the symbol

$$gH = \{gh : h \in H\}$$

is the set of elements gh , where h ranges over elements of H . gH is a **left coset** of H in G . We can also define $Hg = \{hg : h \in H\}$ which is the **right coset** of H in G .

The cosets of H in G are subsets of G , but they aren't (typically) subgroups. You should think of a coset as being a 'translated copy' of H that has the same number of elements as H , but may or may not be a subgroup.

Example 4.3.2 (Cosets of $2\mathbb{Z}$)

Let $H = 2\mathbb{Z} \leq \mathbb{Z}$. Then (using additive notation) the coset $0 + 2\mathbb{Z} = \{0 + k : k \in 2\mathbb{Z}\}$. The coset $1 + 2\mathbb{Z} = \{1 + k : k \in 2\mathbb{Z}\}$ is the set of all odd integers.

These are the only cosets we can obtain with this subgroup, as if we fix some $n \in \mathbb{Z}$, then $n + 2\mathbb{Z}$ will be in $2\mathbb{Z}$ if n is even, and in $1 + 2\mathbb{Z}$ if n is odd.

Example 4.3.3

Let $H = \{e, (1\ 2)\} \leq S_3 = \{e, (1\ 2), (1\ 3), (2\ 3), (1\ 2\ 3), (1\ 3\ 2)\}$.

Considering the cosets of H , we have

$$\begin{aligned} eH &= \{e, (1\ 2)\} = H \\ (1\ 2)H &= \{(1\ 2), e\} = H \\ (1\ 3)H &= \{(1\ 3), (1\ 3)(1\ 2\ 3)\} \\ (2\ 3)H &= \{(2\ 3), (1\ 3\ 2)\} \\ (1\ 2\ 3)H &= \{(1\ 2\ 3), (1\ 3)\} = (1\ 3)H \\ (1\ 3\ 2)H &= \{(1\ 3\ 2), (2\ 3)\} = (2\ 3)H, \end{aligned}$$

and so all together we have 3 distinct cosets.

From the last example, there are some notable details:

- Whenever we choose the identity element, we get the subgroup back: $eH = H$.
- Also, whenever we choose an element of H , we get H back: $hH = H$ for $h \in H$.
- The cosets of a subgroup are always the same size as that subgroup.
- Every element in G appears in at least one coset, that is, $\bigcup_{g \in G} gH = G$.

This leads up to *Lagrange's Theorem*.

Theorem 4.3.4 (Lagrange's Theorem)

Let $H \leq G$ be a subset of a finite group G . Then

- (i) $|H| = |gH|$ for all $g \in G$;
- (ii) For $g_1, g_2 \in G$, either $g_1H = g_2H$ or $g_1H \cap g_2H = \emptyset$;
- (iii) $G = \bigcup_{g \in G} gH$

In particular, defining the **index of H in G** as $|G : H|$ to be the number of distinct cosets of H in G , then $|G| = |G : H| \cdot |H|$.

Proof.

- (i) The function $H \rightarrow gH, h \rightarrow gh$ defined a bijection between H and gH .
- (ii) Suppose $g_1H \cap g_2H \neq \emptyset$. Then there exists $g \in g_1H \cap g_2H$. So $g = g_1h_1 = g_2h_2$

for some $h_1, h_2 \in H$. Then $g_1 = g_2 h_2 h_1^{-1}$, so for any $h \in H$, we have $g_1 h = g_2 h_2 h_1^{-1} h \in g_2 H$, so $g_1 H \subseteq g_2 H$. Similarity, $g_2 H \subseteq g_1 H$, thus $g_2 H = g_1 H$.

- (iii) Given some $g \in G$, then $g \in gH$ (since $e \in H$). Thus $G \subseteq \bigcup_{g \in G} gH$, and certainly $\bigcup gH \subseteq G$, thus $G = \bigcup_{g \in G} gH$.

Finally, $|G|$ is partitioned into the number of distinct cosets of H , thus $|G| = |G : H| \cdot |H|$. $\square$

What this theorem is saying is ‘cosets pave the group’, as all the paving stones (the cosets) are the same size, they don’t overlap, and they cover the whole group.

Here, we used left cosets but we could have used right cosets and would have gotten an analogous result. In general, the left and right cosets are not equal: $gH \neq Hg$. When this is true, it is an interesting property of a subgroup, that we will look at later in this chapter.

So left and right cosets are not generally, the same but what about two left cosets?

Proposition 4.3.5

If H is a subgroup of a group G , and $g_1, g_2 \in G$, then

$$g_1 H = g_2 H \iff g_1^{-1} g_2 \in H.$$

Proof Sketch. Follows from definitions. $\square$

In particular, taking $g' \in gH$ gives $g'H = gH$.

Let us take an element from each of the distinct cosets of a subgroup

$$g_1, g_2, \dots, g_{|G:H|},$$

then

$$G = \bigcup_{i=1}^{|G:H|} g_i H,$$

where the union is the union of disjoint sets. The elements g_i are called **coset representatives** of H in G .

We can use Lagrange’s theorem to immediately derive some useful results.

Corollary 4.3.6 (Order of an Element Divides Order of a Group)

Let G be a finite group, and let $g \in G$. Then $\text{ord}_G(g) \mid |G|$.

Proof. Notice that the subgroup $\langle g \rangle$ is a cyclic group of order $\text{ord}_G(g)$. Then $|\langle g \rangle| \mid |G|$ by Lagrange’s theorem. $\square$

Corollary 4.3.7

Let G be a finite group, and $g \in G$. Then $g^{|G|} = e$.

Proof. The order of g divides $|G|$, and thus $|G| = \text{ord}_G(g) \cdot k$ for some k . Thus $g^{|G|} = g^{\text{ord}_G(g) \cdot k} = e^k = e$. $\square$

Corollary 4.3.8

Groups of prime order are cyclic, and are generated by any non-identity element.

Proof. Let's suppose we have a group G with $|G| = p$, for a prime p . Take $g \in G$. Then $|\langle g \rangle| \mid |G|$ by Lagrange. So $|\langle g \rangle| = 1$ or p . If $g \neq e$, then $|\langle g \rangle| \neq 1$, so it must be p . So $\langle g \rangle = G$. $\square$

We will now see how a theorem from number theory can be proved using Lagrange's theorem. First, recall that $(\mathbb{Z}/n\mathbb{Z})^\times$ is a group made up of the elements of $\{1, 2, \dots, n-1\}$ that have an inverse. We also have $|(\mathbb{Z}/n\mathbb{Z})^\times| = \phi(n)$, which you should recall from 'Numbers and Sets'. We will now prove the following theorem.

Theorem 4.3.9 (Fermat-Euler Theorem)

Let $n \geq 1$, and $a \in \mathbb{Z}$ coprime to n . Then

$$a^{\phi(n)} \equiv 1 \pmod{n}.$$

Proof Sketch. Note that $a \in (\mathbb{Z}/n\mathbb{Z})^\times$ which is a group, then $a^{\phi(n)} = a^{|\mathbb{Z}/n\mathbb{Z}^\times|} = e$, by the corollary we proved earlier. $\square$

§4.3.1 Exploring Group Using Lagrange

Recall that we have $|G| = |G : H| \cdot |H|$, so based on the order of G , we can deduce the possible orders of a subgroup H .

Remark. Just because some $k \mid |G|$, that doesn't imply that there is some subgroup of order k .

Example 4.3.10 (Subgroups of D_{10})

Consider the group D_{10} . The order of this group is 10, so its subgroups must be of order 1, 2, 5 and 10 by Lagrange's theorem. 1 does occur with the subgroup $\{e\}$. Also 10 occurs with the subgroup D_{10} .

If we want a subgroup of order 2, we need to have the identity e and some other element of order 2. There are 5 such elements in D_{10} (reflections), which gives us 5 subgroups of order 2.

If we want a subgroup of order 5, it must be cyclic by [Corollary 4.3.8](#). We have 4 elements of order 5 in D_{10} .

These are all of the subgroups of D_{10} .

We will study groups of small order in this course, and we can already classify groups of order ≤ 5 using Lagrange.

- If $|G| = 1$, then $G = \{e\}$.

- If $|G| = 2, 3$, or 5 , then G is the cyclic group C_2, C_3 , and C_5 respectively, by Corollary 4.3.8.
- If $|G| = 4$, we have two possibilities, as we will see in the following proposition.

Proposition 4.3.11 (Groups of Order 4)

If $|G| = 4$, then $G \cong C_4$ or $G \cong C_2 \times C_2$.

Proof. By Lagrange, the possible orders of elements of G are 1, 2 or 4. If there is an element of order 4, say g , then $\langle g \rangle = G \cong C_4$. If there is no element of order 4, then all non-identity elements have order 2. We proved in Example Sheet 1 (apologies if you have not done this question) that G is abelian. We can take two distinct elements of order 2, say b, c . Then $\langle b \rangle \cap \langle c \rangle = \{e, b\} \cap \{e, c\} = \{e\}$. Also everything commutes as G is abelian, and if we have bc , then $bc \neq b$ and $bc \neq c$. Also $bc \neq e$ as otherwise $b = c^{-1} = c$. Thus bc is the fourth element of the group. Thus by the direct product theorem, $G = \langle b \rangle \times \langle c \rangle \cong C_2 \times C_2$. $\square$

To study groups of order 6 and greater, we are going to need more algebraic machinery.

§4.4 Quotients of Groups

Using the direct product, we have a notion of ‘multiplying’ groups together. We will now think about how and when it makes sense to ‘divide’ one group by another.

§4.4.1 Normal Subgroups

We will also be interested in subgroups for which the left and right cosets coincide.

Definition 4.4.1 (Normal Subgroups)

A subgroup $N \leq L$ is **normal** if $\forall g \in G, gN = Ng$. We write $N \trianglelefteq G$.

Proposition 4.4.2 (Equivalent Conditions for Normal Subgroups)

The following are all equivalent conditions for a subgroup being normal.

- (i) $\forall g \in G, gN = Ng$.
- (ii) $\forall g \in G$, and $\forall n \in N, g^{-1}ng \in N$ (or $gng^{-1} \in N$).
- (iii) $\forall g \in G, g^{-1}Ng = N$.

Proof Sketch. Follows from definitions. $\square$

We will use all of these conditions interchangeably.

Example 4.4.3

The following are all normal subgroups

- (i) $n\mathbb{Z} \trianglelefteq \mathbb{Z}$, as for all $a \in \mathbb{Z}$, we have $a + n\mathbb{Z} = \{a + nk : k \in \mathbb{Z}\} = \{nk + a : k \in \mathbb{Z}\} = n\mathbb{Z} + a$.
- (ii) $A_3 \trianglelefteq S_3$, where $A_3 = \{e, (1\ 2\ 3), (1\ 3\ 2)\}$. Clearly $eA_3 = A_3e$, and $(1\ 2\ 3)A_3 = A_3(1\ 2\ 3)$, $(1\ 3\ 2)A_3 = A_3(1\ 3\ 2)$. Also $(1\ 2)A_3 = \{(1\ 2), (2\ 3), (1\ 3)\} = A_3(1\ 2)$, and similarly for $(1\ 3)$ and $(2\ 3)$.

Proposition 4.4.4

Any subgroup of an abelian group is normal.

Proof. For any subgroup N , if G is abelian, we have $g^{-1}ng = n \in N$, so N is normal. $\square$

Proposition 4.4.5

Any subgroup of index 2 is normal.

Proof. If $H \leq G$ is a subgroup with $|G : H| = 2$, then there are only two cosets. $H = eH = He$ is one of the cosets, and since cosets are disjoint (by Lagrange), the other coset has to be $G \setminus H$ both for left and right cosets. So H is normal. $\square$

These propositions give us two rich sources of normal subgroups, and we will now see something that gives all possible normal subgroups.

Proposition 4.4.6

If $\phi : G \rightarrow H$ is a homomorphism, then $\ker \phi \trianglelefteq G$.

Proof. First we note that the kernel of a homomorphism is a subgroup. Then given some $k \in \ker \phi$, $g \in G$, then

$$\phi(g^{-1}kg) = \phi(g)^{-1}\phi(k)\phi(g) = \phi(g)^{-1}e\phi(g) = e,$$

so $g^{-1}kg \in \ker \phi$, for all $g \in G$ and $k \in \ker \phi$. $\square$

Later on, we will see that normal subgroups are *exactly* kernels of homomorphisms.

Example 4.4.7

The following are all normal subgroups.

1. $\mathrm{SL}_2(\mathbb{R}) \trianglelefteq \mathrm{GL}_2(\mathbb{R})$, as $\mathrm{SL}_2(\mathbb{R}) = \ker(\det)$.
2. $A_n \trianglelefteq S_n$ as A_n is the kernel of the sign homomorphism. Also $|S_n : A_n| = 2$.

With the notion of normal subgroups, we can continue to classify groups of small order.

Proposition 4.4.8 (Groups of Order 6)

If $|G| = 6$, then $G \cong C_6$ or D_6 .

Proof. By Lagrange, possible element orders are 1 (for e), 2, 3 and 6. If there is an element of order 6, then $G \cong C_6$. If there is no such element, then by one of the questions on the example sheet (again sorry), then there is an element of order 3, say r , as otherwise our group would have an order that is a power of 2. So $|\langle r \rangle| = 3$ and by Lagrange, $|G| = 6 = |G : \langle r \rangle| \cdot |\langle r \rangle| = 3|G : \langle r \rangle|$. So $\langle r \rangle \trianglelefteq G$.

There must also be an element s of order 2, since $|G|$ is even (again see the example sheet). We can now consider what $s^{-1}rs \in \langle r \rangle$ can be.

If $s^{-1}rs = e$, then $r = e$, which is not the case. If $s^{-1}rs = r$, then $sr = rs$, which implies that sr has order 6, which we assumed there wasn't. Thus we must have $s^{-1}rs = r^2$, so $G = \langle r, s \rangle$ with $r^3 = s^2 = e$, and $sr = r^2s = r^{-1}s$, which is how we define D_6 . $\square$

§4.4.2 Quotients

We said that the goal of this chapter was to develop the notion of ‘dividing’ groups, but what does that actually mean? As in, why would we attempt to make sense of such an idea? In a previous chapter, we looked at how to recognize when there was some surjective homomorphism from a group G to another group H . We are now going to take this idea further, to see how we can construct *all* groups H such that there is a surjective homomorphism from a given group G to H . Using this, we will be able to select exactly the properties of G that we wish to preserve in H , and which we want to ignore. In the previous section we developed the idea of *normal* subgroups. This will be a key aspect in developing this idea.

We are first going to define how we can ‘multiply’ cosets.

Definition 4.4.9 (Coset Multiplication)

Let G be a group with a subgroup H . We define the multiplication of the coset of a and of b to be the coset of ab , that is,

$$aH \cdot bH = (ab)H.$$

There are some inherent problems with this definition. For one, it's not immediately clear that such a product is well defined. If we had some cosets $aH = a'H$ and $bH = b'H$, it is not necessarily the case that their product will be equal, that is

$$aH = a'H, \quad bH = b'H \quad \text{does not imply} \quad (ab)H = (a'b')H.$$

So when is such a product well defined? It turns out that the required condition is that H must be normal.

Proposition 4.4.10 (Coset Multiplication for Normal Subgroups)

Let H be a normal subgroup of G . Then if $aH = a'H$ and $bH = b'H$, we have $(ab)H = (a'b')H$.

Proof. If $aH = a'H$, then $a \in a'H$, so $a = a'h_1$ for some $h_1 \in H$. Also if $bH = b'H$, we have $b = b'h_2$ for $h_2 \in H$. Thus $ab = a'h_1b'h_2$. Then as H is normal, $h_1b' = b'h_3$ for some $h_3 \in H$. Then $ab = a'b'h_3h_2$, and as $h_3h_2 \in H$, this must be in $(a'b')H$. $\square$

We now get to the central result of this section.

Proposition 4.4.11

Let $N \trianglelefteq G$. The set of cosets of N in G forms a group under coset multiplication.

Proof. This operation is well defined by the proposition above. We now check the group axioms.

- *Closure.* If g_1N and g_2N are cosets, so is g_1g_2N .
- *Identity.* $eN = N$.
- *Associativity.* This follows from the associativity of G : $(g_1N \cdot g_2N) \cdot g_3N = (g_1g_2N) \cdot g_3N = ((g_1g_2)g_3)N = (g_1(g_2g_3))N = g_1N \cdot (g_2N \cdot g_3N)$.

□

Definition 4.4.12 (Quotient Group)

If $N \trianglelefteq G$, then G/N is the group of cosets of N in G is called the **quotient group** of G by N .

Example 4.4.13 (Quotient Groups)

- (i) The group of integers modulo n is the quotient group of $n\mathbb{Z}$ in $\mathbb{Z}$ is a group, $\mathbb{Z}/n\mathbb{Z}$.
- (ii) As $A_3 \trianglelefteq S_3$, we have the quotient group S_3/A_3 , which has 2 elements since $|S_3 : A_3| = 2$. Thus $S_3/A_3 \cong C_2$.
- (iii) If $G = H \times K$, then both H and K are normal in G , and $G/H \cong K$ and $G/K \cong H$.
- (iv) If $N = \langle r^2 \rangle \leq D_8$, then it is a normal subgroup, and $D_8/N \cong C_2 \times C_2$.

Remark. In general, quotients are *not* subgroups. In general, they may not even be isomorphic to a subgroup in a group.

Theorem 4.4.14

Given $N \trianglelefteq G$, the function $\pi : G \rightarrow G/N$ where $\pi(g) = gN$ is a surjective homomorphism called the **quotient map**, and $\ker \pi = N$.

Proof. First we prove that π is a homomorphism. We have $\pi(g)\pi(h) = gN \cdot hN = ghN = \pi(gh)$. It's clearly injective, and also $\pi(g) = gN = N \iff g \in N$. Thus $\ker \pi = N$. □

This is a key result: *normal subgroups are exactly kernels of homomorphisms.*

§4.4.3 The Isomorphism Theorems

Using the idea of quotient groups, we can prove the following theorem.

Theorem 4.4.15 (First Isomorphism Theorem)

Let $\phi : G \rightarrow H$ be a homomorphism. Then $G/\ker \phi \cong \text{img } \phi$.

Proof. Define $\bar{\phi} : G/\ker \phi \rightarrow \text{img } \phi$ via $g\ker \phi \rightarrow \phi(g)$. This is well defined, as if $g_1\ker \phi = g_2\ker \phi$, then $g_1 = g_2k$ for some $k \in \ker \phi$. So $\bar{\phi}(g_1\ker \phi) = \phi(g_1) = \phi(g_2k) = \phi(g_2)\phi(k) = \phi(g_2) = \bar{\phi}(g_2\ker \phi)$.

We can show that $\bar{\phi}$ is a homomorphism, as

$$\bar{\phi}(g\ker \phi \cdot g'\ker \phi) = \bar{\phi}(gg'\ker \phi) = \phi(gg') = \phi(g)\phi(g') = \bar{\phi}(g\ker \phi) \cdot \bar{\phi}(g'\ker \phi).$$

We now show that $\bar{\phi}$ is also an isomorphism, by showing it is a bijection. First $\bar{\phi}$ is surjective as all elements in $\text{img } \phi$ are of the form $\phi(g)$ for some $g \in G$. It is also injective, as if $\bar{\phi}(g\ker \phi) = e = \phi(g)$ in $\text{img } \phi$, then $g \in \ker \phi$, so $g\ker \phi = \ker \phi$. $\square$

Example 4.4.16

- (i) $\det : \text{GL}_2(\mathbb{R}) \rightarrow \mathbb{R}^\times$ has $\text{img } \det = \mathbb{R}^\times$, $\ker \det = \text{SL}_2(\mathbb{R})$, so $\text{GL}_2(\mathbb{R})/\text{SL}_2(\mathbb{R}) \cong \mathbb{R}^\times$.
- (ii) Consider the map $\phi : \mathbb{R} \rightarrow \mathbb{C}^\times$, where $\phi(r) = e^{2\pi ir}$. This is a homomorphism, and its image is the circle of radius 1 in $\mathbb{C}$ (which is S^1), and the kernel is $\mathbb{Z}$. Then by the first isomorphism theorem, we have $\mathbb{R}/\mathbb{Z} \cong S^1$.

Quotient groups also have an interesting subgroup structure.

Theorem 4.4.17 (Correspondence Theorem)

Let $N \trianglelefteq G$, then the subgroups of G/N are in bijective correspondence with subgroups of G containing N .

Proof. If we have some $N \leq M \leq G$, with $N \trianglelefteq G$, then $N \trianglelefteq M$, and clearly $M/N \leq G/N$. Conversely, for every subgroup $H \leq G/N$, we can take the preimage of H under the quotient map $\phi : G \rightarrow G/N$, that is, $\phi^{-1}(H) = \{g \in G : gN \in H\}$. We can check that this is a subgroup of G by checking the group axioms. We have closure by as $g_1, g_2 \in \phi^{-1}(H)$, then $g_1g_2N = g_1N \cdot g_2N$, so $g_1g_2N \in H$, and we inherit identity, inverses and associativity from the parent group. Now $\phi^{-1}(H)$ contains N , since $\forall n \in N$, $nN = N \in H$ (it's the identity coset). We can check that for $N \leq M \leq G$, $\phi^{-1}(M/N) = M$, and for $H \leq G/N$, $\phi^{-1}(H)/N = H$. So this correspondence is bijective. $\square$

This correspondence preserves lots of structure, for example indices, normality, containment.

Example 4.4.18

Suppose $C_4 = \{e, a, a^2, a^3\}$ and $C_2 = \{e, b\}$. Consider the group $\mathbb{C}_4 \times C_2$. Its subgroups are as follows.

We will define $N = \langle (a^2, b) \rangle$, which is normal because our group is abelian. Then if we look at $C_4 \times C_2/N$, then the correspondence theorem tells us that its subgroups are the intermediate subgroups between $C_4 \times C_2$ and N , and thus it has the following subgroup lattice.

$$C_4 \times C_2/N \quad \text{————} \quad C_2 \cong \{N, (e, b)N\} \quad \text{————} \quad \{N\}$$

This also shows us that because $C_4 \times C_2/N$ has order 4 by Lagrange, it must be isomorphic to C_4 (as otherwise it would be isomorphic to $C_2 \times C_2$, which would have a different subgroup lattice).

Now, if we had some subgroup $H \leq G$ that didn't contain $N \trianglelefteq G$, we can still make a normal subgroup of H by intersecting. This is the second isomorphism theorem.

Theorem 4.4.19 (Second Isomorphism Theorem)

Let $H \leq G$ and $N \trianglelefteq G$. Then $H \cap N \trianglelefteq H$ and $H/(H \cap N) \cong HN/N$.

Proof Sketch. When $N \trianglelefteq G$ and $H \leq G$, then $HN = \{hn : h \in H, n \in N\}$ is a subgroup of H , and $HN = \langle H, N \rangle$ (the smallest subgroups of G containing H and N). Then consider the function $\phi : H \rightarrow HN/N$, with $\phi(h) = hN$. We can check this is a well defined, surjective homomorphism, and its kernel is $N \cap H$, and we can apply the first isomorphism to get $H/(N \cap H) \cong HN/N \leq G/N$. $\square$

We mentioned previously that normality is preserved. We can even say something about quotients.

Theorem 4.4.20 (Third Isomorphism Theorem)

Let $N \leq M \leq G$ such that $N \trianglelefteq G$ and $M \trianglelefteq G$. Then $M/N \trianglelefteq G/N$ and $(G/N)/(M/N) \cong G/M$.

Proof. We define $\phi : G/N \rightarrow G/M$ by $\phi(gN) = gM$. ϕ is well-defined since $N \leq M$, and it's a surjective homomorphism. Its kernel is M/N , and thus by the first isomorphism theorem, $(G/N)/(M/N) \cong G/M$. $\square$

Let's have a look at some examples of the isomorphism theorems.

Example 4.4.21

Consider the group $\mathbb{Z}$, and define $H = 3\mathbb{Z}$ and $N = 5\mathbb{Z}$. Note that Then by the second isomorphism theorem as , $H/(H \cap N) \cong HN/N \cong \mathbb{Z}/5\mathbb{Z}$, as $\langle H, N \rangle = \mathbb{Z}$ by Bezout's lemma.

§4.4.4 Simple Groups

We will finish this chapter with the introduction of *simple groups*.

Definition 4.4.22 (Simple Groups)

A group G is **simple** if its only normal subgroups are $\{e\}$ and G .

Example 4.4.23 (Examples of Simple Groups)

The following are simple groups:

- C_p for a prime p .
- A_5 (we will prove this later on).

Finite simple groups are important as they can be thought of as the 'building blocks' of all finite groups. If we have some finite group with a normal subgroup, we can take the quotient by that normal subgroup, and you would obtain two objects (the quotient and the normal subgroup) that are smaller than the original group. These objects can help you understand the groups more, but simple groups can't be decomposed further.

Recently, the classification of all finite simple groups was completed, and you can find a large book with all finite simple groups in it!

§4.5 Group Actions

The next aspect of group theory we shall look at is *group actions*, where we study how groups interact with other objects. This isn't such a foreign concept – if you consider the examples of groups that we have looked at previously, we have in many cases been able to identify elements by their effect on some set. For example, we determined the elements of S_n by how it permuted elements of the set $\{1, 2, \dots, n\}$, and we defined D_{2n} based on the symmetries of an n -gon.

Of course, using the group axioms we can somewhat forget that these were ever groups that acted on certain objects, but by introducing these objects that groups can act upon adds a certain richness to the subject.

Definition 4.5.1 (Group Action)

Let G be a group, and let X be a set. An **action** of G on X is a function $\alpha : G \times X \rightarrow X$ written $\alpha(g, x) = \alpha_g(x)$, satisfying

- $\alpha_g(x) \in X$ for all $g \in G$ and $x \in X$.

- $\alpha_e(x) = x$ for all $x \in X$.
- $\alpha_g \circ \alpha_h(x) = \alpha_{gh}(x)$ for any $g, h \in G$ and $x \in X$.

Example 4.5.2

The following are all examples of groups that act on various sets.

- (i) The group S_n acts on X by permutation.
- (ii) The group D_{2n} acts on the vertices of a regular n -gon, and if we label these vertices $1, 2, \dots, n$, we get an action on the set $\{1, 2, \dots, n\}$.
- (iii) The symmetries of a cube act on a set of vertices, a set of edges, a set of faces, and a set of pairs of opposite faces.

Remark. These examples show us that more than one group can act on a given set, for example in (i) and (ii). A group can also act on many sets.

Lemma 4.5.3

For all $g \in G$ and an action $\alpha_g : X \rightarrow X$, the map $x \mapsto \alpha_g(x)$ is a bijection.

Proof. We have $\alpha_g(\alpha_{g^{-1}}(x)) = \alpha_{gg^{-1}}(x) = \alpha_e(x) = x$ for all $x \in X$, and similarly, $\alpha_{g^{-1}}(\alpha_g(x)) = x$ for all $x \in X$. Hence $\alpha_g \circ \alpha_{g^{-1}}$ and $\alpha_{g^{-1}} \circ \alpha_g$ are the identity functions, so α_g is a bijection. $\square$

We can also define actions by linking G to $\text{Sym}(X)$ in the following way.

Proposition 4.5.4

Let G be a group, and X be a set. Then $\alpha : G \times X \rightarrow X$ is an action if and only if the function $\rho : G \rightarrow \text{Sym}(X)$ where $\rho(g) = \alpha(g)$ is a homomorphism.

Proof. If α is an action, then by [Lemma 4.5.3](#), α_g is a bijection from $X \rightarrow X$, so $\alpha_g \in \text{Sym}(X)$. Now $\rho(gh) = \alpha_{gh}$ and for all $x \in X$, $\alpha_{gh}(x) = \alpha_g \circ \alpha_h(x)$, so $\rho(gh) = \alpha_{gh} = \alpha_g \circ \alpha_h = \rho(g)\rho(h)$, so ρ is a homomorphism.

Otherwise, if we have some homomorphism $\rho : G \rightarrow \text{Sym}(X)$, we can define $\alpha : G \times X \rightarrow X$ by $\alpha(g, x) = \alpha_g(x) = \rho(g)(x)$. Then α is an action. This is true because $\rho(g) \in \text{Sym}(X)$, so $\rho(g)(x) = \alpha_g(x) \in X$, and $\rho(e)$ is the identity in $\text{Sym}(X)$ which implies $\rho(e)(x) = x$, and finally, $\rho(gh) = \rho(g)\rho(h)$ implies that $\alpha_{gh}(x) = \alpha_g \circ \alpha_h(x)$ for all $x \in X$. $\square$

We can make the notation slightly easier. When we write $\alpha_g : X \rightarrow X$, we can really think of g as being a function on x , and we can write $g(x)$ instead.

With the above proposition in mind, we can define the *kernel* of an action.

Definition 4.5.5

The **kernel of an action** $\alpha : G \times X \rightarrow X$ is the kernel of the homomorphism $\rho : G \rightarrow \text{Sym}(X)$ (as above).

These are all of the elements of G that act as the identity of $\text{Sym}(X)$, that is, they do nothing to every $x \in X$. Note that by the first isomorphism theorem, this also implies that $G/\ker \rho \cong \text{img } \rho \leq \text{Sym}(X)$, and thus if $\ker \rho = \{e\}$, then $G \leq \text{Sym}(X)$.

Example 4.5.6

- (i) D_{2n} acting on $\{1, \dots, n\}$ (the labelled vertices on an n -gon) has $\ker \rho = \{e\}$, as every non-trivial element of D_{2n} moves at least one vertex. Thus $D_{2n} \leq S_n$.
- (ii) Let G be the symmetries of a cube, and consider X to be the set of unordered pairs of opposite faces. Then $|X| = 3$. So we get a homomorphism $\rho : G \rightarrow S_3$. Clearly there are symmetries of the cube that realize all of the permutation of X , so ρ is surjective. So, $G/\ker \rho \cong S_3$.

Definition 4.5.7 (Faithful Actions)

An action of G on X is called **faithful** if $\ker \rho = \{e\}$.

§4.5.1 Orbits and Stabilisers

Consider the following two questions: for a group G acting on a set X , what elements of X we can ‘get to’ from a certain $x \in X$ using the action of G ? Also, which group elements leave a given $x \in X$ unchanged?

Definition 4.5.8 (Orbit)

Let G act on X , and let $x \in X$. The **orbit** of x is

$$\text{Orb}(x) = \{g(x) : g \in G\} \subseteq X.$$

Definition 4.5.9 (Stabilizer)

The **stabilizer** of x is

$$\text{Stab}(x) = \{g \in G : g(x) = x\} \subseteq G.$$

We say that an action of **transitive** if $\text{Orb}(x) = X$, that is, if we can get to any element from any other element.

Example 4.5.10

For $G = S_3 = \{e, (1\ 2), (2\ 3), (1\ 3), (1\ 2\ 3), (1\ 3\ 2)\} \leq S_4$. G acts on $\{1, 2, 3, 4\}$, and we have $\text{Orb}(1) = \text{Orb}(2) = \text{Orb}(3) = \{1, 2, 3\}$, but $\text{Orb}(4) = \{4\}$. Also $\text{Stab}(1) = \{e, (2\ 3)\}$, $\text{Stab}(2) = \{e, (1\ 3)\}$, $\text{Stab}(3) = \{e, (1\ 2)\}$ and $\text{Stab}(4) = G$.

Lemma 4.5.11

For any $x \in X$, $\text{Stab}(x)$ is a subgroup of G .

Proof. We check the group axioms.

- *Closure.* If $g, h \in \text{Stab}(x)$, then $(gh)(x) = g(h(x)) = g(x) = x$, so $gh \in \text{Stab}(x)$.
- *Identity.* $e(x) = x$, so $e \in \text{Stab}(x)$.
- *Inverses.* If $g \in \text{Stab}(x)$ then $g(x) = x$ so $x = g^{-1}(x)$, and $g^{-1} \in \text{Stab}(x)$.

□

Now recall that a partition of a set X is a set of subsets of X such that each $x \in X$ belongs to exactly one subset in the partition.

Lemma 4.5.12

Let G act on X . Then the orbits partition X .

Proof. Firstly, for any $x \in X$, $x \in \text{Orb}(x)$. Secondly, if $z \in \text{Orb}(x) \cap \text{Orb}(y)$, then there exists $g_1 \in G$ such that $g_1(x) = z$, and there exists $g_2 \in G$ such that $g_2(y) = z$, that is, $y = g_2^{-1}(z)$. So $y = g_2^{-1}g_1(x)$, and thus for any $g \in G$, $g(y) = (gg_2^{-1}g_1)(x) \in \text{Orb}(x)$. So $\text{Orb}(y) \subseteq \text{Orb}(x)$. Similarly, $\text{Orb}(x) \subseteq \text{Orb}(y)$. Thus orbits are either disjoint or equal. □

Recall the proof that any permutation could be written as the product of disjoint cycles. What we were really doing was finding the orbits in $\{1, 2, \dots, n\}$ under $\langle \sigma \rangle$, which are disjoint.

Remark. Note that unlike cosets, the sizes of orbits can be different.

When we have an action, we can say even more about the structure of our group.

Theorem 4.5.13 (Orbit-Stabiliser Theorem)

Let a finite group G act on X . Then for any $x \in X$,

$$|G| = |\text{Orb}(x)| \cdot |\text{Stab}(x)|.$$

Proof. Note that $g(x) = h(x)$ occurs if and only if $h^{-1}g(x) = x$, that is, when $h^{-1}g \in \text{Stab}(x)$. Then this is true iff the cosets $g\text{Stab}(x) = h\text{Stab}(x)$. Rephrasing, distinct points in the orbit of x are in bijection with distinct cosets of $\text{Stab}(x)$. So $|\text{Orb}(x)| = |G : \text{Stab}(x)| = |G|/|\text{Stab}(x)|$ by Lagrange, and the result follows. □

In particular, notice that all elements in a given coset $g \text{Stab}(x)$ do the same thing to x as g , as an element of this coset $g \text{Stab}(x)$ has the form gh , $h \in \text{Stab}(x)$, so $gh(x) = g(h(x)) = g(x)$.

We can use the orbit-stabiliser theorem to investigate groups further. For example, we already know $|D_{2n}| = 2n$, but we can also show this by the orbit-stabiliser theorem. D_{2n} acts transitively on $\{1, \dots, n\}$, so $|\text{Orb}(1)| = n$, and $\text{Stab}(1) = \{e, s\}$, as the first vertex is fixed by one reflection and the identity. Thus $|D_{2n}| = |\text{Orb}(1)| \cdot |\text{Stab}(1)| = n \cdot 2 = 2n$.

Symmetries of the Tetrahedron

To see the power of using Orbits and Stabilisers, we are going to consider two more involved examples, beginning with the symmetries of a tetrahedron.

The tetrahedron has

- 4 faces (all regular triangles),
- 4 vertices, labelled $\{1, 2, 3, 4\}$,
- 6 edges.

So let G be the group of symmetries of the tetrahedron. Clearly G acts transitively on the vertices, and there's no non-identity symmetry that fixes all of the vertices. So we have an injective homomorphism $\rho : G \rightarrow S_4$.

We can consider the orbit and stabiliser for a vertex of the tetrahedron, say 1. For orbits, there is a symmetry that allows us to get from 1 to any other vertex, thus $\text{Orb}(1) = \{1, 2, 3, 4\}$. Then, the symmetries that leave the vertex 1 fixed are going to be the symmetries of the bottom face (the 2, 3, 4 triangle). Thus $\text{Stab}(1) \cong D_6$, the symmetries of a triangle.

With this information, then orbit stabiliser tells us that

$$|G| = |\text{Orb}(1)| \cdot |\text{Stab}(1)| = 4 \cdot 6 = 24,$$

and as $|S_4| = 4! = 24$, and as $G \leq S_4$, we must have $G = S_4$. So just by considering the symmetries relating to one vertex, we were able to deduce the order of the group G , and also find a group that it's isomorphic to!

We can also consider a group G^+ of the rotations in G . Then in G^+ , $\text{Orb}(1) = \{1, 2, 3, 4\}$ as we can only use rotations, and then $\text{Stab}(1)$ is going to be the rotations of the bottom triangle, thus $\text{Stab}(1) \cong C_3$. Then again by the orbit stabiliser theorem,

$$|G^+| = |\text{Orb}(1)| \cdot |\text{Stab}(1)| = 4 \cdot 3 = 12,$$

and as $G^+ \leq G \cong S_4$, we must have $G^+ = A_4$! Indeed, we can check that G^+ is made up of all of the even permutations of the four vertices, that is, all of the 3-cycles and the elements of the form $(1\ 2)(3\ 4)$.

Symmetries of the Cube

We are now going to look at the symmetries of a cube in a similar way.

We have

- 6 faces (all square),
- 8 vertices, labelled $\{1, 2, 3, 4, 5, 6, 7, 8\}$,
- 12 edges.

Let G be the group of symmetries of the cube. In this example, we will find that it is interesting to consider either acting on the vertices or on the faces.

When G acts on the vertices of the cube, we can find the size of the orbit and stabiliser of a vertex geometrically. G is transitive, hence $|\text{Orb}(1)| = 8$. Then the elements that stabilize the vertex 1 are going to be the identity, the rotations about an axis through 1, and the reflections about planes through 1 and an outgoing edge. These are shown below.

So $|\text{Stab}(1)| = 6$. Then by the orbit-stabiliser theorem,

$$|G| = |\text{Orb}(1)| \cdot |\text{Stab}(1)| = 8 \cdot 6 = 48.$$

We will determine this group completely later.

Now let's look at the group of rotations, G^+ , acting on the 8 vertices. We have $|\text{Orb}(1)| = 8$ as before, but the stabilisers of 1 are only going to be the rotations, so $|\text{Stab}(1)| = 3$. Thus

$$|G^+| = |\text{Orb}(1)| \cdot |\text{Stab}(1)| = 8 \cdot 3 = 24.$$

Now if we let G^+ act on the four diagonals of the cube, giving $\rho : G^+ \rightarrow S_4$. We will have all 4-cycles in $\text{img } \rho$, and also all transpositions². So we have $(1\ 2)$ and $(1\ 2\ 3\ 4)$, but we found previously (in Example Sheet 2) that this generates S_4 , so ρ is surjective. Then as $|G^+| = 24 = |S_4|$, so we must have $G^+ \cong S_4$.

Platonic Solids

The last two shapes were two of the five *platonic solids*.

Definition 4.5.14 (Platonic Solid)

A **platonic solid** is a solid shape in $\mathbb{R}^3$ that has polygonal faces, straight edges and vertices such that the group of the shape's symmetries acts transitively on triples of the form (vertex, incident edge, incident face).

So these solids are particularly symmetric. The other platonic solids are the *octohedron*, *dodecahedron* and *icosahedron*.

²If you don't see why, I encourage you to draw a cube with a diagonal elongated, and see what the rotations do to it.

There are also links between the symmetries of these shapes - the cube and octahedron are **dual**, that is, they can be inscribed in each other with vertices in the middle of faces. The icosahedron and dodecahedron are also dual. In fact, this dual property implies that they have the same symmetry groups. So there is only 3 distinct symmetry groups of platonic solids.

§4.5.2 Cauchy's Theorem

We are now going to see how group actions can be used to prove a beautiful theorem. Back in Example Sheet 1, we had the following problem.

Problem. Let G be a group of even order. Show that G contains an element of order two.

It is *not true* in general that if $k \mid |G|$, then there is an element of order k – but it is true for primes. This result is *Cauchy's theorem*.

Theorem 4.5.15 (Cauchy's Theorem)

Let G be a finite group, and let p be a prime such that $p \mid |G|$. Then G has an element of order p .

Proof. Consider the group $G^p = \underbrace{G \times G \times \cdots \times G}_{p \text{ times}}$, that is, the group formed of p -tuples of elements of G , with component wise composition. Consider the subset $X \subseteq G^p$,

$$X = \{(g_1, \dots, g_p) \in G^p : g_1 g_2 \cdots g_p = e\},$$

Informally, ' p -tuples multiplying to e '. Note that $g \in G$ has order p if and only if $(g, \dots, g) \in X$ where g is not the identity.

Now take a cyclic group $C_p = \langle a \rangle$, and let C_p act on X by 'cycling', where $a(g_1, g_2, \dots, g_p) = (g_2, \dots, g_p, g_1)$. It is easily checked that this is an action. Since orbits partition X , the sum of the sizes of distinct orbits must be $|X|$, but $|X| = |G|^{p-1}$, since we can choose anything to put in the $p-1$ entries, and set the last entry to the inverse of their product. So since $p \mid |G|$, $p \mid |X|$. We have by the orbit-stabiliser

theorem that

$$|\text{Orb}(g_1, \dots, g_p)| \cdot |\text{Stab}(g_1, \dots, g_p)| = |C_p| = p.$$

So any orbit has size 1 or p , and they sum to $|X|$, so

$$|X| = \sum_{\text{orbits of size 1}} 1 + \sum_{\text{orbits of size } p} p.$$

Clearly $|\text{Orb}(e, e, \dots, e)| = 1$, and thus as $p \mid |X|$, there must be some other orbits of size 1. But orbits of size 1 must be of the form $(g, g, \dots, g)$, so there exists some $g \neq e \in G$ such that $g^p = e$. $\square$

§4.5.3 Important Actions

Once you have recovered from how nice the previous theorem was, we will look at some important examples of group actions. We will begin with left multiplication actions.

Lemma 4.5.16 (Left Multiplication is an Action)

Let G be a group. Then G acts on itself by left multiplication. This action is faithful and transitive.

Proof. For any $g \in G$ and $x \in G$, then $gx \in G$. Also, $ex = x$ for any $x \in G$, and lastly, $(gh)x = g(hx)$ is true by the associativity of G , so it is an action. It is faithful as if $gx = x$ then $g = e$ by the uniqueness of the identity. It's also transitive as given $x, y \in G$, set $g = yx^{-1}$, then $g(x) = gx = yx^{-1}x = y$. $\square$

Definition 4.5.17 (Left Regular Action)

The left multiplication action of a group on itself is called the **left regular action**.

With this group action, we can finally prove a result that we have been vaguely alluding to (and which should make intuitive sense).

Theorem 4.5.18 (Cayley's Theorem)

Every group is isomorphic to a subgroup of a symmetric group.

Proof. Let G act on itself by the left regular action. This gives a homomorphism $\rho : G \rightarrow \text{Sym}(G)$, with $\ker \rho = \{e\}$ since the action is faithful. Hence by the first isomorphism theorem, $G/\ker \rho \cong \text{img } \rho \leq \text{Sym}(G)$. $\square$

Proposition 4.5.19 (Left-Coset Action)

Let $H \leq G$. Then G acts on the set of left-cosets by left multiplication, and the action is transitive. This is the **left-coset action**.

Proof. We have $g(g_1H) = gg_1H$, so $g(g_1H)$ is a left coset. Also $e(g_1H) = eg_1H = g_1H$. Finally, $(gg')(g_1H) = gg'g_1H = g(g'(g_1H))$, so this is an action. Also given

g_1H and g_2H , we have $(g_1g_2^{-1})(g_2H) = g_1g_2^{-1}g_2H = g_1H$, so this action is transitive. $\square$

Remark. For $H = \{e\}$, then this is the left-regular action, as the cosets are just the elements of G .

This action gives us a way to induce actions of G onto its quotient groups G/N .

Conjugation

The next idea we will discuss is *conjugation*.

Definition 4.5.20 (Conjugation)

Given $g, h \in G$, the element $ghg^{-1} \in G$ is the conjugate of g by h .

Conjugate elements should be thought of as doing the ‘same thing’ but from ‘different points of view’. The exact meaning of this will be more clear as we look at some examples later on.

Example 4.5.21

Consider the group D_{10} , and consider the conjugate s and rsr^{-1} , where s is reflection through the vertex v_1 , and r is a clockwise rotation sending v_1 to v_2 and so on.

What rsr^{-1} does is rotating so that the reflection can be done through a different axis.

So in this example, we are still performing an action, just from a different point of view.

Example 4.5.22

In the group $GL_n \mathbb{R}$, the conjugate of a matrix represents the same transformation but written with respect to a different basis.

So it's natural to expect that conjugate elements have similar properties. Let's prove some facts about conjugation.

Proposition 4.5.23 (Conjugation is an Action)

A group G acts on itself by conjugation.

Proof. We have $g(x) = gxg^{-1} \in G$ for all $g, x \in G$. Also, $e(x) = exe^{-1} = x$ for all x , and finally, $g(h(x)) = g(hxh^{-1})g^{-1} = (gh)x(gh)^{-1} = (gh)(x)$, for all $g, h, x \in G$. So this is an action. $\square$

This action's kernel, orbits and stabilisers even have their own names.

Definition 4.5.24 (Center)

The kernel of the conjugation action of G on itself is the **center** $Z(G)$ of G :

$$Z(G) = \{g \in G : ghg^{-1} = h, \forall h \in G\}.$$

Equivalently, the center of a group is the set of all elements that commute with every element in the group.

Definition 4.5.25 (Conjugacy Class)

An orbit of the conjugation action is a **conjugacy class**:

$$\text{ccl}(h) = \{ghg^{-1} : g \in G\}.$$

Definition 4.5.26 (centralizers)

The stabilisers of the conjugation action are the **centralizers**:

$$C(h) = \{g \in G : ghg^{-1} = h\}.$$

Equivalently, $C(h)$ is the set of elements that commute with h .

There is a connection between the center and the centralizers, namely

$$Z(G) = \bigcap_{h \in G} C_G(h).$$

Definition 4.5.27 (Subgroup Conjugation)

If $H \leq G$, $g \in G$, then the **conjugate of H by g** is

$$gHg^{-1} = \{ghg^{-1} : h \in H\}.$$

Proposition 4.5.28

Let $H \leq G$ and $g \in G$. Then gHg^{-1} is also a subgroup of G .

Proof. Clearly $e \in gHg^{-1}$, so it is nonempty. Thus we can apply the subgroup criterion. Let $g_1g_2^{-1}$ and $g_3g_4^{-1} \in gHg^{-1}$. Then

$$(g_1g_2^{-1})(g_3g_4^{-1})^{-1} = (g_1g_2^{-1}g_3^{-1}g_4) = g(xy^{-1})g^{-1},$$

and as $H \leq G$, we have $xy^{-1} \in H$ so $g(xy^{-1})g^{-1} \in gHg^{-1}$, so it is a subgroup. $\square$

In fact, $gHg^{-1} \cong H$, which should match our intuition about how conjugate elements act.

Proposition 4.5.29 (Subgroup Conjugation is an Action)

A group G acts by conjugation on the set of its subgroups. The singleton orbits are the normal subgroups.

Proof. Let G act on the set of subsets by conjugation, that is, for $H \leq G$, we define $g(H) = gHg^{-1}$. We will check that this is a group action.

We have closure by the argument above. We have identity, as $eHe^{-1} = H$ for any subgroup H . Also for $g, k \in G$, we have $g \circ k(H) = g(kHk^{-1}) = gkHk^{-1}g^{-1} = (gk)H(gk)^{-1} = (gk)(H)$, so this is indeed an action.

The singleton orbits are the normal subgroups, as a subgroup N is normal if $gNg^{-1} = N$ for any $g \in G$ (which corresponds to every element in G stabilising N). $\square$

Another way to look at normal subgroup is using conjugation. We already established that if and only if N is normal in G , we have $gNg^{-1} = N$, for any $g \in G$.

Proposition 4.5.30

Normal subgroups are unions of conjugacy classes.

Proof. Let $N \trianglelefteq G$. Then if $h \in N$, then $ghg^{-1} \in N$ for any $g \in G$. Hence $\text{ccl}(h) \subseteq N$. So N is a union of conjugacy classes of its elements, that is, $N = \bigcup_{h \in N} \text{ccl}(h)$. Conversely, suppose that we have a subgroup H that is the union of conjugacy classes. Then taking any $g \in G$ and $h \in H$, then $ghg^{-1} \in H$, so $H \trianglelefteq G$. $\square$

Example 4.5.31

Consider the group $A_3 = \{e, (1\ 2\ 3), (1\ 3\ 2)\} \trianglelefteq S_3$. We can write this as $A_3 = \{e\} \cup \{(1\ 2\ 3), (1\ 3\ 2)\}$, which are both conjugacy classes.

Conjugation in S_n and A_n is rather interesting. Let's begin with a lemma.

Lemma 4.5.32 (Conjugation Permutes Elements in a Cycle)

Given k -cycle $(a_1 \ \dots \ a_k)$ and $\sigma \in S_n$, we have

$$\sigma(a_1 \ \dots \ a_k)\sigma^{-1} = (\sigma(a_1) \ \sigma(a_2) \ \dots \ \sigma(a_k)),$$

which is also a k -cycle.

Proof. Note that if we consider the action of $\sigma(a_1 \ \dots \ a_k)\sigma^{-1}$ on a_i , we have

$$\sigma(a_i) \mapsto a_i \mapsto a_{i+1} \mapsto \sigma(a_{i+1}).$$

So $\sigma(a_1 \ \dots \ a_k)\sigma^{-1}$ does the same thing as $(\sigma(a_1) \ \sigma(a_2) \ \dots \ \sigma(a_k))$ on the set $\{\sigma(a_1), \dots, \sigma(a_k)\}$. Then for any $a \notin \{\sigma(a_1), \dots, \sigma(a_k)\}$, then $\sigma(a_1 \ \dots \ a_k)\sigma^{-1}$ and $(\sigma(a_1) \ \sigma(a_2) \ \dots \ \sigma(a_k))$ both leave a unchanged. $\square$

Proposition 4.5.33

Two elements of S_n are conjugate in S_n if and only if they have the same cycle type.

Proof. Two elements that are conjugate will certainly have the same cycle type, as given $\sigma \in S_n$, we can write σ as the product of disjoint cycles $\sigma = \sigma_1 \sigma_2 \cdots \sigma_m$. Then if $\rho \in S_n$, $\rho \sigma \rho^{-1} = (\rho \sigma_1 \rho^{-1})(\rho \sigma_2 \rho^{-1}) \cdots (\rho \sigma_m \rho^{-1})$, and by our previous lemma, $\rho \sigma_i \rho^{-1}$ is a cycle of the same length as σ_i , and $\rho \sigma_i \rho^{-1}$ are all disjoint (as ρ is a bijection). Conversely, if we have σ and τ that are the same cycle type, then we can write

$$\begin{aligned}\sigma &= (a_1 \ a_2 \ \cdots \ a_{k_1})(a_{k_1+1} \ a_{k_1+2} \ \cdots \ a_{k_2}) \cdots \\ \tau &= (b_1 \ b_2 \ \cdots \ b_{k_1})(b_{k_1+1} \ b_{k_1+2} \ \cdots \ b_{k_2}) \cdots\end{aligned}$$

in disjoint cycle notation, including any singletons (those fixed by σ and τ) so that all of $\{1, \dots, n\}$ appears in both σ and τ . Then setting ρ to be $\rho(a_i) = b_i$, we will have $\rho \sigma \rho^{-1} = \tau$. $\square$

Let's have a look at an example: the conjugacy classes of S_4 .

Example 4.5.34 (Normal subgroups of S_4)

Consider the following table of conjugacy classes of S_4 .

Cycle Type	Example Element	Size of ccl	Size of C_{S_4}	Sign
1, 1, 1, 1	e	1	24	+1
2, 1, 1	$(1 \ 2)$	$4 \cdot 3/2 = 6$	4	-1
2, 2	$(1 \ 2)(3 \ 4)$	$4 \cdot 3/(2 \cdot 2) = 3$	8	+1
3, 1	$(1 \ 2 \ 3)$	$4 \cdot 3 \cdot 2/3 = 8$	3	+1
4	$(1 \ 2 \ 3 \ 4)$	$4 \cdot 3 \cdot 2/4 = 6$	4	-1

From this table, we can work out the normal subgroups of S_4 . Each normal subgroup must contain e , and must be the union of conjugacy classes, and we must have the order of the subgroup dividing the order of the group. We can check what combinations of conjugacy classes satisfies these.

We can consider these possibilities by considering the divisors of 24, the order of the group: 1, 2, 3, 4, 6, 8, 12, 24. From these, we have

- Order 1: $\{e\}$
- Order 4: $\{e, (1 \ 2)(3 \ 4), (1 \ 3)(2 \ 4), (1 \ 4)(2 \ 3)\}$, which is $C_2 \times C_2$, also known as V_4 , the Klein four group.
- Order 12: A_4 .
- Order 24: S_4 .

Now because we have all of the normal subgroups, we can also get all of the possible quotients of S_4 , as

- $S_4/\{e\} \cong S_4$.
- $S_4/V_4 \cong S_3$.

- $S_4/A_4 \cong C_2$.
- $S_4/S_4 \cong \{e\}$.

Now let's look at conjugation in the alternating group. Note that $\text{ccl}_{S_n}(\sigma) = \{\tau\sigma\tau^{-1} : \tau \in S_n\}$ and $\text{ccl}_{A_n}(\sigma) = \{\tau\sigma\tau^{-1} : \tau \in A_n\}$, so $\text{ccl}_{A_n}(\sigma) \subseteq \text{ccl}_{S_n}(\sigma)$. But elements that are conjugate in S_n may not be conjugate in A_n . For example, $(2\ 3)(1\ 2\ 3)(2\ 3) = (1\ 3\ 2) \in S_3$, but $(2\ 3) \notin A_3$, and there are no elements $\tau \in A_3$ such that $\tau(1\ 2\ 3)\tau^{-1} = (1\ 3\ 2)$.

Some conjugacy classes of S_n will split into smaller conjugacy classes in A_n . By orbit-stabiliser, $|S_n| = |\text{ccl}_{S_n}(\sigma)| \cdot |C_{S_n}(\sigma)|$, and $|A_n| = |\text{ccl}_{A_n}(\sigma)| \cdot |C_{A_n}(\sigma)|$. But $|S_n| = 2 \cdot |A_n|$ and $|\text{ccl}_{A_n}(\sigma)| \leq |\text{ccl}_{S_n}(\sigma)|$, so either $\text{ccl}_{A_n}(\sigma) = \text{ccl}_{S_n}(\sigma)$ and $|C_{A_n}(\sigma)| = \frac{1}{2}|C_{S_n}(\sigma)|$, or $|\text{ccl}_{A_n}(\sigma)| = \frac{1}{2}|\text{ccl}_{S_n}(\sigma)|$ and $|C_{A_n}(\sigma)| = |C_{S_n}(\sigma)|$.

To consider this further, we will introduce a natural definition.

Definition 4.5.35 (Splitting Conjugacy Classes)

When $|\text{ccl}_{A_n}(\sigma)| = \frac{1}{2}|\text{ccl}_{S_n}(\sigma)|$, we say that the conjugacy class of σ **splits** in A_n .

So when does this happen?

Proposition 4.5.36

The conjugacy class of $\sigma \in A_n$ splits in A_n if and only if no odd permutations commute with σ .

Proof. $|\text{ccl}_{A_n}(\sigma)| = \frac{1}{2}|\text{ccl}_{S_n}(\sigma)| \iff C_{A_n}(\sigma) = C_{S_n}(\sigma)$. Now $C_{A_n}(\sigma) = A_n \cap C_{S_n}(\sigma)$, and $A_n \cap C_{S_n}(\sigma) = C_{S_n}(\sigma)$ if and only if $C_{S_n}(\sigma)$ doesn't contain any odd elements, that is, when no odd permutations commute with σ . $\square$

Example 4.5.37 (Conjugacy classes in A_4)

We will consider the conjugacy classes in A_4 .

Cycle Type	Example Element	Odd Element in C_{S_4} ?	Size of ccl_{S_4}	Size of ccl_{A_4}
1, 1, 1, 1	e	yes, eg. $(1\ 2)$	1	1
2, 2	$(1\ 2)(3\ 4)$	yes, eg. $(1\ 2)$	3	3
3, 1	$(1\ 2\ 3)$	no	8	4

Example 4.5.38 (Conjugacy classes in A_5)

We will consider the conjugacy classes in A_5 .

Cycle Type	Example Element	Odd Element in C_{S_5} ?	Size of ccl_{S_5}	Size of ccl_{A_5}
1, 1, 1, 1	e	yes, eg. $(1\ 2)$	1	1
2, 2, 1	$(1\ 2)(3\ 4)$	yes, eg. $(1\ 2)$	15	15
3, 1, 1	$(1\ 2\ 3)$	yes, eg. $(4\ 5)$	20	20
5	$(1\ 2\ 3\ 4\ 5)$	no	24	12

We can use this result to prove something that was mentioned earlier.

Theorem 4.5.39

A_5 is simple.

Proof. Normal subgroups must be unions of conjugacy classes, must contain e and must divide $|A_5| = 60$. The size of conjugacy classes in A_5 are 1, 15, 20, 12 and 12. To sum these to get a divisor of 60, we can only have 1, and $1 + 15 + 20 + 12 + 12 = 60$, so the only normal subgroups are $\{e\}$ and A_5 . $\square$

Remark. All A_n for $n \geq 5$ are simple.

§4.6 The Möbius Group, Revisited

With group actions, we now have more tools to study the Möbius group M . Recall that we defined the Möbius group as the set of Möbius maps, under composition.

Definition (Möbius Maps)

A **Möbius map** is a function $f : \hat{\mathbb{C}} \rightarrow \hat{\mathbb{C}}$ of the form

$$f(z) = \frac{az + b}{cz + d},$$

with $a, b, c, d \in \mathbb{C}$ and $ad - bc \neq 0$, and with $f(-d/c) = \infty$ and

$$f(\infty) = \begin{cases} \frac{a}{c} & \text{if } c \neq 0 \\ \infty & \text{if } c = 0 \end{cases}.$$

This definition defined an action of the Möbius group on the extended complex plane. This action is faithful.

Proposition 4.6.1

The action of the Möbius group $\mathcal{M}$ on the extended complex plane is faithful, and so $\mathcal{M} \leq \text{Sym}(\hat{\mathbb{C}})$.

Proof. Consider $\rho : M \rightarrow \text{Sym}(\hat{\mathbb{C}})$ given by $\rho(f)(z) = f(z)$. Then if $\rho(f)$ is the identity permutation, then f is the identity in M . So ρ is injective and the action is faithful. $\square$

We can think about points that are invariant under Möbius map.

Definition 4.6.2 (Fixed Point)

A **fixed point** of a Möbius map $f : \hat{\mathbb{C}} \rightarrow \hat{\mathbb{C}}$ is a point $z \in \hat{\mathbb{C}}$ such that $f(z) = z$.

Theorem 4.6.3

A Möbius map with at least three fixed points is the identity.

Proof. Let $f(z) = \frac{az+b}{cz+d}$ have at least 3 fixed points. If ∞ is not a fixed point of f , then $\frac{az+b}{cz+d} = z$ for more than three complex numbers z , that is, $cz^2 + (d-a)z - b = 0$ has more than three roots in $\mathbb{C}$. But this is quadratic, so we can't have more than two roots, unless $c = b = 0$, $d = a$ for all z . But then $f(z) = z$. If ∞ is a fixed point of f , then we have $a/c = \infty \implies c = 0$, and thus $z = \frac{az+b}{d}$ for more than two complex numbers z , which can only occur when $a = d$, $b = 0$, so $f(z) = z$. $\square$

What this theorem really tells us is that knowing what a Möbius map does on 3 points in $\hat{\mathbb{C}}$ uniquely determines it.

Corollary 4.6.4

If two Möbius maps coincide on three distinct points in $\hat{\mathbb{C}}$, then they are equal.

Proof. Let $f, g \in \mathcal{M}$ be such that $f(z_1) = g(z_1)$, $f(z_2) = g(z_2)$ and $f(z_3) = g(z_3)$ for three distinct points z_1, z_2 and $z_3 \in \hat{\mathbb{C}}$. Then $g^{-1}f(z_i) = g^{-1}g(z_i) = z_i$ for $i = 1, 2, 3$, and thus $g^{-1}f$ fixed more than 3 points, and it must be the identity. So $f = g$. $\square$

Theorem 4.6.5 (Existence of Unique Möbius Maps)

There is a unique Möbius map sending any three distinct points of $\hat{\mathbb{C}}$ to any three distinct points of $\hat{\mathbb{C}}$. That is, given $z_1, z_2, z_3 \in \hat{\mathbb{C}}$ and $w_1, w_2, w_3 \in \hat{\mathbb{C}}$ all distinct then there's a unique $f \in \mathcal{M}$ such that $f(z_i) = w_i$ for $i = 1, 2, 3$.

Proof. Note that uniqueness follows from existence by the previous corollary. We will construct the map by supposing that $w_1 = 0$, $w_2 = 1$ and $w_3 = \infty$, and then we will use the group structure. Define $f(z) = \frac{(z_2 - z_3)(z - z_1)}{(z_2 - z_1)(z - z_3)}$. This satisfies $f(z_i) = w_i$ for all i . There are some special cases. If $z_1 = \infty$ use $f(z) = \frac{z_2 - z_3}{z - z_3}$, if $z_2 = \infty$ use $f(z) = \frac{z - z_1}{z - z_3}$, and if $z_3 = \infty$ use $f(z) = \frac{z - z_1}{z_2 - z_1}$.

Thus we can find some f_1 sending (z_1, z_2, z_3) to $(0, 1, \infty)$. But then in the same way we can find some f_2 sending (w_1, w_2, w_3) to $(0, 1, \infty)$. But then we can use the group structure, considering $f = f_2^{-1} \circ f_1$, this will send (z_1, z_2, z_3) to (w_1, w_2, w_3) , as required. $\square$

§4.6.1 Conjugation

For two Möbius maps f and h , we can consider what happens when we conjugate hfh^{-1} . This acts in much the same way that any conjugate in a group structure does. For example, $\text{ord}(hfh^{-1}) = \text{ord}(f)$, since $(hfh^{-1})^n = hf^n h^{-1}$. Also, If f fixes z , then

hfh^{-1} fixes z . In particular, the number of fixed points of a conjugate is the same as that of the original Möbius map. This observation has a partial converse.

Theorem 4.6.6

Every non-identity $f \in \mathcal{M}$ has either 1 or 2 fixed points. If f has 1 fixed point, then it will be conjugate to the map $z \mapsto z + 1$, and if f has 2 fixed points, it will be conjugate to a map of the form $z \mapsto az$ for some non-zero $a \in \mathbb{C}$.

Proof. We know that a non-identity Möbius map has at most 2 fixed points, but we show that there can't be zero fixed points. If $f(z) = \frac{az+b}{cz+d}$, then considering the quadratic $cz^2 + (d-a)z - b = 0$, formed by considering $f(z) = z$, this must have at least one solution.

Now we consider the two cases. If f has exactly 1 fixed point, say z_0 , then choose some $z_1 \in \mathbb{C}$ which is not fixed by f . Then consider the triple $(z_1, f(z_1), z_0)$, which are all distinct points. So there is some $g \in \mathcal{M}$ so that $(z_1, f(z_1), z_0) \mapsto (0, 1, \infty)$. Then we can consider the conjugate of f by g . Then gfg^{-1} sends $0 \mapsto z_1 \mapsto f(z_1) \mapsto 1$, and $\infty \mapsto z_0 \mapsto z_0 \mapsto \infty$, so $gfg^{-1}(0) = 1$, $gfg^{-1}(\infty) = \infty$, so gfg^{-1} must be equal to $z \mapsto az + 1$ for $a \in \mathbb{C}$. If $a \neq 1$, then there is a non-infinity fixed point, $1/(1-a)$, but this is a contradiction, so $a = 1$. Thus f is conjugate via g to the map $z \mapsto z + 1$, as required.

If f has exactly 2 fixed points, z_0 and z_1 , then let g be any Möbius map sending $(z_0, z_1) \mapsto (0, \infty)$. So gfg^{-1} sends $0 \mapsto z_0 \mapsto z_0 \mapsto 0$, and $\infty \mapsto z_1 \mapsto z_1 \mapsto \infty$. So this conjugate fixes 0 and ∞ . We can deduce that gfg^{-1} must have the form $z \mapsto az$, where $a = gfg^{-1}(1)$. $\square$

We can use this to efficiently compute powers of Möbius maps, f^n for all $f \in \mathcal{M}$. We can see that $(gfg^{-1})^m = gf^mg^{-1}$, but this will be easy to compute, because the conjugate can have a nice form. Then we can conjugate back to get f^m .

§4.6.2 Circles and Lines – Geometric Properties of Möbius Maps

We've seen that the image of 3 points in $\mathbb{C}$ under a given Möbius map uniquely determines that map. We also know (from geometry) that 3 points determine lines or circles.

In the complex plane, the a circle with center $b \in \mathbb{C}$ and radius $r > 0 \in \mathbb{C}$ is the locus of points satisfying

$$|z - b| = r.$$

We can then write this as $|z - b|^2 - r^2 = 0$, or $(z - b)(\overline{z - b}) - r^2 = 0$, which we can write as

$$z\bar{z} - \bar{b}z - b\bar{z} + b\bar{b} - r^2 = 0. \quad (*)$$

Also, the equation of a straight line in the complex plane (for $a, b, c \in \mathbb{R}$) is

$$a \cdot \operatorname{re}(z) + bi \cdot \operatorname{im}(z) = c,$$

that is

$$\frac{\overline{a + ib}}{2}z + \frac{a + ib}{2}\bar{z} - c = 0. \quad (\dagger)$$

The form of these equations is slightly unusual but they are put in this form to emphasize the following definition. While we require three points in $\mathbb{C}$ to determine a circle, we

only need two points to determine a line. But if we work in $\hat{\mathbb{C}}$, we consider the point at infinity, ∞ to be on *every* line. In this way, a line is determined by exactly 3 points in $\hat{\mathbb{C}}$, namely two points on the complex plane and a point at infinity.

Thinking in this way, we can unify the concepts of circles and lines in the extended complex plane, by introducing *clines*, a neologism covering both circles and lines.

Definition 4.6.7 (Clines in $\hat{\mathbb{C}}$)

A **cline** in $\hat{\mathbb{C}}$ is the set of points satisfying the equation

$$Az\bar{z} + \bar{B}z + B\bar{z} + C = 0,$$

with $A, C \in \mathbb{R}$, $B \in \mathbb{C}$, and $|B|^2 > AC$. We consider $\infty \in \hat{\mathbb{C}}$ to be a solution if and only if $A = 0$.

Any equation of the form in the definition will match with exactly one of equation $(*)$ or $(\dagger)$.

Looking back at Möbius maps, we get the rather interesting result.

Theorem 4.6.8 (Möbius Maps Preserve Clines)

Möbius send clines in $\hat{\mathbb{C}}$ to clines in $\hat{\mathbb{C}}$.

Proof. Recall that the Möbius group $\mathcal{M}$ is generated by a composition of dilations/rotations, translations and inversions. That is, $z \mapsto az$, $z \mapsto z + b$ and $z \mapsto 1/z$.

Writing $S(A, B, C)$ for the circle satisfying $Az\bar{z} + \bar{B}z + B\bar{z} + C = 0$, we can check what happens under the various maps.

Under $z \mapsto az$, we have $S(A, B, C) \mapsto S\left(\frac{A}{aa}, \frac{B}{a}, C\right)$. Under $z \mapsto z + b$, $S(A, B, C) \mapsto S(A, B - Ab, C + Ab\bar{b} - B\bar{b} - \bar{B}b)$. Finally, under $z \mapsto 1/z$, we have $S(A, B, C) \mapsto S(C, \bar{B}, A)$. $\square$

In practice, because both clines and Möbius maps are determined by 3 points (or where they send 3 points), it is quite straightforward to find a Möbius map which sends a given cline to another cline.

Example 4.6.9

Let's say we wanted to find $f \in \mathcal{M}$ which send the unit circle to the real line.

If we pick three points on the unit circle, say $\{-1, i, 1\}$, and three points on $\mathbb{R}$, say $\{-1, 0, 1\}$, then we could find a map f such that -1 and 1 are fixed, but so that i is sent to 0 . For example,

$$f(z) = \frac{z - i}{1 - iz}$$

works.

§4.6.3 Cross Ratios

Recall that given three points $z_1, z_2, z_3 \in \hat{\mathbb{C}}$, we have a unique Möbius map f such that $f(z_1) = 0$, $f(z_2) = 1$ and $f(z_3) = \infty$.

Definition 4.6.10 (Cross Ratio)

If we have four distinct points $z_1, z_2, z_3, z_4 \in \hat{\mathbb{C}}$, then their **cross-ratio** (z_1, z_2, z_3, z_4) is defined to be $f(z_4)$, where f is the unique Möbius map such that $f(z_1) = 0$, $f(z_2) = 1$ and $f(z_3) = \infty$.

In particular, the cross ratio of $(0, 1, \infty, w) = w$, for all $w \in \hat{\mathbb{C}}$. This is because f is forced to be the identity. There is a way to compute the cross ratio.

Theorem 4.6.11 (Computing Cross Ratios)

For points z_1, z_2, z_3 and $z_4 \in \hat{\mathbb{C}}$, we have

$$(z_1, z_2, z_3, z_4) = \frac{(z_4 - z_1)(z_2 - z_3)}{(z_2 - z_1)(z_4 - z_3)}.$$

Proof Sketch. This follows from the construction of the unique Möbius map. □

Remark. There are many conventions for the cross-ratio, depending on the order of 0, 1 and ∞ . Some of these will be the same.

Proposition 4.6.12

Double transpositions of the z_i fix the cross-ratio, that is,

$$(z_1, z_2, z_3, z_4) = (z_2, z_1, z_4, z_3) = (z_3, z_4, z_1, z_2) = (z_4, z_3, z_2, z_1).$$

Proof Sketch. Note that this follows from the previous theorem. □

There is a connection between cross ratios and Möbius maps.

Theorem 4.6.13

Möbius maps preserve cross-ratio.

Proof. Let $f \in \mathcal{M}$ be the unique Möbius map such that $f : (z_1, z_2, z_3) \mapsto (0, 1, \infty)$, so that $f(z_4) = (z_1, z_2, z_3, z_4)$. Then for any Möbius map $g \in \mathcal{M}$, we have $f \circ g^{-1}$ sends $g(z_1) \mapsto 0$, $g(z_2) \mapsto 1$, and $g(z_3) \mapsto \infty$. Also $f \circ g^{-1}$ is unique, as Möbius maps are uniquely determined by how they transform three points. So, if we have $(g(z_1), g(z_2), g(z_3), g(z_4)) = (f \circ g^{-1})(g(z_4)) = f(z_4) = (z_1, z_2, z_3, z_4)$. □

This has an interesting geometric corollary.

Theorem 4.6.14

Four distinct points $z_1, z_2, z_3, z_4 \in \hat{\mathbb{C}}$ lie on a cline if and only if $(z_1, z_2, z_3, z_4) \in \mathbb{R}$.

Proof. Let f be the unique Möbius map sending $(z_1, z_2, z_3) \rightarrow (0, 1, \infty)$, so that $f(z_4) = (z_1, z_2, z_3, z_4)$. The cline C passing through z_1, z_2, z_3 is sent to the cline through $0, 1, \infty$ (the real axis), and so z_4 lies on C if and only if $f(z_4)$ lies on the real axis, that is, $f(z_4) \in \mathbb{R} \cup \{\infty\}$. But $f(z_3) = \infty$, so $f(z_4) \neq \infty$. Thus z_4 lies on C if and only if $z_4 \in \mathbb{R}$. $\square$

§4.7 Matrix Groups

In this chapter we will look at various groups of matrices. We will look at the actions of matrix groups on related actions, and we will study distance preserving maps (or *isometries*) on $\mathbb{R}^2$ and $\mathbb{R}^3$.

§4.7.1 Examples of Matrix Groups

We are going to write $M_{n \times n}(\mathbb{F})$ to denote the set of $n \times n$ matrices over the field $\mathbb{F}$, which will typically be either $\mathbb{R}$ or $\mathbb{C}$.

Definition 4.7.1 (General Linear Group)

$\text{GL}_n(\mathbb{F}) = \{A \in M_{n \times n}(\mathbb{F}) \mid A \text{ is invertible}\}$ is the **general linear group** over $\mathbb{F}$.

This is indeed a group, and the determinant is a surjective homomorphism, namely $\det : \text{GL}_n(\mathbb{F}) \rightarrow \mathbb{F}^*$, the set of non-zero elements in $\mathbb{F}$.

Definition 4.7.2 (Special Linear Group)

The **special linear group** $\text{SL}_n(\mathbb{F}) \leq \text{GL}_n(\mathbb{F})$ is the kernel of the $\det$ homomorphism, that is, the set of elements of $\text{GL}_n(\mathbb{F})$ with determinant 1.

Recall the following facts about matrices. Given $A, B \in \text{GL}_n(\mathbb{R})$,

- $(AB)^T = B^T A^T$,
- $(A^{-1})^T = (A^T)^{-1}$,
- $AA^T = I \iff A^T A = I \iff A^T = A^{-1}$,
- $(A^T)^T = A$,
- $\det(A^T) = \det(A)$.

With these we can define some groups.

Definition 4.7.3 (Orthogonal Group)

The **orthogonal group** is the group $O_n = \{A \in \text{GL}_n(\mathbb{R}) \mid A^T A = I\}$.

Proposition 4.7.4

$\det : O_n \rightarrow \{\pm 1\}$ is a surjective homomorphism.

Proof. This is a homomorphism as the determinant is a homomorphism in $\mathrm{GL}_n(\mathbb{R})$, and for $A \in \mathrm{O}_n$, then $A^T A = I$, and $1 = \det(AA^T) = \det(A) \det(A^T) = \det(A)^2$, so $\det(A) = \pm 1$. It is surjective as $\det I = 1$, and $\det(\mathrm{diag}(-1, 1, 1, \dots, 1)) = -1$. $\square$

Definition 4.7.5 (Special Orthogonal Group)

The **special orthogonal group** SO_n is the kernel of the determinant homomorphism, that is, $\mathrm{SO}_n = \{A \in \mathrm{O}_n \mid \det A = 1\}$.

These groups of matrices will be the main focus of this chapter. All of the matrix groups defined above act on the corresponding vector spaces. For example, $\mathrm{GL}_n(\mathbb{F})$ and $\mathrm{SL}_n(\mathbb{F})$ act on $\mathbb{F}^n$, and O_n , SO_n acts on $\mathbb{R}^n$.

Example 4.7.6

Let $G \leq \mathrm{GL}_2(\mathbb{R})$ act on $\mathbb{R}^2$. We will find the orbits. Note that $\{\mathbf{0}\}$ is always a singleton orbit, since we are acting by linear maps.

- If $G = \mathrm{GL}_2(\mathbb{R})$, then G acts transitively on $\mathbb{R}^2 \setminus \{\mathbf{0}\}$ since we can complete any $\mathbf{v} \neq \mathbf{0}$ to a basis, and we have an invertible change of basis matrix sending any basis to an other basis.
- If $G = \left\{ \begin{pmatrix} a & b \\ 0 & d \end{pmatrix} \in \mathrm{GL}_2(\mathbb{R}) \right\} = \left\{ \begin{pmatrix} a & b \\ 0 & d \end{pmatrix} \mid a, d \neq 0 \right\}$, then $\mathrm{Orb}(\mathbf{0}) = \{\mathbf{0}\}$, $\mathrm{Orb} \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \left\{ \begin{pmatrix} a \\ 0 \end{pmatrix} \mid a \neq 0 \right\}$, and $\mathrm{Orb} \begin{pmatrix} 0 \\ 1 \end{pmatrix} = \left\{ \begin{pmatrix} b \\ d \end{pmatrix} \mid d \neq 0 \right\}$. This is all of the orbits, since the union gives all of $\mathbb{R}^2$.

§4.7.2 Möbius Maps as Matrices

Let's first examine the connection between Möbius maps and matrices.

Proposition 4.7.7

The function $\phi : \mathrm{SL}_2(\mathbb{C}) \rightarrow \mathcal{M}$ where

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \mapsto f, \quad \text{where } f(z) = \frac{az + b}{cz + d}$$

is a surjective homomorphism, with kernel $\{\pm I\}$.

Proof. First we show that ϕ is a homomorphism. If $f_1(z) = \frac{a_1 z + b_1}{c_1 z + d_1}$ and $f_2(z) = \frac{a_2 z + b_2}{c_2 z + d_2}$, then we have $f_2 \circ f_1(z) = \frac{az+b}{cz+d}$, where

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} a_2 & b_2 \\ c_2 & d_2 \end{pmatrix} \begin{pmatrix} a_1 & b_1 \\ c_1 & d_1 \end{pmatrix}.$$

It follows directly that ϕ is a homomorphism.

To see that it is surjective, we note that if $\frac{az+b}{cz+d}$ is a Möbius map, then the matrix

$$M = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{GL}_2(\mathbb{C}),$$

since $ad - bc \neq 0$. But the determinant may not be zero, so letting $D^2 = \det M$, consider the matrix

$$\frac{M}{D^2} = \begin{pmatrix} \frac{a}{D} & \frac{b}{D} \\ \frac{c}{D} & \frac{d}{D} \end{pmatrix},$$

this has determinant one (and thus is in $\mathrm{SL}_2(\mathbb{C})$) and $\frac{\frac{a}{D}z + \frac{b}{D}}{\frac{c}{D}z + \frac{d}{D}} = \frac{az+b}{cz+d}$, so this homomorphism is surjective.

As for the kernel of ϕ , If $\phi \begin{pmatrix} a & b \\ c & d \end{pmatrix} = Id \in \mathcal{M}$, then $\frac{az+b}{cz+d} = z$, for all $z \in \hat{\mathbb{C}}$. That is, $c = b = 0$ and $a = d$, and thus $\begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} a & 0 \\ 0 & a \end{pmatrix}$. Since this has determinant 1, we also need $a = \pm 1$. Thus $\ker \phi = \{I, -I\}$. $\square$

Corollary 4.7.8

$\mathcal{M} \cong \mathrm{SL}_2(\mathbb{C})/\{\pm I\}$.

Proof. Follows from the first isomorphism theorem. $\square$

This quotient $\mathrm{SL}_2(\mathbb{C})/\{\pm I\}$ is the **projective special linear group**, $\mathrm{PSL}_2(\mathbb{C})$.

§4.7.3 Conjugation and Changes of Basis

We can look at how the conjugation action of $\mathrm{GL}_n(\mathbb{F})$ on $M_{n \times n}(\mathbb{F})$ using the idea of changes of basis.

Recall that if we have some linear map $\alpha : \mathbb{F}^n \rightarrow \mathbb{F}^n$, we can represent α as a matrix A with respect to a basis $\{e_1, e_2, \dots, e_n\}$ of $\mathbb{F}^n$. se a different basis $\{f_1, f_2, \dots, f_n\}$, then α will be represented with respect to this basis by the matrix $P^{-1}AP$, where P is the **change of basis matrix**, defined by

$$f_j = \sum_{i=1}^n P_{ij}e_i.$$

This is an example of conjugation.

Proposition 4.7.9

$\mathrm{GL}_n(\mathbb{F})$ acts on $M_{n \times n}$ by conjugation. The orbit of a matrix $A \in M_{n \times n}(\mathbb{F})$ is the set of matrices representing the same linear map as A with respect to different bases.

Proof. To see that this is an action, if we have a matrix $A \in M_{n \times n}(\mathbb{F})$, then $P(A) = PAP^{-1} \in M_{n \times n}(\mathbb{F})$ for any $P \in \mathrm{GL}_n(\mathbb{F})$. Also, $I(A) = IAI^{-1} = A$, for any matrix A , and finally, if we have $Q, P \in \mathrm{GL}_n(\mathbb{F})$, then $(QP)(A) = QPA(QP)^{-1} = Q(PAP^{-1})Q^{-1} = Q(P(A))$, for any matrix A . So $\mathrm{GL}_n(\mathbb{F})$ acts on $M_{n \times n}(\mathbb{F})$.

By the argument above, we have that A and B are in the same orbit if and only if $A = PBP^{-1}$ for some $P \in \text{GL}_n(\mathbb{F})$, which is true if and only if $B = P^{-1}AP$. That is, B represents the same linear map as A with respect to a different basis. Precisely, this is the basis obtained by the change of basis corresponding to P . $\square$

Let's look at an example of this action.

Example 4.7.10 (Jordan Normal Form)

Recall that any matrix in $M_{2 \times 2}(\mathbb{C})$ is conjugate to a matrix in Jordan Normal Form (JNF). That is, it's conjugate to one of the following types of matrices:

$$\begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix} \text{ (where } \lambda_1 \neq \lambda_2 \text{), } \begin{pmatrix} \lambda & 0 \\ 0 & \lambda \end{pmatrix}, \quad \text{or} \quad \begin{pmatrix} \lambda & 1 \\ 0 & \lambda \end{pmatrix}.$$

In the case of the first type of matrix, the values λ_1 and λ_2 are uniquely determined by the matrix (look at the eigenvalues), but the order is not determined uniquely. Other than that, no two matrices on this list are conjugate.

This gives us a complete description of the orbits of the action of $\text{GL}_2(\mathbb{C})$ on $M_{2 \times 2}(\mathbb{C})$ via conjugation.

§4.7.4 Geometry of Orthogonal Groups

We are now going to look more closely at the orthogonal and special orthogonal group, and also the symmetries of $\mathbb{R}^2$ and $\mathbb{R}^3$.

Consider the standard inner product in $\mathbb{R}^n$: $x \cdot y = \sum_{i=1}^n x_i y_i$. Thinking of these as column vectors, we can write this as $x^T y$. If we consider the columns $p_1, \dots, p_n$ of $P \in O_n$, we have $(P^T P)_{ij} = p_i^T p_j = p_i \cdot p_j$. So since $P \in O_n$ if and only if $P^T P = I$, we have that

$$P \in O_n \iff p_i \cdot p_j = \delta_{ij},$$

using the kronecker delta. This proves the following proposition.

Proposition 4.7.11

$P \in O_n$ if and only if the columns of P form an orthonormal basis.

Thinking of $P \in O_n$ as a change of basis matrix, we get the following result.

Proposition 4.7.12

Consider O_n acting on $M_{n \times n}(\mathbb{R})$ by conjugation^a. Then two matrices will be in the same orbit if and only if they represent the same linear map with respect to two orthonormal bases.

^aThis is an action as O_n is a subgroup of GL_n

Another characterization of O_n is that it is inner-product preserving.

Proposition 4.7.13 (O_n preserves inner products)

$P \in O_n$ if and only if $(Px) \cdot (Py) = x \cdot y$ for any $x, y \in \mathbb{R}^n$.

Proof. If $P \in O_n$, then

$$(Px) \cdot (Py) = (Px)^T(Py) = x^T P^T Py = x^T I y = x^T y = x \cdot y.$$

If $(Px) \cdot (Py) = x \cdot y$ for all $x, y \in \mathbb{R}^n$, then taking the basis vectors e_i and e_j , we have

$$Pe_i \cdot Pe_j = e_i \cdot e_j = \delta_{ij}.$$

so the vectors $Pe_1, \dots, Pe_n$ are orthonormal. Then the columns of P are orthonormal, so $P \in O_n$ by our previous proposition. $\square$

Corollary 4.7.14

For $P \in O_n$, P preserves the length of vectors and the angle between vectors.

Proof. This follows directly from the preservation of inner product. $\square$

Let's investigate what the elements of O_n and SO_n look like. First, a bit of background.

Definition 4.7.15

If $a \in \mathbb{R}^n$ with $|a| = 1$, then the **reflection** in the plane normal to a is the linear map $R_a : \mathbb{R}^n \rightarrow \mathbb{R}^n$ such that $x \rightarrow x - 2(x \cdot a)a$.

Lemma 4.7.16

R_a lies in O_n .

Proof. Let $x, y \in \mathbb{R}^n$. Then

$$\begin{aligned} R_a(x) \cdot R_a(y) &= (x - 2(x \cdot a)a) \cdot (y - 2(y \cdot a)a) \\ &= x \cdot y - 2(x \cdot a)(a \cdot y) - 2(y \cdot a)(x \cdot a) + 4(x \cdot a)(y \cdot a)(a \cdot a) \\ &= x \cdot y, \end{aligned}$$

so $R_a \in O_n$, as it preserves inner products. $\square$

As we might expect, conjugates of reflections are also reflections.

Lemma 4.7.17 (Conjugates of Reflections are Reflections)

Given $P \in O_n$, $PR_aP^{-1} = R_{Pa}$.

Proof. We have

$$\begin{aligned} PR_a P^{-1}(x) &= P(P^{-1}(x) - 2(P^{-1}(x) \cdot a)a) \\ &= x - 2(P^{-1}(x) \cdot a)(Pa), \end{aligned}$$

but $P^{-1} = P^T$, so $P^{-1}(x) \cdot a = P^T x \cdot a = x^T Pa$, which is just $x \cdot Pa$. So $PR_a P^{-1}(x) = x - 2(x \cdot Pa)(Pa) = R_{Pa}(x)$. $\square$

So reflections lie in O_n , but do they lie in SO_n ? We need to know the determinant of a reflection R_a . We know that the determinant of a matrix is the product of its eigenvalues, so eigenvalues of R_a might be a helpful thing to find.

We can spot some straightforward eigenvectors:

$$R_a(a) = a - 2(a \cdot a)a = -a,$$

so a is an eigenvector with eigenvalue -1 . And, for x in the plane normal to a , we get

$$R_a(x) = x - 2(x \cdot a)a = x.$$

so x is an eigenvector with eigenvalue 1 . This is all of the eigenvalues, as the eigenvalue 1 has multiplicity $n - 1$, as we can find $n - 1$ linearly independent eigenvectors in the plane normal to a . Thus we have

$$\det(R_a) = (-1) \cdot (1)^{n-1} = -1.$$

This proves the following proposition.

Proposition 4.7.18 (Reflections are not in SO_n)

$R_a \in O_n \setminus SO_n$.

To think about the elements that *are* in SO_n , we will begin by thinking about SO_2 .

Theorem 4.7.19 (Elements of SO_2)

Every element of SO_2 is of the form

$$\begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix},$$

for some $\theta \in [0, 2\pi)$.^a Conversely every such element lies in SO_2 .

^aThis is an anticlockwise rotation of $\mathbb{R}^2$ about the origin by angle θ .

Proof. Consider the matrix

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SO_2.$$

We have $A^T A = I$, and $\det A = 1$. Thus $A^T = A^{-1}$, so

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} d & -b \\ -c & a \end{pmatrix},$$

and $a = d$, $b = -c$. Also since $ad - bc = 1$, so $a^2 + c^2 = 1$. So we can write $a = \cos \theta$ and $c = \sin \theta$ for a unique $\theta \in [0, 2\pi)$. Hence every matrix in SO_2 has the form as claimed. Conversely, the determinant of the matrix given is always one, and is in O_2 , and hence lies in SO_2 . $\square$

Theorem 4.7.20

The elements of $\text{O}_2 \setminus \text{SO}_2$ are the reflections in lines through the origin.

Proof. Consider the matrix

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \text{O}_2 \setminus \text{SO}_2.$$

Then $A^T A = I$, and $\det A = -1$. Then we have

$$A^T = \begin{pmatrix} a & c \\ b & d \end{pmatrix} = - \begin{pmatrix} d & -b \\ -c & a \end{pmatrix} = A^{-1},$$

and so $a = -d$, $b = c$. Since $ad - bc = -1$, we have $a^2 + c^2 = 1$, so $a = \cos \theta$, $c = \sin \theta$ for unique $\theta \in [0, 2\pi)$, and

$$A = \begin{pmatrix} \cos \theta & \sin \theta \\ \sin \theta & -\cos \theta \end{pmatrix}.$$

We can check that

$$A \begin{pmatrix} \sin \theta/2 \\ -\cos \theta/2 \end{pmatrix} = - \begin{pmatrix} \sin \theta/2 \\ -\cos \theta/2 \end{pmatrix}, \quad \text{and} \quad A \begin{pmatrix} \cos \theta/2 \\ \sin \theta/2 \end{pmatrix} = - \begin{pmatrix} \cos \theta/2 \\ \sin \theta/2 \end{pmatrix},$$

so A is the reflection in the plane orthogonal the unit vector $(\sin \theta/2 \quad -\cos \theta/2)$.

Conversely any reflection in a line through the origin will have this form, and so is in $\text{O}_2 \setminus \text{SO}_2$. $\square$

Corollary 4.7.21

Every element of O_2 is the composition of at most two reflections.

Proof. Every element in $\text{O}_2 \setminus \text{SO}_2$ is a reflection, so if $A \in \text{SO}_2$, then

$$A = \left[A \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} \right] \left[\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} \right],$$

and each of the matrices on the right is in $\text{O}_2 \setminus \text{SO}_2$, and is thus a reflection. $\square$

Moving from two to three dimensions, we have the following theorem.

Theorem 4.7.22

If $A \in \text{SO}_3$, then there exists a vector $v \in \mathbb{R}^3$ such that $|v| = 1$ and $Av = v$.

Proof. Such a v is an eigenvector for the eigenvalue 1, so it suffices to show 1 is an eigenvalue of A . This is equivalent to showing the determinant $\det(A - I) = 0$. We have

$$\begin{aligned}
 \det(A - I) &= \det(A - AA^T) \\
 &= \det(A(I - A^T)) \\
 &= \det A \cdot \det(I - A^T) \\
 &= \det(I - A^T) \\
 &= \det((I - A)^T) \\
 &= \det(I - A) \\
 &= \det(-I) \cdot \det(A - I) = -\det(A - I),
 \end{aligned}$$

so $\det(A - I) = 0$, as required. $\square$

Corollary 4.7.23

Every $A \in \text{SO}_3$ is conjugate in SO_3 to a matrix of the form

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{pmatrix}.$$

Proof. By the previous theorem, there exists $v_1 \in \mathbb{R}^3$ such that $|v_1| = 1$, and $Av_1 = v_1$. We can extend this to an orthonormal basis $\{v_1, v_2, v_3\}$ of $\mathbb{R}^3$. Then for $i = 2, 3$, we have

$$Av_i \cdot v_1 = Av_i \cdot Av_1 = v_i \cdot v_1 = 0,$$

so Av_2 and Av_3 lie in $\langle v_2, v_3 \rangle$. So A maps $\langle v_2, v_3 \rangle$ to itself. Now consider the restriction of A to $\langle v_2, v_3 \rangle$. This still has determinant 1, so A is an element of SO_2 , and its matrix must therefore be of the form

$$\begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}.$$

So A has the matrix

$$A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{pmatrix},$$

with respect to the basis $\{v_1, v_2, v_3\}$. The change of basis matrix P lies in O_3 since $\{v_1, v_2, v_3\}$ is an orthonormal basis, and if P does not lie in SO_3 , then instead we can use the basis $\{-v_1, v_2, v_3\}$. $\square$

Geometrically, this tells us in particular that every element in SO_3 is a rotation about some axis.

Corollary 4.7.24

Every element of O_3 is the composition of at most 3 reflections.

Proof. If $A \in \text{SO}_3$, then there exists $P \in \text{SO}_3$ such that $PAP^{-1} = B$, with

$$B = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & -\sin \theta \\ 0 & \sin \theta & \cos \theta \end{pmatrix}.$$

Since this matrix is the composition of at most 2 reflections by our result in two dimensions, so $B = B_1B_2$. Thus A also is, as the conjugate of a reflection is a reflection.

If $A \in \text{O}_3 \setminus \text{SO}_3$, then $\det A = -1$, then we can write

$$A = \left[A \begin{pmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \right] \left[\begin{pmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \right],$$

and the first lies in SO_3 and is thus the product of at most 2 reflections, and second matrix is a reflection. $\square$

§4.7.5 Symmetries of the Cube Revisited

We will finish our discussion of matrix groups by again considering the symmetries of the cube. We can think of the symmetry groups of any of the platonic solids as subgroups of O_3 . We can do this by placing our solid at the origin, and then any symmetry of the solid will be an element of O_3 .

One fact about O_3 is that we can write it as a direct product.

Lemma 4.7.25

$\text{O}_3 \cong \text{SO}_3 \times C_2$.

Proof Sketch. Apply the direct product theorem. $\square$

Here, the subgroup C_2 is generated by the map $v \mapsto -v$. So if $v \mapsto -v$ is a symmetry of our platonic solid, then its group of symmetries will also split as the direct product $G^+ \times C_2$. Now this is a symmetry of the cube, so we have that the symmetry group of the cube is the group of its rotational symmetries with C_2 , so

$$G^+ \times C_2 \cong S_4 \times C_2,$$

which matches our result from Chapter 5.

§4.8 Groups of Small Order

We are going to finish off by characterizing all groups up to order 8. We have already found some of these, which we will review.

§4.8.1 Groups of Order Up To 7

So far we have established the following classifications.

1. *Prime Order.* Then we only have the cyclic group.
2. *Order 4.* We have C_4 or $C_2 \times C_2$.
3. *Order 6.* We have C_6 and D_6 .

§4.8.2 Groups of Order 8

To study groups of order 8, we'll need to introduce a new group.

Definition 4.8.1 (Quaternions)

Consider the subset of matrices in $\text{GL}_2(\mathbb{C})$ given by

$$\mathbf{1} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \mathbf{i} = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}, \quad \mathbf{j} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad \mathbf{k} = \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix}.$$

The set $\{\pm \mathbf{1}, \pm \mathbf{i}, \pm \mathbf{j}, \pm \mathbf{k}\}$ forms the **quaternion group**, Q_8 .

The elements of this group satisfy the following relations:

- (i) $g^4 = \mathbf{1}$ for any $g \in Q_8$.
- (ii) $(-\mathbf{1})^2 = \mathbf{1}$.
- (iii) $\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = \mathbf{ijk} = -\mathbf{1}$.

With that defined, let's get on to classifying groups of order 8. First, a little lemma.

Lemma 4.8.2

If a finite group has all non-identity elements of order 2, then it is isomorphic to $C_2 \times C_2 \times \cdots \times C_2$.

Proof. Recall from example sheet 1 that G must be abelian, and $|G| = 2^n$. If $|G| = 2$, then $G \cong C_2$, and if $|G| > 2$, then choose a_1 of order 2 in G . Then there exists $a_2 \notin \langle a_1 \rangle$, and by the direct product theorem, $\langle a_1, a_2 \rangle \cong \langle a_1 \rangle \times \langle a_2 \rangle \cong C_2 \times C_2$. If this is isomorphic to G , then we are done. Otherwise, pick $a_3 \notin \langle a_1, a_2 \rangle$, and we get $\langle a_1, a_2, a_3 \rangle = \langle a_1 \rangle \times \langle a_2 \rangle \times \langle a_3 \rangle \cong C_2 \times C_2 \times C_2$. Continuing in this way, we get $G \cong C_2 \times C_2 \times \cdots \times C_2$. $\square$

And now we can get to the heart of the matter.

Theorem 4.8.3 (Groups of order 8)

A group of order 8 is isomorphic to exactly one of C_8 , $C_4 \times C_2$, $C_2 \times C_2 \times C_2$, D_8 , or Q_8 .

Proof. Note that C_8 , $C_4 \times C_2$ and $C_2 \times C_2 \times C_2$ are all abelian and are distinguished by the maximal order of an element in the group. Then D_8 and Q_8 are non-abelian, and are distinguished from each other by the number of elements of order 2.

Not let G be a group such that $|G| = 8$. Then every element has order 1, 2, 4 or 8 by Lagrange. If there is an element of order 8, then $G \cong C_8$. If every element has

order 2, then $G \cong C_2 \times C_2 \times C_2$ by our lemma. Now let's assume that G has at least one element g of order 4, and no element of order 8.

Now $|G : \langle g \rangle| = 2$, and thus if $h \notin \langle g \rangle$, $G = \langle g \rangle \cup h\langle g \rangle$. If $h^2 \in h\langle g \rangle$, we would have $h \in \langle g \rangle$, which is a contradiction. Thus $h^2 \in \langle g \rangle$.

Now if $h^2 = g$ or g^3 , then g would have order 8, which is a contradiction. So $h^2 = e$ or g^2 . We have $\langle g \rangle \trianglelefteq G$, thus $hgh^{-1} = g^k$, for some k . We also have $g = h^2gh^{-2} = hg^kh^{-1} = (hgh^{-1})^k = g^{k^2}$, as g and h^2 commute. This implies $k^2 \equiv 1 \pmod{4}$, giving two cases.

If $k \equiv 1 \pmod{4}$, then $hgh^{-1} = g$, implying G is abelian. If $h^2 = e$, then $G = \langle g \rangle \times \langle h \rangle \cong C_4 \times C_2$ by the direct product theorem. If $h^2 = g^2$, then $(hg^{-1})^2 = e$, so $G = \langle g, hg^{-1} \rangle \cong C_4 \times C_2$.

If $k \equiv -1 \pmod{4}$, then $hgh^{-1} = g^{-1}$. Then if $h^2 = e$, we have $G = \langle g, h \mid g^4 = h^2 = e, gh = hg^{-1} \rangle \cong D_8$. Otherwise, $h^2 = g^2$, and $G \cong Q_8$. $\square$

Remark. We know that in an abelian group, every subgroup is normal. The converse is not true, and Q_8 is a counterexample.

5 Numbers and Sets

‘Numbers and Sets’ is one of the first course in pure mathematics that you will take as an undergraduate at Cambridge. In a sense, it is the ‘starting course’, in that it will introduce you to the ‘pure maths’ way of thinking about things. This introduction will happen through the lense of thinking about objects, beginning with the natural and real numbers. You will be introduced to the ‘thoughtful way’ of thinking about such objects, that you can carry through to almost every other course in pure mathematics.

This article constitutes my notes for the ‘Numbers and Sets’ course, held in Michaelmas 2020 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas.

§5.1 Elementary Number Theory

Number theory is the branch of mathematics that studies the properties of *numbers*, with a particular emphasis on the natural numbers $\mathbb{N}$, the integers $\mathbb{Z}$ and occasionally the rationals $\mathbb{Q}$. In this section, we will study some of the *additive* and *multiplicative* structure of the integers, looking at divisors, primes and tools such as modular arithmetic.

One of the aims of this course (and this section in particular) is to study numbers ‘from the ground up’, being quite careful about what we assume. This goal immediately presents us with a question: what exactly is a ‘number’?

§5.1.1 The Peano Axioms

What are the natural numbers? Intuitively, we might say that they are a set¹ $\mathbb{N} = \{1, 2, 3, \dots\}$, created by starting at 1 and counting forward indefinitely, each time obtaining an object distinct from all of the previous ones. This does answer our question (a natural number is any element of $\mathbb{N}$), but has created a series of other questions. For example, what does it mean to ‘count forward’, and how can it be done ‘indefinitely’? How are we allowed to use these natural numbers, in regard to defining things like addition and multiplication?

Instead of attempting to answer these questions using our informal, intuitive definition of the natural numbers, we will instead use a definition that is more precise. Namely, we will define the natural numbers using the Peano axioms. We will state the rules or *axioms* that natural numbers satisfy, which will define the natural numbers in terms of *how they work*, rather than *what they are*. After clearly setting out this definition, we will be in a much stronger position to write concrete mathematical proofs about the natural numbers.

Definition 5.1.1 (Peano Axioms)

The **natural numbers** are a set $\mathbb{N}$, along with a function $S : \mathbb{N} \rightarrow \mathbb{N}$ and an object ‘1’ satisfying the following axioms:

¹We will look at sets later in the course, but an informal familiarity will be assumed from the beginning

1. $1 \in \mathbb{N}$.
2. If $n \in \mathbb{N}$, then $S(n) \in \mathbb{N}$.
3. $S(n) \neq 1$ for every $n \in \mathbb{N}$.
4. If $n, m \in \mathbb{N}$ and $n \neq m$, then $S(n) \neq S(m)$.
5. *Induction.* Let $P(n)$ be any property about a natural number n . Suppose that $P(0)$ is true, and suppose that whenever $P(n)$ is true, $P(S(n))$ is also true. Then $P(n)$ is true for every natural number n .

This should match with our original, informal definition of the natural numbers. We have formalized the ‘counting forward’ process with the *successor function* $S(n)$.

Remark. We are going to assume various things about the way we write down natural numbers using the decimal system. You can assume that when we write something like $n = 3$, we really mean $n = S(S(1))$ etc.

Addition

Now we have defined natural numbers, but as of yet we can do nothing more look upon them fondly and increment them using the function $S(n)$. We will now begin to remedy that by defining addition and multiplication.

Definition 5.1.2 (Addition)

We define **addition** to be an operation $+$ such that for $m, n \in \mathbb{N}$, we have $m + 1 = S(m)$, and $m + (n + 1) = (m + n) + 1$.

This definition defines addition for all natural numbers by induction. We are now able to state and prove various properties of addition.

Proposition 5.1.3 (Properties of Addition)

For all $a, b, c \in \mathbb{N}$. Then

- (i) *Addition is commutative.* $a + b = b + a$.
- (ii) *Addition is associative.* $(a + b) + c = a + (b + c)$.
- (iii) *Cancellation law.* If $a + b = a + c$ then $b = c$.

Proof Sketch. Use induction.^a □

^aThe proofs for these sorts of statements tend to be slightly dull and laborious, and for this reason they have been excluded. If you wish to read them, I encourage you to consult a textbook/some other reference material.

Order

We can now use addition to define an ordering on the natural numbers.

Definition 5.1.4 (Ordering of the Natural Numbers)

Let $n, m \in \mathbb{N}$. We say that n is **greater than or equal to** m , written $n \geq m$ if and

only if $n = m$ or $n = m + a$ for some $a \in \mathbb{N}$. We say n is **strictly greater than** m if $n \geq m$ and $n \neq m$.

Proposition 5.1.5 (Properties of Ordering)

Let $a, b, c \in \mathbb{N}$. Then

- (i) *Order is reflective.* $a \geq a$.
- (ii) *Order is transitive.* If $a \geq b$ and $b \geq c$, then $a \geq c$.
- (iii) *Order is anti-symmetric.* If $a \geq b$ and $b \geq a$, then $a = b$.
- (iv) *Addition preserves order.* $a \geq b$ if and only if $a + c \geq b + c$.
- (v) $a > b$ if and only if $a \geq b + 1$.

Proposition 5.1.6 (Trichotomy)

Let a and b be natural numbers. Then exactly one of the following is true: $a < b$, $a = b$ or $a > b$.

Multiplication

We can also define another familiar operation, multiplication, in the same inductive/recursive fashion that we defined addition.

Definition 5.1.7 (Multiplication)

We define **multiplication** to be an operation $\times$ such that for $m, n \in \mathbb{N}$, $m \times 1 = m$, and $m \times (n + 1) = (m \times n) + m$.

As before, induction implies that this is defined for all natural numbers. It also guarantees that multiplying two natural numbers is a natural number.

Notation. We will use $a \times b = a \cdot b = ab$ when referring to multiplication.

Proposition 5.1.8 (Properties of Multiplication)

For all $a, b, c \in \mathbb{N}$. Then

- (i) *Multiplication is commutative.* $a \times b = b \times a$.
- (ii) *Multiplication is associative.* $(a \times b) \times c = a \times (b \times c)$.
- (iii) *Distributive law.* $a \times (b + c) = a \times b + a \times c$.
- (iv) *Cancellation law.* If $a \times b = a \times c$ then $b = c$.
- (v) *Multiplication preserves order.* If $a < b$, then $a \times c < b \times c$.

Remark. The final two statements in the proposition above, the cancellation law and that multiplication preserves order, only hold because we are dealing with natural numbers. These properties do not hold in general if we allow a, b or c to be integers.

We could go further and define other common operations such as exponentiation, factorials and so on, all of which can be defined in the same fashion. However, in the interest

of space, these definitions have been omitted.

§5.1.2 Strong Induction

There is a more useful form of induction that can be used, now that we have defined an ordering on the natural numbers.

Proposition 5.1.9 (Strong Induction)

Suppose that we have some property $P(n)$ about a natural number n . If we have $P(1)$, and for all $n \in \mathbb{N}$ we have that $P(m)$ for $m \leq n$ implies $P(n+1)$, then $P(n)$ holds for all $n \in \mathbb{N}$.

Proof. This follows from ordinary induction using the property “ $P(n)$ for all $m \leq n$ ”. $\square$

Informally, the principle of strong induction means that whenever we are proving some property $P(n)$ holds for all $n \in \mathbb{N}$ by induction, we can feel free to assume that $P(m)$ holds for $m \in \mathbb{N}$ with $m < n$.

Remark (For Pedants). Technically, we don’t need to check the case $P(1)$ separately, as it is implied by the condition if suitably interpreted. Still, it’s safer to just check $P(1)$.

Some other equivalent but useful² forms of induction are listed below. Let $P(n)$ be a property, then

- *Existence of a Minimal Counterexample*

If $P(n)$ is false for some $n \in \mathbb{N}$, then there exists $n_0 \in \mathbb{N}$ such that $P(n_0)$ is false but $P(m)$ is true for all $m < n_0$.

- *The Well-Ordering Principle*

If $P(n)$ is true for some $n \in \mathbb{N}$, then there exists a minimal n_0 such that $P(n_0)$ is true.

§5.1.3 The Integers and Rationals

The previous section defined the natural numbers, along with some ways that we can use them. We will now go one step further and define the *integers*, and the *rational*s.

Definition 5.1.10 (Integers)

The **integers** are a set $\mathbb{Z}$ consisting of all symbols n , $-n$ and 0 , where $n \in \mathbb{N}$.

We can then define addition, multiplication and subtraction in (and subtraction) on the integers by extending our definition on the natural numbers in the obvious way. We can also check that the properties of addition we had before still hold. There are some additional properties that the integers have.

²Some texts will claim that we can replace the induction axiom in Peano axioms with one of these other forms. This is incorrect, and typically one will need to add additional axioms alongside to keep the set of axioms equivalent.

Proposition 5.1.11 (Algebraic Properties of the Integers)

Let $a, b \in \mathbb{Z}$. Then^a

- (i) *Identity.* $a + 0 = a$.
- (ii) *Existence of an Additive Inverse.* For all $a \in \mathbb{Z}$, there exists $b \in \mathbb{Z}$ such that $a + b = 0$.

^aThese properties imply that the integers are a *group*.

Proof. $a + 0 = a$ holds automatically due to our definition of addition on the integers. Then, we always have a $b \in \mathbb{Z}$ such that $a + b = 0$, as we can let $b = -a$. $\square$

We also obtain another interesting property of multiplication.

Proposition 5.1.12 (Zero Product Law)

Let a and b be integers such that $a \times b = 0$. Then either $a = 0$, $b = 0$ or both.

Proof. Assume for the purposes of contradiction that both $a \neq 0$ and $b \neq 0$. Then we must have either $a > 0$ or $a < 0$ by trichotomy. If $a > 0$, then $a \times b > 0$ if $b > 0$, or $a \times b < 0$ if $b < 0$. Otherwise, if $a < 0$, then $a \times b < 0$ if $b > 0$, or $a \times b > 0$ if $b < 0$. These are all possible cases, and thus we never have that $a \times b = 0$. Thus at least one of a and b must be zero. $\square$

Remark (Caveats). We noted earlier that there was some properties of the natural numbers that don't hold over the integers. Specifically, if we have $a < b$ for $a, b \in \mathbb{Z}$, and we multiply by a negative number, then the order is no longer preserved (it is switched). Also, the cancellation law only applies when we are cancelling a non-zero integer.

We can now use the integers to define the *rationals*.

Definition 5.1.13 (Rationals)

The **rationals** are a set $\mathbb{Q}$ of expressions a/b for some $a, b \in \mathbb{Z}$, with $b \neq 0$. We will define equality between rationals such that $a/b = c/d \iff ad = bc$.

This definition implicitly defines $\mathbb{Q}$ using *equivalence classes*, which will be discussed later. We need to be slightly more careful in defining addition on $\mathbb{Q}$, as we will need to ensure that it respects the equality relation between rationals.

Definition 5.1.14 (Addition on $\mathbb{Q}$)

For a/b and $c/d \in \mathbb{Q}$, we define addition such that

$$\frac{a}{b} + \frac{c}{d} = \frac{ad + bc}{bd}.$$

We will now need to explicitly check that this definition is valid.

Proposition 5.1.15

Addition is well defined on $\mathbb{Q}$.

Proof. Let $a/b = a'/b'$ and $c/d = c'/d'$ be rationals. We show that

$$\begin{aligned} \frac{a}{b} + \frac{c}{d} &= \frac{a'}{b'} + \frac{c'}{d'} \\ \iff \frac{ad + bc}{bd} &= \frac{a'd' + b'c'}{b'd'} \\ \iff (ad + bc)(b'd') &= (a'd' + b'c')(bd) \\ \iff (ab')dd' + (cd')bb' &= (a'b)d'd + (c'd)bb', \end{aligned}$$

which follows from $ab' = a'b$ and $cd' = c'd$. $\square$

To see why such a check was needed, consider the following example.

Example 5.1.16

We *cannot* define an operation on $\mathbb{Q}$ sending $a/b \rightarrow a^2/b^3$, as we would have $1/2 \rightarrow 1/8$ and $2/4 \rightarrow 4/64 = 1/16$, which is inconsistent.

We can then define multiplication in the same way as it was defined for integers, and we can check that all of the usual properties still hold. We can also define ordering, where $a/b < c/d$ if $ab < bc$. The rules from ordering $\mathbb{Z}$ still hold.

With all of these definitions in place, we can now start looking at some of the more interesting properties of numbers.

§5.1.4 Primes and Divisibility

We will now begin to discuss some actual number theory, beginning with the incredibly important concept of *divisibility*. You are likely to be familiar with this already, so we will jump into some definitions.

Definition 5.1.17 (Divisibility)

For $a, b \in \mathbb{N}$, we say that a **divides** b , written $a \mid b$ if there exists some $c \in \mathbb{N}$ such that $b = ac$.

If this is the case, we say that b is a **multiple** of a , and that a is a **divisor** of b . We can now define one of the most fundamental objects in number theory, the *primes*.

Definition 5.1.18 (Primes)

A natural number $n \geq 2$ is a **prime** if its only divisors are 1 and n . If a natural number is not prime, then it is **composite**.

With this definition, we can begin to state and prove some interesting results about the primes, which should hint at their importance in number theory.

Theorem 5.1.19

Every natural number is expressible as a product of primes.

Proof. We use induction on n . For $n = 2$ this is true, as 2 is prime. Now given $n > 2$, if n is prime, then we are done. If not, then n is composite so $n = ab$ for some $1 < a, b < n$. By our induction hypothesis, we have $a = p_1 p_2 \cdots p_k$ and $b = q_1 q_2 \cdots q_l$ for some (not necessarily distinct) primes $p_1, \dots, p_k, q_1, \dots, q_l$, hence $ab = p_1 \cdots p_k q_1 \cdots q_l$, which is the product of primes. Thus we are done by induction. $\square$

A nice consequence of this theorem is that the primes go on forever.

Theorem 5.1.20 (Euclid)

There are infinitely many primes.

Proof. Suppose there was finitely many primes, say $p_1, \dots, p_k$. Then consider the number $N = p_1 p_2 \cdots p_k + 1$. Then N has no prime factors, contradicting the fact that n can be written as the product of primes^a. $\square$

^aThis theorem has an amusingly large number of proofs. A short discussion can be found in the book ‘Proofs from the Book’.

Remark. There is no ‘pattern’ to the primes, in the sense that there is no algebraic formula for the n th prime.

So we know that a number can be written as the product of primes, but is this unique (up to some reordering)? This would seem to be true from experience, so why can’t we write a number as the product of primes in two ways. For example, why can’t we have $41 \times 101 = 67 \times 73$? Informally, we might think that this is impossible because we can’t have 41 dividing ‘a bit of’ 67 and ‘a bit of 73’. What we really need to show that prime factorization is unique is the following: For a prime p , if $p \mid ab$ then $p \mid a$ or $p \mid b$.

Now should this lemma be easy to prove, or hard to prove? That is, should this follow straight from definitions, or not? The answer is that it *cannot* follow straight from definitions. This is because it’s about ‘primes dividing things’, but we define the primes with ‘things dividing it’. This is the wrong way round! It will take some amount of work to be able to prove this.

Greatest Common Divisors

This section will begin to build some machinery that will allow us to tackle the problem of showing that prime factorizations are unique. We will begin by defining the notion of *greatest common divisor*, also known as *highest common factor*³.

Definition 5.1.21 (Greatest Common Divisor)

For $a, b \in \mathbb{N}$, a natural number d is the **greatest common divisor** of a and b , written $d = \gcd(a, b)$ if

- (i) $d \mid a$ and $d \mid b$;
- (ii) If $c \mid a$ and $c \mid b$, then $c \mid d$.

We want to show that the greatest common divisor always exists.

³This was the term used in the lectures, but I prefer greatest common divisor, so I will use that instead.

Proposition 5.1.22 (Division Algorithm)

For $n, k \in \mathbb{N}$, we can write $n = qk + r$, where $q, r \in \mathbb{N}$ and $0 \leq r < k$.

Proof. We use induction on N . For $n = 1$, this is clearly true. Otherwise, given $n > 1$, we can write $n - 1 = qk + r$ by our inductive hypothesis. Then, if $r < k - 1$, we can write $n = qk + (r + 1)$, and if $r = k - 1$, we can write $n = q(k + 1)$. $\square$

The division algorithm is related to the greatest common divisor using the following lemma.

Lemma 5.1.23 (Euclid)

For $a, b \in \mathbb{N}$, we can write $a = bq + r$ using the division algorithm. Then $\gcd(a, b) = \gcd(b, r)$.

Proof. If $d \mid a$ and $d \mid b$, then $d \mid a - bq = r$. Otherwise, if $d \mid b$ and $d \mid r$, then $d \mid bq + r = a$, hence the set of common divisors between a and b is the same as the set of divisors between b and r . Thus $\gcd(a, b) = \gcd(b, r)$. $\square$

Theorem 5.1.24 (Euclidean Algorithm)

For $a, b \in \mathbb{N}$, if we repeatedly apply the division algorithm to get

$$\begin{aligned} a &= q_1b + r_1 \\ b &= q_2r_1 + r_2 \\ r_1 &= q_3r_2 + r_3 \\ &\vdots \\ r_{n-2} &= q_nr_{n-1}, \end{aligned}$$

then $\gcd(a, b) = r_{n-1}$.

Proof. We repeatedly apply [Lemma 5.1.23](#) until we have $\gcd(a, b) = \gcd(r_{n-1}, 0) = r_{n-1}$. $\square$

The Euclidean Algorithm gives us both a proof that $\gcd(a, b)$ exists for any natural numbers a and b , and it also gives us an efficient way to find it.

Example 5.1.25

To find $\gcd(87, 52)$, we perform the following series of steps.

$$\begin{aligned} 87 &= 1 \times 52 + 35 \\ 52 &= 1 \times 35 + 17 \\ 35 &= 2 \times 17 + 1 \\ 17 &= 17 \times 1, \end{aligned}$$

thus $\gcd(87, 52) = 1$.

Notation. We will sometimes write $\gcd(87, 52) = \text{hcf}(87, 52) = (87, 52) = 1$. And when $\gcd(a, b) = 1$, we say that a and b are **coprime** or **relatively prime**.

The example above showed that $\gcd(87, 52) = 1$, so is it possible to write $1 = 87x + 52y$ for some $x, y \in \mathbb{Z}$? Looking at the computation we performed to find the greatest common divisor, we can work backwards to get

$$\begin{aligned} 1 &= 1 \times 35 - 2 \times 17 \\ &= 1 \times 35 - 2 \times (52 - 35) \\ &= -2 \times 52 + 3 \times 35 \\ &= -2 \times 52 + 3 \times (87 - 52) \\ &= 3 \times 87 - 5 \times 52, \end{aligned}$$

so it is indeed possible. In fact, there was nothing special about 87 and 52 here, we just used the sequence of steps performed in the Euclidean algorithm. We can formalize this.

Theorem 5.1.26

For all $a, b \in \mathbb{N}$, there exists $x, y \in \mathbb{Z}$ such that $ax + by = \gcd(a, b)$.

Proof. Run the Euclidean algorithm on a and b , say with some output r_n . Then we can write r_n as some integer linear combination of r_{n-1} and r_{n-2} . We can continue this to write any r_i as an integer linear combination of r_{i-1} and r_{i-2} . Thus eventually, we be able to write $r_n = ax + by$ for some $x, y \in \mathbb{Z}$, and as $r_n = \gcd(a, b)$, we are done. $\square$

Alternate Proof. Let h be the least positive integer linear combination of a and b . We claim that $h = \gcd(a, b)$. If $d \mid a$ and $d \mid b$, then $d \mid ax + by$ for any $x, y \in \mathbb{Z}$, thus $d \mid h$. Now suppose that $h \nmid a$. Then $a = qh + r$ for some $q, r \in \mathbb{Z}$, with $0 < r < h$. So $r - ah = a - q(ax + by)$, which is also a linear combination of a and b . But this is impossible, as it contradicts the minimality of h . Thus $h \mid a$, and by the same argument $h \mid b$. Thus $h = \gcd(a, b)$. $\square$

Remark. The second proof of the theorem above tells us that the greatest common divisor exists, but offers no way to find it, nor a way to find x or y .

This theorem has an interesting application: solving linear diophantine⁴ equations.

Corollary 5.1.27 (Bezout's Lemma)

Let $a, b, c \in \mathbb{N}$. Then the equation

$$ax + by = c$$

has an integer solution if and only if $\gcd(a, b) = c$.

Proof. Let $h = \gcd(a, b)$. If we have a solution $ax + by = c$, then $h \mid a$ and $h \mid b$, thus $h \mid c$. Now, if $h \mid c$, then we have $h = ax + by$ for $a, b \in \mathbb{Z}$ by our previous theorem, and thus we can write $c = \frac{c}{h}ax + \frac{c}{h}by$. Note that $\frac{c}{h}$ is guaranteed to be an integer by our previous argument. $\square$

⁴A diophantine equation is one where you seek only integer solutions.

The Fundamental Theorem of Arithmetic

We are now in a position to prove the lemma that was discussed quite a few pages ago, which will lead us directly to the uniqueness of prime factorizations.

Theorem 5.1.28 (Euclid's Lemma)

Let p be a prime, and $a, b \in \mathbb{N}$. Then $p \mid ab$ implies $p \mid a$ or $p \mid b$.

Proof. Suppose that $p \nmid a$. We wish to show that $p \mid b$. Then we have $\gcd(a, p) = 1$, which implies that we can write $ax + py = 1$, for some integers x and y . Then we can multiply by b to get $abx + pby = b$. But then $p \mid ab$ by our hypothesis, and thus $p \mid abx + pby = b$, and so we are done. $\square$

Remark. This theorem implies that if $p \mid a_1 a_2 \cdots a_k$, then p must divide at least one of a_i , for $1 \leq i \leq k$.

Theorem 5.1.29 (Fundamental Theorem of Arithmetic)

Every natural number $n \geq 2$ is uniquely expressible as a product of primes, up to re-ordering.

Proof. We already proved that such a product exists, so we will now prove that such a product is unique. We use induction on n . Suppose that $n = p_1 \cdots p_k = q_1 \cdots q_l$, where p_i, q_i are all primes. We wish to show that $k = l$, and after reordering, $p_i = q_i$ for all i . We have $p_1 \mid q_1 \cdots q_l$, so $p_1 \mid q_i$ for some i . We can (without loss of generality) label that prime q_1 . Hence $p_1 = q_1$. So $n/p_1 = p_2 \cdots p_k = q_2 \cdots q_l$, thus by induction $k = l$ and $p_2 = q_2, p_3 = q_3$, etc. $\square$

Aside: Why Unique Factorization Isn't Obvious

In the fundamental theorem of arithmetic, we took the ‘things that can't be broken up’ (the primes) and we broke up every number as a product of these, uniquely. The same concept makes sense in other places.

Consider instead $\mathbb{Z}[\sqrt{-3}]$, the set of complex numbers of the form $x + y\sqrt{-3}$, where $x, y \in \mathbb{Z}$. For example, $2 + 7\sqrt{-3}$. With these objects, we can both addition and multiplication two elements in $\mathbb{Z}[\sqrt{-3}]$, and always get back an element in $\mathbb{Z}[\sqrt{-3}]$. This allows us to talk about the notions of ‘divides’ and ‘multiple of’ etc in $\mathbb{Z}[\sqrt{-3}]$.

You might think that you can take the ‘things you can't break up’ in $\mathbb{Z}[\sqrt{-3}]$, and take any element and break it up into those. This is obviously correct (by definition). You may then want to say that this is unique, but that would not be true. For example,

$$4 = 2 \times 2 = (1 + \sqrt{-3})(1 - \sqrt{-3})$$

and all of the terms in this product are ‘things you can't break up’ in $\mathbb{Z}[\sqrt{-3}]$. This allows us to conclude that unique factorization *fails* in $\mathbb{Z}[\sqrt{-3}]$.

The fundamental theorem of arithmetic has some useful applications.

- *Factors*

Let's consider what are the factors of $2 \cdot 3^7 \cdot 11$ are. Certainly any $2^a \cdot 3^b \cdot 11^c$ where $0 \leq a \leq 3$, $0 \leq b \leq 7$ and $0 \leq c \leq 1$ is a factor. Also, there can't be any others. For example, if $7 \mid 2 \cdot 3^7 \cdot 11$, then we'd get a prime factorization involving a 7, which would contradict the uniqueness of prime factorization.

In general, the factors of $n = p_1^{a_1} \cdots p_k^{a_k}$ are precisely numbers of the form $p_1^{b_1} \cdots p_k^{b_k}$, where $0 \leq b_i \leq a_i$, for all $1 \leq i \leq k$.

- *Greatest Common Divisors*

If we wanted to find the common factors of $2^3 \cdot 3^7 \cdot 5 \cdot 11^3$ and $2^4 \cdot 3^2 \cdot 11 \cdot 13$, we could note that the common factors are $2^a \cdot 3^b \cdot 11^c$, where $0 \leq a \leq 3$, $0 \leq b \leq 2$ and $0 \leq c \leq 1$. So the greatest common divisor is $2^3 \cdot 3^2 \cdot 11$.

In general the greatest common divisor of $p_1^{a_1} \cdots p_k^{a_k}$ and $p_1^{b_1} \cdots p_k^{b_k}$ (with $a_i, b_i \geq 0$) is $p_1^{\min(a_1, b_1)} \cdots p_k^{\min(a_k, b_k)}$.

- *Lowest Common Multiples*

The common multiples of $2^3 \cdot 3^7 \cdot 5 \cdot 11^3$ and $2^4 \cdot 3^2 \cdot 11 \cdot 13$ are all of the form $2^a \cdot 3^b \cdot 5^c \cdot 11^d \cdot 13^e \cdot n$ (for a positive integer n) where $a \geq 4$, $b \geq 7$, $c \geq 1$, $d \geq 3$ and $e \geq 1$. We can then get the lowest common multiple as $2^4 \cdot 3^7 \cdot 5^1 \cdot 11^3 \cdot 13^1$.

Then in general, the lowest common multiple of $p_1^{a_1} \cdots p_k^{a_k}$ and $p_1^{b_1} \cdots p_k^{b_k}$ (with $a_i, b_i \geq 0$) is $p_1^{\max(a_1, b_1)} \cdots p_k^{\max(a_k, b_k)}$.

§5.1.5 Modular Arithmetic

It is a common occurrence in number theory that we will consider numbers that differ by a multiple of some fixed number to be equivalent. An example of this is the value of $(-1)^n$, which depends only on whether n is odd or even – that is, the values of n that differ by a multiple of 2 will give the same result. To give another example, the last digit of two numbers will be the same when the numbers differ by some multiple of 10. Modular arithmetic (or congruence notation) is a way of expressing such equivalences, where we have two integers a and b that differ by some fixed number m .

Definition 5.1.30 (Integers Modulo n)

Let $n \in \mathbb{N}$. The **integers modulo n** , written $\mathbb{Z}/n\mathbb{Z}$ consist of the integers where we regard two to be the same if they differ by a multiple of n .

Definition 5.1.31 (Congruence Notation)

If x and y are integers that are the same modulo n , then we write

$$x \equiv y \pmod{n}.$$

This notation implies that $x \equiv y \pmod{n}$ if and only if $n \mid x - y$, that is, if $x = y + kn$ for some $k \in \mathbb{Z}$. Note that no two of $0, 1, \dots, n-1$ are congruent $\pmod{n}$, and every $x \in \mathbb{Z}$ is congruent to exactly one of these modulo n (this follows from the division algorithm).

We can view $\mathbb{Z}/n\mathbb{Z}$ as the following picture (indeed this is the 'correct picture' of $\mathbb{Z}/n\mathbb{Z}$).

With this mental picture, we can begin to build up some properties of modular arithmetic.

Proposition 5.1.32 (Arithmetic Modulo n)

If $a \equiv a' \pmod{n}$ and $b \equiv b' \pmod{n}$, then $a + b \equiv a' + b' \pmod{n}$ and $ab \equiv a'b' \pmod{n}$.

Proof. We have $a' = a + kn$ and $b' = b + jn$, for some $k, j \in \mathbb{Z}$. So $a' + b' = a + b + (k + j)n \equiv a + b \pmod{n}$, and $a'b' = (a + kn)(b + jn) = ab + (bk + aj + kjn)n \equiv ab \pmod{n}$. $\square$

Many of the other rules of arithmetic are inherited from $\mathbb{Z}$, for example we have $a + b \equiv b + a \pmod{n}$ as $a + b = b + a$ in $\mathbb{Z}$. Also some of the number-theoretic facts we have previously established can be expressed in modular arithmetic.

Example 5.1.33 (Euclid's Lemma in Modular Arithmetic)

The statement that for a prime p , ' $p \mid ab \implies p \mid a$ or $p \mid b$ ' is equivalent saying that $ab \equiv 0 \pmod{p}$ implies that $a \equiv 0 \pmod{p}$ or $b \equiv 0 \pmod{p}$.

Modular Inverses

We will now begin to look at the multiplicative structure of $\mathbb{Z}/n\mathbb{Z}$.

Definition 5.1.34 (Modular Inverses)

For $a, b \in \mathbb{Z}$, we say that b is an **inverse** of a if $ab \equiv 1 \pmod{n}$.^a

^aThis should be reminiscent of the notion of inverses from group theory.

Example 5.1.35

In $\mathbb{Z}/10\mathbb{Z}$, the inverse of 3 is 7, as $3 \times 7 = 21 \equiv 1 \pmod{10}$. The inverse of 4 does not exist, as for all $x \in \mathbb{Z}$, $4x \not\equiv 1 \pmod{10}$, as $4x$ is even.

This example shows that inverses do not always exist for an arbitrary modulus n .

Notation. We write a^{-1} to mean the inverse of a (modulo some n).

Proposition 5.1.36 (Properties of Modular Inverses)

In $\mathbb{Z}/n\mathbb{Z}$,

- (i) If a modular inverse exists, then it is unique modulo n .
- (ii) If a has an inverse, and $ab \equiv ac \pmod{n}$, then $b \equiv c \pmod{n}$. That is, we can cancel invertible elements.^a

^aWe cannot cancel elements in general.

Proof. To show (i), suppose there exists $b, c \in \mathbb{Z}$ such that for some a , $ab \equiv ac \equiv n \pmod{n}$. Then $b(ac) \equiv bab \implies c \equiv b \pmod{n}$. Then to show (ii), we can just multiply both sides by a^{-1} . $\square$

When we are working modulo a prime, things tend to be ‘nicer’.

Proposition 5.1.37

Let p be a prime, then every $a \not\equiv 0 \pmod{p}$ has an inverse modulo p .

Proof. We have $\gcd(a, p) = 1$, so we can write $ax + py = 1$ for some $x, y \in \mathbb{Z}$. But then $ax = 1 - py$, and thus $ax \equiv 1 \pmod{p}$. $\square$

Alternate Proof. In $\mathbb{Z}/n\mathbb{Z}$, consider the multiplies of a : $0 \times a, 1 \times a, 2 \times a, \dots, (p-1) \times a$. We wish to show that one of them is 1. We have p items written down, and I claim these are all *distinct* in $\mathbb{Z}/p\mathbb{Z}$. If $ia = ja \implies (i-j)a \equiv 0$, which implies $a \equiv 0$ or $i-j \equiv 0 \implies i \equiv j \pmod{p}$. Hence, there must be $0, 1, \dots, p-1$ in this list, in some order. Thus $xa \equiv 1 \pmod{p}$, for some $x \in \mathbb{Z}/n\mathbb{Z}$. $\square$

We can generalize this proposition by considering which properties of the primes we used in the previous proof.

Proposition 5.1.38

Let $n \in \mathbb{N}$. Then a has an inverse modulo n if and only if $\gcd(a, n) = 1$.

Proof. We have $\gcd(a, n) = 1 \iff ax + ny = 1$, for some $x, y \in \mathbb{Z}$. Then $ax = 1 - ny \equiv 1 \pmod{n}$. $\square$

There is a commonly used function to count how many elements have an inverse modulo some n .

Definition 5.1.39 (Euler's Totient Function)

Euler's totient function $\phi(n)$ is the number of numbers $1, 2, \dots, n$ that are relatively prime to n . This function counts the number of invertibles or **units** in $\mathbb{Z}/n\mathbb{Z}$.

Example 5.1.40

If p is a prime, then $\phi(p) = p - 1$, $\phi(p^2) = p^2 - p$ (we cannot have $p, 2p, \dots, pp$). If p and q are distinct primes, then $\phi(pq) = pq - p - q + 1$.

Exponentiation

Consider the powers of 2 in $\mathbb{Z}/7\mathbb{Z}$. We have the sequence

$$\begin{aligned} 2^1 &\equiv 2 \pmod{7} \\ 2^2 &\equiv 4 \pmod{7} \\ 2^3 &\equiv 1 \pmod{7} \\ 2^4 &\equiv 2 \pmod{7} \\ &\vdots \end{aligned}$$

This sequence will repeat periodically, with a period of 3. It turns out that in general, this will always occur. This can be seen in the following theorem, which turns out to be an incredibly important result which is used all the time. This theorem has many proofs, but we present one particularly nice one, which emphasizes the theory that we have developed so far.

Theorem 5.1.41 (Fermat's Little Theorem)

Let p be a prime, then for $a \not\equiv 0 \pmod{p}$, we have

$$a^{p-1} \equiv 1 \pmod{p}.$$

Proof. Consider the numbers $1 \cdot a, 2 \cdot a, \dots, (p-1) \cdot a$ modulo p . They are distinct, as if $ai \equiv aj$ then $i \equiv j \pmod{p}$, because a is invertible. They are also non-zero. So we must have the numbers $1, 2, \dots, p-1 \pmod{p}$ in some order. Then, if we multiply together we have

$$a^{p-1}(p-1)! \equiv (p-1)! \pmod{p},$$

so we can cancel $(p-1)!$ as it's the product of invertibles, to obtain $a^{p-1} \equiv 1 \pmod{p}$. $\square$

As before, we can consider what happens in the case of a non-prime modulus.

Theorem 5.1.42 (Fermat-Euler Theorem)

Let $n \in \mathbb{N}$. Then for $a \not\equiv 0 \pmod{n}$, we have

$$a^{\phi(n)} \equiv 1 \pmod{n}.$$

Proof. We copy the proof of Fermat's little theorem. Let the units in $\mathbb{Z}/n\mathbb{Z}$ be $x_1, \dots, x_{\phi(n)}$. Consider $a \cdot x_1, a \cdot x_2, \dots, a \cdot x_{\phi(n)}$. They are distinct and invertible as before, so they must be $x_1, \dots, x_{\phi(n)}$ in some order. Multiplying them all together,

$$a^{\phi(n)} x_1 x_2 \cdots x_{\phi(n)} \equiv x_1 x_2 \cdots x_{\phi(n)} \pmod{n},$$

and then we can cancel each x_i to obtain $a^{\phi(n)} \equiv 1 \pmod{n}$. $\square$

We can pause for a moment and notice that in the proof of Fermat's little theorem, we could cancel $(p-1)! \pmod{p}$ because it was non-zero. So what exactly was it? We can try an example of $p = 5$, then we have $4! = 1 \equiv 24 \equiv -1 \pmod{5}$. We can also try

$p = 7$ to get $6! = 720 \equiv -1 \pmod{7}$. It can be proved that this is always the case.

First, we prove a small lemma.

Lemma 5.1.43

Let p be prime, then $x^2 \equiv 1 \pmod{p}$ implies $x \equiv 1$ or $x \equiv -1 \pmod{p}$.^a

^aNote that this is only true because p is prime. For example, $1^2 \equiv 3^2 \equiv 5^2 \equiv 7^2 \equiv 1 \pmod{8}$.

Proof. $x^2 \equiv 1 \implies x^2 - 1 \equiv 0 \pmod{p}$, which we can factor as $(x+1)(x-1) \equiv 0 \pmod{p}$ and thus $x \equiv 1$ or $x \equiv -1 \pmod{p}$. $\square$

Remark. It turns out that for a prime p , a non-zero polynomial in $\mathbb{Z}/p\mathbb{Z}$ of degree k always has at most k roots.

We can now prove our result about the value of $(p-1)! \pmod{p}$.

Theorem 5.1.44 (Wilson's Theorem)

Let p be a prime, then

$$(p-1)! \equiv -1 \pmod{p}.$$

Proof. Note that this is true for $p = 2$, so we may assume that $p \geq 3$. Consider the numbers $1, 2, \dots, p-1$ modulo p . We can pair up each a with its inverse a^{-1} for $a \neq a^{-1}$. But $a = a^{-1} \iff a^2 = 1$, so the only elements that are their own inverse are 1 and -1 . Thus $1, 2, \dots, p-1$ consists of some pairs a, a^{-1} and 1 and -1 . Thus when we multiply, $(p-1)! \equiv 1^{\frac{p-3}{2}} \cdot 1 \cdot -1 \equiv -1 \pmod{p}$. $\square$

To see how we can use both Wilson's theorem and Fermat's little theorem together, we can consider another question that follows naturally from [Lemma 5.1.43](#).

Lemma 5.1.45 ($x^2 + 1$ Lemma)

Let p be an odd prime. Then $x^2 \equiv -1 \pmod{p}$ has a solution if and only if $p \equiv 1 \pmod{4}$.

Proof. If $p = 4k + 3$, suppose that $x^2 \equiv -1 \pmod{p}$. Then we have from Fermat's little theorem that $x^{4k+2} \equiv 1 \pmod{p}$, but $x^{4k+2} \equiv (x^2)^{2k+1} \equiv (-1)^{2k+1} \equiv -1$, which is a contradiction.

We now construct an example to show that $p \equiv 1 \pmod{4}$ works. By Wilson's theorem, $(4k!) \equiv -1 \pmod{p}$. Then, noting that $4k-j \equiv -j-1 \pmod{p}$, $(2k)!^2 \equiv (2k!)^2 \cdot (-1)^{2k} \equiv (4k!) \equiv -1 \pmod{p}$, so a solution exists. $\square$

Congruence Equations and the Chinese Remainder Theorem

We now return back to the topic of linear diophantine equations, this time looking specifically at linear congruence equations. Let's look at an example.

Example 5.1.46 (Solving a Linear Congruence Equation)

Solve $7x \equiv 4 \pmod{30}$.

Solution. First we *find a solution*.

We have $\gcd(7, 30) = 1$, so we can run the Euclidean algorithm on 7 and 30 to obtain $7 \times 13 - 30 \times 3 = 1$. So $7 \times 13 \equiv 1 \pmod{30}$, hence $7 \times 52 \equiv 4 \pmod{30}$. So $x \equiv 52 \pmod{30}$ is a solution.

Now we show there is *no more solutions*.

If x' is a solution, then we have $7x \equiv 4 \pmod{30}$ and $7x' \equiv 4 \pmod{30}$. Thus $7x \equiv 7x' \pmod{30}$, which implies that $x \equiv x' \pmod{30}$ as 7 is invertible. So $x \equiv 52 \pmod{30}$ is the only solution. $\square$

There is a shorter method that can be used too, if we can quickly spot the inverse of the coefficient of our variable.

Example 5.1.47

Solve $3x \equiv 9 \pmod{28}$.

Solution. $3x \equiv 9 \pmod{28} \iff 19 \cdot 3x \equiv 19 \cdot 9 \pmod{28}$, as 19 is invertible. Thus $x \equiv 171 \equiv 3 \pmod{28}$. $\square$

If we don't have that the coefficient and the modulus is coprime, it's typically easier to write the equation as a standard linear diophantine equation.

Example 5.1.48

Solve $10x \equiv 12 \pmod{34}$.

Solution. $10x \equiv 12 \pmod{34} \iff 10x = 12 + 34y$ for some $y \in \mathbb{Z}$. Then $10x = 12 + 34y \iff 5x = 6 + 17y$, which we can write as $5x \equiv 6 \pmod{17}$. We can then solve as before. $\square$

Now consider a simultaneous congruence equation. Specifically, consider the equations

$$x \equiv 6 \pmod{17}$$

$$x \equiv 2 \pmod{19}.$$

Do we expect a solution to this? We might guess yes, as 17 and 19 are coprime, so intuitively 'modulo 17 and modulo 19 should be independent of each other'. What about these equations:

$$x \equiv 6 \pmod{34}$$

$$x \equiv 11 \pmod{36}.$$

We shouldn't expect solutions to these equations. Even if you try and figure out if x is even or odd, you'll run into issues. This intuition can be formalized into a theorem.

Theorem 5.1.49 (Chinese Remainder Theorem)

Let m and n be relatively prime positive integers. Then for any integers a and b ,

there is solution to

$$\begin{aligned}x &\equiv a \pmod{m} \\x &\equiv b \pmod{n},\end{aligned}$$

and this solution is unique modulo mn .

Proof. First we prove existence. We have $ms + nt = 1$ for some $s, t \in \mathbb{Z}$ by Bezout's lemma. Then $ms \equiv 0 \pmod{m}$ and $1 \pmod{n}$ and $nt \equiv 0 \pmod{n}$ and $1 \pmod{m}$. Hence $x = a(nt) + b(ms)$ has $x \equiv a \pmod{m}$ and $x \equiv b \pmod{n}$.

To show uniqueness, certainly any $x' \equiv x \pmod{mn}$ is also a solution. Conversely, suppose x' has $x' \equiv a \pmod{m}$ and $b \pmod{n}$. Then $x' \equiv x \pmod{m}$ and $x' \equiv x \pmod{n}$, that is, $m \mid x' - x$ and $n \mid x' - x$. Thus $mn \mid x' - x$, as $\gcd(m, n) = 1$, and thus $x' \equiv x \pmod{mn}$. $\square$

This theorem generalizes directly.

Theorem 5.1.50 (General Chinese Remainder Theorem)

Let $m_1, \dots, m_k$ be pairwise relatively prime positive integers, and let

$$M = m_1 m_2 \cdots m_k.$$

Then for all integers $x_1, \dots, x_k$, the equations

$$\begin{aligned}x &\equiv x_1 \pmod{m_1} \\x &\equiv x_2 \pmod{m_2} \\&\vdots \\x &\equiv x_k \pmod{m_k}\end{aligned}$$

have a solution x that is unique modulo M .

Proof Sketch. Reduce the number of equations by applying the two variable Chinese remainder theorem to the last two equations. $\square$

An Application of the Fermat-Euler Theorem: RSA Encryption

RSA is an algorithm that underpins a huge amount of modern cryptography and security.

Normally, to send a coded message to someone, you would encode the message, which you could then send to the intended receiver who would decode it. This decoding would be performing the encoding operation in reverse – they are inverse operations. Because of this, it would seem obvious in this way that knowing how to encode is the same as knowing how to decode. For example, if your encoding is ‘add 1 to each letter’, a *Caesar cipher*, then you immediately know how to decode: ‘take 1 from each letter’. For another example, if your encoding is ‘add 1 to each letter then reverse each word’, then to decode you ‘reverse each word and subtract 1 to each letter’. This belief, that knowing how to encrypt implies knowing how to decrypt, was held for centuries, but it isn't quite correct. We will see this in the RSA encryption system.

Begin with two large distinct primes p and q , and let $n = pq$. Let's say we want to

encrypt some element $x \in \mathbb{Z}/n\mathbb{Z}$ – this may involve taking the message we want to send and splitting it up in some way. We will do that in the following way.

Fix a ‘coding exponent’ e . To encode a message $x \in \mathbb{Z}/n\mathbb{Z}$, raise it to the power e .

$$x \mapsto x^e.$$

Now let’s figure out how to decode this message. We want some $d \in \mathbb{Z}/n\mathbb{Z}$ so that $(x^e)^d \equiv x \pmod{n}$. First, assume that x and n are coprime (ensure that the message x is constructed to have this condition). We know from the Fermat-Euler theorem that $x^{\phi(n)} \equiv 1 \pmod{n}$, and also that $x^{k\phi(n)} \equiv 1 \pmod{n}$, for all $k \in \mathbb{Z}$. So we have

$$x^{k\phi(n)+1} \equiv x \pmod{n}.$$

So it suffices to find a d such that $de = k\phi(n) + 1$, for some $k \in \mathbb{Z}$. That is, we want an inverse of e modulo $\phi(n)$. We can do this by running the Euclidean algorithm on the numbers e and $\phi(n)$. This implies we needed to have picked e coprime with $\phi(n)$.

With the encryption and decryption methods defined, we can now consider what information is needed to perform each step.

To encode, we take $x \mapsto x^e \pmod{n}$ ⁵. This means we need to know that will need to know n (so you know what modulus to use) and also the power e .

To decode, we take $y \mapsto y^d \pmod{n}$, so we need to know n and d . But we worked out d as the inverse of e modulo $\phi(n)$, so we really need n , e and $\phi(n)$. Recall that

$$\phi(n) = n - p - q + 1.$$

So to compute $\phi(n)$, we need to know the factors of n . However, the problem of factoring n is thought to be incredibly hard, and the best known methods of today would take longer than the age of the universe to factor n into two 100 digit long primes. This means that if e and n were published, then anyone could encode a message, but only you (or someone who knows the factors of n) would be able to decode. So, with RSA encryption, anyone can encrypt a message and send it to you, but only you can decrypt it.

§5.2 The Reals

Moving on from number theory, this chapter will center on the questions of *what is a real number* and *what can we assume like them*. Unlike when we defined the natural numbers, in this chapter we will not just define the reals formally and then proceed as normal; instead, we will try and understand some of the more subtle aspects of the real numbers, that will eventually be carried through in ‘Analysis’.

§5.2.1 Why We Need Real Numbers

Recall that in [section 5.1](#), we began by defining the natural numbers $\mathbb{N}$, extended them to the integers $\mathbb{Z}$, and extended them to the rationals $\mathbb{Q}$. So why would we not stop there? In the following example, we will show that for some (many) purposes, the rationals are not adequate.

⁵This process can be done quite quickly by squaring the number whenever possible.

Proposition 5.2.1

There is no $x \in \mathbb{Q}$ such that $x^2 = 2$.

Proof. Assume that $x \geq 0$. If there was such a rational, we could write

$$x = \frac{a}{b},$$

where $a, b \in \mathbb{Z}$. We can square this to get

$$x^2 = \frac{a^2}{b^2} = 2 \implies a^2 = 2b^2,$$

but this is a contradiction of the fundamental theorem of arithmetic, as the power of 2 in a^2 would have to be odd^a. $\square$

Alternate Proof. Suppose that for some $x = a/b \in \mathbb{Q}$ where $a, b \in \mathbb{N}$, we have $x^2 = 2$. Note that for any integers c and d , the number $cx + d$ is of the form e/b , for some $e \in \mathbb{Z}$. So, if $cx + d > 0$, then $cd + d > \frac{1}{b}$. But $x^2 = 2 \implies 0 < x - 1 < 1$, we can say $0 < (x - 1)^k < 1/b$ for large enough k . But this is a contradiction, because $(x - 1)^k$ is of the form $cx + d$. $\square$

^aThe same proof shows that if there exists $x \in \mathbb{Q}$ so that $x^2 = n$, for $n \in \mathbb{N}$, then n must be a square number. This is because each exponent in the prime factorisation of n must be even.

Informally, what this result shows is that $\mathbb{Q}$ has a ‘gap’ at $\sqrt{2}$, and in constructing the reals, we will try formally define a number system that has no such ‘gaps’. This immediately raises the question of how we can define such a system, formalizing our rather vague notion of a ‘gap’. This must be done while only making statements about the rationals.

Consider again our example that there is no rational x such that $x^2 = 2$. With this in mind, define the set S as follows:

$$S = \{x \in \mathbb{Q} : x^2 < 2\}.$$

We will now think about bounds on the elements in this set.

Definition 5.2.2

A set S is **bounded above** if there exists $x \in \mathbb{R}$ with $x \geq y$ for all $y \in S$. Such an x is a **least upper bound** of S if x is an upper bound for S , and every upper bound x' of S satisfies $x < x'$.

It should be clear that 1.5 is an upper bound on the elements in this set. 1.42 is also an upper bound. By setting such upper bounds, we can get arbitrarily close to a number x such that $x^2 = 1$, that is there cannot be a *least* upper bound. If there was, it would have to be a number so that $x^2 = 2$, but we know there isn’t such a rational. It’s using this idea of ‘least upper bounds’ that we can define the reals.

Definition 5.2.3 (The Reals)

The **reals** are a set $\mathbb{R}$ with elements 0 and 1 (where $0 \neq 1$), along with operations $+$ and $\times$ and an ordering $<$ such that:

1. $+$ is commutative, associative, has an identity 0, and every $x \in \mathbb{R}$ has an inverse.
2. $\times$ is commutative, associative, has an identity 1, and every $x \in \mathbb{R}$ where $x \neq 0$ has an inverse.
3. $\times$ is distributive over $+$.
4. $\forall a, b$, exactly one of $a < b$, $a = b$ and $b < a$ holds. Also if $a < b$ and $b < c \implies a < c$.
5. $\forall a, b, c \in \mathbb{R}$, $a < b \implies a + c < b + c$ and $a < b \implies ac < bc$ if $c > 0$.
6. *Least Upper Bound.* Every non-empty set of reals that is bounded above has a least upper bound.

It's worth noting that the conditions in axiom 6 of the set of reals being 'non-empty' and 'bounded above' is needed because if there was no upper bound, then there is certainly no *least* one. Also, if the set was empty then every $x \in \mathbb{R}$ would be an upper bound, and there would be no least one.

From these axioms, it's straightforward to check some very basic facts, for example that $0 < 1$.

Example 5.2.4

We have $0 < 1$.

Proof. If that were not the case, as we have $0 \neq 1$ as an axiom, we would need $1 < 0$. This would imply $0 < -1$ and thus it is 'positive', so we can multiply by the 'positive' -1 to get $0 < 1$, which contradicts our assumption. $\square$

We can also (as you may expect) view $\mathbb{Q}$ as contained in $\mathbb{R}$, by identifying $a/b \in \mathbb{Q}$ with $a, b^{-1} \in \mathbb{R}$. In this system, axioms 1 to 5 hold, but axiom 6 does not hold. We have defined the reals here by specifying the axioms that they satisfy, but that is not the only way. It is possible to construct $\mathbb{R}$ from $\mathbb{Q}$, in a way that is (vaguely) similar to the way we constructed $\mathbb{Q}$ from $\mathbb{Z}$. This is, surprisingly, not as helpful as one might imagine, so we will skip over this topic for now.

Least Upper Bounds

The notion of least upper bounds is so central to the real numbers that we will consider some examples of different sets and their least upper bounds, in order for you to get see some of the properties. We will use the following notation for the least upper bound.

Definition 5.2.5 (Supremum)

The least upper bound of a set S is also known as the **supremum** of S , written $\sup S$.

Example 5.2.6 (Sets and Least Upper Bounds)

1. The set $S = \{x \in \mathbb{R} : 0 \leq x \leq 1\}$ has a least upper bound $x = 1$. This is

because 1 is an upper bound, and also every upper bound y has $y \geq 1$, as $1 \in S$.

2. Consider the set $S = \{x \in \mathbb{R} : 0 < x < 1\}$. We have 2 as an upper bound, as $x \in S$ has $x < 1 < 2$. Also $3/4$ is not an upper bound, as $7/8 \in S$, and $3/4 < 7/8$. Now the least upper bound of S is 1, because 1 is an upper bound, and no upper bound c has $c < 1$, as otherwise, $c \in S$, and we can take $c + (1 - c)/2 \in S$.
3. $S = \{1 - \frac{1}{n} : n \in \mathbb{N}\} = \{0, \frac{1}{2}, \frac{2}{3}, \frac{3}{4}, \dots\}$. Clearly 1 is an upper bound, and we will return to this example to show that it is the least upper bound.

Theorem 5.2.7 (Axiom of Archimedes)

$\mathbb{N}$ is not bounded above in $\mathbb{R}$.

Proof. Let's suppose that it was bounded above, in which case we would have $c = \sup \mathbb{N}$, for some $c \in \mathbb{R}$. So $c - 1$ is *not* an upper bound for $\mathbb{N}$. That implies that there is a natural number n with $n > c - 1$. But then $n + 1 \in \mathbb{N}$, and $n + 1 > c$, which is a contradiction. $\square$

Corollary 5.2.8

For each $t > 0$, there exists $n \in \mathbb{N}$ with $\frac{1}{n} < t$.

Proof. We have some $n \in \mathbb{N}$ with $n > \frac{1}{t}$ by the previous result, so $\frac{1}{n} < t$. $\square$

Remark. Informally, these two results are telling us that $\mathbb{R}$ does not contain any ‘infinitely big’ or ‘infinitesimally small’ elements.

We can return to the third example above, and we can now show that $\sup S = 1$, as if there was some $c < 1$ that was an upper bound, then $1 - \frac{1}{n} < c$ for every $n \in \mathbb{N}$, so $1 - c < \frac{1}{n}$, which is impossible (by the corollary we just proved).

Remark (Warning). If a set S has a greatest element (like $[0, 1]$), then that greatest element is $\sup S$, so $\sup S \in S$. But if S has no greatest element (like $(0, 1)$), then $\sup S \notin S$.

We have been discussing upper bounds of sets, but the least upper bound axiom also implies some facts about lower bounds.

Definition 5.2.9

A set S is **bounded below** if there exists $x \in \mathbb{R}$ with $x \leq y$ for all $y \in S$. Such an x is a **greatest lower bound** of S if x is a lower bound for S , and every lower bound $x' \neq x$ of S satisfies $x < x'$. We write $x = \inf S$.

Proposition 5.2.10

If a set S is non-empty and has a lower bound, then it has a greatest lower bound.

Proof. Let the set $-S = \{-y : y \in S\}$. It is non-empty and bounded above, so it has a least upper bound c . So $-c$ is the greatest lower bound of S , $\inf S$. $\square$

Rationals and Irrationals

Let's return to our original question which prompted our discussion of the real numbers: that there is no $x \in \mathbb{Q}$ with $x^2 = 2$. If we have in any way succeeded, we should be able to do somewhat better than that in the reals.

Proposition 5.2.11

There is some $x \in \mathbb{R}$ such that $x^2 = 2$.

Proof. Let $S = \{x \in \mathbb{R}, x^2 < 2\}$. We have S is nonempty, and it is bounded above, so $c = \sup S$ for some $c \in \mathbb{R}$. We claim that $c^2 = 2$. If this wasn't the case, then either $c^2 < 2$ or $c^2 > 2$. If $c^2 < 2$, then for $t < \frac{2-c^2}{4}$ we have $(c+t)^2 < 2$, which contradicts c being an upper bound for S . If $c^2 > 2$, then we can let $t < \frac{c^2-2}{4}$ and then $(c-t)^2 > 2$, which contradicts that c is the *least* upper bound for S . So we must have $c^2 = 2$. $\square$

This same proof also shows that $\sqrt[n]{x}$ exists for all $n \in \mathbb{N}$ and $x \in \mathbb{R}$. We regularly distinguish between a real number that is also a rational number, and a real number that is not also a rational.

Definition 5.2.12

A real that is not rational is called an **irrational**.

Example 5.2.13

$\sqrt{2}$, $\sqrt{3}$, $\sqrt{6}$ and $\sqrt{15}$ are all irrational, as is $2 + 3\sqrt{5}$.

It's worth noting that the rationals are **dense** in the reals.

Theorem 5.2.14 ($\mathbb{Q}$ is dense in $\mathbb{R}$)

The rationals are **dense** in $\mathbb{R}$, that is, for $a, b \in \mathbb{R}$, there exists $q \in \mathbb{Q}$ such that $a \leq q \leq b$.

Proof. Without loss of generality, assume that $a, b \geq 0$. Then choose some $n \in \mathbb{N}$ such that $\frac{1}{n} < b - a$. Then among $\frac{0}{n}, \frac{1}{n}, \dots$, there is a *final* one that is less than or equal to a , say $\frac{k}{n}$. So $a < \frac{k+1}{n} < b$. $\square$

Slightly more interesting is the following result.

Theorem 5.2.15

The irrationals are dense, that is, for $a, b \in \mathbb{R}$ with $a < b$, there exists an irrational c such that $a < c < b$.

Proof. This follows from the rational case, as we can find a rational c between $\sqrt{2}a$ and $\sqrt{2}b$, then $c/\sqrt{2}$ is irrational, and lies between a and b . $\square$

§5.2.2 Sequences

We are now going to discuss one of the major uses of the least upper bound statement – sequences. We are going to consider some questions like

What should $1 + \frac{1}{2} + \frac{1}{4} + \dots = 2$ mean?

and

What should $0.3333\dots = \frac{1}{3}$ mean?

For the first question, presumably the first sequence should ‘tend to’ 2, and the second should ‘tend to’ $1/3$. So what does it mean for a sequence $x_1, x_2, \dots$ to ‘tend to’ some c ? It should not mean that x_n is getting closer to c , for example, we would not want $1/2, 2/3, 3/4, \dots$ to tend to 17. We also don’t mean that x_n gets arbitrarily close to c , as for example, the sequence $1/2, 10, 2/3, 10, \dots$ should not tend to 1. The correct way to think of it is that we will get arbitrarily close *and stay* within some value of c .

Definition 5.2.16

We say that a sequence of reals $x_1, x_2, \dots$ **tends to** $c \in \mathbb{R}$ if $\forall \varepsilon > 0$, there exists $N \in \mathbb{N}$ such that for all $n \geq N$,

$$|x_n - c| < \varepsilon.$$

We will also say that c is the **limit** of $x_1, x_2, \dots$.

Remark (Informal). We can think of this say saying ‘ $\forall \varepsilon > 0$, x_n eventually is within ε of c ’.

There is quite a lot of subtlety to this definition, so we will spend some time considering its consequences.

Notation. If x_n tends to c , we will write $x_n \rightarrow c$, or $x_n \rightarrow c$ as $n \rightarrow \infty$, or $\lim_{n \rightarrow \infty} x_n = c$.

Example 5.2.17

Consider the sequence

$$\frac{1}{2}, \frac{1}{2} + \frac{1}{4}, \frac{1}{2} + \frac{1}{4} + \frac{1}{8}, \dots,$$

this is the sequence $x_1, x_2, \dots$ where $x_n = 1 - \frac{1}{2^n}$ (inductively). We claim $x_n \rightarrow 1$.

Proof. Given $\varepsilon > 0$, choose $N \in \mathbb{N}$ with $N > \frac{1}{\varepsilon}$. Then $\forall n \geq N$, $|x_n - 1| = \frac{1}{2^n} \leq \frac{1}{n} \leq \frac{1}{N} < \varepsilon$. $\square$

Example 5.2.18

The constant sequence $c, c, c, \dots$ (where $x_n = c$ for all n), then $x_n \rightarrow c$.

Proof. Given $\epsilon > 0$, we have $|x_n - c| < \epsilon$ for all n . $\square$

Example 5.2.19

The sequence $-1, 1, -1, 1, \dots$ where $x_n = (-1)^n$ has no $c \in \mathbb{R}$ with $x_n \rightarrow c$.

Proof. Suppose that $x_n \rightarrow c$, then choose $\epsilon = 1$. So there exists $N \in \mathbb{N}$ such that for $n \geq N$, we have $|x_n - c| < 1$, in particular, $|1 - c|$ and $|(-1) - c| < 1$, so $|1 - (-1)| < 2$ by the triangle inequality, which is a contradiction. $\square$

Example 5.2.20

The sequence $1, 0, 1/3, 0, 1/5, \dots$ with x_n given by

$$x_n = \begin{cases} 1 & \text{if } n \equiv 0 \pmod{5} \\ 5 & \text{if } n \equiv 1 \pmod{5} \\ \frac{1}{n} & \text{if } n \text{ is odd} \\ 0 & \text{if } n \text{ is even} \end{cases},$$

then $x_n \rightarrow 0$.

Proof. Given $\epsilon > 0$, choose $N \in \mathbb{N}$ with $\frac{1}{N} < \epsilon$. Then $\forall n \geq N$, $x_n = \frac{1}{n}$ or 0 , so $|x_n - 0| \leq \frac{1}{n} \leq \frac{1}{N} < \epsilon$. $\square$

Definition 5.2.21 (Convergent and Divergent Sequences)

If $x_n \rightarrow c$ for some c , we say that the sequence $x_1, x_2, x_3, \dots$ is **convergent**. If a sequence is not convergent, we say it is **divergent**.

We now show that if a sequence converges, then it converges to a unique value.

Proposition 5.2.22 (Limits Are Unique)

If a sequence $(x_n) \rightarrow c$, and $(x_n) \rightarrow d$, then $c = d$.

Proof. Suppose $c \neq d$, and choose $\epsilon = \frac{1}{2}|c - d|$. then $\exists N \in \mathbb{N}$ with $|x_n - c| < \epsilon$ for all $n \geq N$, and some $M \in \mathbb{N}$ with $|x_n - d| < \epsilon$ for all $n \geq M$. But now for any $n \geq \max(M, N)$, we have $|x_n - c|, |x_n - d| < \epsilon$, so $|c - d| < 2\epsilon$, which is a contradiction. $\square$

Some special notation can be used if a sequence is written in a particular form.

Definition 5.2.23 (Series)

A sequence given in the form $x_1, x_1 + x_2, x_1 + x_2 + x_3 + \dots$ is called a **series**, and can be written as

$$\sum_{n=1}^{\infty} x_n.$$

The k th term of this sequence is $\sum_{n=1}^k x_n$, the k th **partial sum** of this series.

If the series $x_1, x_1 + x_2, x_1 + x_2 + x_3, \dots$ is convergent say to c , then we will write

$$\sum_{n=1}^{\infty} x_n = c.$$

Remark (Warning). We *cannot* write $\sum_{n=1}^{\infty} x_n$ unless we know that the limit of the partial sums exist.

Limits do generally behave as we would expect.

Proposition 5.2.24

If $x_n \rightarrow c$ and $y_n \rightarrow d$, then $x_n + y_n \rightarrow c + d$.

Proof. Given $\epsilon > 0$, then as $x_n \rightarrow c$, so there exists $N \in \mathbb{N}$ such that $|x_n - c| < \epsilon/2 \forall n \geq N$. Also, as $y_n \rightarrow d$, so there exists $M \in \mathbb{N}$ such that $|x_m - d| < \epsilon/2$ for $m \geq N$. Then we can take $m \geq \max(M, N)$, and $|(x_n + y_n) - (c + d)| \leq |x_n - c| + |y_n - d| < \epsilon/2 + \epsilon/2 = \epsilon$. $\square$

In the proofs above, we have only been claiming what the limit is, and then proving that it converges to that. This isn't always necessary, and sometimes you can prove that a sequence converges without knowing the limit that it converges to.

Definition 5.2.25 (Increasing Sequence)

A sequence $x_1, x_2, \dots$ is **increasing** if $x_{n+1} \geq x_n$ for all n .

Theorem 5.2.26 (Monotone Convergence Theorem)

If an increasing sequence is bounded above, then it converges.^a

^aThis also holds for a decreasing sequence, bounded below.

Proof. Let the sequence be $x_1, x_2, \dots$, and let $c = \sup\{x_1, x_2, \dots\}$. I claim that this sequence converges to c . Then there exists N such that $x_N > c - \epsilon$ (as otherwise $c - \epsilon$ would be an upper bound, which is a contradiction). So for all $n \geq N$, we have $c - \epsilon < x_n \leq x_N < c$, hence $|x_n - c| < \epsilon$. $\square$

To see how this can be used to prove that a series converges (or diverges) without finding the limit, consider the following two examples.

Proposition 5.2.27

- (i) $\sum_{n=1}^{\infty} \frac{1}{n}$ diverges.
- (ii) $\sum_{n=1}^{\infty} \frac{1}{n^2}$ converges.

Proof.

- (i) We have $1/3 + 1/4 \geq 1/2$, and $1/5 + 1/6 + 1/7 + 1/8 \geq 1/2$. In general,

$$\frac{1}{2^n + 1} + \frac{1}{2^n + 2} + \cdots + \frac{1}{2^{n+1} - 1} \geq \frac{2^n}{2^{n+1}} = \frac{1}{2}, \quad \forall n.$$

Hence the partial sum of $\sum_{n=1}^{\infty} \frac{1}{n}$ is unbounded, and thus the series is not convergent.

- (ii) We have $1/2^2 + 1/3^2 \leq 2/2^2 = 1/2$, and $1/4^2 + 1/5^2 + 1/6^2 + 1/7^2 \leq 4/4^2 = 1/4$, and in general,

$$\frac{1}{(2^n)^2} + \frac{1}{(2^n + 1)^2} + \cdots + \frac{1}{(2^{n+1} - 1)^2} \leq \frac{2^n}{(2^n)^2} = \frac{1}{2^n}, \quad \forall n.$$

Hence the partial sums of $\sum_{n=1}^{\infty} \frac{1}{n^2}$ are bounded by $1 + 1/2 + 1/4 + \cdots = 2$, and thus this series converges by the monotone convergence theorem.

□

The value of the second series (the value that it converges to) is $\pi^2/6$. Also, the first series is quite important, and it has its own name.

Definition 5.2.28 (Harmonic Series)

The series

$$1 + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \cdots$$

is the **harmonic series**.

The monotone convergence theorem also tells us something about decimal expansions. Let the decimal expansion

$$0.a_1a_2a_3\ldots$$

with $0 \leq a_n < 9$ for each n to be

$$\sum_{n=1}^{\infty} \frac{a_n}{10^n}$$

This must converge by the monotone convergence theorem, as all of the terms are at least zero and the partial sums are bounded by (for example 1). The converse of this is true, that given some $x \in \mathbb{R}$ with $0 < x < 1$, we can write it as $0.a_1a_2\ldots$ for $a_i \in \{0, \dots, 9\}$.

Begin by choosing the greatest $a_1 \in \{0, 1, \dots, 9\}$ such that $\frac{a_1}{10} \leq x$ thus $0 \leq x - \frac{a_1}{10} < \frac{1}{10}$. Then we can take the greatest $a_2 \in \{0, 1, \dots, 9\}$ such that $\frac{a_1}{10} + \frac{a_2}{100} \leq x$, so $0 \leq x - \frac{a_1}{10} - \frac{a_2}{100} < \frac{1}{100}$. We can continue this inductively to obtain $a_1, a_2, \dots \in \{0, 1, \dots, 9\}$ such that

$$0 \leq x - \sum_{n=1}^k \frac{a_n}{10^n} < \frac{1}{10^k},$$

for all k . Thus

$$\sum_{n=1}^{\infty} \frac{a_n}{10^n} = x.$$

Remark. We call a decimal expansion $0.a_1a_2\dots$ **recurrent** if there exists some $a_{n+k} = a_n$ for all $n \geq N$, for some N and k . For example, $0.3178426426426\dots$ is recurrent. It can be checked that a number has a recurrent decimal expansion if and only if that number is rational.

Remark (Uniqueness of Expansions). Decimal expansions need not be unique. For example, $0.370000\dots = 0.36999\dots$. However, this is the only case of non-uniqueness (where we have a ‘terminating’ decimal or a string of 9s).

Theorem 5.2.29 (e Exists)

We define

$$e = 1 + \frac{1}{1!} + \frac{1}{2!} + \dots = \sum_{n=0}^{\infty} \frac{1}{n!},$$

and we claim that it exists.

Proof. The sequence of partial sums converge as all terms are positive, and the partial sums are bounded by $1 + 1 + \frac{1}{2} + \frac{1}{4} + \dots = 3$, since $1/n! \leq \frac{1}{2^{n-1}}$ (which is true by induction). $\square$

We can also show that this number e is irrational.

Theorem 5.2.30 (Irrationality of e)

e is not rational.

Proof. Suppose that e was rational, then write $e = p/q$ where $p, q \in \mathbb{N}$, and also suppose that $q > 1$. So, multiplying by $q!$ we have

$$\sum_{n=0}^{\infty} \frac{q!}{n!} = p(q-1)!,$$

which is an integer. This works, as if $x_n \rightarrow c$, then $kx_n \rightarrow kc$ for $k \in \mathbb{R}$. So

$$p(q-1)! = \underbrace{q! + \frac{q!}{1!} + \frac{q!}{2!} + \dots + \frac{q!}{q!}}_{\in \mathbb{Z}} + \frac{q!}{(q+1)!} + \dots$$

But in general,

$$\frac{q!}{(q+n)!} \leq \frac{1}{(q+1)^n}.$$

so we can bound part of the series with

$$\sum_{n=q+1}^{\infty} \frac{q!}{(q+n)!} \leq \frac{1}{q+1} + \frac{1}{(q+1)^2} + \dots = \frac{1}{q} < 1,$$

and thus we have a contradiction, as it implies $p(q-1)!$ is not an integer. $\square$

§5.2.3 Algebraic Numbers

Now we know that numbers can be rational or irrational, but we can also divide up numbers based on if they are the root of some integer polynomial.

Definition 5.2.31 (Algebraic)

We say that a real number x is **algebraic** if it is a root of a (non-zero) polynomial with integer coefficients. A number that is not algebraic is **transcendental**.

When we talk about algebraic numbers, we typically care about *irrational* algebraic numbers, because of the following proposition.

Proposition 5.2.32

Every rational is algebraic.

Proof. The number p/q for $p, q \in \mathbb{Z}$ with $q \neq 0$ is a root of $qx - p = 0$. $\square$

Let's have a look at some irrational algebraic numbers.

Example 5.2.33

$\sqrt{2}$ is algebraic as it satisfies $x^2 - 2 = 0$.

A natural question to ask is whether there are any non-algebraic, that is, transcendental numbers. We are going to construct one.

Theorem 5.2.34 (Example of a Transcendental Number)

The following number c is transcendental^a.

$$c = \sum_{n=1}^{\infty} \frac{1}{10^{n!}} = 0.110001000000000000000000010000\dots$$

^aThis is going to be the hardest proof on the course.

To prove that this number is indeed transcendental, we are going to need recall some facts about polynomials.

Proposition 5.2.35 (Properties of Polynomials)

- (i) For any polynomial p , there exists a constant k such that $|p(x) - p(y)| \leq k|x - y|$ for all $0 \leq x, y \leq 1$.
- (ii) A non-zero polynomial of degree d has at most d roots.

Proof.

- (i) Say $p(x) = a_d x^d + \dots + a_0$. Then $p(x) - p(y) = a_d(x^d - y^d) + \dots + a_1(x - y) =$

$(x - y) [a_d(x^{d-1} + x^{d-2}y + \cdots + y^{d-1}) + \cdots + a_1]$. so $|p(x) - p(y)| \leq |x - y| (|a_d|d + |a_{d-1}|d + \cdots + |a_1|d)$, because $0 \leq x, y \leq 1$.

- (ii) Given a polynomial p of degree d , if p has no roots, then we are done. Otherwise, it has a root, say a , then $p(x) = (x - a)q(x)$ for some polynomial q of degree $d - 1$. So each root of p is either a or a root of q , but q has at most $d - 1$ roots by induction.

□

We are now ready to prove that our number c is transcendental. The idea of the proof is summarized in the image below

Proof of Theorem 5.2.34. Write $c_n = \sum_{k=0}^n \frac{1}{10^{k!}}$, so $c_n \rightarrow c$. Suppose the polynomial $p = a_dx^d + \cdots + a_0$ of degree d has c as a root. Then there exists k such that $|p(x) - p(y)| \leq k|x - y|$, for all $0 \leq x, y \leq 1$. Now

$$|c - c_n| = \sum_{k=1}^{\infty} \frac{1}{10^{k!}} \leq \frac{2}{10^{(n+1)!}}.$$

Also, $c_n = \frac{1}{10^{n!}}$ for some $a \in \mathbb{Z}$, so $p(c_n) = \frac{b}{10^{dn!}}$, for some $b \in \mathbb{Z}$ (since $p(\frac{s}{t}) = \frac{q}{t^d}$ for some integer q whenever $s, t \in \mathbb{Z}$). But, for n large enough, c_n is *not* a root of p (as it has finitely many roots). So $|p(c_n)| \geq \frac{1}{10^{dn!}}$.

This implies that $|p(c_n) - p(c)| \geq \frac{1}{10^{dn!}}$. Thus $\frac{1}{10^{dn!}} \leq k \frac{2}{10^{(n+1)!}}$, which is a contradiction for n sufficiently large. □

Remark. The same proof shows that any real x such that $\forall n$, there exists $\frac{p}{q} \in \mathbb{Q}$ with $0 < |x - \frac{p}{q}| < \frac{1}{q^n}$ is transcendental. Informally, ‘ x has very good rational approximations’. Such x are often called **Liouville numbers**, and this says that ‘every Liouville number’ is transcendental.

§5.3 Sets and Functions

In a sense, this is a chapter of notation. We really just get some terminology, notation and straightforward concepts and make sure we agree with them. It’s got some theorems, but there isn’t any amazing theorems or proofs that are really hard, and the theorems are going to be rather unsurprising.

However, the concepts will be important, as is the way of thinking that we will develop.

§5.3.1 Sets

Let's begin with a definition, that will have a few caveats.

Definition 5.3.1 (Set)

A **set** is any^a collection of (mathematical) objects.

^awe are going to change this later

Example 5.3.2

$\mathbb{R}$, $\mathbb{N}$, $\mathbb{Q}$ are all sets.

We say that two sets with the same members are the same (that is, a set is determined by its members). Symbolically, if A and B are sets, then if $\forall x, x \in A \iff x \in B$, then $A = B$. For example, the sets $\{1, 3, 7\}$ and $\{1, 7, 3\}$ equal, as are $\{3, 4, 4, 6\}$ and $\{3, 4, 6\}$.

So that's what a set is, but what's more important is how we can build sets. We are going to enter a series of sections which informally can be grouped as 'creating new sets from old sets'.

Subsets

When we have a set, we are able to choose certain elements of that set with some condition, to create another set.

Axiom 5.3.3 (Subset Selection)

Given a set A and a property $p(x)$, we can form $\{x \in A : p(x)\}$, the set of all members of A with property p .

Definition 5.3.4 (Subsets)

We say that B is a **subset** of A if $\forall x$ where $x \in B$ implies $x \in A$. This is written $B \subseteq A$.

Note that this implies that $A = B$ if and only if $A \subseteq B$ and $B \subseteq A$.

Unions and Intersections

We have two main ways of joining two sets.

Definition 5.3.5 (Union and Intersection)

Given sets A and B , we can form their **union** $A \cup B = \{x : x \in A \text{ or } x \in B\}$, and their **intersection** $A \cap B = \{x : x \in A \text{ and } x \in B\}$.

Definition 5.3.6 (Disjoint)

If the intersection of two sets A and B is the empty set, $A \cap B = \emptyset$, then we say that A and B are **disjoint**.

Note that union and intersection are commutative and associative. Also, union is distributive over intersection, that is, $A \cup (B \cap C) = (A \cup B) \cap (A \cup C)$, and $A \cap (B \cup C) = (A \cap B) \cup (A \cap C)$. This can be proven by checking definitions.

We can also take a bigger union.

Example 5.3.7 (Infinite Union)

If $A_n = \{n^2, n^3\}$ for each $n \in \mathbb{N}$, then $A_1 \cup A_2 \cup \dots$ is going to be the set of all squares or cubes. We can write this as

$$A_1 \cup A_2 \cup \dots = \bigcup_{n=1}^{\infty} A_n = \bigcup_{n \in \mathbb{Z}} A_n.$$

Of course, unlike our previous use of similar notation, this is not a limiting process but an *indexing process*.

In general, given a set I and sets A_i where $i \in I$, then we can form

$$\bigcup_{i \in I} A_i = \{x : x \in A_i \text{ for some } i \in I\},$$

and similarly,

$$\bigcap_{i \in I} A_i = \{x : x \in A_i \text{ } \forall i \in I\}.$$

However, this section set can only be defined for a *non-empty index set*, for reasons that we will see later.

Ordered Pairs

Definition 5.3.8 (Ordered Pair)

For any a, b , we can form the **ordered pair** (a, b) , such that $(a, b) = (c, d) \iff a = c \text{ and } b = d$.

Using the idea of an ordered pair, we can form the *product* of sets

Definition 5.3.9 (Cartesian Product)

For sets A and B , their **cartesian product** $A \times B = \{(a, b) : a \in A, b \in B\}$.

Remark. If we wished, we could define ordered pairs using sets, $(a, b) = \{\{a\}, \{a, b\}\}$, and then we can check that the equality case is the same.

Power Set

Definition 5.3.10

For any set X , we can form the **power set** $\mathcal{P}(X)$ consisting of all subsets of X .

$$\mathcal{P}(X) = \{Y : Y \subseteq X\}.$$

Example 5.3.11

If $X = \{1, 2\}$, then $\mathcal{P}(X) = \{\emptyset, \{1\}, \{2\}, \{1, 2\}\}$.

Defining Sets

For a set A , we can form $\{x \in A : p(x)\}$. However, we *cannot* form $\{x, p(x)\}$. Indeed, if we could, then consider the set

$$X = \{x : x \notin X\}.$$

So is $X \in X$? If yes, then $X \notin X$, but this is a contradiction. But if no, then $x \notin X$, but that would imply that it is in X ! So this doesn't make any sense. This is Russell's paradox.

Similarity, there is no 'universal' set Y , such that $\forall x, x \in Y$. This is because by subset selection, we could create the group $X = \{x : x \notin X\}$, which would be a contradiction.

Thus to guarantee that a given set exists, we must obtain it in some way (for example with the rules given above) from known sets.

§5.3.2 Finite Sets

Now let's have a look at the sizes of sets. We are going to write $\mathbb{N}_0 = \mathbb{N} \cup \{0\} = \{0, 1, \dots\}$.

Definition 5.3.12 (Size)

For $n \in \mathbb{N}_0$, a set A has **size** n if it can be written $A = \{a_1, a_2, \dots, a_n\}$ with the a_i all distinct.

Definition 5.3.13 (Finite)

We will say that a set A is **finite** if there exists some n such that the size of A is n . Otherwise, we say that the size of the set is **infinite**.

Proposition 5.3.14 (Counting Subsets)

A set of size n has exactly 2^n subsets.

Proof. Assume that our set is $\{1, \dots, n\}$. To specify a subset S , we must say if $1 \in S$, or $1 \notin S$, then if $2 \in S$ or if $2 \notin S$, and so on. So the number of independent choices needed to form S is $\underbrace{2 \times 2 \times \dots \times 2}_{n \text{ times}} = 2^n$.

Alternate Proof. We do induction on n . This is true for $n = 0$, and given some $n > 0$, for $T \subseteq \{1, 2, \dots, n-1\}$, then we can count how many $S \subseteq \{1, 2, \dots, n\}$ have $S \cap \{1, \dots, n-1\} = T$. There is exactly 2, namely T and $T \cup \{n\}$. Hence

the number of subsets of $\{1, \dots, n\}$ is twice the number of subsets of $\{1, \dots, n-1\}$. Then we are done by induction. $\square$

Remark. We could view the second proof as a ‘more formal version’ of the first proof.

As a bit of notation, if A has size n , then we write $|A| = n$. Using this notation, our counting subsets proposition says that

$$|A| = n \implies |\mathcal{P}(A)| = 2^n.$$

§5.3.3 Finite Sets and their Sizes

Given a set A , we are now going to think of how many subsets of A there is of size k .

Definition 5.3.15 (Binomial Coefficients)

For $n \in \mathbb{N}_0$ and $0 \leq k \leq n$, we write $\binom{n}{k}$ for the number of subsets of an n -element set that are of size k :

$$\binom{n}{k} = |\{S \subset \{1, 2, \dots, n\} : |S| = k\}|.$$

Example 5.3.16

The 2-element sets in a 4-element set, say $\{1, 2, 3, 4\}$ are $\{1, 2\}$, $\{1, 3\}$, $\{1, 4\}$, $\{2, 3\}$, $\{2, 4\}$, $\{3, 4\}$. So $\binom{4}{2} = 6$.

We will also write $\binom{n}{0} = 1$, $\binom{n}{n} = 1$, and note that $\binom{n}{1} = n$.

With this definition of binomial coefficients, we can deduce some nice properties.

Proposition 5.3.17 (Properties of Binomial Coefficients)

- (i) $\binom{n}{0} + \binom{n}{1} + \dots + \binom{n}{n} = 2^n$.
- (ii) $\binom{n}{k} = \binom{n}{n-k}$, for all $n \in \mathbb{N}_0$ with $0 \leq k \leq n$.
- (iii) $\binom{n}{k} = \binom{n-1}{k-1} + \binom{n-1}{k}$, for all $n \geq 1$, and $0 < k < n$.^a

^aThis property can be used to compute small binomial coefficients with ‘Pascal’s triangle’.

Proof. (i) Each side counts the number of subsets of $\{1, \dots, n\}$.

(ii) Picking a k element subset from an n element set, is the same as choosing $n - k$ elements to not pick.

(iii) The number of subsets of $\{1, 2, \dots, n\}$ with k elements is made up of the k -element subsets of $\{1, 2, \dots, n-1\}$ and also the $k-1$ -element subsets of $\{1, 2, \dots, n-1\}$, along with n .

$\square$

Sometimes we will have to compute binomial coefficients, and indeed there is a formula for binomial coefficients. However, what’s more important is where the formula comes from.

Proposition 5.3.18 (Binomial Coefficient Formula)

We have for integers n and k ,

$$\binom{n}{k} = \frac{n(n-1)(n-2)\cdots(n-k+1)}{k!}.$$

Proof. The number of ways to have a k -set is $n(n-1)\cdots(n-k+1)$, as there is n ways to name one element, $n-1$ ways to name a different element, and so on. This does grossly overcount though. The number of times a given k -set was named is $k(k-1)\cdots 1$. Hence the number of k -sets is

$$\frac{n(n-1)\cdots(n-k+1)}{k!}.$$

□

Example 5.3.19

We have

$$\binom{n}{2} = \frac{n(n+1)}{2}.$$

Remark. You could, if you wanted, write

$$\binom{n}{k} = \frac{n!}{k!(n-k)!},$$

but this is rather odd, as we have just multiplied my loads of terms that will cancel.

The formula we derived is also good for approximating the size of binomial coefficients. For example,

$$\binom{n}{3} = \frac{n(n-1)(n-2)}{6} \approx \frac{n^3}{6}$$

for large n .

An important application of binomial coefficients (and why we call them binomial coefficients) is the binomial theorem.

Theorem 5.3.20 (Binomial Theorem)

For a positive integer n ,

$$(a+b)^n = \binom{n}{0}a^n + \binom{n}{1}a^{n-1}b + \cdots + \binom{n}{n}b^n = \sum_{k=0}^n \binom{n}{k}a^k b^{n-k}.$$

Proof. When we expand $(a+b)^n = (a+b)(a+b)\cdots(a+b)$, we obtain terms of the form $a^k b^{n-k}$, where $0 \leq k \leq n$. The number of such terms $a^k b^{n-k}$ is the number of ways of choosing k brackets with an a , out of n . That is, the number of times the

term $a^k b^{n-k}$ occurs is $\binom{n}{k}$. So

$$(a+b)^n = \sum_{k=0}^n \binom{n}{k} a^k b^{n-k}.$$

□

Example 5.3.21

We can expand $(1+x)^n$ using the binomial theorem as

$$(1+x)^n = 1 + nx + \frac{n(n-1)}{2}x^2 + \cdots + nx^{n-1} + x^n,$$

so for small x , a good approximation for $(1+x)^n$ is $1+nx$. For example, $1.00001^8 \approx 1.0008$. A better approximation could be obtained by taking an extra term.

So this describes sizes of a single finite set, but what about the sizes of unions and intersections of finite sets? For example, how big is $|A \cup B|$?

We could try and write down $|A \cup B| = |A| + |B|$, but then we would count every element that's in both sets twice. That is, we have double counted $A \cap B$. So we really have

$$|A \cup B| = |A| + |B| - |A \cap B|.$$

For three sets, we could try and write down $|A \cup B \cup C| = |A| + |B| + |C|$, but then we have over counted many elements.

Specifically, we would have overcounted every element that's in A and B , every element in A and C , and every element in B and C . So we need to subtract and get $|A| + |B| + |C| - |A \cap B| - |A \cap C| - |B \cap C|$. But we have then undercounted elements in all 3 sets! We really have

$$|A \cup B \cup C| = |A| + |B| + |C| - |A \cap B| - |A \cap C| - |B \cap C| + |A \cap B \cap C|.$$

In general, we have the following theorem.

Theorem 5.3.22 (Inclusion-Exclusion Theorem)

Let $S_1, \dots, S_n$ be finite sets. Then

$$|S_1 \cup \dots \cup S_n| = \sum_{|A|=1} |S_A| - \sum_{|A|=2} |S_A| + \sum_{|A|=3} |S_A| - \dots + (-1)^{n+1} \sum_{|A|=n} |S_A|,$$

where S_A is $\bigcap_{i \in A} S_i$, and $\sum_{|A|=r}$ is taken over all $A \subset \{1, \dots, n\}$ of size r .

Proof. Let x be some element in one of the sets. We wish to show that it has been counted exactly once. Suppose that x is contained in exactly k of the sets. Then the number of A such that $|A| = r$ and $x \in S_A$ is $\binom{k}{r}$, as we must choose r of the sets of which x is an element. So the number of times x is counted on the right hand side is

$$k - \binom{k}{2} + \binom{k}{3} - \dots + (-1)^{k+1} \binom{k}{k},$$

for $r \leq k$. But $(1 + (-1))^k$ is exactly this by the binomial theorem, so the number of times x is counted is exactly $1 - (1 + (-1))^k = 1$. $\square$

§5.3.4 Functions

For some sets A and B , we would intuitively think of a function as some rule that each $a \in A$ is assigned to a point $f(a) \in B$. We can define this notion more precisely.

Definition 5.3.23 (Function)

A **function** from A to B is a set $f \subset A \times B$ such that for each $x \in A$ there exists a unique $y \in B$ with $(x, y) \in f$.

If $(x, y) \in f$, we write $f(x) = y$.

Example 5.3.24 (Examples of Functions)

$f : \mathbb{R} \rightarrow \mathbb{R}$ with $f(x) = x^2$ is a function.

$f : \mathbb{R} \rightarrow \mathbb{R}$ where $f(x) = 1$ if x is rational, and $f(x) = 0$ otherwise is a function.

The second example given is slightly subtle. Using the intuitive notion of a function, one might wonder whether the ‘rule’ of $f(x) = 1$ if x is rational and $f(x) = 0$ otherwise is valid. For example, we know that $f(2) = 1$ and $f(e) = 0$, but what about $f(e + \pi)$? Well the definition of a function tells us that we only need to make sure that this is a ‘well defined’ thing, and indeed as every real number is either rational or irrational, this is a valid function. Let’s state some not-so valid functions.

Example 5.3.25 (Non-Examples of Functions)

$f : \mathbb{R} \rightarrow \mathbb{R}$ with $f(x) = \frac{1}{x}$ is *not* a function because it doesn’t specify the value of $f(0)$.

$f : \mathbb{R} \rightarrow \mathbb{R}$ with $f(x) = \pm\sqrt{|x|}$ is *not* a function because it assigns multiple values to every value of $|x|$.

Let’s continue looking at examples of valid functions.

Example 5.3.26

The following are all functions.

- (i) Let $A = \{1, 2, 3, 4, 5\}$ and $B = \{1, 2, 4, 5\}$. Then $f : A \rightarrow B$ given by:

is a function.

- (ii) f from $\{1, 2, 3\}$ to $\{1, 2, 3\}$ with $1 \mapsto 1$, $2 \mapsto 3$, and $3 \mapsto 2$ is a function.

We frequently deal with functions that have certain interesting properties, which we will describe in the following definitions.

Definition 5.3.27 (Injectivity)

A function $f : A \rightarrow B$ is **injective** if for any $a, a' \in A$, then $a \neq a' \implies f(a) \neq f(a')$.

Definition 5.3.28 (Surjectivity)

A function $f : A \rightarrow B$ is **surjective** if for all $b \in B$, there exists $a \in A$ such that $f(a) = b$.

Definition 5.3.29 (Bijectivity)

A function $f : A \rightarrow B$ is **bijective** if it is injective and surjective.

We also name certain parts of a function.

Definition 5.3.30

For $f : A \rightarrow B$, we say A is the **domain**, and B is the **range**. We also say the **image** of f is the set $\{f(a) \mid a \in A\}$.

Also, when specifying a function, you must say what the domain and range are. For example, is the function $f(x) = x^2$ injective? The answer is that this is meaningless, as we haven't defined what the domain or range are. If $f : \mathbb{N} \rightarrow \mathbb{N}$, then it is injective, but it is not injective if $f : \mathbb{R} \rightarrow \mathbb{R}$.

When we are dealing with functions on finite sets, some obvious facts are true.

Proposition 5.3.31

For A and B finite, the following are true:

- (i) There is no surjection from $A \rightarrow B$ if $|B| > |A|$.

- (ii) There is no injection from $A \rightarrow B$ if $|A| > |B|$.
- (iii) For $f : A \rightarrow A$, if f is injective then f is also surjective (and vice versa).
- (iv) There is no bijection from A to any proper subset of A .

Proof Sketch. Check definitions. □

However, this *does not* hold when A and/or B is not finite. For example, consider the function $f_0 : \mathbb{N} \rightarrow \mathbb{N}$ with $f(x) = x+1$. Then f_0 is injective but not surjective. Similarly, define $f_0 : \mathbb{N} \rightarrow \mathbb{N}$, so that $f(1) = 1$ and $f(x) = x-1$ if $x > 1$. Then this function is surjective but not injective. Lastly, define $g : \mathbb{N} \rightarrow \mathbb{N} \setminus \{0\}$ with $x \mapsto x+1$. Then this is a bijection between a proper subset of $\mathbb{N}$ to $\mathbb{N}$.

Let's look at more functions!

Example 5.3.32

The following are functions.

- (i) For any set X , the **identity function** $1_X : X \rightarrow X$ such that $1_X(x) = x$ for all $x \in X$.
- (ii) For any set X and $A \subset X$ the **indicator function** or **characteristic function** $\chi_A : X \rightarrow \{0, 1\}$ with $\chi_A(x) = 1$ if $x \in A$ and 0 otherwise.

This function is important because it carries all of the information about what is in the set A .

- (iii) A sequence $x_1, x_2, \dots$ of reals is a function from $\mathbb{N} \rightarrow \mathbb{R}$ with $n \mapsto x_n$.
- (iv) The operation $+$ on $\mathbb{N}$ is a function from $\mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$.
- (v) A set X has size $|n|$ if there is a bijective function from $\{1, 2, \dots, n\} \rightarrow X$.

One thing that we regularly do with functions is *compose* them, that is, apply one after another.

Definition 5.3.33

Given $f : A \rightarrow B$ and $g : B \rightarrow C$, the **composition** $g \circ f : A \rightarrow C$ is defined by

$$(g \circ f)(a) = g(f(a)).$$

Example 5.3.34

If $f : \mathbb{R} \rightarrow \mathbb{R}$ is defined as $f(x) = 2x$, and $g : \mathbb{R} \rightarrow \mathbb{R}$ is defined as $g(x) = x+1$, then

$$(g \circ f)(x) = 2x + 1, \quad \text{and} \quad (f \circ g)(x) = 2x + 2.$$

In general (and in the example above), composition isn't commutative. However, composition is associative.

Composition is useful in talking about the idea of inverting functions.

Definition 5.3.35

We say a function $f : A \rightarrow B$ is **invertible** if there exists a function $g : B \rightarrow A$ such that $g \circ f = 1_A$ and $f \circ g = 1_B$.

Remark. It is not sufficient to show just that $g \circ f = 1_A$ or $f \circ g = 1_B$. Both must be checked.

Proposition 5.3.36

A function $f : A \rightarrow B$ is invertible if and only if it is bijective.

Proof. Let's say that g is inverse to f . Then for any $b \in B$, we have $f(g(b)) = b$, so f is surjective. Also, $f(a) = f(a')$ implies $g(f(a)) = g(f(a'))$, and $a = a'$, so f is injective and thus bijective.

Now let's suppose that f is bijective, and let $g(b)$ be the unique $a \in A$ with $f(a) = b$. Then g is the inverse of f . $\square$

§5.3.5 Equivalence Relations

The last item we will discuss in this chapter is equivalence relations. These appear throughout mathematics, and they induce phenomena that quite commonly appear when we define something.

First, we must define what a relation is.

Definition 5.3.37 (Relation)

A **relation** on a set X is a subset R of $X \times X$.

We normally write aRb for $(a, b) \in R$.

Example 5.3.38

The following are all relations.

- (i) On $\mathbb{N}$, aRb if $a \cong b \pmod{5}$. For example, $2R12$ but not $2R11$.
- (ii) On $\mathbb{N}$, aRb if $a \mid b$.
- (iii) On $\mathbb{N}$, aRb if $a = b \pm 1$.

Some properties a relation might satisfy are the following.

Definition 5.3.39 (Reflexive)

A relation R is **reflexive** if for all $x \in X$, xRx .

Definition 5.3.40 (Symmetric)

A relation R is **symmetric** if for all $x, y \in X$, then $xRy \implies yRx$.

Definition 5.3.41 (Transitive)

A relation R is **transitive** if for all $x, y, z \in X$, then xRy and yRz implies xRz .

When all of these properties are satisfied, we have an equivalence relation.

Definition 5.3.42 (Equivalence Relation)

An equivalence relation is a relation that is reflexive, symmetric and transitive.

To get a feel for what equivalence relations actually are, consider the following slightly natural yet slightly contrived example.

Example 5.3.43

Imagine we had a map of the world X , divided up into countries.

There are people in the world, and let's suppose each person is in just one country and there are no border disputes.

The relation 'is in the same country as' is an equivalence relation.

This relation is reflexive (you're in the same country as yourself), symmetric (if a is in the same country as b , then surely b is in the same country as a), and it's also transitive (if x and y are in the same country, and y and z are in the same country, then x and z are in the same country).

We can phrase this example in a more sensible way.

Example 5.3.44

Let X be a set, and let $\{C_i \mid i \in I\}$ be a **partition** of X , such that each C_i is non-empty, they are disjoint, and $\bigcup_{i \in I} C_i = X$.

Then aRb if there exists i such that $a, b \in C_i$ is an equivalence relation on X .

It actually turns out that all examples look like this! We will need a definition first.

Definition 5.3.45 (Equivalence Class)

For an equivalence relation R on a set X , and $x \in X$, the **equivalence class**, $[x]$, is the set $\{y \in X \mid yRx\}$. That is, the set of everything in X that is related to x .

Proposition 5.3.46 (Equivalence Classes Partition a Set)

Let R be an equivalence relation on a set X . Then the equivalence classes of R partition X .

Proof. Each equivalence class $[x]$ is non-empty (as $x \in [x]$), and $\cup_{x \in X} [x] = X$, as $x \in [x]$ for all $x \in X$. Thus it suffices to show that all equivalence classes are either disjoint or equal.

Given x, y with $[x] \cap [y] \neq \emptyset$. We wish to show $[x] = [y]$. Take $z \in [x] \cap [y]$. Then zRx and zRy so xRy . Thus $[x] = [y]$. $\square$

Definition 5.3.47 (Quotient and Quotient Map)

Given an equivalence relation R on a set X , the **quotient** of x by R is $X/R = \{[x] \mid x \in X\}$.

The map $q : X \rightarrow X/R$ is the **quotient map**, $x \mapsto [x]$. It is also known as the **projection map**.

§5.4 Countability

In this chapter we will discuss something we completely ignored in the previous discussion of sets – the sizes of infinite sets. Of course, we are going to have to introduce some ways of talking about the sizes of infinite sets...

Definition 5.4.1 (Countability)

We say that a set X is **countable** if X is finite or if there is a bijection with $\mathbb{N}$. Equivalently, X is countable if and only if we can list X as $a_1, a_2, \dots$ which might terminate.

§5.4.1 Countable Sets

Let's use this definition to look at some countable sets.

Example 5.4.2 (Trivially Countable Sets)

Any finite set is countable, and $\mathbb{N}$ is countable, by definition.

Example 5.4.3 ($\mathbb{Z}$ is Countable)

$\mathbb{Z}$ is countable, as we can list it as $0, 1, -1, 2, -2, \dots$.

It's sometimes easier to work with the following characterization of countability.

Proposition 5.4.4

A set X is countable if and only if there exists an injection $f : X \rightarrow \mathbb{N}$.

Proof. If X is finite or bijects with $\mathbb{N}$, then of course X injects in $\mathbb{N}$.

Now assume that X is not finite (if it was finite, then it's already countable), and has an injection $f : X \rightarrow \mathbb{N}$. Then we have a bijection from X with its image $f(X) = \{f(x) \mid x \in X\}$.

Set a_1 to be $\min f(X)$, a_2 to be $\min f(X) \setminus \{a_1\}$, and so on. Then $f(X) = \{a_1, a_2, \dots\}$ – each $a \in X$ is a_n for some n , because $a = a_n$ for some $n \leq a$. So $f(x)$ is countable. $\square$

Remark (A Warning). In $\mathbb{R}$, let $X = \{\frac{1}{2}, \frac{2}{3}, \frac{3}{4}, \dots\} \cup \{1\}$. Then X is countable, as we can list it as $1, 1/2, 2/3, \dots$. But if we counted by ‘least element’, 1 would not be on the list. So the counting method used in the proof above does not always work.

Let's look at some more countable sets.

Theorem 5.4.5

$\mathbb{N} \times \mathbb{N}$ is countable.

Proof. Define $a_1 = (1, 1)$, and inductively letting $a_{n-1} = (p, q)$,

$$a_n = \begin{cases} (p-1, q+1) & \text{if } p \neq 1, \\ (1, p+1) & \text{if } p = 1. \end{cases}$$

Then a_n hits every point $(x, y) \in \mathbb{N} \times \mathbb{N}$, by induction on $x + y$, so we have listed $\mathbb{N} \times \mathbb{N}$, and thus it is countable. $\square$

Alternate Proof. We will look for an injection $f : \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$. Indeed, $f(x, y) = 2^x 3^y$ works, and thus $\mathbb{N} \times \mathbb{N}$ is countable. $\square$

The same proof shows the following theorem.

Theorem 5.4.6

Let $A_1, A_2, \dots$ be countable sets. Then $A_1 \cup A_2 \cup \dots$ is countable.

Proof. For each i , we have A_i countable, so we can list A_i as $a_{i,1}, a_{i,2}, \dots$, which might terminate. Then define $f : \bigcup_{n \in \mathbb{N}} A_n \rightarrow \mathbb{N}$, so that $x \rightarrow 2^i 3^j$, where $x = a_{ij}$ for the least such i . This is an injection. $\square$

This is a quite powerful way of showing that sets are countable, as we shall see.

Example 5.4.7

$\mathbb{Q}$ is countable, as $\mathbb{Q} = \mathbb{Z} \cup \frac{1}{2}\mathbb{Z} \cup \frac{1}{3}\mathbb{Z} \cup \dots$, where $\frac{1}{k}\mathbb{Z} = \{\frac{x}{k} \mid x \in \mathbb{Z}\}$. So $\mathbb{Q}$ is countable.

Example 5.4.8

The set $\mathbb{A}$ of all algebraic numbers is countable.

Indeed, it's enough to show that the set of all integer polynomials is countable, as each has finitely many roots, so $\mathbb{A}$ would be a countable union of finite sets.

So, to show that the collection of integer polynomials is countable, it's enough to

show that for each d , the set of all integer polynomials of degree d is countable. But this set injects into $\mathbb{Z}^{d+1}$ with its coefficients, and $\mathbb{Z}^n$ is countable for any n , by our previous theorem.

§5.4.2 Uncountable Sets

All of the examples we have given so far have been countable sets, but don't start thinking that all sets are countable!

Definition 5.4.9 (Uncountability)

A set X is **uncountable** if it is not countable.

Theorem 5.4.10

$\mathbb{R}$ is uncountable.

Proof. It suffices to show that $(0, 1)$ is uncountable. Given a sequence $r_1, r_2, \dots$ in $(0, 1)$, we wish to find some $s \in (0, 1)$ that's not in this list.

For each r_n , we have a decimal expansion $r_n = 0.r_{n,1}r_{n,2}\dots$. Define $s = 0.s_1s_2\dots$ by

$$s_i = \begin{cases} 5 & \text{if } r_{i,i} \neq 5, \\ 6 & \text{if } r_{i,i} = 5. \end{cases}$$

Then s cannot be on our list (as $s \neq r_n$ as they differ at decimal digit n). $\square$

The proof is known as a **diagonal argument**, or **cantor's diagonal argument**.

Interestingly, now that we know $\mathbb{R}$ is uncountable, but $\mathbb{A}$ is countable, there must be a transcendental number! Indeed, 'most' numbers are transcendental, in that $\mathbb{R} \setminus \mathbb{A}$ is uncountable.

Let's look at another uncountable set, which we will show is uncountable using a diagonal argument.

Theorem 5.4.11

The power set of $\mathbb{N}$, $\mathcal{P}(\mathbb{N})$ is uncountable.

Proof. Suppose $\mathcal{P}(\mathbb{N})$ is listed as $S_1, S_2, \dots$. We wish to find some $S \subset \mathbb{N}$ that's not on this list. For every $i \in \mathbb{N}$, we take $i \in S$ iff $i \notin S_i$. Then S cannot be on this list, since $S \neq S_n$ for all n , as they differ at element n . Hence $\mathcal{P}(\mathbb{N})$ is uncountable. $\square$

In fact, our result about the power set of $\mathbb{N}$ shows the following theorem.

Theorem 5.4.12

For any set X , there is no bijection from X to $\mathcal{P}(X)$.

Proof. Given any function $f : X \rightarrow \mathcal{P}(X)$, we will show f is not surjective.

Let $S = \{x \in X \mid x \notin f(x)\}$. Then S does not belong to the image of f , since for every x , $S \neq f(x)$, as S and $f(x)$ differ at element x . $\square$

Remark. This proof is vaguely reminiscent of Russell's paradox. In fact, this theorem proves that there is no universal set, just as Russell's paradox did. This is because otherwise, we would have $\mathcal{P}(V) \subset V$, where certain that V would surject to $\mathcal{P}(V)$.

Now we're going to look at an example of how we can think about countability.

Example 5.4.13

Let A_i , $i \in I$ be a family of open intervals that are pairwise disjoint. Must the family be countable?

The answer is yes. Each A_i contains a rational, and $\mathbb{Q}$ is countable. So this family is countable.

Another proof is that we can note the set $\{i \in I \mid A_i \text{ has length } \geq \frac{1}{k}\}$ is countable (it injects into $\mathbb{Z}$). So the family be countable.

In general, to show a set X is uncountable, we had two approaches.

1. Run the diagonal argument on X .
2. Inject your favorite uncountable set into X .

To show a set X is countable, we could do something like

1. List it (which can be ugly)
2. Inject it into $\mathbb{N}$
3. Use 'countable union of countable sets is countable'. This is usually the best one.
4. If in or near $\mathbb{R}$, sometimes using the countability of $\mathbb{Q}$ helps.

§5.4.3 Bijections

Intuitively, we can think of ' A bijects with B ' as saying that A and B are the same size. Similarly, we can think of ' A injects into B ' as sort of saying that A is at most as large as B . Similarly we can think of ' A surjects to B ' as saying A is at least as large as B .

For these to make sense, we want for A and B nonempty that there exists an injection $f : A \rightarrow B$ if and only if there exists a surjection $g : B \rightarrow A$.

This is easy to show. Fix some $a_0 \in A$, and define $g : B \rightarrow A$ so that b maps to the unique $a \in A$ with $f(a) = b$, and a_0 if that does not exist. Also, if g is surjective, then for each $a \in A$ we have $a' \in B$ with $g(a') = a$. Then let $f(a) = a'$. Then f is injective.

Theorem 5.4.14 (Schröder-Bernstein Theorem)

If $f : A \rightarrow B$ and $g : B \rightarrow A$ are injections, then there exists a bijection $h : A \rightarrow B$.

Proof. For $a \in A$, we write $g^{-1}(a)$ for the $b \in B$ such that $g(b) = a$, if it exists. We write $f^{-1}(b)$ for $b \in B$ similarly.

The *ancestor sequence* of $a \in A$ is $g^{-1}(a), f^{-1}(g^{-1}(a)), \dots$, which may terminate.

Let A_0 be the set of $a \in A$ such that the ancestor sequence stops in A , and A_1 the set of $a \in A$ such that the sequence stops in B . Lastly define A_∞ for the $a \in A$ whose ancestor sequence does not stop. Define B_0, B_1 and B_∞ similarly.

Then f bijects A_0 with B_1 (noting that every $b \in B_1$ is $f(a)$ for some $a \in A_0$). Similarly g bijects A_1 with B_0 . Finally, f or g bijects A_∞ with B_∞ .

Thus the function $h : A \rightarrow B$ with

$$h(a) = \begin{cases} f(a) & \text{if } a \in A_0, \\ g^{-1}(a) & \text{if } a \in A_1, \\ f(a) & \text{if } a \in A_\infty \end{cases}$$

is a bijection. □

Example 5.4.15

Do $[0, 1]$ and $[0, 1] \cup [2, 3]$ biject?

By Schröder-Bernstein this is trivial. Consider the identity function $f : [0, 1] \rightarrow [0, 1] \cup [2, 3]$, and the function $g : [0, 1] \cup [2, 3] \rightarrow [0, 1]$ with $g(x) = x/3$ are both injections, so there is a bijection between these sets.

In the same vein, a nice result to have would be ‘for any sets A and B , either A injects into B or B injects into A ’. This is true, but is not proved in this course.

§5.4.4 Sizes of Sets

Going back to the sizes of sets, we have seen that we can have finite sets, countable sets and uncountable sets. We also know that in the realm of uncountable sets, taking power sets makes you bigger. So the sequence $\mathbb{N}, \mathcal{P}(\mathbb{N}), \mathcal{P}(\mathcal{P}(\mathbb{N})), \dots$ may make us wonder does every set X inject into one of these?

This is not true. For example, take the set $X = \mathbb{N} \cup \mathcal{P}(\mathbb{N}) \cup \mathcal{P}(\mathcal{P}(\mathbb{N})) \cup \dots$. This isn’t the biggest set either, as we can take $X' = X \cup \mathcal{P}(X) \cup \dots$. And this isn’t biggest either, as we could just do the same thing all over again, and again, and again.

6 Probability

Probability is the art of reasoning precisely about uncertainty. Starting from a small collection of axioms, we will build up a theory that lets us make (often surprisingly strong) quantitative statements about randomness – from coin tosses and card shuffles all the way up to random walks, branching processes and the celebrated central limit theorem. One of the joys of the subject is how far a few simple ideas (independence, expectation, indicators, generating functions) can be pushed, and we will try to emphasise these recurring techniques throughout.

This article constitutes my notes for the ‘Probability’ course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§6.1 Setting Up Probability

We are going to build up probability from the very basic axioms. This will give us a firm mathematical basis to work from, but also will match the intuitive notions of probability that you have hopefully developed before reading this handout.

§6.1.1 Probability Spaces

The basic object of study in probability theory is that of *probability spaces*. We begin by defining how we can talk about the idea of ‘events’ formally. What we want from our definition will be some way to have a set of possible ‘outcomes’ (a *sample space*), from which we can combine different outcomes to form various ‘events’. This leads almost directly to the definition of an *event space*.

Definition 6.1.1 (Event Space)

The collection $\mathcal{F}$ of subsets of the sample space Ω is an **event space** or **σ -algebra** if

1. $\mathcal{F}$ is non-empty,
2. if $A \in \mathcal{F}$, then $\Omega \setminus A \in \mathcal{F}$,
3. if $A_1, A_2, \dots \in \mathcal{F}$, then $\bigcup_{i=1}^{\infty} A_i \in \mathcal{F}$.

Within this system, $A \cup B$ corresponds to either A or B occurring, $A \cap B$ corresponds to both A and B occurring, and $\Omega \setminus A$ corresponds with anything but A occurring. You get the idea.

Our main goal in the study of probability is to assign some sort of ‘likelihood’ to events in the event space. This is done through the introduction of a *probability measure*.

Definition 6.1.2 (Probability Measure)

We say that a function $\mathbb{P} : \mathcal{F} \rightarrow \mathbb{R}$ is a **probability measure** on $(\Omega, \mathcal{F})$ if

1. $\mathbb{P}(A) \geq 0$ for all $A \in \mathcal{F}$,
2. $\mathbb{P}(\Omega) = 1$,
3. if $A_1, A_2, \dots$ are disjoint events in $\mathcal{F}$, then $\mathbb{P}(\bigcup_{i=1}^{\infty} A_i) = \sum_{i=1}^{\infty} \mathbb{P}(A_i)$.

These properties of the probability measure should match your own intuition about the way that probability works. Putting all the pieces together, we get our main object of study: the *probability space*.

Definition 6.1.3 (Probability Space)

A **probability space** is a triple $(\Omega, \mathcal{F}, \mathbb{P})$ such that Ω is non empty, $\mathcal{F}$ is an event space on Ω , and $\mathbb{P}$ is a probability measure on $(\Omega, \mathcal{F})$.

If we only have to deal with say finite (or even countable) Ω , then it makes sense to usually take $\mathcal{F}$ to just be the power set of Ω . In this case, if $\Omega = \{\omega_1, \omega_2, \dots\}$, then we can construct any probability measure $\mathbb{P}$ by just specifying $\mathbb{P}(\{\omega_i\})$ for all i , as then for $A \in \mathcal{F}$, we can get $\mathbb{P}(A) = \sum_{\omega \in A} \mathbb{P}(\{\omega\})$.

Before going any further, we should note some basic properties of probability measures, all of which follow pretty quickly from the definition.

Proposition 6.1.4 (Properties of Probability Measures)

Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space, and let $A, B \in \mathcal{F}$. Then

- (i) $\mathbb{P}(\Omega \setminus A) = 1 - \mathbb{P}(A)$,
- (ii) $\mathbb{P}(\emptyset) = 0$,
- (iii) if $A \subseteq B$ then $\mathbb{P}(A) \leq \mathbb{P}(B)$,
- (iv) $\mathbb{P}(A \cup B) = \mathbb{P}(A) + \mathbb{P}(B) - \mathbb{P}(A \cap B)$.

Proof. For (i), the events A and $\Omega \setminus A$ are disjoint with union Ω , so $\mathbb{P}(A) + \mathbb{P}(\Omega \setminus A) = \mathbb{P}(\Omega) = 1$. Then (ii) follows by taking $A = \Omega$. For (iii), we can write B as the disjoint union $B = A \cup (B \setminus A)$, so $\mathbb{P}(B) = \mathbb{P}(A) + \mathbb{P}(B \setminus A) \geq \mathbb{P}(A)$. Finally for (iv), we write $A \cup B$ as the disjoint union $A \cup (B \setminus (A \cap B))$, giving

$$\mathbb{P}(A \cup B) = \mathbb{P}(A) + \mathbb{P}(B \setminus (A \cap B)) = \mathbb{P}(A) + \mathbb{P}(B) - \mathbb{P}(A \cap B),$$

where the last step uses that $A \cap B \subseteq B$. □

§6.1.2 Classical Probability and Counting

The setting in which probability historically began (think gambling problems in the 17th century) is what's now called *classical probability*: a finite sample space in which every outcome is equally likely. That is, we take $\Omega = \{\omega_1, \dots, \omega_n\}$ and

$$\mathbb{P}(A) = \frac{|A|}{|\Omega|} \quad \text{for } A \subseteq \Omega.$$

Computing probabilities in this setting amounts to *counting*, so it is worth pausing to build up a small toolbox of combinatorial facts. We will state them briefly, since they

should be mostly familiar.

Fact 6.1.5 (Counting Toolbox)

Let Ω be a set of n elements. Then

- (i) the number of orderings (permutations) of Ω is $n! = n(n-1) \cdots 1$,
- (ii) the number of subsets of Ω of size k is $\binom{n}{k} = \frac{n!}{k!(n-k)!}$,
- (iii) the number of ways to partition Ω into k disjoint subsets $\Omega_1, \dots, \Omega_k$ with $|\Omega_i| = n_i$ and $n_1 + \cdots + n_k = n$ is the **multinomial coefficient**

$$\binom{n}{n_1, n_2, \dots, n_k} = \binom{n}{n_1} \binom{n-n_1}{n_2} \cdots \binom{n-n_1-\cdots-n_{k-1}}{n_k} = \frac{n!}{n_1! n_2! \cdots n_k!}.$$

Armed with these, let's do some classical probability. The following examples are, well, classics.

Example 6.1.6 (Aces on Top)

A standard deck of 52 cards is shuffled so that all $52!$ orderings are equally likely. What is the probability that the top two cards are both aces?

We take Ω to be the set of all $52!$ orderings. The number of orderings with aces in the top two positions is $4 \times 3 \times 50!$ (choose which aces go first and second, then order the rest freely). So the probability is

$$\frac{4 \cdot 3 \cdot 50!}{52!} = \frac{4 \cdot 3}{52 \cdot 51} = \frac{1}{221}.$$

Example 6.1.7 (The Birthday Problem)

There are n people in a room. What is the probability that at least two of them share a birthday^a?

Take $\Omega = \{1, \dots, 365\}^n$, with all outcomes equally likely. Let A be the event that at least two birthdays coincide. It's much easier to count the complement, the event that all n birthdays are distinct. There are $365 \cdot 364 \cdots (365 - n + 1)$ such outcomes, so

$$\mathbb{P}(A) = 1 - \frac{365 \cdot 364 \cdots (365 - n + 1)}{365^n}.$$

Plugging in numbers gives a somewhat surprising result: with $n = 22$ we get $\mathbb{P}(A) \approx 0.476$, and with $n = 23$ we get $\mathbb{P}(A) \approx 0.507$. So in a room of just 23 people, it's more likely than not that two people share a birthday.

^aWe'll assume that there's 365 days in a year, that no one is born on the 29th of February, and that all birthdays are equally likely.

The trick of 'counting the complement' used above is worth remembering – it is frequently much easier to count the outcomes avoiding some property than those with it.

Since factorials appear all over the place in these calculations, it is quite helpful to know how fast $n!$ actually grows. The definitive answer is given by *Stirling's formula*. We write $a_n \sim b_n$ to mean $a_n/b_n \rightarrow 1$ as $n \rightarrow \infty$.

Theorem 6.1.8 (Stirling's Formula)

As $n \rightarrow \infty$, we have

$$n! \sim n^n e^{-n} \sqrt{2\pi n}.$$

We will prove the following weaker statement, which is enough for many applications (it pins down $\log n!$ to first order, but not the constant $\sqrt{2\pi}$).

Proposition 6.1.9 (Weak Stirling)

As $n \rightarrow \infty$, $\log n! \sim n \log n$.

Proof. Let $l_n = \log n! = \log 2 + \log 3 + \cdots + \log n$. Since $\log$ is increasing, for any integer k we have $\log k \leq \log x \leq \log(k+1)$ for $x \in [k, k+1]$, and integrating over such intervals gives

$$\sum_{k=1}^{n-1} \log k \leq \int_1^n \log x \, dx \leq \sum_{k=2}^n \log k,$$

that is, $l_{n-1} \leq n \log n - n + 1 \leq l_n$. Using both bounds, for all n we get

$$n \log n - n + 1 \leq l_n \leq (n+1) \log(n+1) - n,$$

and dividing through by $n \log n$ and letting $n \rightarrow \infty$ gives $l_n/(n \log n) \rightarrow 1$, as required. $\square$

The proof of the full result is a little involved (the constant $\sqrt{2\pi}$ is usually extracted from the asymptotics of the central binomial coefficient $\binom{2n}{n}$, using Wallis' product), and we will not give it here. A fact worth keeping from that analysis is

$$2^{-2n} \binom{2n}{n} \sim \frac{1}{\sqrt{\pi n}},$$

which says that the probability of getting exactly n heads in $2n$ tosses of a fair coin decays like $1/\sqrt{\pi n}$ – slowly!

§6.1.3 Conditional Probability and Independence

In our day-to-day experience, we know that knowledge about one event can influence how likely we determine another event is to occur. This type of thinking motivates the introduction of *conditional probability*.

Definition 6.1.10 (Conditional Probability)

If $A, B \in \mathcal{F}$ and $\mathbb{P}(B) > 0$, the **probability of A given B** is denoted $\mathbb{P}(A \mid B)$, and is given by

$$\mathbb{P}(A \mid B) = \frac{\mathbb{P}(A \cap B)}{\mathbb{P}(B)}.$$

It's not hard to check that $\mathbb{P}(\cdot \mid B)$ is a probability measure, as we would expect – it's just assigning probabilities to events in $\mathcal{F}$ in a different way!

A natural thing to care about is if knowledge about an event *doesn't* influence how likely another event is. We call such events independent.

Definition 6.1.11 (Independent Events)

We say that events A, B in a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ are **independent** if

$$\mathbb{P}(A \cap B) = \mathbb{P}(A)\mathbb{P}(B),$$

and **dependent** otherwise.

We can see immediately that A, B independent implies that

$$\mathbb{P}(A \mid B) = \mathbb{P}(A) \quad \text{and} \quad \mathbb{P}(B \mid A) = \mathbb{P}(B),$$

if $\mathbb{P}(A), \mathbb{P}(B) \neq 0$. However, this definition is slightly more general than this property since it handles events with zero probability. We can generalise this notion of independence to multiple events, and we get a criterion that's stronger than pairwise independence¹.

Definition 6.1.12 (Mutually Independent Events)

We say that the events $A_1, A_2, A_3, \dots$ are **mutually independent** if

$$\mathbb{P}(A_{i_1} \cap A_{i_2} \cap \dots \cap A_{i_r}) = \mathbb{P}(A_{i_1})\mathbb{P}(A_{i_2}) \cdots \mathbb{P}(A_{i_r}),$$

for any $i_1, i_2, \dots, i_r$ and $r \geq 2$.

So if conditional probability tells us about the likelihood of a certain event in one particular scenario, then it's easy to imagine that knowing about the likelihood in every scenario would then just give you the likelihood in general. Such thinking is formalised in the *law of total probability*, also known as the *partition theorem*.

Theorem 6.1.13 (Partition Theorem)

Let $\{B_1, B_2, \dots\}$ be a collection of disjoint events such that $\mathbb{P}(B_i) > 0$ for all i and $\bigcup_{i=1}^{\infty} B_i = \Omega$. Then

$$\mathbb{P}(A) = \sum_i \mathbb{P}(A \mid B_i)\mathbb{P}(B_i),$$

for any $A \in \mathcal{F}$.

Proof. We can compute that

$$\sum_i \mathbb{P}(A \mid B_i)\mathbb{P}(B_i) = \sum_i \mathbb{P}(A \cap B_i) = \mathbb{P}\left(\bigcup_i (A \cap B_i)\right) = \mathbb{P}(A),$$

as required. □

Using the partition theorem, we can establish the famous **Bayes' theorem**, which allows us to use knowledge about $\mathbb{P}(A \mid B_j)$ to give information about $\mathbb{P}(B_j \mid A)$:

$$\mathbb{P}(B_j \mid A) = \frac{\mathbb{P}(A \mid B_j)\mathbb{P}(B_j)}{\mathbb{P}(A)} = \frac{\mathbb{P}(A \mid B_j)\mathbb{P}(B_j)}{\sum_i \mathbb{P}(A \mid B_i)\mathbb{P}(B_i)}.$$

¹It's not hard to construct an example of events that are pairwise independent but wouldn't be independent in any reasonable sense.

Bayes' theorem is the basis of essentially all of Bayesian statistics – it lets us 'reverse the direction' of conditioning, updating our beliefs about which scenario B_j we are in, given that we observed A . It also has a habit of producing answers that clash violently with intuition, as the next example shows.

Example 6.1.14 (False Positives)

Suppose that 0.1% of the population suffer from a certain rare condition, and that we have a test for the condition which is positive for 98% of sufferers, but also (falsely) positive for 1% of non-sufferers. A person is chosen at random and tests positive. What is the probability that they actually have the condition?

Let A be the event that the person has the condition, and P the event that they test positive. The situation is summarised by the following tree, with the two stages of conditioning shown left to right.

Then by Bayes' theorem,

$$\begin{aligned}\mathbb{P}(A | P) &= \frac{\mathbb{P}(P | A)\mathbb{P}(A)}{\mathbb{P}(P | A)\mathbb{P}(A) + \mathbb{P}(P | A^c)\mathbb{P}(A^c)} \\ &= \frac{0.98 \times 0.001}{0.98 \times 0.001 + 0.01 \times 0.999} \approx 0.09.\end{aligned}$$

So despite the test looking quite accurate, a positive result only means a 9% chance of having the condition! The point is that the false positive rate (1%) utterly dwarfs the prevalence of the condition (0.1%): in a population of 1000 people, we expect about 1 true positive but about 10 false positives, so only about 1 in 11 positive tests is genuine.

Another recurring subtlety is that the answer to a conditional probability question depends delicately on *exactly* what information you condition on.

Example 6.1.15 (Two Children)

I have two children. Consider the following three statements:

- (a) at least one of them is a boy;
- (b) the eldest is a boy;
- (c) at least one of them is a boy born on a Thursday.

Given each statement in turn, what is the probability that I have two boys? (Assume boys and girls, and days of the week, are equally likely and independent.)

Writing the sexes in age order, the equally likely possibilities are BB, BG, GB, GG .

Given (a), we condition on $\{BB, BG, GB\}$, so

$$\mathbb{P}(BB \mid BB \cup BG \cup GB) = \frac{1/4}{3/4} = \frac{1}{3}.$$

Given (b), we condition on $\{BB, BG\}$, and the answer is $\frac{1}{2}$ – so (a) and (b) genuinely differ, even though both ‘tell you there’s a boy’.

For (c), splitting each boy into ‘born on Thursday’ (T , probability $\frac{1}{14}$ per child) or ‘boy not born on Thursday’ (N , probability $\frac{6}{14}$), a short computation with the equally likely fine-grained outcomes gives

$$\mathbb{P}(\text{two boys} \mid \text{at least one } T) = \frac{\frac{1}{14} \cdot \frac{1}{14} + 2 \cdot \frac{1}{14} \cdot \frac{6}{14}}{\frac{1}{14} \cdot \frac{1}{14} + 2 \cdot \frac{1}{14} \cdot \frac{6}{14} + 2 \cdot \frac{1}{14} \cdot \frac{7}{14}} = \frac{13}{27} \approx 0.48.$$

Astonishingly, the (apparently irrelevant!) day of birth moves the answer from $\frac{1}{3}$ towards $\frac{1}{2}$. Intuitively, ‘a boy born on a Thursday’ is more likely to be reportable in a two-boy family, since there are two chances for it to occur.

Conditioning can be genuinely subtle, and it’s worth seeing one famous trap: aggregating data across dissimilar populations can *reverse* the direction of an inequality between conditional probabilities.

Example 6.1.16 (Simpson’s Paradox)

A university admits students from two types of school, and it’s observed that applicants from state schools are admitted at a higher rate than applicants from independent schools *both* among men and among women – yet when the data is aggregated, independent school applicants are admitted at a higher rate overall.

This can genuinely happen with real numbers, and there is no contradiction. Writing A for admission, C for coming from a state school and B for being a man, the ‘paradoxical’ data amounts to

$$\mathbb{P}(A \mid B \cap C) > \mathbb{P}(A \mid B \cap C^c), \quad \mathbb{P}(A \mid B^c \cap C) > \mathbb{P}(A \mid B^c \cap C^c),$$

but $\mathbb{P}(A \mid C) < \mathbb{P}(A \mid C^c)$. If we try to ‘average’ the first two inequalities using the partition theorem, we find

$$\mathbb{P}(A \mid C) = \mathbb{P}(A \mid B \cap C)\mathbb{P}(B \mid C) + \mathbb{P}(A \mid B^c \cap C)\mathbb{P}(B^c \mid C),$$

and similarly for C^c – but the weights $\mathbb{P}(B \mid C)$ and $\mathbb{P}(B \mid C^c)$ need not be equal! It is only when the populations are mixed in the same proportions ($\mathbb{P}(B \mid C) = \mathbb{P}(B \mid C^c)$) that the intuitive conclusion $\mathbb{P}(A \mid C) > \mathbb{P}(A \mid C^c)$ actually follows. The moral: be very careful about pooling conditional probabilities.

§6.1.4 Continuity of Probability Measures

In the definitions for event spaces (σ -algebras) and probability measures, you may notice that we specify rules for countably infinite sequences of events. This is for good reason – there’s plenty of natural scenarios where such a setup is useful. For example, consider the experiment of tossing a coin until you get heads, in which it is possible to get an arbitrarily long run of tails before you stop tossing. To make working with such scenarios

easier, we can establish a result which allows us study events as limits of a sequence of events – that the probability measure is continuous.

Definition 6.1.17 (Limits of Events)

We say that a sequence of events $A_1, A_2, \dots$ is *increasing* if $A_1 \subseteq A_2 \subseteq \dots$. We define the **limit** as

$$\lim_{n \rightarrow \infty} A_n = \bigcup_{n=1}^{\infty} A_n.$$

Theorem 6.1.18 (Continuity of Probability Measures)

Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space. If $A_1, A_2, \dots$ is an increasing sequence of events in $\mathcal{F}$ with limit A , then $\mathbb{P}(A) = \lim_{n \rightarrow \infty} \mathbb{P}(A_n)$.

Proof. Define $B_i = A_i \setminus A_{i-1}$, with $B_1 = A_1$. Then we have

$$A = B_1 \cup B_2 \cup B_3 \cup \dots$$

which is the union of disjoint events in $\mathcal{F}$. Thus we have

$$\begin{aligned} \mathbb{P}(A) &= \mathbb{P}\left(\bigcup_{n=1}^{\infty} A_n\right) = \mathbb{P}\left(\bigcup_{n=1}^{\infty} B_n\right) \\ &= \lim_{n \rightarrow \infty} \sum_{i=1}^n \mathbb{P}(B_i) = \lim_{n \rightarrow \infty} \mathbb{P}(B_1 \cup \dots \cup B_n) \\ &= \lim_{n \rightarrow \infty} \mathbb{P}(A_n), \end{aligned}$$

as required. □

As a side note, the type of construction used to define B_i can be quite helpful when we want to deal with a disjoint union, rather than some non-disjoint sequence of events (since it works nicely with the definition of the probability space!)

Another rather intuitive notion is that of probabilities being ‘subadditive’ when events are *not* disjoint, which we can see in the following result.

Theorem 6.1.19 (Boole’s Inequality – The Union Bound)

For any sequence of events $A_1, A_2, \dots$ we have

$$\mathbb{P}\left(\bigcup_{i=1}^{\infty} A_i\right) \leq \sum_{i=1}^{\infty} \mathbb{P}(A_i).$$

Proof. We use a similar construction to the previous proof. Let $B_1 = A_1$, and define $B_i = A_i \setminus \bigcup_{k=1}^{i-1} A_k$. Then we have

$$\mathbb{P}\left(\bigcup_{i=1}^{\infty} A_i\right) = \mathbb{P}\left(\bigcup_{i=1}^{\infty} B_i\right) = \sum_{i=1}^{\infty} \mathbb{P}(B_i) \leq \sum_{i=1}^{\infty} \mathbb{P}(A_i),$$

where the inequality occurs since $B_i \subseteq A_i$ implies $\mathbb{P}(B_i) \leq \mathbb{P}(A_i)$. $\square$

§6.1.5 Inclusion-Exclusion

We saw earlier that $\mathbb{P}(A \cup B) = \mathbb{P}(A) + \mathbb{P}(B) - \mathbb{P}(A \cap B)$: if we just add up the two probabilities, we've double counted the overlap, so we subtract it off once. If we try the same thing with three events, adding up the pairwise corrections over-corrects for the triple overlap, and we need to add that back on:

$$\mathbb{P}(A \cup B \cup C) = \mathbb{P}(A) + \mathbb{P}(B) + \mathbb{P}(C) - \mathbb{P}(A \cap B) - \mathbb{P}(B \cap C) - \mathbb{P}(A \cap C) + \mathbb{P}(A \cap B \cap C).$$

Continuing this alternating pattern of corrections gives the general *inclusion-exclusion formula*.

Theorem 6.1.20 (Inclusion-Exclusion)

Let $A_1, \dots, A_n$ be events. Then

$$\mathbb{P}\left(\bigcup_{i=1}^n A_i\right) = \sum_{k=1}^n (-1)^{k+1} \sum_{1 \leq i_1 < \dots < i_k \leq n} \mathbb{P}(A_{i_1} \cap \dots \cap A_{i_k}).$$

Proof. We induct on n , with the case $n = 2$ already established. Assuming the result for $n - 1$ events, we have

$$\mathbb{P}\left(\bigcup_{i=1}^n A_i\right) = \mathbb{P}\left(\bigcup_{i=1}^{n-1} A_i\right) + \mathbb{P}(A_n) - \mathbb{P}\left(\bigcup_{i=1}^{n-1} (A_i \cap A_n)\right).$$

Now we apply the inductive hypothesis to both unions on the right hand side, the second with $B_i = A_i \cap A_n$. The first gives all of the terms not involving A_n , the term $\mathbb{P}(A_n)$ gives the term involving only A_n , and expanding the second union gives (after noting $B_{i_1} \cap \dots \cap B_{i_k} = A_{i_1} \cap \dots \cap A_{i_k} \cap A_n$, and with a sign flip from the minus sign) exactly the terms involving A_n and at least one other event. Collecting everything up gives the required formula. $\square$

Remark. In the classical setting where $\mathbb{P}(A) = |A|/|\Omega|$, multiplying through by $|\Omega|$ gives the corresponding counting formula

$$|A_1 \cup \dots \cup A_n| = \sum_{k=1}^n (-1)^{k+1} \sum_{i_1 < \dots < i_k} |A_{i_1} \cap \dots \cap A_{i_k}|,$$

which you may well have seen in ‘Numbers and Sets’.

If we don't need an exact answer, we can truncate the inclusion-exclusion sum, and it's useful to know which way the truncation errs. The answer alternates: stopping after an odd number of terms overestimates, and after an even number underestimates. These are the *Bonferroni inequalities*.

Theorem 6.1.21 (Bonferroni Inequalities)

Let $A_1, \dots, A_n$ be events and $1 \leq r \leq n$. If r is odd, then

$$\mathbb{P}\left(\bigcup_{i=1}^n A_i\right) \leq \sum_{k=1}^r (-1)^{k+1} \sum_{i_1 < \dots < i_k} \mathbb{P}(A_{i_1} \cap \dots \cap A_{i_k}),$$

and if r is even the reverse inequality holds.

Proof. We induct on n , exactly as in the proof of inclusion-exclusion (the case $n = 2$ is easy to check directly). Suppose r is odd, and write

$$\mathbb{P}\left(\bigcup_{i=1}^n A_i\right) = \mathbb{P}\left(\bigcup_{i=1}^{n-1} A_i\right) + \mathbb{P}(A_n) - \mathbb{P}\left(\bigcup_{i=1}^{n-1} B_i\right),$$

where $B_i = A_i \cap A_n$. Applying the inductive hypothesis with r (odd) to the first union, and with $r - 1$ (even) to the second union – noting the minus sign flips the direction of that inequality – and collecting terms as before gives the required overestimate. The case of r even is identical with the inequalities reversed. $\square$

Note that the case $r = 1$ of the Bonferroni inequalities is just Boole's inequality (for finitely many events).

Let's now see inclusion-exclusion doing some real work.

Example 6.1.22 (Derangements)

A **derangement** is a permutation with no fixed points. If we pick a permutation σ of $\{1, \dots, n\}$ uniformly at random, what is the probability that σ is a derangement?

Let A_i be the event that $\sigma(i) = i$. Then we want to compute $1 - \mathbb{P}(A_1 \cup \dots \cup A_n)$. For any distinct indices $i_1 < \dots < i_k$, the permutations fixing all of $i_1, \dots, i_k$ number $(n - k)!$, so

$$\mathbb{P}(A_{i_1} \cap \dots \cap A_{i_k}) = \frac{(n - k)!}{n!}.$$

There are $\binom{n}{k}$ such sets of indices, so by inclusion-exclusion,

$$\mathbb{P}\left(\bigcup_{i=1}^n A_i\right) = \sum_{k=1}^n (-1)^{k+1} \binom{n}{k} \frac{(n - k)!}{n!} = \sum_{k=1}^n \frac{(-1)^{k+1}}{k!},$$

and thus

$$\mathbb{P}(\sigma \text{ is a derangement}) = 1 - \sum_{k=1}^n \frac{(-1)^{k+1}}{k!} = \sum_{k=0}^n \frac{(-1)^k}{k!} \rightarrow \frac{1}{e}$$

as $n \rightarrow \infty$. So for large n , a bit over a third of permutations are derangements – and remarkably, the answer barely depends on n .

Example 6.1.23 (Counting Surjections)

How many functions $f : \{1, \dots, n\} \rightarrow \{1, \dots, m\}$ are surjective? Let A_i be the set of functions that miss the value i . Then the surjections are exactly the functions

in none of the A_i , and $|A_{i_1} \cap \dots \cap A_{i_k}| = (m - k)^n$ since such functions map into a set of size $m - k$. So by the counting form of inclusion-exclusion, the number of surjections is

$$m^n - \sum_{k=1}^m (-1)^{k+1} \binom{m}{k} (m - k)^n = \sum_{k=0}^m (-1)^k \binom{m}{k} (m - k)^n.$$

§6.2 Discrete Random Variables

Imagine the following scenario. You are in a lecture hall, and you decide to perform an experiment where choose a student at random and ask them how they performed in the admissions test. It would be natural to model this scenario with a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ where $\Omega = \{\omega_1, \dots, \omega_n\}$ where each ω_i corresponds to a student in the lecture hall, $\mathcal{F}$ is all possible subsets of Ω , and $\mathbb{P}$ is the probability measure describing the likelihoods of given students being chosen in the experiment.

So how does the ‘asking for the student’s test score’ fit into this setup? A natural way to deal with this is by defining a function $X : \Omega \rightarrow \mathbb{R}$ where $X(\omega_i)$ is the admissions test score of the student ω_i . We call such a function a *discrete random variable*.

Definition 6.2.1 (Discrete Random Variables)

A **discrete random variable** X on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ is a function $X : \Omega \rightarrow \mathbb{R}$ such that the image $X(\Omega)$ is a countable subset of $\mathbb{R}$ and $\{\omega \in \Omega : X(\omega) = x\} \in \mathcal{F}$ for $x \in \mathbb{R}$.

A natural mental picture to go along with this definition (which roughly follows our motivating example) is shown below.

§6.2.1 Probability Mass Functions

With the introduction of discrete random variables, we can change our view from probabilities of events occurring to the probabilities that a discrete random variable takes on specific values. A nice way to do this is by introducing the *probability mass function*.

Definition 6.2.2 (Probability Mass Function)

The **probability mass function** or **pmf** of a discrete random variable X is a function $p_X : \mathbb{R} \rightarrow [0, 1]$ defined by

$$p_X(x) = \mathbb{P}(X = x) = \mathbb{P}(\{\omega \in \Omega : X(\omega) = x\}).$$

It turns out that the probability mass function encodes pretty much all information about the discrete random variable X , so much so that if we have some function p_X that acts like a probability mass function, we can say things like ‘let X be a random variable taking value x_i with probability $p_X(x_i)$ ’ and have it be completely well defined.

Theorem 6.2.3

Let $p_X : \mathbb{R} \rightarrow [0, 1]$ be a function such that $p_X(x) \neq 0$ for countably many x and $\sum_{x \in \mathbb{R}} p_X(x) = 1$. Then there is a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ and a random variable X on this space where X has probability mass function p_X .

Proof. Take $\Omega = \{x \in \mathbb{R} : p_X(x) \neq 0\}$, $\mathcal{F}$ to be all subsets of Ω , and

$$\mathbb{P}(A) = \sum_{\omega \in A} p_X(\omega) \quad \text{for } A \in \mathcal{F},$$

and define $X : \Omega \rightarrow \mathbb{R}$ by $X(\omega) = \omega$. □

§6.2.2 Expected Value

A common question when dealing with discrete random variables is ‘what is the mean of this discrete random variable?’. Thinking back to our lecture hall example, this would correspond with asking what the mean test score in the lecture hall was. We answer such questions by defining the *expectation* of a random variable.

Definition 6.2.4 (Expected Value)

If X is a discrete random variable, we define the **expected value** of X to be

$$\mathbb{E}[X] = \sum_{x \in \text{img } X} x \mathbb{P}(X = x)$$

whenever this sum converges absolutely^a.

^aWe require this because we rearranging the sum shouldn’t change the expected value – see Analysis I.

There are a few ‘tricks’ which make the computation of expected value somewhat easier. For example, if we have a discrete random variable defined on some probability space $(\Omega, \mathcal{F}, \mathbb{P})$, then we can sum over the elements of Ω rather than the elements of $\text{img } X$. Also, since random variables are really just functions, we can obtain new random variables by composing them with other functions, for example $X \mapsto X^2$. In such scenarios, we can use a seemingly obvious result.

Theorem 6.2.5 (Law of The Subconscious Statistician)

If X is a discrete random variable and $g : \mathbb{R} \rightarrow \mathbb{R}$, then

$$\mathbb{E}[g(X)] = \sum_{x \in \text{img } X} g(x) \mathbb{P}(X = x),$$

whenever this sum converges absolutely.

Proof. Let $Y = g(X)$ be a discrete random variable. Then

$$\begin{aligned}\mathbb{E}[Y] &= \sum_{y \in \text{img } Y} y \mathbb{P}(Y = y) = \sum_{y \in \text{img } Y} y \sum_{x \in \text{img } X: g(x)=y} \mathbb{P}(X = x) \\ &= \sum_{x \in \text{img } X} g(x) \mathbb{P}(X = x),\end{aligned}$$

provided this converges absolutely. $\square$

Another thing we can do very easily is find the expected value of a sum of random variables, using *linearity of expectation*.

Theorem 6.2.6 (Linearity of Expectation)

For any random variables $X_1, X_2, \dots, X_n$ for which the following expectations exist,

$$\mathbb{E}[X_1 + \dots + X_n] = \mathbb{E}[X_1] + \dots + \mathbb{E}[X_n].$$

Proof. We sum over the elements of the sample space Ω to get

$$\begin{aligned}\mathbb{E}[X] &= \sum_{\omega \in \Omega} p(\omega)[X_1(\omega) + \dots + X_n(\omega)] \\ &= \sum_{\omega \in \Omega} p(\omega)X_1(\omega) + \dots + \sum_{\omega \in \Omega} p(\omega)X_n(\omega) \\ &= \mathbb{E}[X_1] + \dots + \mathbb{E}[X_n].\end{aligned}$$

$\square$

It's important to note that there's absolutely no requirement that the random variables be independent for this to hold – one of the reasons why it's an incredibly useful result!

So if expected value measures something like the ‘mean’ of a random variable, it's natural to think about how we can measure how we can expect the random variable deviates from this mean. This is done through the notion of *variance*.

Definition 6.2.7 (Variance)

The **variance** $\text{Var}(X)$ of a discrete random variable X is defined to be

$$\text{Var}(X) = \mathbb{E}[(X - \mathbb{E}[X])^2].$$

By just working through the definitions we can see that $\text{Var}(X) = \mathbb{E}[X^2] - \mathbb{E}[X]^2$, which is often an easy way to calculate this quantity.

§6.2.3 Indicator Functions

There's one type of random variable which is so useful that it needs to be brought to your attention immediately – indicator functions.

Definition 6.2.8 (Indicator Functions)

The **indicator function** of an event A is the random variable $\mathbb{1}_A$ where

$$\mathbb{1}_A(\omega) = \begin{cases} 1 & \text{if } \omega \in A, \\ 0 & \text{if } \omega \notin A. \end{cases}$$

Indicator functions have nice algebraic facts which reflect common ways to manipulate events:

$$\begin{aligned} \mathbb{1}_{A^c} &= 1 - \mathbb{1}_A, \\ \mathbb{1}_{A \cap B} &= \mathbb{1}_A \mathbb{1}_B, \\ \mathbb{1}_{A \cup B} &= \mathbb{1}_A + \mathbb{1}_B - \mathbb{1}_A \mathbb{1}_B. \end{aligned}$$

Still one of the best things about indicator functions is that they allow us to talk about probabilities of events using expectations, since

$$\mathbb{E}[\mathbb{1}_A] = \mathbb{P}(A).$$

All of these properties are straightforward and easy to check (just do casework), but they can make proving things and solving problems much easier. Nontrivial example time!

Example 6.2.9 (Solving Problems With Indicator Functions)

A total of n bar magnets are placed end to end in a line with random independent orientations. Adjacent like poles repel, ends with opposite polarities join to form blocks. Let X be the number of blocks of joined magnets. Find $\mathbb{E}[X]$ and $\text{Var}(X)$.

Solution. The situation looks something like this:

Let $\mathbb{1}_i$ be the indicator function for magnets i and $i+1$ repelling, for $1 \leq i \leq n-1$. We can then rewrite X as

$$X = \mathbb{1}_1 + \mathbb{1}_2 + \cdots + \mathbb{1}_{n-1} + 1.$$

Then since $\mathbb{E}[\mathbb{1}_i] = \mathbb{P}(\text{two magnets of random orientation repel}) = 1/2$, we have

$$\begin{aligned} \mathbb{E}[X] &= \mathbb{E}[\mathbb{1}_1] + \cdots + \mathbb{E}[\mathbb{1}_{n-1}] + 1 \\ &= \frac{1}{2} + \cdots + \frac{1}{2} + 1 = \frac{n+1}{2}. \end{aligned}$$

To compute the variance, we need to calculate $\mathbb{E}[X^2]$. Writing $S = \mathbb{1}_1 + \cdots + \mathbb{1}_{n-1}$, so that $X = 1 + S$, we can expand

$$X^2 = 1 + 2S + S^2 = 1 + 2S + (\mathbb{1}_1^2 + \cdots + \mathbb{1}_{n-1}^2) + \sum_{i \neq j} \mathbb{1}_i \mathbb{1}_j = 1 + 3S + \sum_{i \neq j} \mathbb{1}_i \mathbb{1}_j,$$

using that $\mathbb{1}_i^2 = \mathbb{1}_i$ for indicators. Now $\mathbb{E}[\mathbb{1}_i \mathbb{1}_j] = \mathbb{P}(\text{both pairs repel}) = 1/4$ for $i \neq j$ (the two events involve at least one distinct magnet orientation each, and one

can check they are independent), and there are $(n-1)(n-2)$ ordered pairs $i \neq j$. So

$$\mathbb{E}[X^2] = 1 + 3 \cdot \frac{n-1}{2} + (n-1)(n-2) \cdot \frac{1}{4} = \frac{3n-1}{2} + \frac{(n-1)(n-2)}{4},$$

and thus

$$\begin{aligned} \text{Var}(X) &= \mathbb{E}[X^2] - \mathbb{E}[X]^2 = \frac{3n-1}{2} + \frac{(n-1)(n-2)}{4} - \frac{(n+1)^2}{4} \\ &= \frac{2(3n-1) + (n^2 - 3n + 2) - (n^2 + 2n + 1)}{4} = \frac{n-1}{4}. \end{aligned}$$

As a sanity check: the indicators $\mathbb{1}_1, \dots, \mathbb{1}_{n-1}$ are actually mutually independent (each depends on whether consecutive orientations differ), so $X-1$ is a sum of $n-1$ independent ‘coin flips’ and we should expect variance $(n-1) \cdot \frac{1}{2} \cdot \frac{1}{2} = \frac{n-1}{4}$, which matches. $\square$

One more nice trick with indicators: if X is a random variable taking values in the non-negative integers, then writing $X = \sum_{k \geq 1} \mathbb{1}_{\{X \geq k\}}$ (an integer m is the sum of m ones!) and taking expectations gives the occasionally very convenient formula

$$\mathbb{E}[X] = \sum_{k=1}^{\infty} \mathbb{P}(X \geq k).$$

§6.2.4 A Zoo of Standard Distributions

There are a handful of distributions that show up over and over again, both in applications and throughout the rest of this course, so we will now go through them and compute their expectations and variances. Recall that the distribution of a discrete random variable is specified entirely by its probability mass function.

The Bernoulli Distribution

The simplest random experiment imaginable has two outcomes: success (with probability p) or failure. We say X has the **Bernoulli distribution** with parameter $p \in [0, 1]$, written $X \sim \text{Bernoulli}(p)$, if

$$\mathbb{P}(X = 1) = p, \quad \mathbb{P}(X = 0) = 1 - p.$$

Immediately we get $\mathbb{E}[X] = p$, and since $X^2 = X$,

$$\text{Var}(X) = \mathbb{E}[X^2] - \mathbb{E}[X]^2 = p - p^2 = p(1 - p).$$

Of course, an indicator function $\mathbb{1}_A$ is exactly a Bernoulli random variable with parameter $\mathbb{P}(A)$.

The Binomial Distribution

Now toss the same coin n times independently, and count the number of successes. This gives the **binomial distribution** $X \sim \text{Bin}(n, p)$, with

$$\mathbb{P}(X = k) = \binom{n}{k} p^k (1-p)^{n-k}, \quad k \in \{0, 1, \dots, n\},$$

the binomial coefficient counting which of the n trials were the successes. The binomial theorem shows these probabilities sum to 1 (hence the name).

Writing $X = \mathbb{1}_1 + \cdots + \mathbb{1}_n$ as a sum of indicators of success in each trial, linearity of expectation instantly gives

$$\mathbb{E}[X] = np.$$

For the variance, the slickest elementary route is via $\mathbb{E}[X(X-1)]$ (a *factorial moment* – these interact very well with binomial coefficients):

$$\begin{aligned}\mathbb{E}[X(X-1)] &= \sum_{k=2}^n k(k-1) \binom{n}{k} p^k (1-p)^{n-k} \\ &= n(n-1)p^2 \sum_{k=2}^n \binom{n-2}{k-2} p^{k-2} (1-p)^{n-k} = n(n-1)p^2,\end{aligned}$$

using the identity $k(k-1)\binom{n}{k} = n(n-1)\binom{n-2}{k-2}$ and then the binomial theorem. Hence

$$\text{Var}(X) = \mathbb{E}[X(X-1)] + \mathbb{E}[X] - \mathbb{E}[X]^2 = n(n-1)p^2 + np - n^2p^2 = np(1-p).$$

Remark (The Multinomial Distribution). If each trial has not two but k possible outcomes, with probabilities $p_1, \dots, p_k$ summing to 1, then the vector $(N_1, \dots, N_k)$ of counts of each outcome over n independent trials has the **multinomial distribution**:

$$\mathbb{P}(N_1 = n_1, \dots, N_k = n_k) = \binom{n}{n_1, \dots, n_k} p_1^{n_1} \cdots p_k^{n_k},$$

for $n_1 + \cdots + n_k = n$, with the multinomial coefficient counting the arrangements of outcomes among the trials. Each marginal N_i is $\text{Bin}(n, p_i)$.

The Geometric Distribution

Instead of a fixed number of tosses, toss the coin repeatedly until the first success, and let X be the number of tosses used. This is the **geometric distribution** $X \sim \text{Geom}(p)$ (with $p > 0$), where

$$\mathbb{P}(X = k) = (1-p)^{k-1}p, \quad k \in \{1, 2, 3, \dots\},$$

since we need $k-1$ failures followed by a success². Summing a geometric series confirms the total probability is 1 – in particular, the first success comes eventually with probability 1.

For the expectation, note $\mathbb{P}(X \geq k) = (1-p)^{k-1}$ (the first $k-1$ tosses all fail), so using our tail-sum formula,

$$\mathbb{E}[X] = \sum_{k=1}^{\infty} \mathbb{P}(X \geq k) = \sum_{k=1}^{\infty} (1-p)^{k-1} = \frac{1}{p},$$

which matches intuition: an event of probability p takes about $1/p$ attempts to see. For the variance we again use factorial moments, this time with the second derivative of the geometric series $\sum_k q^k = (1-q)^{-1}$:

$$\mathbb{E}[X(X-1)] = \sum_{k=2}^{\infty} k(k-1)(1-p)^{k-1}p = p(1-p) \sum_{k=2}^{\infty} k(k-1)(1-p)^{k-2} = \frac{2(1-p)}{p^2},$$

²Some authors instead count the number of *failures* before the first success, giving pmf $(1-p)^k p$ on $\{0, 1, 2, \dots\}$ – watch out for the convention in use.

and thus

$$\text{Var}(X) = \frac{2(1-p)}{p^2} + \frac{1}{p} - \frac{1}{p^2} = \frac{1-p}{p^2}.$$

The geometric distribution has a property worth flagging now, as we will meet its continuous cousin later: it is *memoryless*. If the first s tosses were all failures, the number of *further* tosses needed is distributed just like a fresh geometric:

$$\mathbb{P}(X > s+t \mid X > s) = \frac{(1-p)^{s+t}}{(1-p)^s} = (1-p)^t = \mathbb{P}(X > t).$$

The coin does not remember its past – which is also why the ‘gambler’s fallacy’ (a run of losses making a win ‘due’) is a fallacy.

The Hypergeometric Distribution

Suppose an urn contains N balls, K of which are red, and we draw n balls *without replacement*. The number X of red balls drawn has the **hypergeometric distribution**, with

$$\mathbb{P}(X = k) = \frac{\binom{K}{k} \binom{N-K}{n-k}}{\binom{N}{n}},$$

for the possible values of k . Indicators make the expectation painless: letting $\mathbb{1}_i$ indicate that the i -th draw is red, each draw is (by symmetry) equally likely to be any of the N balls, so $\mathbb{E}[\mathbb{1}_i] = K/N$ and

$$\mathbb{E}[X] = \frac{nK}{N}.$$

Note this matches the binomial mean with $p = K/N$ – drawing without replacement doesn’t change the expectation, though it does shrink the variance.

The Poisson Distribution

Our final distribution models the number of events occurring in a fixed window of time, when events occur ‘at a constant rate, independently’: the number of buses passing in an hour, misprints on a page, radioactive decays in a second, and so on. We say X has the **Poisson distribution** with parameter $\lambda > 0$, written $X \sim \text{Poisson}(\lambda)$, if

$$\mathbb{P}(X = k) = e^{-\lambda} \frac{\lambda^k}{k!}, \quad k \in \{0, 1, 2, \dots\}.$$

The total probability is $e^{-\lambda} \sum_k \lambda^k / k! = e^{-\lambda} e^\lambda = 1$, as needed. The expectation is

$$\mathbb{E}[X] = \sum_{k=1}^{\infty} k e^{-\lambda} \frac{\lambda^k}{k!} = \lambda e^{-\lambda} \sum_{k=1}^{\infty} \frac{\lambda^{k-1}}{(k-1)!} = \lambda,$$

so the parameter λ is exactly the average number of events. Similarly $\mathbb{E}[X(X-1)] = \lambda^2 e^{-\lambda} \sum_{k \geq 2} \lambda^{k-2} / (k-2)! = \lambda^2$, giving

$$\text{Var}(X) = \lambda^2 + \lambda - \lambda^2 = \lambda.$$

The mean and the variance are both λ – a distinctive fingerprint of the Poisson distribution.

Where does the Poisson distribution come from? It arises naturally as a limit of binomials with many trials, each individually unlikely – this is sometimes called the *law of rare events*.

Theorem 6.2.10 (Poisson Approximation to the Binomial)

Fix $\lambda > 0$, and let $X_n \sim \text{Bin}(n, \lambda/n)$. Then for each fixed $k \geq 0$,

$$\mathbb{P}(X_n = k) \longrightarrow e^{-\lambda} \frac{\lambda^k}{k!} \quad \text{as } n \rightarrow \infty.$$

Proof. We compute directly:

$$\begin{aligned} \mathbb{P}(X_n = k) &= \binom{n}{k} \left(\frac{\lambda}{n}\right)^k \left(1 - \frac{\lambda}{n}\right)^{n-k} \\ &= \frac{\lambda^k}{k!} \cdot \frac{n(n-1) \cdots (n-k+1)}{n^k} \cdot \left(1 - \frac{\lambda}{n}\right)^n \left(1 - \frac{\lambda}{n}\right)^{-k}. \end{aligned}$$

As $n \rightarrow \infty$ with k fixed, the middle factor tends to 1, the last factor tends to 1, and $(1 - \lambda/n)^n \rightarrow e^{-\lambda}$. So $\mathbb{P}(X_n = k) \rightarrow e^{-\lambda} \lambda^k / k!$ as claimed. $\square$

To interpret this: divide an hour into n tiny intervals, and suppose a bus arrives in each interval with probability λ/n , independently. The number of buses in the hour is $\text{Bin}(n, \lambda/n)$, and letting the intervals shrink gives exactly $\text{Poisson}(\lambda)$.

§6.3 Multiple Random Variables

Most interesting probabilistic questions involve the interaction of *several* random variables – and this is where notions like independence, covariance and conditional expectation come into play.

§6.3.1 Joint Distributions and Independence

So far we have studied random variables one at a time. To capture how several random variables interact, we record all of their values at once.

Definition 6.3.1 (Joint Distribution)

Let $X_1, \dots, X_n$ be discrete random variables on a probability space. Their **joint distribution** is the collection of probabilities

$$\mathbb{P}(X_1 = x_1, X_2 = x_2, \dots, X_n = x_n),$$

over all possible values $x_1, \dots, x_n$.

The joint distribution knows everything about the individual random variables: summing out all but one variable recovers what is called the **marginal distribution**,

$$\mathbb{P}(X_1 = x_1) = \sum_{x_2, \dots, x_n} \mathbb{P}(X_1 = x_1, X_2 = x_2, \dots, X_n = x_n),$$

which is just the partition theorem in disguise. The converse fails badly – the marginals alone don't determine the joint distribution, as they say nothing about how the variables *depend* on each other. The simplest possible dependence structure is no dependence at all.

Definition 6.3.2 (Independent Random Variables)

Discrete random variables $X_1, \dots, X_n$ are **independent** if for all values $x_1, \dots, x_n$,

$$\mathbb{P}(X_1 = x_1, \dots, X_n = x_n) = \mathbb{P}(X_1 = x_1) \cdots \mathbb{P}(X_n = x_n).$$

Example 6.3.3 (Coin Tossing, Formally)

Let's model tossing a biased coin n times, formally. Take $\Omega = \{0, 1\}^n$, and for $\omega = (\omega_1, \dots, \omega_n)$ set

$$\mathbb{P}(\{\omega\}) = \prod_{k=1}^n p^{\omega_k} (1-p)^{1-\omega_k},$$

and let $X_k(\omega) = \omega_k$ be the result of the k th toss. Then each $X_k \sim \text{Bernoulli}(p)$, and multiplying out shows that $\mathbb{P}(X_1 = x_1, \dots, X_n = x_n) = \prod_k \mathbb{P}(X_k = x_k)$, so the tosses are genuinely independent in our formal sense. The number of heads $S_n = X_1 + \dots + X_n$ then has the $\text{Bin}(n, p)$ distribution.

A very useful consequence of independence is that expectations of products factorise.

Theorem 6.3.4 (Expectation of a Product)

If X and Y are independent discrete random variables and $f, g : \mathbb{R} \rightarrow \mathbb{R}$, then

$$\mathbb{E}[f(X)g(Y)] = \mathbb{E}[f(X)] \mathbb{E}[g(Y)],$$

whenever the expectations on the right exist.

Proof. Summing over the possible pairs of values,

$$\begin{aligned} \mathbb{E}[f(X)g(Y)] &= \sum_{x,y} f(x)g(y)\mathbb{P}(X=x, Y=y) \\ &= \sum_{x,y} f(x)g(y)\mathbb{P}(X=x)\mathbb{P}(Y=y) \\ &= \left(\sum_x f(x)\mathbb{P}(X=x) \right) \left(\sum_y g(y)\mathbb{P}(Y=y) \right) = \mathbb{E}[f(X)] \mathbb{E}[g(Y)], \end{aligned}$$

where the rearrangement is justified by absolute convergence. $\square$

Contrast this with linearity of expectation, which required no independence whatsoever: for products, independence is really doing work.

We can also ask about the distribution of a *sum* of independent random variables. Conditioning on the value of one of them gives

$$\mathbb{P}(X + Y = z) = \sum_y \mathbb{P}(X = z - y, Y = y) = \sum_y \mathbb{P}(X = z - y)\mathbb{P}(Y = y),$$

a formula known as the **convolution** of the two distributions.

Example 6.3.5 (Sum of Independent Poissons)

Let $X \sim \text{Poisson}(\lambda)$ and $Y \sim \text{Poisson}(\mu)$ be independent. Then

$$\begin{aligned}\mathbb{P}(X + Y = n) &= \sum_{r=0}^n e^{-\lambda} \frac{\lambda^r}{r!} \cdot e^{-\mu} \frac{\mu^{n-r}}{(n-r)!} \\ &= \frac{e^{-(\lambda+\mu)}}{n!} \sum_{r=0}^n \binom{n}{r} \lambda^r \mu^{n-r} = e^{-(\lambda+\mu)} \frac{(\lambda + \mu)^n}{n!},\end{aligned}$$

using the binomial theorem. So $X + Y \sim \text{Poisson}(\lambda + \mu)$ – the Poisson family is closed under adding independent members, which is exactly what you’d hope for from a distribution modelling counts of events (two independent streams of buses form one stream with the combined rate).

§6.3.2 Covariance

If independence is the absence of dependence, we’d also like a way to *measure* dependence. The first-order tool for this is covariance.

Definition 6.3.6 (Covariance)

The **covariance** of random variables X and Y is

$$\text{Cov}(X, Y) = \mathbb{E}[(X - \mathbb{E}[X])(Y - \mathbb{E}[Y])],$$

whenever this exists.

Roughly, $\text{Cov}(X, Y) > 0$ means X and Y tend to be large together, and $\text{Cov}(X, Y) < 0$ means one tends to be large when the other is small. Covariance has a pile of easily-verified properties, which we collect here.

Proposition 6.3.7 (Properties of Covariance)

For random variables X, Y, Z and a constant c :

- (i) $\text{Cov}(X, Y) = \text{Cov}(Y, X)$, and $\text{Cov}(X, X) = \text{Var}(X)$,
- (ii) $\text{Cov}(X, Y) = \mathbb{E}[XY] - \mathbb{E}[X]\mathbb{E}[Y]$,
- (iii) $\text{Cov}(cX, Y) = c \text{Cov}(X, Y)$ and $\text{Cov}(X + c, Y) = \text{Cov}(X, Y)$,
- (iv) $\text{Cov}(X + Y, Z) = \text{Cov}(X, Z) + \text{Cov}(Y, Z)$,
- (v) $\text{Var}(X + Y) = \text{Var}(X) + \text{Var}(Y) + 2 \text{Cov}(X, Y)$.

Proof. Part (i) is immediate from the definition. For (ii), expand

$$(X - \mathbb{E}[X])(Y - \mathbb{E}[Y]) = XY - X\mathbb{E}[Y] - Y\mathbb{E}[X] + \mathbb{E}[X]\mathbb{E}[Y]$$

and take expectations. Parts (iii) and (iv) then follow from linearity of expectation applied to (ii). For (v), write $\tilde{X} = X - \mathbb{E}[X]$ and $\tilde{Y} = Y - \mathbb{E}[Y]$; then

$$\text{Var}(X + Y) = \mathbb{E}[(\tilde{X} + \tilde{Y})^2] = \mathbb{E}[\tilde{X}^2] + \mathbb{E}[\tilde{Y}^2] + 2\mathbb{E}[\tilde{X}\tilde{Y}],$$

which is exactly the claim. $\square$

Iterating (iv) and (v) gives the general and very useful formula

$$\text{Var}\left(\sum_{i=1}^n X_i\right) = \sum_{i=1}^n \text{Var}(X_i) + \sum_{i \neq j} \text{Cov}(X_i, X_j).$$

If X and Y are independent, then $\mathbb{E}[XY] = \mathbb{E}[X]\mathbb{E}[Y]$ by the product theorem, so property (ii) gives $\text{Cov}(X, Y) = 0$, and hence variance becomes additive:

$$\text{Var}(X + Y) = \text{Var}(X) + \text{Var}(Y) \quad \text{for independent } X, Y.$$

(This gives another derivation of the binomial variance $np(1-p)$, summing the variances of n independent Bernoulli trials.)

It's very important to remember that the converse is *false*: zero covariance does not imply independence.

Example 6.3.8 (Uncorrelated but Dependent)

Let X_1, X_2, X_3 be independent Bernoulli($1/2$) random variables, and set $Y_i = 2X_i - 1$ (so the Y_i are random signs), and consider $Z_1 = X_3Y_1$ and $Z_2 = X_3Y_2$. Then $\mathbb{E}[Z_1] = \mathbb{E}[Z_2] = 0$ and

$$\text{Cov}(Z_1, Z_2) = \mathbb{E}[Z_1Z_2] = \mathbb{E}[X_3^2] \mathbb{E}[Y_1] \mathbb{E}[Y_2] = 0,$$

using independence of X_3, Y_1, Y_2 . But Z_1, Z_2 are certainly not independent: since Y_1, Y_2 are never zero, $Z_1 = 0$ happens exactly when $X_3 = 0$, and likewise for Z_2 , so

$$\mathbb{P}(Z_1 = 0, Z_2 = 0) = \mathbb{P}(X_3 = 0) = \frac{1}{2} \neq \frac{1}{4} = \mathbb{P}(Z_1 = 0)\mathbb{P}(Z_2 = 0).$$

Since covariance scales with the variables (property (iii)), it is often more meaningful to normalise it, defining the **correlation**

$$\text{Corr}(X, Y) = \frac{\text{Cov}(X, Y)}{\sqrt{\text{Var}(X) \text{Var}(Y)}},$$

when the variances are finite and nonzero. We will see later (from the Cauchy-Schwarz inequality) that correlation always lies in $[-1, 1]$.

§6.3.3 Conditional Expectation

We now bring conditioning into the world of random variables. If B is an event with $\mathbb{P}(B) > 0$, we define the **conditional expectation** of X given B to be

$$\mathbb{E}[X \mid B] = \frac{\mathbb{E}[X \mathbb{1}_B]}{\mathbb{P}(B)} = \sum_x x \mathbb{P}(X = x \mid B),$$

the average of X over only those outcomes lying in B . Just as knowing conditional probabilities in every scenario gives the total probability, conditional expectations recombine to give the full expectation.

Theorem 6.3.9 (Law of Total Expectation)

Let $\{B_1, B_2, \dots\}$ be disjoint events with $\bigcup_i B_i = \Omega$ and $\mathbb{P}(B_i) > 0$. Then for any random variable X for which $\mathbb{E}[X]$ exists,

$$\mathbb{E}[X] = \sum_i \mathbb{E}[X \mid B_i] \mathbb{P}(B_i).$$

Proof. Since $\mathbb{1}_{B_1} + \mathbb{1}_{B_2} + \dots = 1$, we can write $X = \sum_i X \mathbb{1}_{B_i}$, and taking expectations (using linearity, or countable additivity of expectation in the infinite case, applied first to non-negative parts) gives

$$\mathbb{E}[X] = \sum_i \mathbb{E}[X \mathbb{1}_{B_i}] = \sum_i \mathbb{E}[X \mid B_i] \mathbb{P}(B_i). \quad \square$$

Now for a genuinely important idea. Given two random variables X and Y , for each possible value y of Y we can compute the number $g(y) = \mathbb{E}[X \mid Y = y]$. This defines a function of y , and plugging the random variable Y back into it yields a *random variable*

$$\mathbb{E}[X \mid Y] = g(Y),$$

called the **conditional expectation of X given Y** . You should think of $\mathbb{E}[X \mid Y]$ as the best guess of X made by someone who knows the value of Y : it is random precisely because Y is.

Example 6.3.10

Toss a biased coin n times, let X_i be the indicator that toss i is a head, and let $Y_n = X_1 + \dots + X_n$ be the total number of heads. What is $\mathbb{E}[X_1 \mid Y_n]$?

We compute, for $y \geq 1$,

$$\begin{aligned} \mathbb{E}[X_1 \mid Y_n = y] &= \mathbb{P}(X_1 = 1 \mid Y_n = y) = \frac{\mathbb{P}(X_1 = 1, X_2 + \dots + X_n = y - 1)}{\mathbb{P}(Y_n = y)} \\ &= \frac{p \binom{n-1}{y-1} p^{y-1} (1-p)^{n-y}}{\binom{n}{y} p^y (1-p)^{n-y}} = \frac{\binom{n-1}{y-1}}{\binom{n}{y}} = \frac{y}{n}, \end{aligned}$$

and this also holds (trivially) for $y = 0$. So $\mathbb{E}[X_1 \mid Y_n] = Y_n/n$. Note the answer doesn't even depend on p : given the total number of heads, each toss is equally likely to have contributed, by symmetry.

The key properties of conditional expectation are as follows.

Proposition 6.3.11 (Properties of Conditional Expectation)

Let X, Y, Z be discrete random variables, and $c \in \mathbb{R}$. Then, whenever the relevant expectations exist:

- (i) (Linearity) $\mathbb{E}[cX + Z \mid Y] = c\mathbb{E}[X \mid Y] + \mathbb{E}[Z \mid Y]$.
- (ii) (Tower property) $\mathbb{E}[\mathbb{E}[X \mid Y]] = \mathbb{E}[X]$.
- (iii) (Taking out what is known) $\mathbb{E}[h(Y)X \mid Y] = h(Y)\mathbb{E}[X \mid Y]$ for any function h .

(iv) (Independence) If X and Y are independent, then $\mathbb{E}[X | Y] = \mathbb{E}[X]$.

Proof. Part (i) holds since $\mathbb{E}[\cdot | Y = y]$ is an expectation with respect to the probability measure $\mathbb{P}(\cdot | Y = y)$, and expectations are linear.

For (ii), we use the law of total expectation with the partition $\{Y = y\}$:

$$\mathbb{E}[\mathbb{E}[X | Y]] = \sum_y \mathbb{E}[X | Y = y] \mathbb{P}(Y = y) = \mathbb{E}[X].$$

For (iii), conditionally on $Y = y$ the random variable $h(Y)$ is just the constant $h(y)$, so

$$\mathbb{E}[h(Y)X | Y = y] = h(y)\mathbb{E}[X | Y = y],$$

and substituting Y for y gives the claim. Finally for (iv), if X, Y are independent then $\mathbb{P}(X = x | Y = y) = \mathbb{P}(X = x)$ for every y , so $\mathbb{E}[X | Y = y] = \mathbb{E}[X]$ for all y . $\square$

The tower property is used *constantly* – it lets us compute a difficult expectation by first conditioning on some helpful piece of information. We will lean on it heavily when we study branching processes.

§6.4 Inequalities and the Law of Large Numbers

Exact computations are all well and good, but much of the power of probability theory comes from *inequalities* – results that let us bound probabilities and expectations with only partial information about a distribution. We will build up the standard toolkit, and then use it to prove our first genuine limit theorem.

Everything in this section works for arbitrary random variables (discrete or otherwise); the proofs we give need nothing beyond basic properties of expectation.

§6.4.1 Markov and Chebyshev

Our first inequality says: a non-negative random variable with a small mean is unlikely to be large. Crude, but astonishingly useful.

Theorem 6.4.1 (Markov's Inequality)

Let $X \geq 0$ be a random variable. Then for any $a > 0$,

$$\mathbb{P}(X \geq a) \leq \frac{\mathbb{E}[X]}{a}.$$

Proof. The whole proof is the pointwise inequality $X \geq a\mathbb{1}_{\{X \geq a\}}$, which is easily checked in both the cases $X \geq a$ and $X < a$ (using $X \geq 0$ for the latter). Taking expectations,

$$\mathbb{E}[X] \geq a \mathbb{E}[\mathbb{1}_{\{X \geq a\}}] = a \mathbb{P}(X \geq a),$$

and dividing by a gives the result. $\square$

Applying Markov's inequality to the squared deviation of X from its mean gives a bound

in terms of the variance – a much sharper tool, since it captures fluctuations rather than just size.

Theorem 6.4.2 (Chebyshev's Inequality)

Let X be a random variable with finite mean. Then for any $a > 0$,

$$\mathbb{P}(|X - \mathbb{E}[X]| \geq a) \leq \frac{\text{Var}(X)}{a^2}.$$

Proof. The event $\{|X - \mathbb{E}[X]| \geq a\}$ is the same as the event $\{(X - \mathbb{E}[X])^2 \geq a^2\}$, and applying Markov's inequality to the non-negative random variable $(X - \mathbb{E}[X])^2$ gives

$$\mathbb{P}((X - \mathbb{E}[X])^2 \geq a^2) \leq \frac{\mathbb{E}[(X - \mathbb{E}[X])^2]}{a^2} = \frac{\text{Var}(X)}{a^2}. \quad \square$$

In words: a random variable is unlikely to be many standard deviations away from its mean – the probability of being at least k standard deviations away is at most $1/k^2$, whatever the distribution. This universality is what makes Chebyshev so valuable.

§6.4.2 Cauchy-Schwarz

The next inequality should look familiar from any setting with an inner product; expectation of a product behaves exactly like one.

Theorem 6.4.3 (Cauchy-Schwarz Inequality)

For random variables X and Y ,

$$|\mathbb{E}[XY]| \leq \sqrt{\mathbb{E}[X^2] \mathbb{E}[Y^2]}.$$

Proof. If either of $\mathbb{E}[X^2]$ or $\mathbb{E}[Y^2]$ is infinite the inequality is trivial, so assume both are finite (note $|XY| \leq \frac{1}{2}(X^2 + Y^2)$ ensures $\mathbb{E}[XY]$ exists). Further, if $\mathbb{E}[Y^2] = 0$ then $Y = 0$ with probability 1 and both sides vanish, so assume $\mathbb{E}[Y^2] > 0$.

Now for any $t \in \mathbb{R}$, we have $(X - tY)^2 \geq 0$, so taking expectations,

$$f(t) = \mathbb{E}[(X - tY)^2] = \mathbb{E}[X^2] - 2t\mathbb{E}[XY] + t^2\mathbb{E}[Y^2] \geq 0.$$

This is a quadratic in t which never goes negative, so evaluating at its minimum $t^* = \mathbb{E}[XY]/\mathbb{E}[Y^2]$,

$$0 \leq f(t^*) = \mathbb{E}[X^2] - \frac{\mathbb{E}[XY]^2}{\mathbb{E}[Y^2]},$$

which rearranges to $\mathbb{E}[XY]^2 \leq \mathbb{E}[X^2]\mathbb{E}[Y^2]$, as required. $\square$

Remark. Chasing through the proof shows when equality holds: we need $\mathbb{E}[(X - t^*Y)^2] = 0$, which forces $X = t^*Y$ with probability 1. So equality in Cauchy-Schwarz means the variables are (almost surely) proportional.

Applying Cauchy-Schwarz to the centred variables $X - \mathbb{E}[X]$ and $Y - \mathbb{E}[Y]$ gives

$$|\text{Cov}(X, Y)| \leq \sqrt{\text{Var}(X) \text{Var}(Y)},$$

which is exactly the promised fact that correlations lie in $[-1, 1]$, with ± 1 attained precisely for (almost surely) linear relationships.

§6.4.3 Jensen's Inequality

Our final inequality concerns *convex* functions. Recall that $f : \mathbb{R} \rightarrow \mathbb{R}$ is **convex** if for all $x, y \in \mathbb{R}$ and $t \in [0, 1]$,

$$f(tx + (1 - t)y) \leq tf(x) + (1 - t)f(y),$$

that is, chords of the graph of f lie above the graph. We say f is **concave** if $-f$ is convex.

The definition of convexity says that f of an average of *two* points is at most the average of the values. Jensen's inequality upgrades this from two-point averages to arbitrary expectations.

Theorem 6.4.4 (Jensen's Inequality)

Let X be a random variable with finite mean and let $f : \mathbb{R} \rightarrow \mathbb{R}$ be convex. Then

$$\mathbb{E}[f(X)] \geq f(\mathbb{E}[X]).$$

A helpful mnemonic for the direction: $f(x) = x^2$ is convex, and $\mathbb{E}[X^2] \geq \mathbb{E}[X]^2$ is just the statement $\text{Var}(X) \geq 0$.

The proof rests on a fundamental geometric property of convex functions: at every point, there is a line through the graph lying entirely below it (a *supporting line*).

Lemma 6.4.5 (Supporting Lines)

Let f be convex and $m \in \mathbb{R}$. Then there exist $a, b \in \mathbb{R}$ such that $f(m) = am + b$ and $f(x) \geq ax + b$ for all x .

Proof. Fix $x < m < y$. Writing m as a convex combination of x and y and rearranging the convexity inequality, one obtains

$$\frac{f(m) - f(x)}{m - x} \leq \frac{f(y) - f(m)}{y - m},$$

i.e. slopes of chords to the left of m are at most slopes of chords to the right. So if we let

$$a = \sup_{x < m} \frac{f(m) - f(x)}{m - x},$$

then a is finite, and for all $x < m < y$ we have

$$\frac{f(m) - f(x)}{m - x} \leq a \leq \frac{f(y) - f(m)}{y - m}.$$

Rearranging both inequalities gives $f(x) \geq a(x - m) + f(m)$ for every x (on both sides of m , and trivially at $x = m$). Taking $b = f(m) - am$ finishes the proof. $\square$

Proof of Jensen's Inequality. Let $m = \mathbb{E}[X]$, and take a supporting line $f(m) = am + b$ with $f(x) \geq ax + b$ for all x . Then the random variable $f(X)$ satisfies $f(X) \geq aX + b$ pointwise, so taking expectations,

$$\mathbb{E}[f(X)] \geq a\mathbb{E}[X] + b = am + b = f(\mathbb{E}[X]). \quad \square$$

Remark. If f is *strictly* convex (the supporting line touches only at m), then chasing the equality case shows $\mathbb{E}[f(X)] = f(\mathbb{E}[X])$ forces $X = \mathbb{E}[X]$ with probability 1, i.e. X is essentially constant.

As a first application, we can obtain a classical inequality about means, seemingly for free.

Corollary 6.4.6 (AM-GM Inequality)

For any positive reals $x_1, \dots, x_n$,

$$\left(\prod_{k=1}^n x_k \right)^{1/n} \leq \frac{1}{n} \sum_{k=1}^n x_k.$$

Proof. Let X be a random variable taking each of the values $x_1, \dots, x_n$ with probability $1/n$, and let $f(x) = -\log x$, which is convex on the positive reals (its second derivative $1/x^2$ is positive, and the supporting line argument goes through verbatim on $(0, \infty)$). Jensen's inequality gives $\mathbb{E}[-\log X] \geq -\log \mathbb{E}[X]$, that is,

$$-\frac{1}{n} \sum_{k=1}^n \log x_k \geq -\log \left(\frac{1}{n} \sum_{k=1}^n x_k \right).$$

Negating and exponentiating (both order-reversing and order-preserving respectively) gives exactly AM-GM. $\square$

Remark. For *concave* f the inequality reverses: $\mathbb{E}[f(X)] \leq f(\mathbb{E}[X])$, simply by applying Jensen to $-f$. Thus for instance $\mathbb{E}[\log X] \leq \log \mathbb{E}[X]$ for positive X – which is really what powered the AM-GM proof above. Weighted versions of AM-GM come for free too: giving the value x_k probability w_k instead of $1/n$ proves $\prod_k x_k^{w_k} \leq \sum_k w_k x_k$ for any weights $w_k \geq 0$ summing to 1.

§6.4.4 The Weak Law of Large Numbers

We now have the tools to prove something that underpins the whole interpretation of probability: if you repeat an experiment independently many times, the empirical average converges to the expectation. This is the mathematical justification for the

frequentist intuition that ‘probability is long-run frequency’.

Theorem 6.4.7 (Weak Law of Large Numbers)

Let $X_1, X_2, \dots$ be independent identically distributed random variables with mean μ and finite variance σ^2 , and let $S_n = X_1 + \dots + X_n$. Then for every fixed $\epsilon > 0$,

$$\mathbb{P}\left(\left|\frac{S_n}{n} - \mu\right| > \epsilon\right) \longrightarrow 0 \quad \text{as } n \rightarrow \infty.$$

Proof. By linearity, $\mathbb{E}[S_n/n] = \mu$, and by independence the variances add:

$$\text{Var}\left(\frac{S_n}{n}\right) = \frac{1}{n^2} \text{Var}(S_n) = \frac{n\sigma^2}{n^2} = \frac{\sigma^2}{n}.$$

So by Chebyshev’s inequality,

$$\mathbb{P}\left(\left|\frac{S_n}{n} - \mu\right| > \epsilon\right) \leq \frac{\sigma^2}{n\epsilon^2} \longrightarrow 0. \quad \square$$

Look at how little was needed: Chebyshev plus the fact that variances of independent variables add. The theorem remains true assuming only that the mean exists (no variance needed), but the proof is then harder.

Example 6.4.8 (Frequencies Converge to Probabilities)

Fix an event A in some repeatable experiment, and let $X_i = \mathbb{1}_A$ for the i th independent repetition, so that S_n/n is the proportion of the first n trials in which A occurred. The X_i are independent Bernoulli(p) variables with $p = \mathbb{P}(A)$, so the weak law gives

$$\mathbb{P}\left(\left|\frac{S_n}{n} - \mathbb{P}(A)\right| > \epsilon\right) \leq \frac{p(1-p)}{n\epsilon^2} \longrightarrow 0.$$

So observed frequencies converge (in probability) to the abstract probability assigned by the measure – the theory validates the intuition that inspired its axioms. Note also the explicit bound: since $p(1-p) \leq \frac{1}{4}$, roughly $n \approx 1/(4\delta\epsilon^2)$ trials suffice to know $\mathbb{P}(A)$ to within ϵ with confidence $1 - \delta$, whatever the experiment.

Remark (The Strong Law). The type of convergence appearing in the weak law is called **convergence in probability**. There is a genuinely stronger statement, the *strong law of large numbers*: under the same hypotheses,

$$\mathbb{P}\left(\lim_{n \rightarrow \infty} \frac{S_n}{n} = \mu\right) = 1,$$

i.e. the sample averages converge to μ **almost surely**. We won’t prove this here (a proof assuming finite fourth moments is a nice exercise using Markov’s inequality on S_n^4), but it is worth knowing the distinction between the two modes of convergence: the strong law says that with probability one the entire sequence of averages settles down to μ , not merely that large deviations at each fixed time become unlikely.

§6.5 Random Walks

We now look at our first *random process* – a sequence of random variables $X_0, X_1, X_2, \dots$ evolving in time. The simplest and most fundamental example is the random walk.

Definition 6.5.1 (Simple Random Walk)

Let $Y_1, Y_2, \dots$ be independent identically distributed random variables with

$$\mathbb{P}(Y_i = 1) = p, \quad \mathbb{P}(Y_i = -1) = q = 1 - p.$$

The process

$$X_n = x + Y_1 + \dots + Y_n$$

is called a **simple random walk** started from $x \in \mathbb{Z}$. If $p = q = \frac{1}{2}$ the walk is called **symmetric**.

You should picture a particle on the integers, taking a step up with probability p or down with probability q at each tick of a clock – or a gambler making a sequence of one pound bets. A crucial feature of the walk is that it has no memory: where it goes next depends only on where it is now, not on how it got there.

§6.5.1 Gambler's Ruin

Here is the classical question. A gambler starts with $\mathcal{L}x$ and repeatedly bets $\mathcal{L}1$, winning each bet with probability p ; they stop when they either hit their target of $\mathcal{L}a$ or go bankrupt. What is the probability they reach the target?

In terms of the walk, we start at x with $0 \leq x \leq a$, and we want the probability that the walk hits a before it hits 0. We write $\mathbb{P}_x$ for probabilities of the walk started at x , and define

$$h(x) = \mathbb{P}_x(X_n \text{ hits } a \text{ before hitting } 0).$$

A typical path of the walk, started from x and absorbed at the barrier a , looks like this:

The technique – worth internalising, since it applies to a huge family of such problems – is to *condition on the first step*. By the partition theorem, for $0 < x < a$,

$$\begin{aligned} h(x) &= \mathbb{P}_x(\text{hit } a \text{ first} \mid Y_1 = 1)p + \mathbb{P}_x(\text{hit } a \text{ first} \mid Y_1 = -1)q \\ &= ph(x+1) + qh(x-1), \end{aligned}$$

since after the first step the walk is just a fresh random walk started from $x \pm 1$. Together with the boundary conditions $h(0) = 0$ and $h(a) = 1$, this recurrence determines h completely.

Theorem 6.5.2 (Gambler's Ruin)

For the simple random walk with $0 \leq x \leq a$,

$$h(x) = \begin{cases} \frac{(q/p)^x - 1}{(q/p)^a - 1} & \text{if } p \neq q, \\ \frac{x}{a} & \text{if } p = q = \frac{1}{2}. \end{cases}$$

Proof. We solve the linear recurrence $ph(x+1) - h(x) + qh(x-1) = 0$. Trying $h(x) = \lambda^x$ gives the auxiliary equation $p\lambda^2 - \lambda + q = 0$, which factors as $(\lambda - 1)(p\lambda - q) = 0$, so $\lambda = 1$ or $\lambda = q/p$.

If $p \neq q$ these roots are distinct, so the general solution is $h(x) = A + B(q/p)^x$. The boundary conditions $h(0) = 0$, $h(a) = 1$ give $A + B = 0$ and $A + B(q/p)^a = 1$, so

$$h(x) = \frac{(q/p)^x - 1}{(q/p)^a - 1}.$$

If $p = q = \frac{1}{2}$, the root $\lambda = 1$ is repeated and the general solution is $h(x) = A + Bx$; the boundary conditions immediately give $h(x) = x/a$. $\square$

There is a sobering message here for gamblers. Suppose $p < \frac{1}{2}$ (as in every casino), so $q/p > 1$. Letting the target $a \rightarrow \infty$, the probability of ever reaching it is

$$h(x) = \frac{(q/p)^x - 1}{(q/p)^a - 1} \rightarrow 0,$$

and moreover the probability of *avoiding bankruptcy forever* tends to 0 too: the walk with downward drift hits 0 with probability

$$1 - \lim_{a \rightarrow \infty} h(x) = 1.$$

Even in a fair game ($p = 1/2$), the probability x/a of reaching a large target before ruin is small – the moral being that with a finite bankroll against an effectively infinite house, ruin is essentially certain.

§6.5.2 Expected Duration

We can play the same first-step game with expectations. Let T be the first time the walk hits 0 or a , and let $\tau_x = \mathbb{E}_x[T]$ denote its expected value for the walk started at x . Conditioning on the first step, using the law of total expectation, gives for $0 < x < a$

$$\tau_x = p(1 + \tau_{x+1}) + q(1 + \tau_{x-1}) = 1 + p\tau_{x+1} + q\tau_{x-1},$$

with boundary conditions $\tau_0 = \tau_a = 0$. (The ‘1+’ accounts for the step just taken.)

Proposition 6.5.3 (Expected Time to Absorption)

For the symmetric walk ($p = q = \frac{1}{2}$),

$$\tau_x = x(a - x),$$

and for $p \neq q$,

$$\tau_x = \frac{x}{q-p} - \frac{a}{q-p} \cdot \frac{(q/p)^x - 1}{(q/p)^a - 1}.$$

Proof. This is now an inhomogeneous linear recurrence, so we need a particular solution plus the general solution of the homogeneous equation found above.

If $p = q = \frac{1}{2}$: trying $\tau_x = Ax^2$ as a particular solution gives

$$Ax^2 = 1 + \frac{A}{2} ((x+1)^2 + (x-1)^2) = 1 + Ax^2 + A,$$

so $A = -1$. The general solution is thus $\tau_x = -x^2 + Bx + C$, and the boundary conditions give $C = 0$ and $B = a$, so $\tau_x = x(a - x)$.

If $p \neq q$: trying $\tau_x = Cx$ gives $Cx = 1 + pC(x+1) + qC(x-1) = 1 + Cx + C(p-q)$, so $C = 1/(q-p)$. The general solution is

$$\tau_x = \frac{x}{q-p} + A + B \left(\frac{q}{p}\right)^x,$$

and imposing $\tau_0 = \tau_a = 0$ gives $A = -B$ and $B((q/p)^a - 1) = -a/(q-p)$, yielding the stated formula. $\square$

It's worth pausing at the symmetric case: starting in the middle, $\tau_{a/2} = a^2/4$, so the duration of a fair game grows *quadratically* in the stakes – fair games are long games.

§6.6 Probability Generating Functions

We now introduce one of the most powerful bookkeeping devices in discrete probability. The idea is to encode the entire distribution of a random variable into a single function, whereupon many operations on random variables (particularly adding independent copies) become simple algebraic operations on functions.

Definition 6.6.1 (Probability Generating Function)

Let X be a random variable taking values in $\{0, 1, 2, \dots\}$, with $p_r = \mathbb{P}(X = r)$. The **probability generating function** (or **pgf**) of X is

$$p(z) = \mathbb{E}[z^X] = \sum_{r=0}^{\infty} p_r z^r, \quad \text{for } |z| \leq 1.$$

Since $\sum_r p_r = 1$, the series converges absolutely for $|z| \leq 1$, so the pgf is always well defined there, and $p(1) = 1$. The first thing to establish is that no information is lost in passing to the pgf.

Theorem 6.6.2 (The pgf Determines the Distribution)

The probability generating function of X uniquely determines the distribution of X .

Explicitly,

$$p_n = \frac{1}{n!} p^{(n)}(0).$$

Proof. Suppose (p_r) and (q_r) are pmfs whose generating functions agree for all $|z| \leq 1$. Setting $z = 0$ gives $p_0 = q_0$. Inductively, if $p_r = q_r$ for all $r \leq n$, then

$$\sum_{r=n+1}^{\infty} p_r z^r = \sum_{r=n+1}^{\infty} q_r z^r$$

for $0 < z < 1$; dividing by z^{n+1} and letting $z \rightarrow 0^+$ gives $p_{n+1} = q_{n+1}$ (the tails of both series tend to 0, being bounded by $z \cdot \sum_r p_r$ and so on). So the distributions agree. The explicit formula is just the standard formula for coefficients of a power series in terms of derivatives at 0. $\square$

§6.6.1 Extracting Moments

Differentiating the series $\sum_r p_r z^r$ term by term (valid inside the radius of convergence) gives $p'(z) = \sum_r r p_r z^{r-1}$, and evaluating at $z = 1$ *formally* gives $\sum_r r p_r = \mathbb{E}[X]$. Making this precise requires a small limiting argument, since the radius of convergence may be exactly 1.

Theorem 6.6.3 (Moments From the pgf)

Let X have pgf p . Then

$$\lim_{z \rightarrow 1^-} p'(z) = \mathbb{E}[X],$$

where both sides may be $+\infty$, and we write $p'(1^-)$ for this limit. More generally,

$$p^{(k)}(1^-) = \mathbb{E}[X(X-1)\cdots(X-k+1)].$$

Proof. For $0 < z < 1$ we have $p'(z) = \sum_r r p_r z^{r-1}$, which is an increasing function of z , bounded above by $\sum_r r p_r = \mathbb{E}[X]$. So the limit $p'(1^-)$ exists (possibly infinite) and is at most $\mathbb{E}[X]$.

For the reverse bound, fix $\epsilon > 0$ (supposing first that $\mathbb{E}[X] < \infty$) and pick N with $\sum_{r=0}^N r p_r \geq \mathbb{E}[X] - \epsilon$. Then for $0 < z < 1$,

$$p'(z) \geq \sum_{r=1}^N r p_r z^{r-1} \longrightarrow \sum_{r=1}^N r p_r \geq \mathbb{E}[X] - \epsilon \quad \text{as } z \rightarrow 1^-,$$

so $p'(1^-) \geq \mathbb{E}[X] - \epsilon$ for every ϵ , giving the result. If $\mathbb{E}[X] = \infty$, the same argument with $\sum_{r=0}^N r p_r \geq M$ for arbitrary M shows $p'(1^-) = \infty$. The claim for higher derivatives follows in exactly the same way. $\square$

In particular, we get a formula for the variance which is often the fastest route in computations:

$$\text{Var}(X) = p''(1^-) + p'(1^-) - p'(1^-)^2.$$

Example 6.6.4 (Geometric Moments, the Painless Way)

Let $X \sim \text{Geom}(p)$, with pgf $p(z) = pz/(1 - qz)$ where $q = 1 - p$ (computed below, but easy to check directly). Differentiating with the quotient rule,

$$p'(z) = \frac{p}{(1 - qz)^2}, \quad p''(z) = \frac{2pq}{(1 - qz)^3},$$

so $\mathbb{E}[X] = p'(1) = p/p^2 = 1/p$, and

$$\text{Var}(X) = \frac{2pq}{p^3} + \frac{1}{p} - \frac{1}{p^2} = \frac{2q + p - 1}{p^2} = \frac{q}{p^2} = \frac{1 - p}{p^2},$$

recovering our earlier answers with strictly less summation.

§6.6.2 Sums of Independent Random Variables

Here is where pgfs really earn their keep.

Theorem 6.6.5 (pgfs of Sums)

Let $X_1, \dots, X_n$ be independent random variables with pgfs $p_1, \dots, p_n$. Then the pgf of $X_1 + \dots + X_n$ is

$$\mathbb{E}[z^{X_1 + \dots + X_n}] = p_1(z) p_2(z) \cdots p_n(z).$$

Proof. Since the X_i are independent, so are the random variables $z^{X_1}, \dots, z^{X_n}$ (they are functions of the X_i), and so the expectation of their product factorises:

$$\mathbb{E}[z^{X_1} z^{X_2} \cdots z^{X_n}] = \mathbb{E}[z^{X_1}] \cdots \mathbb{E}[z^{X_n}]. \quad \square$$

So convolution of distributions – a messy sum – becomes multiplication of functions. Let's compute the pgfs of our standard distributions and put this to use.

Example 6.6.6 (Standard pgfs) (i) If $X \sim \text{Bernoulli}(p)$, then $\mathbb{E}[z^X] = (1 - p) + pz$.

(ii) If $X \sim \text{Bin}(n, p)$, then by the binomial theorem (or by (i) and independence!)

$$\mathbb{E}[z^X] = \sum_{r=0}^n \binom{n}{r} (pz)^r (1 - p)^{n-r} = (1 - p + pz)^n.$$

(iii) If $X \sim \text{Geom}(p)$ (support $\{1, 2, \dots\}$), then

$$\mathbb{E}[z^X] = \sum_{r=1}^{\infty} (1 - p)^{r-1} p z^r = \frac{pz}{1 - (1 - p)z}.$$

(iv) If $X \sim \text{Poisson}(\lambda)$, then

$$\mathbb{E}[z^X] = \sum_{r=0}^{\infty} e^{-\lambda} \frac{(\lambda z)^r}{r!} = e^{\lambda(z-1)}.$$

Example 6.6.7 (Sums Revisited)

If $X \sim \text{Bin}(n, p)$ and $Y \sim \text{Bin}(m, p)$ are independent, then $X + Y$ has pgf

$$(1 - p + pz)^n (1 - p + pz)^m = (1 - p + pz)^{n+m},$$

so $X + Y \sim \text{Bin}(n + m, p)$ by uniqueness – obvious probabilistically (concatenate the trials), but now completely mechanical. Similarly for independent Poissons, $e^{\lambda(z-1)} e^{\mu(z-1)} = e^{(\lambda+\mu)(z-1)}$ recovers $X + Y \sim \text{Poisson}(\lambda + \mu)$ with none of the earlier convolution work.

§6.6.3 Random Sums

Pgfs handle beautifully a situation that would otherwise be quite awkward: adding up a *random number* of random variables. Think of the total claim against an insurer in a year (a random number of claims, each of random size), or – as we'll see in the next section – the number of children in a generation of a branching process.

Theorem 6.6.8 (Random Sums – Compounding)

Let $X_1, X_2, \dots$ be independent identically distributed random variables with pgf $p(z)$, and let N be a random variable with values in $\{0, 1, 2, \dots\}$, independent of the X_i , with pgf $q(z)$. Then the pgf of the random sum

$$S_N = X_1 + \dots + X_N$$

is $r(z) = q(p(z))$.

Proof. We condition on N using the tower property:

$$r(z) = \mathbb{E}[z^{S_N}] = \mathbb{E}[\mathbb{E}[z^{S_N} | N]].$$

Given $N = n$, the sum S_N is just $X_1 + \dots + X_n$, which is independent of N , so

$$\mathbb{E}[z^{S_N} | N = n] = \mathbb{E}[z^{X_1 + \dots + X_n}] = p(z)^n.$$

Hence $\mathbb{E}[z^{S_N} | N] = p(z)^N$, and

$$r(z) = \mathbb{E}[p(z)^N] = q(p(z)).$$

□

Differentiating $r = q \circ p$ and evaluating at 1^- (using $p(1^-) = 1$) gives the pleasingly interpretable formulas

$$\mathbb{E}[S_N] = q'(1^-)p'(1^-) = \mathbb{E}[N] \mathbb{E}[X_1],$$

and, after a short computation with second derivatives,

$$\text{Var}(S_N) = \mathbb{E}[N] \text{Var}(X_1) + \text{Var}(N) \mathbb{E}[X_1]^2.$$

The first says the expected total is the expected count times the expected size – entirely reasonable – while the second shows both sources of randomness contribute to the variance.

§6.7 Branching Processes

Armed with generating functions, we can analyse a rather beautiful random process. Imagine an organism that produces a random number of offspring, each of which independently produces its own offspring in the same way, and so on – a model equally at home describing family surnames, nuclear chain reactions, or the early spread of an epidemic. The central question: does the population survive forever, or die out?

Definition 6.7.1 (Branching Process)

Let $(Y_{k,n})_{k,n \geq 1}$ be independent identically distributed random variables with values in $\{0, 1, 2, \dots\}$, where $Y_{k,n}$ represents the number of children of the k th individual in generation n . The **branching process** (X_n) is defined by $X_0 = 1$ and

$$X_{n+1} = \begin{cases} Y_{1,n} + \dots + Y_{X_n,n} & \text{if } X_n \geq 1, \\ 0 & \text{if } X_n = 0. \end{cases}$$

So X_n is the size of the n th generation. The common distribution of the $Y_{k,n}$ is called the **offspring distribution**.

Note that each generation is exactly a *random sum* of the type we just studied: X_{n+1} is a sum of X_n independent copies of the offspring distribution. This observation makes the theory almost write itself. A typical family tree looks something like the following.

§6.7.1 Expected Generation Size

The first natural question to ask about a branching process is how big we expect the n th generation to be.

Theorem 6.7.2 (Mean Growth)

Let $\mu = \mathbb{E}[X_1]$ be the mean of the offspring distribution. Then

$$\mathbb{E}[X_n] = \mu^n.$$

Proof. By our random sums formula (or directly by conditioning on X_n with the tower property),

$$\mathbb{E}[X_{n+1}] = \mathbb{E}[\mathbb{E}[X_{n+1} \mid X_n]] = \mathbb{E}[X_n \mu] = \mu \mathbb{E}[X_n],$$

and since $\mathbb{E}[X_0] = 1$, induction gives $\mathbb{E}[X_n] = \mu^n$. $\square$

So in expectation the population grows or decays geometrically, with the critical threshold at $\mu = 1$. This suggests – correctly, as we will see – that the fate of the process hinges on whether each individual has more or less than one child on average.

§6.7.2 Generating Functions of Generations

Let $G(z) = \mathbb{E}[z^{X_1}]$ be the pgf of the offspring distribution, and let $G_n(z) = \mathbb{E}[z^{X_n}]$ be the pgf of the n th generation.

Theorem 6.7.3 (Iterating the pgf)

For all $n \geq 0$,

$$G_{n+1}(z) = G_n(G(z)) = \underbrace{G(G(\cdots G(z)\cdots))}_{n+1 \text{ times}}.$$

Proof. Since X_{n+1} is a random sum of X_n independent copies of the offspring distribution, the compounding theorem gives $G_{n+1}(z) = G_n(G(z))$ directly. Unwinding the recursion (with $G_1 = G$) shows G_n is the n -fold iterate of G , and in particular the composition can be taken in either order. $\square$

So the entire distributional structure of the branching process is encoded in iterating a single function – a lovely fact, even if iterates are rarely explicitly computable.

§6.7.3 Extinction

We say the process goes **extinct** if $X_n = 0$ for some n . Let

$$q = \mathbb{P}(\text{extinction}), \quad q_n = \mathbb{P}(X_n = 0).$$

Since $X_n = 0$ forces $X_{n+1} = 0$, the events $\{X_n = 0\}$ are increasing, and their union is the event of extinction. So by continuity of the probability measure (finally paying off!),

$$q_n \longrightarrow q \quad \text{as } n \rightarrow \infty.$$

Moreover, $q_n = \mathbb{P}(X_n = 0) = G_n(0)$, so the extinction probabilities are obtained by iterating G starting from 0:

$$q_{n+1} = G(q_n),$$

and letting $n \rightarrow \infty$, continuity of G on $[0, 1]$ gives the key equation

$$q = G(q).$$

So the extinction probability is a fixed point of the offspring pgf. But G may have several fixed points in $[0, 1]$ (note $G(1) = 1$ always!), so which one is q ? The picture below, showing the iteration $q_{n+1} = G(q_n)$ climbing the ‘staircase’ between the graph of G and the diagonal, should be rather suggestive: starting from $q_0 = 0$, the iterates converge to the *first* crossing of the curve and the diagonal.

**Theorem 6.7.4** (Extinction Probability)

The extinction probability q is the *smallest* non-negative solution of $G(t) = t$. Moreover, if $\mathbb{P}(X_1 = 1) < 1$, then

$$q < 1 \iff \mu > 1,$$

where $\mu = \mathbb{E}[X_1]$.

Proof. First, minimality. Let $t \geq 0$ satisfy $G(t) = t$; we show $q_n \leq t$ for all n by induction, whence $q = \lim q_n \leq t$. Indeed $q_0 = 0 \leq t$, and if $q_n \leq t$ then since G has non-negative power series coefficients it is increasing on $[0, 1]$, so

$$q_{n+1} = G(q_n) \leq G(t) = t.$$

Since q itself solves $G(q) = q$, it must be the smallest such solution.

Now for the criterion. Write $g_r = \mathbb{P}(X_1 = r)$. If $g_0 + g_1 = 1$ (so no individual ever has two or more children) then $\mu \leq 1$; and unless $g_1 = 1$ (excluded), extinction is certain since the single line of descent dies at each step with probability $g_0 > 0$ – consistent with the claim. So suppose $g_0 + g_1 < 1$, which makes

$$G''(z) = \sum_{r \geq 2} r(r-1)g_r z^{r-2} > 0 \quad \text{for } z \in (0, 1),$$

i.e. G is strictly convex on $(0, 1)$. Consider $H(z) = G(z) - z$, which satisfies $H(1) = 0$ and $H(0) = g_0 \geq 0$, and is strictly convex. A strictly convex function can have at most two roots in $[0, 1]$, so besides $z = 1$ there is at most one other root of H .

Suppose $\mu = G'(1^-) > 1$. Then $H'(1^-) = G'(1^-) - 1 > 0$, so $H(z) < 0$ for z slightly less than 1. Since $H(0) \geq 0$ and H is continuous, H has a root $r \in [0, 1)$, and by minimality $q \leq r < 1$. So the process survives with positive probability.

Conversely suppose $\mu \leq 1$. Then for $z \in (0, 1)$, by strict convexity $G'(z) < G'(1^-) = \mu \leq 1$, so $H'(z) = G'(z) - 1 < 0$ on $(0, 1)$: H is strictly decreasing there. Since $H(1) = 0$, we get $H(z) > 0$ for all $z \in [0, 1)$, i.e. there is no fixed point below 1, and hence $q = 1$: extinction is certain. $\square$

This is a genuinely striking result. If $\mu \leq 1$ the population dies out with probability 1 – even in the critical case $\mu = 1$ where the *expected* population size stays constant forever!

And if $\mu > 1$, survival is possible but by no means guaranteed: the survival probability is $1 - q$ where q is the smaller fixed point.

Example 6.7.5

Suppose each individual has 0, 1 or 2 children with probability $\frac{1}{4}, \frac{1}{4}, \frac{1}{2}$ respectively. Then $\mu = \frac{5}{4} > 1$, so we expect $q < 1$. The pgf is $G(z) = \frac{1}{4} + \frac{1}{4}z + \frac{1}{2}z^2$, and solving $G(t) = t$:

$$\frac{1}{2}t^2 - \frac{3}{4}t + \frac{1}{4} = 0 \iff 2t^2 - 3t + 1 = 0 \iff (2t - 1)(t - 1) = 0,$$

so $t = \frac{1}{2}$ or $t = 1$. The extinction probability is the smaller root, $q = \frac{1}{2}$.

§6.8 Continuous Random Variables

So far all of our random variables have taken countably many values. But plenty of natural quantities – waiting times, positions, measurement errors – vary over a continuum, and for these a new framework is needed: no pmf can describe a random variable for which every individual value has probability zero.

§6.8.1 Distribution Functions

The right object to focus on turns out to be the following.

Definition 6.8.1 (Distribution Function)

Let X be a random variable, i.e. a function $X : \Omega \rightarrow \mathbb{R}$ with $\{\omega : X(\omega) \leq x\} \in \mathcal{F}$ for all x^a . The **distribution function** of X is

$$F_X(x) = \mathbb{P}(X \leq x).$$

^aNote this condition is a slight refinement of the one we used for discrete random variables – for those, the two conditions agree.

The distribution function makes sense for *any* random variable, discrete or not, and it completely determines the distribution. Its basic properties are as follows.

Proposition 6.8.2 (Properties of Distribution Functions)

Let $F = F_X$ be a distribution function. Then

- (i) F is non-decreasing,
- (ii) $\mathbb{P}(a < X \leq b) = F(b) - F(a)$ for $a < b$,
- (iii) F is right continuous, and has left limits with $F(x^-) = \mathbb{P}(X < x)$,
- (iv) $F(x) \rightarrow 0$ as $x \rightarrow -\infty$ and $F(x) \rightarrow 1$ as $x \rightarrow \infty$.

Proof. (i) follows since $\{X \leq x\} \subseteq \{X \leq y\}$ for $x \leq y$, and (ii) since $\{X \leq b\}$ is the disjoint union of $\{X \leq a\}$ and $\{a < X \leq b\}$.

For (iii), the events $A_n = \{x < X \leq x + \frac{1}{n}\}$ are decreasing with empty intersection,

so their complements are increasing with union $\Omega \setminus \bigcap_n A_n$, and continuity of $\mathbb{P}$ gives $\mathbb{P}(A_n) \rightarrow 0$; but $\mathbb{P}(A_n) = F(x + \frac{1}{n}) - F(x)$, which together with monotonicity gives right continuity. Similarly, $B_n = \{X \leq x - \frac{1}{n}\}$ is an increasing sequence of events with union $\{X < x\}$, so $F(x - \frac{1}{n}) \rightarrow \mathbb{P}(X < x)$, and monotonicity upgrades this to the full left limit. Part (iv) is another application of continuity of $\mathbb{P}$, with the events $\{X \leq -n\}$ (decreasing to $\emptyset$) and $\{X \leq n\}$ (increasing to Ω). $\square$

For a discrete random variable, F is a step function, jumping by $\mathbb{P}(X = x)$ at each x in the image (shown below on the left). The random variables of interest in this section sit at the other extreme, with no jumps at all (below right).

Definition 6.8.3 (Continuous Random Variable)

A random variable X is **continuous** if its distribution function F is continuous. In this course we work with the (slightly stronger, but much more usable) assumption that F is differentiable^a, and we call

$$f(x) = F'(x)$$

the **probability density function** (or **density**) of X .

^aStrictly, such random variables are called *absolutely continuous*; we will not fuss over the distinction, and ‘continuous random variable’ will always mean this.

Note that for a continuous random variable, $\mathbb{P}(X = x) = F(x) - F(x^-) = 0$ for every single x – and yet X certainly takes *some* value. Individual values are all negligible; only ranges of values carry probability. By the fundamental theorem of calculus,

$$\mathbb{P}(a < X \leq b) = F(b) - F(a) = \int_a^b f(x) \, dx,$$

and more generally $\mathbb{P}(X \in S) = \int_S f(x) \, dx$ for reasonable sets S . So the density is exactly what its name suggests: probability per unit length. For a small interval,

$$\mathbb{P}(x < X \leq x + \delta) \approx f(x) \delta,$$

which is the right intuition to have – $f(x)$ is the continuous analogue of $\mathbb{P}(X = x)$, but it is not itself a probability (indeed, densities can exceed 1!). Any density satisfies $f \geq 0$ and $\int_{-\infty}^{\infty} f(x) \, dx = 1$, and conversely any such function defines a distribution.

§6.8.2 Expectation and Variance

The definition of expectation transfers from the discrete world by replacing sums with integrals (and pmfs with densities).

Definition 6.8.4 (Expectation)

Let X be a continuous random variable with density f . If $X \geq 0$, we define

$$\mathbb{E}[X] = \int_0^\infty x f(x) \, dx,$$

which is either finite or $+\infty$. In general, writing $X = X^+ - X^-$ with $X^+ = \max(X, 0)$ and $X^- = \max(-X, 0)$, we set $\mathbb{E}[X] = \mathbb{E}[X^+] - \mathbb{E}[X^-] = \int_{-\infty}^\infty x f(x) \, dx$, provided at least one of the two parts is finite.

The expectation retains all of its old properties: it is linear, monotone, and satisfies the law of the subconscious statistician

$$\mathbb{E}[g(X)] = \int_{-\infty}^\infty g(x) f(x) \, dx,$$

along with the same definitions and identities for variance and covariance as before, e.g. $\text{Var}(X) = \mathbb{E}[X^2] - \mathbb{E}[X]^2$. The tail-sum formula also survives, now in integral form.

Proposition 6.8.5 (Tail Formula)

If $X \geq 0$ is a continuous random variable, then

$$\mathbb{E}[X] = \int_0^\infty \mathbb{P}(X \geq x) \, dx.$$

Proof. We write $x = \int_0^x dy$ inside the definition and swap the order of integration^a:

$$\mathbb{E}[X] = \int_0^\infty \int_0^x dy f(x) \, dx = \int_0^\infty \int_y^\infty f(x) \, dx \, dy = \int_0^\infty \mathbb{P}(X \geq y) \, dy. \quad \square$$

^aJustified since the integrand is non-negative (this is Fubini's theorem, or can be checked directly here).

Likewise, our inequalities (Markov, Chebyshev, Cauchy-Schwarz, Jensen) were proved using only properties of expectation, so they hold verbatim for continuous random variables.

§6.8.3 The Uniform and Exponential Distributions

Let's meet the continuous analogues of the 'standard' discrete distributions.

The Uniform Distribution

The **uniform distribution** on $[a, b]$, written $X \sim U[a, b]$, models a point chosen 'completely at random' from the interval:

$$f(x) = \begin{cases} \frac{1}{b-a} & x \in [a, b], \\ 0 & \text{otherwise,} \end{cases} \quad F(x) = \frac{x-a}{b-a} \text{ for } x \in [a, b].$$

The density (left) and distribution function (right) look as follows.

A quick integration gives $\mathbb{E}[X] = \frac{a+b}{2}$ (no surprises), and computing $\mathbb{E}[X^2] = \frac{a^2+ab+b^2}{3}$ leads to $\text{Var}(X) = \frac{(b-a)^2}{12}$.

The Exponential Distribution

The **exponential distribution** with rate $\lambda > 0$, written $X \sim \text{Exp}(\lambda)$, has

$$f(x) = \lambda e^{-\lambda x} \quad (x > 0), \quad F(x) = 1 - e^{-\lambda x}.$$

It is the continuous model of a waiting time for an event occurring ‘at rate λ ’. The density decays exponentially (left), and the distribution function climbs towards 1 (right); here $\lambda = 1$.

Integrating by parts (or by the tail formula, $\int_0^\infty e^{-\lambda x} dx$) gives

$$\mathbb{E}[X] = \frac{1}{\lambda}, \quad \text{Var}(X) = \frac{1}{\lambda^2}.$$

The exponential distribution should be thought of as a continuous limit of the geometric distribution: if $T \sim \text{Exp}(\lambda)$ then $\lfloor nT \rfloor$ satisfies

$$\mathbb{P}(\lfloor nT \rfloor \geq k) = \mathbb{P}(T \geq k/n) = (e^{-\lambda/n})^k,$$

which is a geometric tail with success probability $1 - e^{-\lambda/n} \approx \lambda/n$ – checking a coin with tiny success chance many times a second.

The property that really characterises the exponential distribution is that it is *memoryless*: knowing you have already waited s minutes tells you nothing about how much longer you’ll wait.

Theorem 6.8.6 (Memorylessness)

Let T be a positive continuous random variable, not identically 0 or ∞ . Then

$$\mathbb{P}(T > t + s \mid T > s) = \mathbb{P}(T > t) \text{ for all } s, t \geq 0$$

if and only if $T \sim \text{Exp}(\lambda)$ for some $\lambda > 0$.

Proof. If $T \sim \text{Exp}(\lambda)$, then

$$\mathbb{P}(T > t + s \mid T > s) = \frac{\mathbb{P}(T > t + s)}{\mathbb{P}(T > s)} = \frac{e^{-\lambda(t+s)}}{e^{-\lambda s}} = e^{-\lambda t} = \mathbb{P}(T > t).$$

Conversely, suppose T is memoryless, and let $g(t) = \mathbb{P}(T > t)$, so that g satisfies the functional equation $g(t + s) = g(t)g(s)$. Then for positive integers m, n ,

$$g(m) = g(1)^m, \quad g(m/n)^n = g(m) \implies g(m/n) = g(1)^{m/n},$$

so $g(q) = g(1)^q$ for all rationals $q > 0$. Now $g(1) \in (0, 1)$: if $g(1) = 0$ then $g(q) = 0$ for all rational $q > 0$ and $T = 0$ almost surely; if $g(1) = 1$ then similarly $T = \infty$ almost surely – both excluded. So we may define $\lambda = -\log g(1) > 0$, giving

$g(q) = e^{-\lambda q}$ on the rationals. Finally, g is decreasing, so for real t , squeezing t between rationals $r \leq t \leq s$ with $s - r$ small gives $e^{-\lambda s} \leq g(t) \leq e^{-\lambda r}$, and hence $g(t) = e^{-\lambda t}$ everywhere. $\square$

§6.8.4 The Normal Distribution

We now come to the most important distribution in all of probability – the reason for its ubiquity being the central limit theorem, which we will meet in due course.

Definition 6.8.7 (Normal Distribution)

The **normal** (or **Gaussian**) **distribution** with mean $\mu \in \mathbb{R}$ and variance $\sigma^2 > 0$, written $N(\mu, \sigma^2)$, has density

$$f(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right), \quad x \in \mathbb{R}.$$

The case $N(0, 1)$ is called the **standard normal distribution**, and its distribution function is denoted Φ , with density $\phi(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2}$.

The density is the famous ‘bell curve’, symmetric about μ , with the standard deviation σ setting the width of the bell ($\mu \pm \sigma$ are precisely its points of inflection):

We should first check that this is actually a density – the source of the mysterious $\sqrt{2\pi}$.

Proposition 6.8.8

$$\int_{-\infty}^{\infty} \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right) dx = 1.$$

Proof. Substituting $u = (x - \mu)/\sigma$ reduces to showing $I = \int_{-\infty}^{\infty} e^{-u^2/2} du = \sqrt{2\pi}$. We use the famous squaring trick: writing I^2 as a double integral and changing to polar coordinates $(u, v) = (r \cos \theta, r \sin \theta)$,

$$I^2 = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{-(u^2+v^2)/2} du dv = \int_0^{2\pi} \int_0^{\infty} e^{-r^2/2} r dr d\theta = 2\pi \left[-e^{-r^2/2}\right]_0^{\infty} = 2\pi,$$

and since $I > 0$ we get $I = \sqrt{2\pi}$. $\square$

The parameters deserve their names: if $X \sim N(\mu, \sigma^2)$ then

$$\mathbb{E}[X] = \int_{-\infty}^{\infty} \frac{x-\mu}{\sqrt{2\pi\sigma^2}} e^{-(x-\mu)^2/2\sigma^2} dx + \mu = 0 + \mu = \mu,$$

the first integral vanishing since the integrand is odd about μ ; and substituting $u =$

$(x - \mu)/\sigma$ and integrating by parts,

$$\text{Var}(X) = \sigma^2 \int_{-\infty}^{\infty} \frac{u^2}{\sqrt{2\pi}} e^{-u^2/2} du = \sigma^2.$$

Also note the symmetry $\phi(x) = \phi(-x)$, which gives the frequently-used relation $\Phi(-x) = 1 - \Phi(x)$.

§6.8.5 Transformations of Random Variables

Given a random variable X with known density and a function g , what is the density of $g(X)$? For monotone g there is a clean answer, and the proof is simply ‘differentiate the distribution function’.

Theorem 6.8.9 (Densities Under Monotone Maps)

Let X be a continuous random variable with density f , and let g be strictly monotone with differentiable inverse. Then $Y = g(X)$ is a continuous random variable with density

$$f_Y(y) = f(g^{-1}(y)) \left| \frac{d}{dy} g^{-1}(y) \right|.$$

Proof. Suppose first that g is strictly increasing. Then $g(X) \leq y \iff X \leq g^{-1}(y)$, so

$$F_Y(y) = \mathbb{P}(g(X) \leq y) = F(g^{-1}(y)),$$

and differentiating with the chain rule gives $f_Y(y) = f(g^{-1}(y)) \cdot (g^{-1})'(y)$, where the derivative is positive. If instead g is strictly decreasing, then $g(X) \leq y \iff X \geq g^{-1}(y)$, so $F_Y(y) = 1 - F(g^{-1}(y))$, and differentiating gives $f_Y(y) = f(g^{-1}(y)) \cdot (-(g^{-1})'(y))$, where now $-(g^{-1})' = |(g^{-1})'|$. Both cases match the claimed formula. $\square$

Rather than memorising this, it is usually safer to redo the two-line calculation with distribution functions – but the formula gives an important structural fact about the normal family.

Corollary 6.8.10 (Linear Maps of Normals)

If $X \sim N(\mu, \sigma^2)$ and $a \neq 0, b \in \mathbb{R}$, then

$$aX + b \sim N(a\mu + b, a^2\sigma^2).$$

In particular, $(X - \mu)/\sigma \sim N(0, 1)$.

Proof. Applying the theorem with $g(x) = ax + b$, so $g^{-1}(y) = (y - b)/a$,

$$f_Y(y) = \frac{1}{\sqrt{2\pi}\sigma^2} \exp\left(-\frac{(\frac{y-b}{a} - \mu)^2}{2\sigma^2}\right) \cdot \frac{1}{|a|} = \frac{1}{\sqrt{2\pi}a^2\sigma^2} \exp\left(-\frac{(y - (a\mu + b))^2}{2a^2\sigma^2}\right),$$

which is the $N(a\mu + b, a^2\sigma^2)$ density. $\square$

The process of passing from X to $(X - \mu)/\sigma$ is called *standardisation*, and is how one

uses tables of Φ in practice: every question about a normal random variable reduces to one about the standard normal.

§6.9 Joint Densities

Just as in the discrete setting, the interesting questions about continuous random variables involve several of them at once, and for this we need joint densities.

§6.9.1 Joint Densities and Independence

Just as in the discrete setting, understanding several continuous random variables at once means studying their joint behaviour.

Definition 6.9.1 (Joint Density)

Random variables $X_1, \dots, X_n$ have **joint density** $f : \mathbb{R}^n \rightarrow [0, \infty)$ if

$$\mathbb{P}(X_1 \leq x_1, \dots, X_n \leq x_n) = \int_{-\infty}^{x_1} \cdots \int_{-\infty}^{x_n} f(y_1, \dots, y_n) \, dy_1 \cdots dy_n$$

for all $x_1, \dots, x_n \in \mathbb{R}$.

As before, this extends to $\mathbb{P}((X_1, \dots, X_n) \in B) = \int_B f$ for reasonable sets $B \subseteq \mathbb{R}^n$, and the density can be recovered by (partial) differentiation of the joint distribution function. The density of a single coordinate, called its **marginal density**, is obtained by integrating out the others:

$$f_{X_1}(x_1) = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} f(x_1, y_2, \dots, y_n) \, dy_2 \cdots dy_n.$$

For independence, we can no longer compare with products of point probabilities (they're all zero!), so we phrase everything in terms of distribution functions: $X_1, \dots, X_n$ are **independent** if

$$\mathbb{P}(X_1 \leq x_1, \dots, X_n \leq x_n) = \mathbb{P}(X_1 \leq x_1) \cdots \mathbb{P}(X_n \leq x_n) \quad \text{for all } x_i.$$

The key practical criterion is that independence corresponds exactly to the joint density factorising.

Theorem 6.9.2 (Factorisation Criterion)

Suppose $(X_1, \dots, X_n)$ has joint density f .

- (i) If $X_1, \dots, X_n$ are independent with marginal densities $f_1, \dots, f_n$, then

$$f(x_1, \dots, x_n) = f_1(x_1) \cdots f_n(x_n).$$

- (ii) Conversely, if $f(x_1, \dots, x_n) = g_1(x_1) \cdots g_n(x_n)$ for some non-negative functions g_i , then the X_i are independent, with densities proportional to the g_i .

Proof. For (i), independence lets us factor the joint distribution function into $\prod_i \int_{-\infty}^{x_i} f_i$, which is precisely the statement that $\prod_i f_i$ serves as a joint density.

For (ii), let $c_i = \int_{-\infty}^{\infty} g_i(y) dy$. Since f integrates to 1 over $\mathbb{R}^n$, we get $c_1 c_2 \cdots c_n = 1$. Now integrating out all variables except the i th shows the marginal density of X_i is $g_i \cdot \prod_{j \neq i} c_j = g_i/c_i$. Then

$$\mathbb{P}(X_1 \leq x_1, \dots, X_n \leq x_n) = \prod_i \int_{-\infty}^{x_i} g_i(y_i) dy_i = \prod_i \int_{-\infty}^{x_i} \frac{g_i(y_i)}{c_i} dy_i = \prod_i \mathbb{P}(X_i \leq x_i),$$

using $\prod_i c_i = 1$, so the X_i are independent with the claimed densities. $\square$

§6.9.2 Sums of Continuous Random Variables

The distribution of a sum of independent continuous random variables is again given by a convolution, with the sum over values replaced by an integral.

Proposition 6.9.3 (Convolution)

Let X and Y be independent with densities f_X and f_Y . Then $X + Y$ has density

$$f_{X+Y}(z) = \int_{-\infty}^{\infty} f_X(x) f_Y(z - x) dx.$$

Proof. We compute the distribution function of the sum by integrating the joint density $f_X(x)f_Y(y)$ over the half plane $\{x + y \leq z\}$:

$$\mathbb{P}(X+Y \leq z) = \int_{-\infty}^{\infty} \int_{-\infty}^{z-x} f_X(x) f_Y(y) dy dx = \int_{-\infty}^z \left(\int_{-\infty}^{\infty} f_X(x) f_Y(u - x) dx \right) du,$$

substituting $u = y + x$ in the inner integral and then swapping the order of integration. The result is the integral up to z of the claimed density, which proves the claim. $\square$

§6.9.3 Conditional Densities

Conditioning on the value of a continuous random variable looks dangerous – the conditioning event $\{Y = y\}$ has probability zero – but at the level of densities everything goes through smoothly.

Definition 6.9.4 (Conditional Density)

Let X, Y have joint density $f_{X,Y}$, and let y be such that $f_Y(y) > 0$. The **conditional density of X given $Y = y$** is

$$f_{X|Y}(x | y) = \frac{f_{X,Y}(x, y)}{f_Y(y)}.$$

This is the exact analogue of $\mathbb{P}(X = x | Y = y)$, and one can justify it by conditioning on the event $\{y < Y \leq y + \delta\}$ and letting $\delta \rightarrow 0$. Integrating out the conditioning value

gives the continuous law of total probability,

$$f_X(x) = \int_{-\infty}^{\infty} f_{X|Y}(x | y) f_Y(y) \, dy,$$

and we can define conditional expectation just as before: $\mathbb{E}[X | Y] = g(Y)$ where

$$g(y) = \int_{-\infty}^{\infty} x f_{X|Y}(x | y) \, dx.$$

All the properties from the discrete case (linearity, the tower property, taking out what is known) continue to hold.

§6.9.4 Transformations in Higher Dimensions

The change of variables formula for densities generalises to $\mathbb{R}^d$, with the derivative replaced by a Jacobian determinant – exactly mirroring the change of variables formula for multiple integrals.

Theorem 6.9.5 (Multidimensional Change of Variables)

Let X be a random variable with values in $D \subseteq \mathbb{R}^d$ and density f_X , and let $g : D \rightarrow g(D)$ be a bijection with continuous derivative and $\det g'(x) \neq 0$ on D . Then $Y = g(X)$ has density

$$f_Y(y) = f_X(g^{-1}(y)) |J|, \quad \text{where } J = \det \left(\frac{\partial x_i}{\partial y_j} \right)_{i,j}$$

is the Jacobian of the inverse map $x = g^{-1}(y)$.

We won't prove this (it is essentially the substitution rule for multiple integrals, which we take on trust from Vector Calculus), but let's see it in action on a genuinely useful example.

Example 6.9.6 (Polar Coordinates of a Gaussian Pair)

Let X, Y be independent standard normals, and let (R, Θ) be the polar coordinates of the point (X, Y) , so $X = R \cos \Theta$ and $Y = R \sin \Theta$. The Jacobian of the map $(r, \theta) \mapsto (r \cos \theta, r \sin \theta)$ is

$$J = \det \begin{pmatrix} \cos \theta & -r \sin \theta \\ \sin \theta & r \cos \theta \end{pmatrix} = r,$$

which is geometrically just the statement that a small 'polar rectangle' with sides dr and $r \, d\theta$ has area $r \, dr \, d\theta$:

So for $r > 0$ and $\theta \in [0, 2\pi)$,

$$f_{R,\Theta}(r, \theta) = f_{X,Y}(r \cos \theta, r \sin \theta) \cdot r = \frac{1}{2\pi} r e^{-r^2/2} = \underbrace{\frac{1}{2\pi}}_{f_{\Theta}(\theta)} \cdot \underbrace{r e^{-r^2/2}}_{f_R(r)}.$$

The joint density factorises, so by the factorisation criterion R and Θ are *independent*, with $\Theta \sim U[0, 2\pi)$ and R having density $r e^{-r^2/2}$. (Run backwards, this observation is a practical recipe for generating normal random variables – the ‘Box-Muller’ method – which we will return to at the end of these notes.)

§6.9.5 Order Statistics

Given independent identically distributed random variables $X_1, \dots, X_n$, we often care about their sorted values – the smallest, the largest, the median. Sorting them into increasing order gives the **order statistics**

$$Y_1 = X_{(1)} \leq Y_2 = X_{(2)} \leq \dots \leq Y_n = X_{(n)}.$$

For instance, with $n = 5$ the picture might be as follows – the samples X_i land in some scattered order on the line, and the order statistics simply relabel them from left to right.

Suppose the X_i have distribution function F and density f . The extremes are easy to handle directly:

$$\begin{aligned} \mathbb{P}(Y_n \leq x) &= \mathbb{P}(X_1 \leq x, \dots, X_n \leq x) = F(x)^n, \\ \mathbb{P}(Y_1 \leq x) &= 1 - \mathbb{P}(X_1 > x, \dots, X_n > x) = 1 - (1 - F(x))^n, \end{aligned}$$

using independence, and differentiating gives their densities

$$f_{Y_n}(x) = nF(x)^{n-1}f(x), \quad f_{Y_1}(x) = n(1 - F(x))^{n-1}f(x).$$

For the full joint behaviour, we have the following.

Proposition 6.9.7 (Joint Density of Order Statistics)

The order statistics $(Y_1, \dots, Y_n)$ have joint density

$$f_{Y_1, \dots, Y_n}(x_1, \dots, x_n) = \begin{cases} n! f(x_1) \cdots f(x_n) & \text{if } x_1 < x_2 < \dots < x_n, \\ 0 & \text{otherwise.} \end{cases}$$

Proof. For $x_1 < \dots < x_n$, the event $\{Y_1 \leq x_1, \dots, Y_n \leq x_n\}$ splits according to which of the X_i lands in which position of the ordering; since the X_i are independent and identically distributed (and ties have probability zero), each of the $n!$ orderings contributes equally, and so

$$\mathbb{P}(Y_1 \leq x_1, \dots, Y_n \leq x_n) = n! \mathbb{P}(X_1 \leq x_1, \dots, X_n \leq x_n, X_1 < X_2 < \dots < X_n).$$

Writing the right hand side as an integral of $f(u_1) \cdots f(u_n)$ over the region $\{u_1 \leq$

$x_1, \dots, u_n \leq x_n, u_1 < \dots < u_n\}$ and differentiating in each variable gives the claimed density. $\square$

Note the factor $n!$ and the ordering constraint: the joint density does *not* factorise, so the order statistics are certainly not independent (knowing the minimum is large forces the maximum to be larger still). For the exponential distribution, though, something special happens with the *gaps*.

Example 6.9.8 (Exponential Spacings)

Let $X_1, \dots, X_n$ be independent $\text{Exp}(\lambda)$, with order statistics $Y_1 \leq \dots \leq Y_n$, and consider the spacings $Z_1 = Y_1$ and $Z_i = Y_i - Y_{i-1}$ for $i \geq 2$. The map from $(y_1, \dots, y_n)$ to $(z_1, \dots, z_n)$ is linear with determinant 1, and $y_i = z_1 + \dots + z_i$, so

$$\begin{aligned} f_{Z_1, \dots, Z_n}(z_1, \dots, z_n) &= n! \lambda^n e^{-\lambda(y_1 + \dots + y_n)} = n! \lambda^n e^{-\lambda(nz_1 + (n-1)z_2 + \dots + z_n)} \\ &= \prod_{i=1}^n (n-i+1) \lambda e^{-(n-i+1)\lambda z_i}. \end{aligned}$$

The joint density factorises! So the spacings are independent, with $Z_i \sim \text{Exp}((n-i+1)\lambda)$. This is really memorylessness at work: when $i-1$ of the clocks have rung, the remaining $n-i+1$ have (conditionally) fresh exponential lifetimes, and the minimum of k independent $\text{Exp}(\lambda)$ variables is $\text{Exp}(k\lambda)$ – a fact worth checking directly:

$$\mathbb{P}(\min(X_1, \dots, X_k) > z) = \prod_{i=1}^k \mathbb{P}(X_i > z) = e^{-k\lambda z}.$$

§6.10 Moment Generating Functions

Probability generating functions served us wonderfully for random variables with values in $\{0, 1, 2, \dots\}$, but they make no sense for continuous random variables. The right generalisation is to replace z^X with $e^{\theta X}$.

Definition 6.10.1 (Moment Generating Function)

The **moment generating function** (or **mgf**) of a random variable X is

$$m(\theta) = \mathbb{E} \left[e^{\theta X} \right],$$

defined for those $\theta \in \mathbb{R}$ where the expectation is finite. For a continuous random variable with density f , this is $\int_{-\infty}^{\infty} e^{\theta x} f(x) dx$.

Note $m(0) = 1$ always, but the mgf may well be infinite for every other θ , in which case it's useless. The good situation is when m is finite on an open interval around 0; then the mgf shares the two crucial properties of the pgf. The first we must take on trust (its proof needs tools beyond this course).

Theorem 6.10.2 (Uniqueness)

If the moment generating function of X is finite on some open interval containing

0, then it uniquely determines the distribution of X .

Theorem 6.10.3 (Moments From the mgf)

If m is finite on an open interval around 0, then for each $r \geq 0$,

$$m^{(r)}(0) = \mathbb{E}[X^r].$$

The idea behind the second result is simply to expand $e^{\theta X} = \sum_k \theta^k X^k / k!$ and differentiate term by term (the finiteness assumption is what justifies the exchanges of limits) – so the mgf is precisely the exponential generating function of the moments, whence the name. And as with pgfs, independence turns sums into products:

Theorem 6.10.4 (mgfs of Sums)

If $X_1, \dots, X_n$ are independent, then

$$\mathbb{E} \left[e^{\theta(X_1 + \dots + X_n)} \right] = \prod_{i=1}^n \mathbb{E} \left[e^{\theta X_i} \right].$$

Proof. The random variables $e^{\theta X_i}$ are independent, so the expectation of their product factorises. $\square$

§6.10.1 Examples: Gamma, Normal, and a Warning

Let's put moment generating functions to work on some concrete distributions.

Example 6.10.5 (The Gamma Distribution)

The **gamma distribution** $\Gamma(n, \lambda)$, for $n \in \mathbb{N}$ and $\lambda > 0$, has density

$$f(x) = e^{-\lambda x} \frac{\lambda^n x^{n-1}}{(n-1)!}, \quad x > 0.$$

(One checks this integrates to 1 by repeated integration by parts, reducing to the exponential case $n = 1$: indeed $\Gamma(1, \lambda) = \text{Exp}(\lambda)$.) For $\theta < \lambda$, the mgf is

$$\begin{aligned} m(\theta) &= \int_0^\infty e^{\theta x} e^{-\lambda x} \frac{\lambda^n x^{n-1}}{(n-1)!} dx = \left(\frac{\lambda}{\lambda - \theta} \right)^n \int_0^\infty e^{-(\lambda - \theta)x} \frac{(\lambda - \theta)^n x^{n-1}}{(n-1)!} dx \\ &= \left(\frac{\lambda}{\lambda - \theta} \right)^n, \end{aligned}$$

since the final integrand is the $\Gamma(n, \lambda - \theta)$ density. (For $\theta \geq \lambda$ the integral diverges, but finiteness on $(-\infty, \lambda)$ is plenty.) Multiplying mgfs, we conclude that if $X \sim \Gamma(n, \lambda)$ and $Y \sim \Gamma(m, \lambda)$ are independent then $X + Y \sim \Gamma(n + m, \lambda)$; in particular, a sum of n independent $\text{Exp}(\lambda)$ waiting times has the $\Gamma(n, \lambda)$ distribution.

Example 6.10.6 (The Normal Distribution)

Let $X \sim N(\mu, \sigma^2)$. Completing the square in the exponent,

$$\theta x - \frac{(x - \mu)^2}{2\sigma^2} = \theta\mu + \frac{\theta^2\sigma^2}{2} - \frac{(x - (\mu + \theta\sigma^2))^2}{2\sigma^2},$$

so

$$m(\theta) = \exp\left(\theta\mu + \frac{\theta^2\sigma^2}{2}\right) \int_{-\infty}^{\infty} \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x - (\mu + \theta\sigma^2))^2}{2\sigma^2}\right) dx = e^{\theta\mu + \theta^2\sigma^2/2},$$

the integral being that of the $N(\mu + \theta\sigma^2, \sigma^2)$ density. This mgf is finite for *all* θ – the normal distribution has very thin tails. As an immediate payoff, if $X \sim N(\mu, \sigma^2)$ and $Y \sim N(\nu, \tau^2)$ are independent then

$$\mathbb{E}[e^{\theta(X+Y)}] = e^{\theta\mu + \theta^2\sigma^2/2} e^{\theta\nu + \theta^2\tau^2/2} = e^{\theta(\mu+\nu) + \theta^2(\sigma^2+\tau^2)/2},$$

so $X + Y \sim N(\mu + \nu, \sigma^2 + \tau^2)$: sums of independent normals are normal.

Example 6.10.7 (The Cauchy Distribution – A Warning)

The **Cauchy distribution** has density

$$f(x) = \frac{1}{\pi(1+x^2)}, \quad x \in \mathbb{R}.$$

Its tails decay so slowly that $\mathbb{E}[e^{\theta X}] = \infty$ for every $\theta \neq 0$ – indeed even $\mathbb{E}[X]$ fails to exist. So mgfs tell us nothing here: X and $2X$ have identical mgfs but different distributions. The moral is that all the mgf machinery genuinely requires finiteness on an open interval.

§6.11 The Central Limit Theorem

We have arrived at the crown jewel of the course. The weak law of large numbers says the sample mean S_n/n concentrates around μ ; the central limit theorem describes, with remarkable precision, the *shape* of the fluctuations around μ – and the answer is universal: whatever distribution you start with, the fluctuations look normal.

First, we need to say what it means for distributions to converge.

Definition 6.11.1 (Convergence in Distribution)

Random variables X_n **converge in distribution** to X , written $X_n \rightarrow X$ in distribution, if

$$F_{X_n}(x) \longrightarrow F_X(x) \quad \text{as } n \rightarrow \infty$$

for every $x \in \mathbb{R}$ at which F_X is continuous.

(The restriction to continuity points is a technicality that avoids silly counterexamples with point masses; for a continuous limit like the normal distribution, it is no restriction at all.) The bridge between mgfs and convergence in distribution is the following theorem, which we state without proof.

Theorem 6.11.2 (Continuity Theorem)

Let X have mgf m , finite on an open interval around 0, and let X_n have mgfs m_n . If $m_n(\theta) \rightarrow m(\theta)$ for all θ , then $X_n \rightarrow X$ in distribution.

With this in hand, the central limit theorem is within reach.

Theorem 6.11.3 (Central Limit Theorem)

Let $X_1, X_2, \dots$ be independent identically distributed random variables with mean μ and variance $\sigma^2 \in (0, \infty)$, and let $S_n = X_1 + \dots + X_n$. Then for every $x \in \mathbb{R}$,

$$\mathbb{P}\left(\frac{S_n - n\mu}{\sigma\sqrt{n}} \leq x\right) \rightarrow \Phi(x) = \int_{-\infty}^x \frac{1}{\sqrt{2\pi}} e^{-y^2/2} dy \quad \text{as } n \rightarrow \infty.$$

That is, $(S_n - n\mu)/\sigma\sqrt{n} \rightarrow N(0, 1)$ in distribution.

Note the choice of scaling: $S_n - n\mu$ has variance $n\sigma^2$, so dividing by $\sigma\sqrt{n}$ is exactly what's needed to stabilise the fluctuations at unit size. Informally, the theorem says

$$S_n \approx n\mu + \sigma\sqrt{n}Z, \quad Z \sim N(0, 1),$$

for large n : the sum is its mean, plus a normal fluctuation of order $\sqrt{n}$.

Proof (assuming an mgf exists). We give the proof under the additional assumption that the mgf of X_1 is finite on an open interval around 0 – this is how the result is proved in this course, and covers all the standard distributions; the general case requires characteristic functions.

By replacing X_i with $(X_i - \mu)/\sigma$, we may assume $\mu = 0$ and $\sigma = 1$, and must show $S_n/\sqrt{n} \rightarrow N(0, 1)$ in distribution. Let $m(\theta) = \mathbb{E}[e^{\theta X_1}]$. By independence,

$$\mathbb{E}\left[e^{\theta S_n/\sqrt{n}}\right] = \prod_{i=1}^n \mathbb{E}\left[e^{(\theta/\sqrt{n})X_i}\right] = m\left(\frac{\theta}{\sqrt{n}}\right)^n,$$

so by the continuity theorem it suffices to show that for each fixed θ ,

$$m\left(\frac{\theta}{\sqrt{n}}\right)^n \rightarrow e^{\theta^2/2} = \mathbb{E}[e^{\theta Z}].$$

Since m is finite near 0, it has derivatives of all orders at 0 given by the moments, and Taylor's theorem gives, as $t \rightarrow 0$,

$$m(t) = 1 + t \mathbb{E}[X_1] + \frac{t^2}{2} \mathbb{E}[X_1^2] + o(t^2) = 1 + \frac{t^2}{2} + o(t^2),$$

using $\mathbb{E}[X_1] = 0$ and $\mathbb{E}[X_1^2] = \text{Var}(X_1) = 1$. Applying this with $t = \theta/\sqrt{n}$,

$$m\left(\frac{\theta}{\sqrt{n}}\right)^n = \left(1 + \frac{\theta^2}{2n} + o\left(\frac{1}{n}\right)\right)^n,$$

and taking logarithms, $n \log\left(1 + \frac{\theta^2}{2n} + o\left(\frac{1}{n}\right)\right) = \frac{\theta^2}{2} + o(1) \rightarrow \frac{\theta^2}{2}$, using $\log(1+u) = u + o(u)$. So $m(\theta/\sqrt{n})^n \rightarrow e^{\theta^2/2}$, completing the proof. $\square$

The really remarkable feature is *universality*: the limit doesn't remember anything about the distribution of the X_i except its mean and variance. This is why the normal distribution is everywhere – any quantity that is a sum of many small independent contributions (measurement errors, say, or heights in a population) should be approximately normally distributed.

§6.11.1 Applications

The real value of the central limit theorem is as an approximation tool, so let's see it in action.

Example 6.11.4 (Normal Approximation to the Binomial)

If $S_n \sim \text{Bin}(n, p)$, then S_n is a sum of n independent Bernoulli variables, so by the CLT

$$\frac{S_n - np}{\sqrt{np(1-p)}} \approx N(0, 1), \quad \text{i.e.} \quad S_n \approx N(np, np(1-p))$$

for large n . The picture below shows the pmf of $\text{Bin}(16, \frac{1}{2})$ with the approximating $N(8, 4)$ density drawn over it – the fit is already rather good.

Note the contrast with the Poisson approximation: there we let $p = \lambda/n$ shrink as n grew (so the CLT does not apply – the summands change with n), whereas here p is fixed. The rough rule: rare events give Poisson, common events give normal. Similarly, $\text{Poisson}(n)$ is a sum of n independent $\text{Poisson}(1)$ variables, so $\text{Poisson}(n) \approx N(n, n)$ for large n .

Example 6.11.5 (Opinion Polling)

Suppose each member of a large population independently supports a proposition with unknown probability p , and we poll N random individuals, estimating p by $\hat{p}_N = S_N/N$ where $S_N \sim \text{Bin}(N, p)$. How large must N be so that $|\hat{p}_N - p| \leq 0.04$ with probability at least 0.99?

By the CLT, $\hat{p}_N \approx p + \sqrt{p(1-p)/N} Z$ with $Z \sim N(0, 1)$, so we need

$$\mathbb{P} \left(\sqrt{\frac{p(1-p)}{N}} |Z| \leq 0.04 \right) \geq 0.99.$$

From tables, $\mathbb{P}(|Z| \leq 2.58) = 0.99$, so we require $0.04\sqrt{N/p(1-p)} \geq 2.58$. The

worst case is $p = \frac{1}{2}$ (maximising $p(1-p) = \frac{1}{4}$), giving

$$N \geq \frac{2.58^2}{4 \times 0.04^2} \approx 1040.$$

Only about a thousand people – regardless of the size of the population! The $1/\sqrt{N}$ decay of sampling error is entirely responsible for the feasibility of opinion polling.

§6.12 The Multivariate Normal Distribution

Given how central the normal distribution is, we should understand its multidimensional version – both because it arises in its own right (via a multidimensional CLT), and because it has some genuinely special structure not shared by other distributions.

In this section vectors are columns, and we write $u^\top$ for the transpose.

§6.12.1 Gaussian Vectors

We begin by pinning down exactly what it means for a whole vector of random variables to be normally distributed.

Definition 6.12.1 (Gaussian Vector)

A random vector $X = (X_1, \dots, X_n)^\top$ is a **Gaussian vector** (or **multivariate normal**) if for every $u \in \mathbb{R}^n$, the scalar random variable

$$u^\top X = u_1 X_1 + \dots + u_n X_n$$

is normally distributed (where we allow degenerate ‘normals’ of zero variance, i.e. constants).

Note this asks for far more than each X_i being normal individually – *every* linear combination must be normal. An immediate consequence of the definition is stability under affine maps: if X is Gaussian in $\mathbb{R}^n$, A is an $m \times n$ matrix and $b \in \mathbb{R}^m$, then $AX + b$ is Gaussian in $\mathbb{R}^m$, since $u^\top (AX + b) = (A^\top u)^\top X + u^\top b$ is a normal random variable plus a constant.

The distribution of a Gaussian vector turns out to be pinned down by two pieces of data: the **mean vector** and **covariance matrix**

$$\mu = \mathbb{E}[X] = (\mathbb{E}[X_1], \dots, \mathbb{E}[X_n])^\top, \quad V = \mathbb{E}[(X - \mu)(X - \mu)^\top],$$

so that $V_{ij} = \text{Cov}(X_i, X_j)$. The matrix V is symmetric, and for any $u \in \mathbb{R}^n$, bilinearity of covariance gives

$$\mathbb{E}[u^\top X] = u^\top \mu, \quad \text{Var}(u^\top X) = \sum_{i,j} u_i u_j \text{Cov}(X_i, X_j) = u^\top V u.$$

In particular $u^\top V u = \text{Var}(u^\top X) \geq 0$, so V is non-negative definite, and

$$u^\top X \sim N(u^\top \mu, u^\top V u).$$

This last observation computes the mgf of X for free: taking the definition $m(\lambda) = \mathbb{E}[e^{\lambda^\top X}]$ for $\lambda \in \mathbb{R}^n$, the exponent $\lambda^\top X$ is $N(\lambda^\top \mu, \lambda^\top V \lambda)$, so evaluating the one-dimensional normal mgf at $\theta = 1$,

$$m(\lambda) = \exp\left(\lambda^\top \mu + \frac{\lambda^\top V \lambda}{2}\right).$$

By uniqueness of mgfs, we conclude that a Gaussian vector is completely determined by (μ, V) , and we write $X \sim N(\mu, V)$.

§6.12.2 Construction and Density

Do Gaussian vectors with arbitrary prescribed μ and (non-negative definite) V actually exist? Yes – and the construction is a direct generalisation of writing $X = \mu + \sigma Z$ in one dimension.

Start with $Z = (Z_1, \dots, Z_n)^\top$ where the Z_i are independent standard normals. Then Z is a Gaussian vector: for any u , the mgf of $u^\top Z$ factorises over the independent coordinates as

$$\mathbb{E}[e^{\theta u^\top Z}] = \prod_{i=1}^n e^{\theta^2 u_i^2 / 2} = e^{\theta^2 |u|^2 / 2},$$

which is the mgf of $N(0, |u|^2)$. So $Z \sim N(0, I)$.

Now given μ and non-negative definite V , diagonalise $V = U^\top D U$ with U orthogonal and D diagonal with non-negative entries, and let $\sigma = U^\top \sqrt{D} U$, where $\sqrt{D}$ takes square roots of the diagonal. Then σ is symmetric with $\sigma^2 = V$, and setting

$$X = \mu + \sigma Z$$

gives a Gaussian vector (affine image of a Gaussian vector) with $\mathbb{E}[X] = \mu$ and

$$\text{Var}(X) = \mathbb{E}[\sigma Z Z^\top \sigma^\top] = \sigma \mathbb{E}[Z Z^\top] \sigma^\top = \sigma I \sigma = V,$$

so $X \sim N(\mu, V)$ as desired.

When V is actually positive definite (no zero eigenvalues), σ is invertible and we can compute the density of X from that of Z by our change of variables formula, with $z = \sigma^{-1}(x - \mu)$ and Jacobian $|\det \sigma^{-1}| = 1/\sqrt{\det V}$:

$$f_X(x) = \frac{1}{(2\pi)^{n/2}} e^{-|z|^2/2} \cdot \frac{1}{\sqrt{\det V}} = \frac{1}{\sqrt{(2\pi)^n \det V}} \exp\left(-\frac{(x - \mu)^\top V^{-1}(x - \mu)}{2}\right),$$

using $z^\top z = (x - \mu)^\top \sigma^{-2}(x - \mu) = (x - \mu)^\top V^{-1}(x - \mu)$. (If V is singular, X lives on a lower-dimensional affine subspace and has no density on $\mathbb{R}^n$; restricting to that subspace recovers the formula above.)

§6.12.3 Independence and Covariance for Gaussians

We saw earlier that zero covariance does not imply independence in general. For Gaussian vectors, wonderfully, it does.

Theorem 6.12.2 (Independence Equals Zero Covariance)

Let $X = (X_1, \dots, X_n)^\top$ be a Gaussian vector. Then $X_1, \dots, X_n$ are independent if and only if $V = \text{Var}(X)$ is diagonal, i.e. $\text{Cov}(X_i, X_j) = 0$ for all $i \neq j$.

Proof. Independence always forces the off-diagonal covariances to vanish, so only the converse needs proof. Suppose V is diagonal with entries λ_i . Then the mgf factorises:

$$m(\theta) = \exp\left(\theta^\top \mu + \frac{\theta^\top V \theta}{2}\right) = \prod_{i=1}^n \exp\left(\theta_i \mu_i + \frac{\theta_i^2 \lambda_i}{2}\right),$$

which is the product of the mgfs of independent $N(\mu_i, \lambda_i)$ random variables. By uniqueness of (multivariate) mgfs, X has the same distribution as a vector of independent normals, so the X_i are independent. (When V is positive definite one can equally see this from the density, which factorises as a product of one-dimensional normal densities.) $\square$

§6.12.4 The Bivariate Normal

The case $n = 2$ deserves special attention. Let (X_1, X_2) be a Gaussian vector, with means μ_k , variances $\sigma_k^2 > 0$, and correlation

$$\rho = \text{Corr}(X_1, X_2) = \frac{\text{Cov}(X_1, X_2)}{\sigma_1 \sigma_2} \in [-1, 1].$$

The covariance matrix is then

$$V = \begin{pmatrix} \sigma_1^2 & \rho \sigma_1 \sigma_2 \\ \rho \sigma_1 \sigma_2 & \sigma_2^2 \end{pmatrix},$$

and any such matrix with $\rho \in [-1, 1]$ is a legitimate covariance matrix (one can check $u^\top V u \geq 0$ directly by writing it as $(1 - \rho)(\sigma_1^2 u_1^2 + \sigma_2^2 u_2^2) + \rho(\sigma_1 u_1 + \sigma_2 u_2)^2$ and the analogous expression with $1 + \rho$).

By the previous theorem, X_1 and X_2 are independent exactly when $\rho = 0$. Even when they're correlated, we can compute conditional expectations cleanly with a decorrelation trick that is worth remembering.

Proposition 6.12.3 (Conditioning in the Bivariate Normal)

Let (X_1, X_2) be bivariate normal as above, and let $a = \rho \sigma_2 / \sigma_1$. Then

$$\mathbb{E}[X_2 \mid X_1] = \mu_2 + a(X_1 - \mu_1),$$

and conditionally on X_1 , X_2 has the $N(\mu_2 + a(X_1 - \mu_1), \sigma_2^2(1 - \rho^2))$ distribution.

Proof. Consider $Y = X_2 - aX_1$, and choose a so that Y is uncorrelated with X_1 :

$$\text{Cov}(Y, X_1) = \text{Cov}(X_2, X_1) - a \text{Var}(X_1) = \rho \sigma_1 \sigma_2 - a \sigma_1^2 = 0 \iff a = \frac{\rho \sigma_2}{\sigma_1}.$$

Now (X_1, Y) is a Gaussian vector (an affine image of (X_1, X_2)), so uncorrelated

implies *independent*. Writing $X_2 = Y + aX_1$,

$$\mathbb{E}[X_2 | X_1] = \mathbb{E}[Y | X_1] + a\mathbb{E}[X_1 | X_1] = \mathbb{E}[Y] + aX_1 = \mu_2 - a\mu_1 + aX_1,$$

using independence for the first term and ‘taking out what is known’ for the second. Moreover, given X_1 , the only remaining randomness in $X_2 = Y + aX_1$ is the independent normal Y , so conditionally X_2 is normal with the stated mean and variance

$$\text{Var}(Y) = \text{Var}(X_2) + a^2 \text{Var}(X_1) - 2a \text{Cov}(X_1, X_2) = \sigma_2^2 + \rho^2 \sigma_2^2 - 2\rho^2 \sigma_2^2 = \sigma_2^2(1 - \rho^2). \quad \square$$

Notice that the conditional expectation is an affine function of X_1 – the ‘regression line’ – and the conditional variance $\sigma_2^2(1 - \rho^2)$ doesn’t depend on the observed value of X_1 at all. Both are special features of the Gaussian world.

§6.13 Geometric Probability and Simulation

We close with two lighter topics that showcase continuous probability in action: problems about ‘random’ geometric objects, and the question of how to actually *generate* random variables with a computer.

§6.13.1 Bertrand's Paradox

Geometric probability has a famous health warning attached, and it is best delivered immediately: the phrase ‘at random’ has no meaning until you specify the distribution.

Example 6.13.1 (Bertrand's Paradox)

Draw a chord ‘at random’ in a circle of radius r . What is the probability that its length C is less than r ?

Interpretation 1. Choose the chord by picking a distance $X \sim \text{U}[0, r]$ and drawing the chord perpendicular to a fixed radius at distance X from the centre. By Pythagoras, $C = 2\sqrt{r^2 - X^2}$, so

$$\mathbb{P}(C \leq r) = \mathbb{P}(4(r^2 - X^2) \leq r^2) = \mathbb{P}\left(X \geq \frac{\sqrt{3}}{2}r\right) = 1 - \frac{\sqrt{3}}{2} \approx 0.134.$$

Interpretation 2. Choose the chord by fixing one endpoint A on the circle and picking the other endpoint at a uniformly random angle: let $\Theta \sim \text{U}[0, 2\pi]$ be the angle subtended at the centre. Then $C = 2r \sin(\Theta/2)$, so

$$\mathbb{P}(C \leq r) = \mathbb{P}\left(\sin \frac{\Theta}{2} \leq \frac{1}{2}\right) = \mathbb{P}\left(\Theta \leq \frac{\pi}{3}\right) + \mathbb{P}\left(\Theta \geq \frac{5\pi}{3}\right) = \frac{1}{6} + \frac{1}{6} = \frac{1}{3}.$$

The two procedures are illustrated below: chords perpendicular to a fixed radius at a uniform distance (left), and chords from a fixed point A at a uniform angle (right).

Two perfectly reasonable readings of ‘a random chord’; two different answers. There is no paradox once we accept that the two procedures generate genuinely different distributions on chords – the lesson is that in continuous settings, the model must be specified, not assumed.

§6.13.2 Buffon’s Needle

Our second classic has a happier punchline: a probabilistic experiment that computes π .

Example 6.13.2 (Buffon’s Needle)

A floor is ruled with parallel lines a distance L apart, and a needle of length $\ell \leq L$ is dropped on it at random. What is the probability that the needle crosses a line?

We model the drop by two independent random variables: the distance $X \sim U[0, L]$ from the needle’s lower end^a to the nearest line above it, and the angle $\Theta \sim U[0, \pi]$ the needle makes with the lines. The needle crosses a line precisely when $\ell \sin \Theta \geq X$, so

$$p = \mathbb{P}(X \leq \ell \sin \Theta) = \int_0^\pi \int_0^L \frac{1}{\pi L} \mathbb{1}_{\{x \leq \ell \sin \theta\}} dx d\theta = \frac{1}{\pi L} \int_0^\pi \ell \sin \theta d\theta = \frac{2\ell}{\pi L}.$$

^aLower in the direction perpendicular to the lines, say.

Since $\pi = 2\ell/pL$, we can *estimate* π by dropping n needles, letting $\hat{p}_n$ be the observed proportion of crossings, and computing $\hat{\pi}_n = 2\ell/\hat{p}_n L$. How good is this? This is exactly the sampling problem from the previous section: by the CLT,

$$\hat{p}_n \approx p + \sqrt{\frac{p(1-p)}{n}} Z, \quad Z \sim N(0, 1),$$

and applying the first-order Taylor expansion $f(\hat{p}_n) \approx f(p) + (\hat{p}_n - p)f'(p)$ to $f(x) = 2\ell/xL$ (which has $f'(p) = -\pi/p$),

$$\hat{\pi}_n - \pi \approx -\pi \sqrt{\frac{1-p}{pn}} Z.$$

Asking for $|\hat{\pi}_n - \pi| \leq 0.001$ with probability 0.99 and consulting tables ($\mathbb{P}(|Z| \leq 2.58) = 0.99$) leads to n of order 10^7 drops. As numerical integration schemes go, this one converges *very* slowly – the $1/\sqrt{n}$ error decay of averages is no match for even basic quadrature – but as a party trick it remains unbeatable.

§6.13.3 Simulating Random Variables

Suppose we have a source of uniform randomness – a computer’s random number generator handing us independent $U[0, 1]$ variables – and we want to manufacture a random variable with some other prescribed distribution F . There is a beautifully simple recipe: feed the uniform through the inverse of F .

Theorem 6.13.3 (Inverse Transform Sampling)

Let F be a continuous, strictly increasing distribution function, and let $U \sim U[0, 1]$. Then

$$X = F^{-1}(U) \quad \text{has distribution function } F.$$

Proof. Since F is increasing, $F^{-1}(U) \leq x \iff U \leq F(x)$, and so

$$\mathbb{P}(X \leq x) = \mathbb{P}(U \leq F(x)) = F(x),$$

as $F(x) \in [0, 1]$ and U is uniform. $\square$

The intuition: $F^{-1}(p)$ is the value that the distribution places probability p below, so sampling a uniform ‘probability level’ and inverting produces values with exactly the right frequencies.

Example 6.13.4

Taking $F(x) = 1 - e^{-x}$, we get that if $U \sim U[0, 1]$ then $F^{-1}(U) = -\log(1 - U)$ is $\text{Exp}(1)$ – and since $1 - U$ is also uniform, more simply $-\log U \sim \text{Exp}(1)$. Similarly, the Box-Muller observation from our polar coordinates example gives a normal sampler: with independent $U_1, U_2 \sim U[0, 1]$, the variables

$$X = \sqrt{-2 \log U_1} \cos(2\pi U_2), \quad Y = \sqrt{-2 \log U_1} \sin(2\pi U_2)$$

are independent standard normals, since $\sqrt{-2 \log U_1}$ has the density $re^{-r^2/2}$ of the Gaussian radius and $2\pi U_2$ is a uniform angle.

Inverse transform sampling needs a computable F^{-1} , which is often unavailable (already for the normal distribution one has to work around it, as above). Our final method needs only the density – and the willingness to throw samples away.

Theorem 6.13.5 (Rejection Sampling)

Let $A \subseteq [0, 1]^d$ have volume $|A| > 0$, and let $U_1, U_2, \dots$ be independent uniform points in $[0, 1]^d$. Let $N = \min\{n \geq 1 : U_n \in A\}$. Then U_N is uniformly distributed on A .

Proof. Let $B \subseteq [0, 1]^d$. Splitting according to the value of N and using independence,

$$\mathbb{P}(U_N \in B) = \sum_{n=1}^{\infty} \mathbb{P}(U_n \in A \cap B, U_{n-1} \notin A, \dots, U_1 \notin A)$$

$$= \sum_{n=1}^{\infty} |A \cap B| (1 - |A|)^{n-1} = \frac{|A \cap B|}{|A|},$$

summing the geometric series. This is exactly the uniform distribution on A . $\square$

To simulate a random variable on $[0, 1]^{d-1}$ with a bounded density $f \leq \lambda$, we apply this with the region *under the (scaled) graph of f* :

$$A = \left\{ (x_1, \dots, x_d) \in [0, 1]^d : x_d \leq \frac{f(x_1, \dots, x_{d-1})}{\lambda} \right\}.$$

Generate a uniform point of A by rejection, and keep only its first $d - 1$ coordinates X . For any $B \subseteq [0, 1]^{d-1}$, integrating out the last coordinate gives

$$\mathbb{P}(X \in B) = \frac{|(B \times [0, 1]) \cap A|}{|A|} = \frac{\frac{1}{\lambda} \int_B f(x) \, dx}{\frac{1}{\lambda} \int f(x) \, dx} = \int_B f(x) \, dx,$$

so X has density f , as desired. In words: throw uniform darts at the box, keep the ones landing under the graph of the density, and read off their horizontal coordinates. It is a fittingly concrete note on which to end – the abstract machinery of densities, built up from three axioms about measures, cashing out as instructions you could implement in ten lines of code.

7 Vector Calculus

Vector calculus takes the differentiation and integration that we know and love from single-variable calculus and asks what they look like in two, three (and more) dimensions. The objects of study become scalar and vector *fields*, and the ways of differentiating them – the gradient, divergence and curl – turn out to be linked to integration by a family of remarkable ‘integral theorems’, all of which generalise the fundamental theorem of calculus. This language is the natural setting for much of mathematical physics, and we will see it at work in electromagnetism through Maxwell’s equations.

This article constitutes my notes for the ‘Vector Calculus’ course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered. If you spot any errors or have any feedback, I can be contacted at ak2316@cam.ac.uk.

§7.1 Notation

Throughout this course, a column vector

$$\begin{pmatrix} a \\ b \\ c \end{pmatrix}$$

is to be interpreted as the vector $\mathbf{x} = a\mathbf{e}_x + b\mathbf{e}_y + c\mathbf{e}_z$, where $\{\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z\}$ are basis vectors aligned with the fixed Cartesian x , y and z axes in $\mathbb{R}^3$.

We may also use the notation $\mathbf{e}_1 = \mathbf{e}_x$, $\mathbf{e}_2 = \mathbf{e}_y$ and $\mathbf{e}_3 = \mathbf{e}_z$, and then we can write $\mathbf{x} = x_i \mathbf{e}_i$.

We will also be using the summation convention frequently, which you can read more about in the ‘Vectors and Matrices’ course notes.

§7.2 Differential Geometry of Curves

We will begin by studying the differential geometry of curves in $\mathbb{R}^3$, which sounds exciting but isn’t.

§7.2.1 Parameterized Curves & Arc Length

The first object we shall study is *parameterized curves*.

Definition 7.2.1 (Parameterized Curve)

A **parameterized curve** C in $\mathbb{R}^3$ is the image of a continuous map $\mathbf{x} : [a, b] \rightarrow \mathbb{R}^3$ in which $t \mapsto \mathbf{x}(t)$.

In Cartesian coordinates, we can write

$$\mathbf{x}(t) = \begin{pmatrix} x_1(t) \\ x_2(t) \\ x_3(t) \end{pmatrix} = \begin{pmatrix} x(t) \\ y(t) \\ z(t) \end{pmatrix}.$$

We also give the curve an orientation, based on the map going from the image of A to the image of B .

Definition 7.2.2 (Differentiability and Smoothness)

We say that a curve C is **differentiable** if each of the components $\{x_1(t), x_2(t), x_3(t)\}$ are differentiable, and say C is **regular** if $|\mathbf{x}'(t)| \neq 0$. If C is differentiable and regular then we say C is **smooth**.

Remark. The ‘regular’ condition exists to avoid ‘spikes’ in the curve. For example, consider the curve $\mathbf{x}(t) = (t^3, t^2)$. Clearly this is differentiable, but $\mathbf{x}(t)$ has a cusp at $t = 0$. At $t = 0$, we have $|\mathbf{x}'(0)| = 0$. If this was not the case, there would be no cusp.

Recall that the function $x_i(t)$ is differentiable at t if $x_i(t+h) = x_i(t) + x'_i(t)h + o(h)$, where $\frac{o(h)}{h} \rightarrow 0$ as $h \rightarrow 0$. We can write this in terms of vectors, where

$$\mathbf{x}(t+h) = \mathbf{x}(t) + \mathbf{x}'(t)h + o(h),$$

where $o(h)$ is a vector for which $\frac{|o(h)|}{h} \rightarrow 0$ as $h \rightarrow 0$.

Now given some curve C , we may want to find the length of the curve. We can try to do this by approximating the curve using straight lines.

For $C : [a, b] \rightarrow \mathbb{R}^3$ with $t \mapsto \mathbf{x}(t)$, we introduce a partition P of $[a, b]$ with $t_0 = a$, $t_N = b$ and $t_0 < t_1 < \dots < t_N$, and we set $\Delta t_i = t_{i+1} - t_i$ and $\Delta t = \max_i \Delta t_i$.

Definition 7.2.3 (Length Relative to a Partition)

For some curve C and partition P as above, we define the **length** of C relative to P by

$$\ell(C, P) = \sum_{i=0}^{N-1} |\mathbf{x}(t_{i+1}) - \mathbf{x}(t_i)|.$$

We would expect that this length would get closer to the true length of C as $\Delta t \rightarrow 0$. Indeed, we will define the length of C in this way.

Definition 7.2.4 (Length of a Curve)

We define the length of a curve C by

$$\ell(C) = \lim_{\Delta t \rightarrow 0} \sum_{i=0}^{N-1} |\mathbf{x}(t_{i+1}) - \mathbf{x}(t_i)| = \lim_{\Delta t \rightarrow 0} \ell(C, P).$$

If this limit does not exist, we say the curve is **non-rectifiable**.

In this course, we will not worry too much about non-rectifiable curves, so we will assume that this notion is always well defined.

Now suppose C is a differentiable curve. Then we have that

$$\begin{aligned} \mathbf{x}(t_{i+1}) &= \mathbf{x}(t_i + t_{i+1} - t_i) \\ &= \mathbf{x}(t_i + \Delta t_i) \\ &= \mathbf{x}(t_i) + \mathbf{x}'(t_i) \Delta t_i + o(\Delta t_i). \end{aligned}$$

It follows that

$$|\mathbf{x}(t_{i+1}) - \mathbf{x}(t_i)| = |\mathbf{x}'(t_i)| \Delta t_i + o(\Delta t_i).$$

So if C is differentiable, we get the expression

$$\ell(C, P) = \sum_{i=0}^{N-1} (|\mathbf{x}'(t_i)| \Delta t_i + o(\Delta t_i)).$$

Recall that $o(\Delta t_i)$ represents a function for which $\frac{o(\Delta t_i)}{\Delta t_i} \rightarrow 0$ as $\Delta t_i \rightarrow 0$. So for any $\epsilon > 0$, if $\Delta t = \max_i \Delta t_i$ is sufficiently small, then we have

$$|o(\Delta t_i)| < \left(\frac{\epsilon}{b-a} \right) \Delta t_i,$$

for $i = \{0, \dots, N-1\}$. So

$$\begin{aligned} \left| \ell(C, P) - \sum_{i=0}^{N-1} |\mathbf{x}'(t_i)| \Delta t_i \right| &= \left| \sum_{i=0}^{N-1} o(\Delta t_i) \right| \\ &< \frac{\epsilon}{b-a} \sum_{i=0}^{N-1} \Delta t_i = \epsilon. \end{aligned}$$

Thus the LHS tends to zero as $\Delta t \rightarrow 0$. So we get that

$$\begin{aligned} \ell(C) &= \lim_{\Delta t \rightarrow 0} \ell(C, P) = \lim_{\Delta t \rightarrow 0} \sum_{i=0}^{N-1} |\mathbf{x}'(t_i)| \Delta t_i \\ &= \int_a^b |\mathbf{x}'(t)| \, dt, \end{aligned}$$

by the definition of the Riemann integral. So, we can restate our definition in this other form.

Definition 7.2.5 (Length of a Curve)

If $C : [a, b] \rightarrow \mathbb{R}^3$ is a differentiable curve with $t \mapsto \mathbf{x}(t)$, then its **length** is

$$\ell(C) = \int_a^b |\mathbf{x}'(t)| \, dt = \int_C ds,$$

where ds is the **arc-length element**, $ds = |\mathbf{x}'(t)| \, dt$.

With this defined, we can define the integral of a function along a curve.

Definition 7.2.6 (Integral on a Curve)

For a function $f : \mathbb{R}^3 \rightarrow \mathbb{R}$ and a differentiable curve $C : [a, b] \rightarrow \mathbb{R}^3$ with $t \mapsto \mathbf{x}(t)$, we define the **integral of f along C** to be

$$\int_C f(\mathbf{x}) \, ds = \int_a^b f(\mathbf{x}(t)) |\mathbf{x}'(t)| \, dt.$$

Now consider a curve C made up of M smooth curves $C_1, C_2, \dots, C_M$.

Then writing $C = C_1 + C_2 + \dots + C_M$, we can define

$$\int_C f(\mathbf{x}) \, ds = \sum_{i=1}^M \int_{C_i} f(\mathbf{x}) \, ds,$$

so we can integrate over piecewise smooth curves.

Note that informally, we have

$$ds = |\mathbf{x}'(t)| \, dt = \sqrt{\left(\frac{dx}{dt}\right)^2 + \left(\frac{dy}{dt}\right)^2 + \left(\frac{dz}{dt}\right)^2} \, dt.$$

So being somewhat sacrilegious, we have

$$ds^2 = dx^2 + dy^2 + dz^2.$$

Example 7.2.7 (Circumference of a Circle)

Let C be a circle of radius $r > 0$ in $\mathbb{R}^3$,

$$\mathbf{x}(t) = \begin{pmatrix} r \cos t \\ r \sin t \\ 0 \end{pmatrix}, \quad t \in [0, 2\pi].$$

We can differentiate this to get

$$\mathbf{x}'(t) = \begin{pmatrix} -r \sin t \\ r \cos t \\ 0 \end{pmatrix}, \quad t \in [0, 2\pi].$$

Then integrating over C we have

$$\begin{aligned} \int_C ds &= \int_0^{2\pi} \sqrt{r^2 \sin^2 t + r^2 \cos^2 t} \, dt \\ &= \int_0^{2\pi} r \, dt \\ &= 2\pi r, \end{aligned}$$

as we would expect.

Example 7.2.8 (Integrating over a Circle)

With C being a circle as before, we can integrate over the curve. For example

$$\begin{aligned} \int_C x^2 y \, ds &= \int_0^{2\pi} (r \cos t)^2 (r \sin t) \underbrace{r \, dt}_{|\mathbf{x}'(t)| \, dt} \\ &= 0 \end{aligned}$$

There is one subtlety that we have looked over - does $\ell(C)$ depend on the parameterization used?

For example, if we had $\mathbf{x}(t) = (r \cos t, r \sin t, 0)$ with $t \in [0, 2\pi]$ and $\tilde{\mathbf{x}}(t) = (r \cos(2t), r \sin(2t), 0)$ with $t \in [0, \pi]$, these represent the same circle and they should have the same length.

We will clear up this possible ambiguity now.

Proposition 7.2.9

If $f : \mathbb{R}^3 \rightarrow \mathbb{R}$ is a function and C is a differentiable curve, then $\int_C f(\mathbf{x}) \, ds$ is independent of the parameterization of C used.

Proof. Suppose C has two different parameterizations,

$$\begin{aligned}\mathbf{x} &= \mathbf{x}_1(t), & a \leq t \leq b \\ \mathbf{x} &= \mathbf{x}_2(\tau), & \alpha \leq \tau \leq \beta\end{aligned}$$

We must then have $\mathbf{x}_2(\tau) = \mathbf{x}_1(t(\tau))$ for some function $t(\tau)$. We can assume that $\frac{dt}{d\tau} \neq 0$ so the map between t and τ is invertible and differentiable (this is the inverse function theorem, covered in Analysis and Topology in Part IB). Note then that

$$\begin{aligned}\mathbf{x}'_2(\tau) &= \frac{d}{d\tau} \mathbf{x}_2(t) \\ &= \frac{d}{d\tau} \mathbf{x}_1(t(\tau)) \\ &= \frac{dt}{d\tau} \mathbf{x}'_1(t(\tau)).\end{aligned}$$

Then from our definition,

$$\int_C f(\mathbf{x}) \, ds = \int_a^b f(\mathbf{x}_1(t)) |\mathbf{x}'_1(t)| \, dt.$$

We can make the substitution $t = t(\tau)$, and assuming $dt/d\tau > 0$, the latter integral becomes

$$\int_\alpha^\beta f(\mathbf{x}_2(\tau)) \underbrace{|\mathbf{x}'_1(t(\tau))| \frac{dt}{d\tau}}_{|\mathbf{x}'_2(\tau)|} \, d\tau,$$

which is precisely the same as $\int_C f(\mathbf{x}) \, ds$ using the $\mathbf{x}_2(t)$ parameterization.

We assumed here that $\frac{dt}{d\tau} > 0$, but the same holds if it is negative. Thus our definition of integrating over a curve C does not depend on the choice of parameterization of C . $\square$

We can parameterize curves in many different ways. One useful way to parameterise regular curves is with respect to arc-length. If we write $\mathbf{r}(s) = \mathbf{x}(t(s))$ where $0 \leq s \leq \ell(C)$, then by the chain rule

$$\frac{dt}{ds} = \frac{1}{ds/dt} = \frac{1}{|\mathbf{x}'(t(s))|},$$

so

$$\begin{aligned}\mathbf{r}'(s) &= \frac{d}{ds} \mathbf{x}(t(s)) \\ &= \frac{dt}{ds} \mathbf{x}'(t(s)) \\ &= \frac{\mathbf{x}'(t(s))}{|\mathbf{x}'(t(s))|},\end{aligned}$$

that is, $|\mathbf{r}'(s)| = 1$. This (consistently) gives $\ell(C) = \int_0^{\ell(C)} |\mathbf{r}'(s)| \, ds = \int_0^{\ell(C)} 1 \, ds$. So the way to picture $\mathbf{r}'(s)$ is as the unit tangent vector to the curve.

§7.2.2 Curvature and Torsion

Throughout this section, we will talk about a generic regular curve C , parameterized by arc-length, and we will write $s \mapsto \mathbf{r}(s)$.

Definition 7.2.10 (Tangent Vector)

For a regular curve C parameterized by arc length, we define the **tangent vector** to be $\mathbf{t}(s) = \mathbf{r}'(s)$.

We already established that $|\mathbf{t}(s)| = 1$, and thus as the second derivative $\mathbf{r}''(s) = \mathbf{t}'(s)$ only measures the change in *direction*.

Intuitively, if $|\mathbf{r}''(s)|$ is large, then the curve rapidly changes in direction, whereas if $|\mathbf{r}''(s)|$ is small, we would expect the curve to be approximately flat.

Definition 7.2.11 (Curvature)

We define the **curvature** of C to be $\kappa(s) = |\mathbf{r}''(s)| = |\mathbf{t}'(s)|$.

Now since $\mathbf{t} = \mathbf{r}'(s)$ is a unit vector, if we differentiate $\mathbf{t} \cdot \mathbf{t} = 1$ we get $\mathbf{t} \cdot \mathbf{t}' = 0$. Because of this we can introduce the following definition.

Definition 7.2.12 (Principal Normal)

The **principal normal** $\mathbf{n}$ is the vector given by $\mathbf{t}' = \kappa \mathbf{n}$.

The principal normal $\mathbf{n}$ is everywhere normal to the curve C , since it's always perpendicular to the tangent vector ($\mathbf{t} \cdot \mathbf{n} = 0$). Then we have two perpendicular vectors, so we can extend $\{\mathbf{t}, \mathbf{n}\}$ to an orthonormal basis by defining the following.

Definition 7.2.13 (Binormal)

The **binormal** $\mathbf{b}$ is the unit vector perpendicular to $\mathbf{t}$ and $\mathbf{n}$, $\mathbf{b} = \mathbf{t} \times \mathbf{n}$.

Since $|\mathbf{b}| = 1$, we have $\mathbf{b}' \cdot \mathbf{b} = 0$. Also since $\mathbf{t} \cdot \mathbf{b} = 0$ and $\mathbf{n} \cdot \mathbf{b} = 0$,

$$\begin{aligned} 0 &= (\mathbf{t} \cdot \mathbf{b})' = \mathbf{t}' \cdot \mathbf{b} + \mathbf{t} \cdot \mathbf{b}' \\ &= \cancel{\kappa \mathbf{n} \cdot \mathbf{b}} + \mathbf{t} \cdot \mathbf{b}', \end{aligned}$$

thus $\mathbf{b}'$ is orthogonal to $\mathbf{t}$ and $\mathbf{b}$, and thus it is parallel to $\mathbf{n}$. We define the following.

Definition 7.2.14 (Torsion)

We define the **torsion** τ by $\mathbf{b}' = -\tau \mathbf{n}$.

Informally, torsion measures a twisting motion along a curve. So we have two equations.

$$\mathbf{t}' = \kappa \mathbf{n}, \quad \mathbf{b}' = -\tau \mathbf{n}.$$

Proposition 7.2.15 (Fundamental Theorem of Curves)

The curvature $\kappa(s)$ and torsion $\tau(s)$ define a curve up to translation and orientation.

Proof Sketch. Since $\mathbf{n} = \mathbf{b} \times \mathbf{t}$, we have

$$\mathbf{t}' = \kappa(\mathbf{b} \times \mathbf{t}), \quad \mathbf{b}' = -\tau(\mathbf{b} \times \mathbf{t}).$$

This gives six equations for six unknowns. Given $\kappa(s)$, $\tau(s)$, $\mathbf{t}(0)$ and $\mathbf{b}(0)$, we can construct the functions $\mathbf{t}(s)$, $\mathbf{b}(s)$, and hence $\mathbf{n} = \mathbf{b} \times \mathbf{t}$. Hence the result. $\square$

§7.2.3 Radius of Curvature

Consider some generic curve $s \mapsto \mathbf{r}(s)$, and consider the Taylor expansion about $s = 0$. Write $\mathbf{t} = \mathbf{t}(0)$, $\mathbf{n} = \mathbf{n}(0)$, etc. Then we get

$$\begin{aligned} \mathbf{r}(s) &= \mathbf{r}(0) + s\mathbf{r}'(0) + \frac{1}{2}s^2\mathbf{r}''(0) + o(s^2) \\ &= \mathbf{r} + s\mathbf{t} + \frac{1}{2}s^2\kappa\mathbf{n} + o(s^2). \end{aligned}$$

So this gives us a good approximation of the curve around $s = 0$, and now we want to try and draw a circle through the point $\mathbf{r}(0)$ such that the circle is tangent to the curve at that point. Specifically, what would the radius of that circle be?

Suppose, without loss of generality, that $\mathbf{t}$ is horizontal.

A point on this circle can be described by

$$\mathbf{x}(\theta) = \mathbf{r} + R(1 - \cos \theta)\mathbf{n} + R \sin \theta \mathbf{t}.$$

Then expanding for $|\theta|$ small, we get

$$\mathbf{x}(\theta) = \mathbf{r} + R\theta\mathbf{t} + \frac{1}{2}R\theta^2\mathbf{n} + o(\theta^2).$$

On this circle, the arc-length is $s = R\theta$. Thus if we express the above in terms of arc-length, we get

$$\mathbf{x}(\theta) = \mathbf{r} + s\mathbf{t} + \frac{1}{2R}s^2\mathbf{n} + o(s^2).$$

As we want this to match the curve, we compare it to the equation for the curve near $\mathbf{r}$, and to match quadratic terms we need $R = 1/\kappa$.

Definition 7.2.16 (Radius of Curvature)

We define $R(s) = 1/\kappa(s)$ to be the **radius of curvature** of the curve $s \mapsto \mathbf{r}(s)$.

§7.3 Coordinates, Differentials and Gradients

§7.3.1 Differentials and First Order Changes

Recall that for $f = f(u_1, \dots, u_n)$, we define the **differential** of f , written df , by

$$df = \frac{\partial f}{\partial u_i} du_i,$$

using the summation convention. We call $\{du_i\}$ **differential forms**. We will treat these differential forms as formal objects that are the elements of some abstract vector space, and treat them as linear independent if $\{u_1, \dots, u_n\}$ are independent, that is, if $\alpha_i du_i = 0$ implies $\alpha_i = 0$ for $i = 1, \dots, n$.

Similarly, if we had $\mathbf{x} = \mathbf{x}(u_1, \dots, u_n)$, we define

$$d\mathbf{x} = \frac{\partial \mathbf{x}}{\partial u_i} du_i.$$

Example 7.3.1 (Using Differentials)

If $f(u, v, w) = u^2 + w \sin(v)$, then

$$df = 2u du + w \cos(v) dv + \sin(v) dw.$$

Similarly, if we had $\mathbf{x}(u, v, w) = \begin{pmatrix} u^2 - v^2 \\ w \\ e^v \end{pmatrix}$, then

$$d\mathbf{x} = \begin{pmatrix} 2u \\ 0 \\ 0 \end{pmatrix} du + \begin{pmatrix} -2v \\ 0 \\ e^v \end{pmatrix} dv + \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} dw.$$

Differentials encode information about how a function/field changes when we ‘wobble’ our coordinates. Indeed, by calculus we know

$$f(u_1 + \delta u_1, \dots, u_n + \delta u_n) - f(u_1, \dots, u_n) = \frac{\partial f}{\partial u_i} \delta u_i + o(\delta \mathbf{u}),$$

where $\delta \mathbf{u} = (\delta u_1, \dots, \delta u_n)$. So differentials allow to discuss first order changes in f .

So if δf denotes a change in $f(u_1, \dots, u_n)$ under perturbation of coordinates $(u_1, \dots, u_n) \mapsto (u_1 + \delta u_1, \dots, u_n + \delta u_n)$, we have, to first order,

$$\delta f \approx \frac{\partial f}{\partial u_i} \delta u_i.$$

Similarly for vector fields,

$$\delta \mathbf{x} \approx \frac{\partial \mathbf{x}}{\partial u_i} \delta u_i.$$

§7.3.2 Coordinates and Line Elements

You have already seen at least two sets of coordinates before taking this course for $\mathbb{R}^2$: Cartesian coordinates (x, y) , and polar coordinates (r, θ) . They have an invertible (except at the origin) relationship,

$$x = r \cos \theta, y = r \sin \theta.$$

A general set of coordinates (u, v) on $\mathbb{R}^2$ can be specified by their relationship to (x, y) , the Cartesian coordinates. That is, we can specify smooth functions $x = x(u, v)$, $y = y(u, v)$ that are a bijection. Of course we have the same thing for $\mathbb{R}^3$.

Let’s look at some examples.

Example 7.3.2 (Cartesian Coordinates)

In the standard Cartesian coordinate system we have $\mathbf{x}(x, y) = \begin{pmatrix} x \\ y \end{pmatrix} = x\mathbf{e}_x + y\mathbf{e}_y$, where $\{\mathbf{e}_x, \mathbf{e}_y\}$ are orthogonal vectors. We have $\mathbf{e}_x$ is in the direction of changing x with y fixed.

Said differently, we have

$$\mathbf{e}_x = \frac{\frac{\partial}{\partial x} \mathbf{x}(x, y)}{\left| \frac{\partial}{\partial x} \mathbf{x}(x, y) \right|}, \quad \text{and} \quad \mathbf{e}_y = \frac{\frac{\partial}{\partial y} \mathbf{x}(x, y)}{\left| \frac{\partial}{\partial y} \mathbf{x}(x, y) \right|}.$$

A feature of Cartesian coordinates is that

$$d\mathbf{x} = \frac{\partial \mathbf{x}}{\partial x} dx + \frac{\partial \mathbf{x}}{\partial y} dy = dx\mathbf{e}_x + dy\mathbf{e}_y,$$

that is, a change in coordinate $x \mapsto x + \delta x$ cause a change to the vector (to the first order) by $\mathbf{x} \mapsto \mathbf{x} + \delta x\mathbf{e}_x$. We call $d\mathbf{x}$ the **line element**, which tells us how small changes in coordinates produce changes in position vectors.

That was slightly tame, we’re going to look at something slightly more interesting.

Example 7.3.3 (Polar Coordinates)

For polar coordinates (r, θ) we have

$$\mathbf{x}(r, \theta) = \begin{pmatrix} r \cos \theta \\ r \sin \theta \end{pmatrix} = r \mathbf{e}_r.$$

We have used the basis vectors $\{\mathbf{e}_r, \mathbf{e}_\theta\}$ where

$$\mathbf{e}_r = \begin{pmatrix} \cos \theta \\ \sin \theta \end{pmatrix}, \quad \mathbf{e}_\theta = \begin{pmatrix} -\sin \theta \\ \cos \theta \end{pmatrix}.$$

Note that $\{\mathbf{e}_r, \mathbf{e}_\theta\}$ are orthonormal at each (r, θ) , but not the same for each (r, θ) . Note that as before,

$$\mathbf{e}_r = \frac{\frac{\partial}{\partial r} \mathbf{x}(r, \theta)}{\left| \frac{\partial}{\partial r} \mathbf{x}(r, \theta) \right|}, \quad \text{and} \quad \mathbf{e}_\theta = \frac{\frac{\partial}{\partial \theta} \mathbf{x}(r, \theta)}{\left| \frac{\partial}{\partial \theta} \mathbf{x}(r, \theta) \right|}.$$

Since $\{\mathbf{e}_r, \mathbf{e}_\theta\}$ are orthogonal, it makes sense to call (r, θ) **orthogonal, curvilinear coordinates**.

We also have the line element

$$d\mathbf{x} = \frac{\partial \mathbf{x}}{\partial r} dr + \frac{\partial \mathbf{x}}{\partial \theta} d\theta = \mathbf{e}_r dr + r d\theta \mathbf{e}_\theta,$$

and so we can see that a change $\theta \mapsto \theta + \delta\theta$ produces a (first order) change

$$\mathbf{x} \mapsto \mathbf{x} + r\delta\theta \mathbf{e}_\theta,$$

which is notably *not* $\mathbf{x} \mapsto \mathbf{x} + \delta\theta \mathbf{e}_\theta$.

Orthogonal Curvilinear Coordinates

We can state properly what it means for a coordinate system to be orthogonal curvilinear.

Definition 7.3.4 (Orthogonal Curvilinear)

We say that (u, v, w) are a set of **orthogonal curvilinear coordinates** if the vectors

$$\mathbf{e}_u = \frac{\partial \mathbf{x} / \partial u}{\left| \partial \mathbf{x} / \partial u \right|}, \quad \mathbf{e}_v = \frac{\partial \mathbf{x} / \partial v}{\left| \partial \mathbf{x} / \partial v \right|}, \quad \mathbf{e}_w = \frac{\partial \mathbf{x} / \partial w}{\left| \partial \mathbf{x} / \partial w \right|}$$

form a right-handed^a, orthonormal basis for each (u, v, w) .

^a $\mathbf{e}_u \times \mathbf{e}_v = \mathbf{e}_w$.

Just as with polar coordinates, we have these vectors $\{\mathbf{e}_u, \mathbf{e}_v, \mathbf{e}_w\}$ form an orthonormal basis for $\mathbb{R}^3$ with each choice of (u, v, w) , but *not* necessarily the same basis at each point.

It is standard to write

$$h_u = \left| \frac{\partial \mathbf{x}}{\partial u} \right|, \quad h_v = \left| \frac{\partial \mathbf{x}}{\partial v} \right|, \quad h_w = \left| \frac{\partial \mathbf{x}}{\partial w} \right|,$$

which we call **scale factors**. Note that the line element is

$$\begin{aligned} d\mathbf{x} &= \frac{\partial \mathbf{x}}{\partial u} du + \frac{\partial \mathbf{x}}{\partial v} dv + \frac{\partial \mathbf{x}}{\partial w} dw \\ &= h_u \mathbf{e}_u du + h_v \mathbf{e}_v dv + h_w \mathbf{e}_w dw. \end{aligned}$$

Scale factors tell us how small changes in coordinates ‘scale-up’ to changes in position $\mathbf{x}$.

Cylindrical Polar Coordinates

We define the coordinate system (ρ, ϕ, z) by

$$\mathbf{x}(\rho, \phi, z) = \begin{pmatrix} \rho \cos \phi \\ \rho \sin \phi \\ z \end{pmatrix},$$

with $0 \leq \rho < \infty$, $0 \leq \phi < 2\pi$ and $-\infty < z < \infty$.

We find that

$$\mathbf{e}_\rho = \begin{pmatrix} \cos \phi \\ \sin \phi \\ 0 \end{pmatrix}, \quad \mathbf{e}_\phi = \begin{pmatrix} -\sin \phi \\ \cos \phi \\ 0 \end{pmatrix}, \quad \mathbf{e}_z = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix},$$

and $h_\rho = 1$, $h_\phi = \rho$, $h_z = 1$. Thus the line element is

$$d\mathbf{x} = d\rho \mathbf{e}_\rho + \rho d\phi \mathbf{e}_\phi + dz \mathbf{e}_z.$$

Note also that we can write

$$\mathbf{x} = \begin{pmatrix} \rho \cos \phi \\ \rho \sin \phi \\ z \end{pmatrix} = \rho \begin{pmatrix} \cos \phi \\ \sin \phi \\ 0 \end{pmatrix} + z \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} = \rho \mathbf{e}_\rho + z \mathbf{e}_z.$$

Spherical Polar Coordinates

We can define the spherical polar coordinates (r, θ, ϕ) by

$$\mathbf{x}(r, \theta, \phi) = \begin{pmatrix} r \cos \phi \sin \theta \\ r \sin \phi \sin \theta \\ r \cos \theta \end{pmatrix},$$

with $0 \leq r < \infty$, $0 \leq \theta \leq \pi$ and $0 \leq \phi < 2\pi$.

We have the corresponding basis vectors

$$\mathbf{e}_r = \begin{pmatrix} \cos \phi \sin \theta \\ \sin \phi \sin \theta \\ \cos \theta \end{pmatrix}, \quad \mathbf{e}_\theta = \begin{pmatrix} \cos \phi \cos \theta \\ \sin \phi \cos \theta \\ -\sin \theta \end{pmatrix}, \quad \mathbf{e}_\phi = \begin{pmatrix} -\sin \phi \\ \cos \phi \\ 0 \end{pmatrix}.$$

We also have $h_r = 1$, $h_\theta = r$ and $h_\phi = r \sin \theta$, so

$$d\mathbf{x} = dr\mathbf{e}_r + r d\theta\mathbf{e}_\theta + r \sin \theta d\phi\mathbf{e}_\phi,$$

and we can write

§7.3.3 The Gradient Operator

We will now introduce an ‘upgraded’ version of differentiation.

Definition 7.3.5 (Gradient)

For $f : \mathbb{R}^3 \rightarrow \mathbb{R}$, we define the **gradient** of f written ∇f by

$$f(\mathbf{x} + \mathbf{h}) = f(\mathbf{x}) + \nabla f(\mathbf{x}) \cdot \mathbf{h} + o(\mathbf{h}),$$

as $\mathbf{h} \rightarrow 0$.

The gradient doesn’t exist for every function (just like the derivative), but in this course we will deal with functions for which it does.

We can interpret the gradient using directional derivatives.

Definition 7.3.6 (Directional Derivative)

The **directional derivative** of f in the direction $\mathbf{v}$, denoted $D_{\mathbf{v}}f$ or $\frac{\partial f}{\partial \mathbf{v}}$, is defined by

$$D_{\mathbf{v}}f(\mathbf{x}) = \lim_{t \rightarrow 0} \frac{f(\mathbf{x} + t\mathbf{v}) - f(\mathbf{x})}{t},$$

that is, $f(\mathbf{x} + t\mathbf{v}) = f(\mathbf{x}) + tD_{\mathbf{v}}f(\mathbf{x}) + o(t)$, as $t \rightarrow 0$.

This expression is the same as if we substituted $\mathbf{h} = t\mathbf{v}$ into the definition of the gradient operator. So

$$D_{\mathbf{v}}f = \mathbf{v} \cdot \nabla f.$$

By Cauchy-Schwartz, we know that $\mathbf{a} \cdot \mathbf{b}$ is maximized when $\mathbf{a}$ and $\mathbf{b}$ are parallel. Thus to maximize the directional derivative, we would choose $\mathbf{v}$ to be in the same direction as ∇f .

Thus ∇f points in the direction of the greatest increase of f . Similarly, $-\nabla f$ points in the direction of greatest decrease of f .

Example 7.3.7

Suppose $f(\mathbf{x}) = \frac{1}{2}|\mathbf{x}|^2$. Then

$$\begin{aligned} f(\mathbf{x} + \mathbf{h}) &= \frac{1}{2}(\mathbf{x} + \mathbf{h}) \cdot (\mathbf{x} + \mathbf{h}) \\ &= \frac{1}{2}|\mathbf{x}|^2 + \frac{1}{2}(2\mathbf{x} \cdot \mathbf{h}) + \frac{1}{2}|\mathbf{h}|^2 \\ &= f(\mathbf{x}) + \mathbf{x} \cdot \mathbf{h} + o(\mathbf{h}), \end{aligned}$$

as $\mathbf{h} \rightarrow 0$. Thus $\nabla f(\mathbf{x}) = \mathbf{x}$.

Now suppose we have a curve $t \mapsto \mathbf{x}(t)$. We might wonder how f changes as we evaluate it along the curve. We write $F(t) = f(\mathbf{x}(t))$, and we will write $\delta\mathbf{x} = \mathbf{x}(t + \delta t) - \mathbf{x}(t)$. We want to consider

$$\begin{aligned} F(t + \delta t) &= f(\mathbf{x}(t + \delta t)) \\ &= f(\mathbf{x}(t) + \delta\mathbf{x}) \\ &= f(\mathbf{x}(t)) + \nabla f(\mathbf{x}(t)) \cdot \delta\mathbf{x} + o(\delta\mathbf{x}). \end{aligned}$$

Since $\delta\mathbf{x} = \mathbf{x}'(t)\delta t + o(\delta t)$, we get

$$F(t + \delta t) = F(t) + \mathbf{x}'(t) \cdot \nabla f(\mathbf{x}(t))\delta t + o(\delta t).$$

Thus

$$\frac{dF}{dt} = \frac{d}{dt}f(\mathbf{x}(t)) = \frac{d\mathbf{x}}{dt} \cdot \nabla f(\mathbf{x}(t)).$$

Another use of the gradient is with surfaces. Suppose a surface S is defined implicitly by $S = \{\mathbf{x} \in \mathbb{R}^3 \mid f(\mathbf{x}) = 0\}$. If $t \mapsto \mathbf{x}(t)$ is *any* curve in S , then $f(\mathbf{x}(t)) = 0$ identically. So if we differentiated, we would get

$$0 = \frac{d}{dt}f(\mathbf{x}(t)) = \nabla f(\mathbf{x}(t)) \cdot \frac{d\mathbf{x}}{dt}.$$

So ∇f is orthogonal to the tangent vector of *any* curve in S . That is, $\nabla f(\mathbf{x})$ is *normal* to the surface at the point $\mathbf{x}$.

§7.3.4 Computing Gradients

In the example in the previous section, computing the gradient was somewhat difficult, requiring various expansions. We might wonder if it is possible to compute it more efficiently, in some orthogonal curvilinear coordinates.

In Cartesian coordinates, things are straightforward. To get the change $\mathbf{x} \mapsto \mathbf{x} + \mathbf{h}$, we could just get the change $x \mapsto x + h_1$, $y \mapsto y + h_2$, $z \mapsto z + h_3$, then

$$\begin{aligned} f(\mathbf{x} + \mathbf{h}) &= f(x + h_1, y + h_2, z + h_3) \\ &= f(\mathbf{x}) + \frac{\partial f}{\partial x} h_1 + \frac{\partial f}{\partial y} h_2 + \frac{\partial f}{\partial z} h_3 + o(\mathbf{h}) \\ &= f(\mathbf{x}) + \begin{pmatrix} \partial f / \partial x \\ \partial f / \partial y \\ \partial f / \partial z \end{pmatrix} \cdot \mathbf{h} + o(\mathbf{h}), \end{aligned}$$

so

$$\nabla f = \begin{pmatrix} \partial f / \partial x \\ \partial f / \partial y \\ \partial f / \partial z \end{pmatrix}.$$

Or, using suffix notation,

$$\nabla f = \mathbf{e}_i \frac{\partial f}{\partial x_i}, \quad \text{or} \quad [\nabla f]_i = \frac{\partial f}{\partial x_i}.$$

We can see that ∇ is a kind of vector differential operator.

So let's try and see how to apply this to other coordinate systems. Recall that in Cartesian coordinates, the line element was

$$d\mathbf{x} = dx\mathbf{e}_x + dy\mathbf{e}_y + dz\mathbf{e}_z = dx_i\mathbf{e}_i.$$

Also a function $f = f(x, y, z)$ has differential

$$df = \frac{\partial f}{\partial x_i} dx_i.$$

Then

$$\begin{aligned} \nabla f \cdot d\mathbf{x} &= \left(\mathbf{e}_i \frac{\partial f}{\partial x_i} \right) \cdot (\mathbf{e}_j dx_j) \\ &= \frac{\partial f}{\partial x_i} \underbrace{\mathbf{e}_i \cdot \mathbf{e}_j}_{\delta_{ij}} dx_j \\ &= \frac{\partial f}{\partial x_i} dx_i \\ &= df. \end{aligned}$$

So we have the following important result:

$$\boxed{\nabla f \cdot d\mathbf{x} = df}$$

This result is important because it is *coordinate independent*.

Remark (Abuse of Notation). So far we have jumped from writing $f(\mathbf{x}) \rightarrow f(x, y, z)$. Really, what we should have written is $F(x, y, z) = f(\mathbf{x}(x, y, z))$. This seems over the top in Cartesian coordinates, but would be far more proper to write $F(u, v, w) = f(\mathbf{x}(u, v, w))$.

Proposition 7.3.8

If (u, v, w) are orthogonal curvilinear coordinates and $f = f(u, v, w)$, then

$$\nabla f = \frac{1}{h_u} \frac{\partial f}{\partial u} \mathbf{e}_u + \frac{1}{h_v} \frac{\partial f}{\partial v} \mathbf{e}_v + \frac{1}{h_w} \frac{\partial f}{\partial w} \mathbf{e}_w.$$

Proof. If $f = f(u, v, w)$ and $\mathbf{x} = \mathbf{x}(u, v, w)$, then

$$df = \frac{\partial f}{\partial u} du + \frac{\partial f}{\partial v} dv + \frac{\partial f}{\partial w} dw,$$

and

$$d\mathbf{x} = h_u du \mathbf{e}_u + h_v dv \mathbf{e}_v + h_w dw \mathbf{e}_w.$$

Using $df = \nabla f \cdot d\mathbf{x}$, and writing

$$\nabla f = [\nabla f]_u \mathbf{e}_u + [\nabla f]_v \mathbf{e}_v + [\nabla f]_w \mathbf{e}_w,$$

we find that

$$\frac{\partial f}{\partial u} du + \frac{\partial f}{\partial v} dv + \frac{\partial f}{\partial w} dw = h_u [\nabla f]_u du + h_v [\nabla f]_v dv + h_w [\nabla f]_w dw.$$

Since $\{du, dv, dw\}$ are linearly independent, we can compare components, and we get

$$[\nabla f]_u = \frac{1}{h_u} \frac{\partial f}{\partial u}, \quad [\nabla f]_v = \frac{1}{h_v} \frac{\partial f}{\partial v}, \quad [\nabla f]_w = \frac{1}{h_w} \frac{\partial f}{\partial w},$$

as required. $\square$

Example 7.3.9 (Gradient in Cylindrical/Spherical Coordinates)

In cylindrical polar coordinates (ρ, ϕ, z) , we have $h_\rho = 1$, $h_\phi = \rho$, and $h_z = 1$. So

$$\nabla f = \frac{\partial f}{\partial \rho} \mathbf{e}_\rho + \frac{1}{\rho} \frac{\partial f}{\partial \phi} \mathbf{e}_\phi + \frac{\partial f}{\partial z} \mathbf{e}_z.$$

In spherical polar coordinates (r, θ, ϕ) , we have $h_r = 1$, $h_\theta = r$ and $h_\phi = r \sin \theta$. Then

$$\nabla f = \frac{\partial f}{\partial r} \mathbf{e}_r + \frac{1}{r} \frac{\partial f}{\partial \theta} \mathbf{e}_\theta + \frac{1}{r \sin \theta} \frac{\partial f}{\partial \phi} \mathbf{e}_\phi.$$

§7.4 Integration over Lines, Surfaces and Volumes

We are now going to move on to the other (possibly more interesting) side of Calculus – integration! We are going to study how integration can be performed over various objects, beginning with lines (a rather simple generalization of ‘normal’ integration), followed by surfaces and volumes.

§7.4.1 Line Integrals

We will begin by defining the line integral.

Definition 7.4.1 (Line Integral)

For a vector field $\mathbf{F} = \mathbf{F}(\mathbf{x})$ and a piecewise smooth parameterized curve $t \mapsto \mathbf{x}(t)$ with $t \in [a, b]$, we define the **line integral**

$$\int_C \mathbf{F} \cdot d\mathbf{x} = \int_a^b \mathbf{F}(\mathbf{x}(t)) \cdot \frac{d\mathbf{x}}{dt} dt.$$

Note that the direction is important (we integrate over ‘increasing t ’). If we wanted to integrate in the opposite direction over the curve, we would consider $\int_{-C}$.

Example 7.4.2

Consider the vector field

$$\mathbf{F} = \begin{pmatrix} x^2y \\ yz \\ 2zx \end{pmatrix},$$

and consider two curves connecting the origin to $(1, 1, 1)$,

$$C_1 : t \mapsto \begin{pmatrix} t \\ t \\ t \end{pmatrix}, \quad t \in [0, 1], \quad C_2 : t \mapsto \begin{pmatrix} t \\ t \\ t^2 \end{pmatrix}, \quad t \in [0, 1].$$

So

$$\int_{C_1} \mathbf{F} \cdot d\mathbf{x} = \int_0^1 \begin{pmatrix} t^3 \\ t^2 \\ 2t^2 \end{pmatrix} \cdot \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix} dt = \frac{5}{4}.$$

and

$$\int_{C_2} \mathbf{F} \cdot d\mathbf{x} = \int_0^1 \begin{pmatrix} t^3 \\ t^2 \\ 2t^2 \end{pmatrix} \cdot \begin{pmatrix} 1 \\ 1 \\ 2t \end{pmatrix} dt = \frac{13}{10}.$$

We can see from the above example that the line integral between two points depends on the path taken.

Example 7.4.3

A particle at $\mathbf{x}$ experiences a force in cylindrical polars of

$$\mathbf{F}(\mathbf{x}) = z\rho\mathbf{e}_\phi.$$

We will calculate the work done by travelling along

$$C : t \mapsto \begin{pmatrix} a \cos t \\ a \sin t \\ t \end{pmatrix}, \quad t \in [0, 2\pi].$$

Recall the line element in cylindrical polars is

$$d\mathbf{x} = d\rho\mathbf{e}_\rho + \rho d\phi\mathbf{e}_\phi + dz\mathbf{e}_z.$$

So

$$\mathbf{F} \cdot d\mathbf{x} = z\rho^2 d\phi.$$

Also on the path $(\rho, \phi, z) = (a, t, t)$, so $(d\rho, d\phi, dz) = (0, dt, dt)$. So $\mathbf{F} \cdot d\mathbf{x} = a^2 t dt$. Finally,

$$\int_C \mathbf{F} \cdot d\mathbf{x} = a^2 \int_0^{2\pi} t dt = 2\pi^2 a^2.$$

A curve $\mathbf{x}(t)$ with $t \in [a, b]$ might be such that $\mathbf{x}(a) = \mathbf{x}(b)$, that is, the curve is *closed*. In this case, we write

$$\oint_C \mathbf{F} \cdot d\mathbf{x}.$$

Sometimes we call integrals of this form the **circulation** of $\mathbf{F}$ about C .

Example 7.4.4

Using C_1 and C_2 from [Example 7.4.2](#), we define the curve $C = C_1 - C_2$. Then

$$\oint_C \mathbf{F} \cdot d\mathbf{x} = \int_{C_1} \mathbf{F} \cdot d\mathbf{x} - \int_{C_2} \mathbf{F} \cdot d\mathbf{x} = -\frac{2}{15}.$$

§7.4.2 Conservative Forces and Exact Differentials

We have seen how to interpret things like $\mathbf{F} \cdot d\mathbf{x}$ when they're inside an integral. This is another differential form, that is, in coordinates (u, v, w) ,

$$\mathbf{F} \cdot d\mathbf{x} = () du + () dv + () dw,$$

where there's *something* inside the brackets.

Definition 7.4.5 (Exactness)

We say that $\mathbf{F} \cdot d\mathbf{x}$ is **exact** if $\mathbf{F} \cdot d\mathbf{x} = df$, for some scalar function f .

Recall that $df = \nabla f \cdot d\mathbf{x}$, so $\mathbf{F} \cdot d\mathbf{x}$ is exact if and only if $\mathbf{F} = \nabla f$ for some scalar function f . We call such vector fields **conservative**.

For a vector field $\mathbf{F}$, we have $\mathbf{F} \cdot d\mathbf{x}$ is exact if and only if $\mathbf{F}$ is conservative.

Using properties such as $d(\alpha f + \beta g) = \alpha df + \beta dg$ for constant α, β and $d(fg) = g df + f dg$, usually it is easy to see if a differential form $\mathbf{F} \cdot d\mathbf{x}$ is exact.

Proposition 7.4.6

If θ is an exact differential form, then

$$\oint_C \theta = 0,$$

for any closed curve C .

Proof. If θ is exact, then $\theta = \nabla f \cdot d\mathbf{x}$ for some scalar f . If $C : t \mapsto \mathbf{x}(t)$ with

$t \in [a, b]$,

$$\begin{aligned}\oint_C \theta &= \oint_C \nabla f \cdot d\mathbf{x} \\ &= \int_a^b \nabla f(\mathbf{x}(t)) \cdot \frac{d\mathbf{x}}{dt} dt \\ &= \int_a^b \frac{d}{dt} [f(\mathbf{x}(t))] dt \\ &= f(\mathbf{x}(b)) - f(\mathbf{x}(a)) \\ &= 0,\end{aligned}$$

if $\mathbf{x}(a) = \mathbf{x}(b)$. □

Equivalently, if $\mathbf{F}$ is conservative, then the circulation of $\mathbf{F}$ around any closed loop curve C vanishes, $\oint_C \mathbf{F} \cdot d\mathbf{x} = 0$.

Also if $\mathbf{F}$ is conservative (and $\mathbf{F} \cdot d\mathbf{x}$ is exact), then the line integral between points $A = \mathbf{x}(a)$ and $B = \mathbf{x}(b)$ is *independent* of path.

Now let (u, v, w) be an arbitrary set of orthonormal curvilinear coordinates. Let

$$\mathbf{F} \cdot d\mathbf{x} = \theta = \underbrace{A(u, v, w)}_{\theta_1} du + \underbrace{B(u, v, w)}_{\theta_2} dv + \underbrace{C(u, v, w)}_{\theta_3} dw = \theta_i du_i.$$

A *necessary* condition for θ to be exact is

$$\frac{\partial \theta_i}{\partial u_j} = \frac{\partial \theta_j}{\partial u_i}, \quad \text{for each } i, j.$$

Indeed, if θ is exact, then $\theta = df$ for some f . Then

$$\theta = \frac{\partial f}{\partial u_i} du_i \iff \theta_i = \frac{\partial f}{\partial u_i}, \quad (*)$$

and so

$$\frac{\partial \theta_i}{\partial u_j} = \frac{\partial^2 f}{\partial u_j \partial u_i} = \frac{\partial^2 f}{\partial u_i \partial u_j} = \frac{\partial \theta_j}{\partial u_i}.$$

If a differential form satisfies $(*)$, we call it **closed**. So if θ is exact, then θ is closed.

The reverse implication is true if the domain $\Omega \subset \mathbb{R}^3$ on which θ is defined is simply-connected¹. We will be able to prove this later on, using Stokes' theorem.

Example 7.4.7

Consider $\theta = y dx - x dy$. We will check if it is closed. If so, we need to have

$$\frac{\partial y}{\partial y} = \frac{\partial (-x)}{\partial x},$$

which is clearly not the case, as $1 \neq -1$. Thus θ is not exact.

¹All closed loops in Ω can be 'continuously shrunk' to any point inside Ω without leaving it.

Example 7.4.8 (Silly Example)

We will compute the line integral

$$\oint_C 3x^2y \, dx + x^3 \, dy,$$

over the curve

$$C : t \mapsto \begin{pmatrix} \cos(\operatorname{Im}(\zeta(1/2 + it))) \\ \sin(\operatorname{Re}(\zeta(1/2 + it))) \\ 0 \end{pmatrix}, \quad t \in [\alpha_1, \alpha_{100}],$$

where α_1 and α_{100} are the 1st and 100th zero of $\zeta(1/2 + it)$, so that $\zeta(1/2 + i\alpha_1) = \zeta(1/2 + i\alpha_{100}) = 0$.

Now this differential form is exact, as $3x^2y \, dx + x^3 \, dy = d(x^3y)$, and C is a closed curve (both endpoints are $(1, 0, 0)$), thus $\oint_C 3x^2y \, dx + x^3 \, dy = 0$.

§7.4.3 Integration in $\mathbb{R}^2$

We want to integrate over some bounded region say $D \subset \mathbb{R}^2$. To do this, we will cover D with small, disjoint sets A_{ij} , each with area δA_{ij} , so that each of these are contained in a disk of radius $\epsilon > 0$. Let (x_i, y_j) be points contained in each A_{ij} .

Now define

$$\int_D f(\mathbf{x}) \, dA = \lim_{\epsilon \rightarrow 0} \sum_{i,j} f(x_i, y_j) \delta A_{ij}$$

We will say that the integral exists if it is independent of our choice of A_{ij} and choice of (x_i, y_j) .

An obvious choice of partition would be to use rectangles with $\delta A_{ij} = \delta x \delta y$. We could sum over horizontal strips of width δy , then take the limit as $\delta x \rightarrow 0$. This gives

$$\delta y \int_{X_y} f(x, y) \, dx,$$

where $X_y = \{x \mid (x, y) \in D\}$. Summing over each such strip, we'd end up with

$$\int_D f(x, y) \, dA = \int_Y \left(\int_{X_y} f(x, y) \, dx \right) dy,$$

where Y is as in the diagram below.

If we instead sum over vertical strips, we get

$$\int_D f(x, y) \, dA = \int_X \left(\int_{Y_x} f(x, y) \, dy \right) dx.$$

More concisely, we have

$$dA = dx \, dy = dy \, dx.$$

This is known as Fubini's theorem (with a few caveats that we won't worry about), which you may meet properly in a later course.

Example 7.4.9

Let D be a triangle with vertices at $(0, 0)$, $(1, 0)$ and $(0, 1)$.

If $f(x, y) = xy^2$, then if we integrate over horizontal strips,

$$\begin{aligned} \int_D f \, dA &= \int_0^1 \left(\int_0^{1-y} xy^2 \, dx \right) dy \\ &= \int_0^1 y^2 \left[\frac{1}{2}x^2 \right]_0^{1-y} dy \\ &= \int_0^1 \frac{1}{2}y^2(1-y)^2 dy = \frac{1}{60}. \end{aligned}$$

If we did the same with vertical strips, we could get

$$\int_D f \, dA = \int_0^1 \left(\int_0^{1-x} xy^2 \, dy \right) dx$$

$$= \int_0^1 x \left[\frac{1}{3} y^3 \right]_0^{1-x} dx = \frac{1}{60},$$

and they are the same.

A special case is when $f(x, y) = g(x)h(y)$ and D is a rectangle, $D = \{(x, y) \mid a \leq x \leq b, c \leq y \leq d\}$, then

$$\int_D f(x, y) \, dA = \left(\int_a^b g(x) \, dx \right) \left(\int_c^d h(y) \, dy \right).$$

It is often useful to introduce a change of variables to compute $\int_a^b f(x) \, dx$. If we introduce $x = x(u)$ with $x(\alpha) = a$ and $x(\beta) = b$, then

$$\int_a^b f(x) \, dx = \begin{cases} + \int_\alpha^\beta f(x(u)) \frac{dx}{du} \, du & \text{if } \beta > \alpha, \\ - \int_\beta^\alpha f(x(u)) \frac{dx}{du} \, du & \text{if } \alpha > \beta. \end{cases}$$

So if $I = [a, b]$ is the image under x of an interval I' , then

$$\int_I f(x) \, dx = \int_{I'} f(x(u)) \left| \frac{dx}{du} \right| \, du.$$

There is a similar formula in two dimensions.

Proposition 7.4.10

Let $x = x(u, v)$ and $y = y(u, v)$ be a smooth, invertible transformation with smooth inverse that maps the region D' in the (u, v) plane to the region D in the (x, y) -plane. Then

$$\int_D f(x, y) \, dx \, dy = \int_{D'} f(x(u, v), y(u, v)) \left| \frac{\partial(x, y)}{\partial(u, v)} \right| \, du \, dv,$$

where

$$\frac{\partial(x, y)}{\partial(u, v)} = \det \begin{pmatrix} \partial x / \partial u & \partial x / \partial v \\ \partial y / \partial u & \partial y / \partial v \end{pmatrix}$$

is the *Jacobian*, often denoted by J .

The short version is that $dx \, dy = |J| \, du \, dv$.

Example 7.4.11

Using polar coordinates (ρ, ϕ) ,

$$x(\rho, \phi) = \rho \cos \phi, \quad y(\rho, \phi) = \rho \sin \phi.$$

Hence

$$J = \det \begin{pmatrix} \cos \phi & -\rho \sin \phi \\ \sin \phi & \rho \cos \phi \end{pmatrix} = \rho,$$

So if $D = \{(x, y) \mid x > 0, y > 0, x^2 + y^2 < R^2\}$, then $D' = \{(\rho, \phi) \mid 0 < \rho < R, 0 < \phi < \pi/2\}$, and

$$\int_D f(x, y) \, dx \, dy = \int_{D'} f(\rho \cos \phi, \rho \sin \phi) \rho \, d\rho \, d\phi,$$

so $dx dy = \rho d\rho d\phi$.

Taking $R \rightarrow \infty$, we get

$$\int_{x=0}^{\infty} \int_{y=0}^{\infty} f(x, y) dy dx = \int_{\phi=0}^{\pi/2} \int_{\rho=0}^{\infty} f(\rho \cos \phi, \rho \sin \phi) \rho d\rho d\phi.$$

Now consider $I = \int_0^{\infty} e^{-x^2} dx$. Using the previous result, we have

$$\begin{aligned} I^2 &= \int_0^{\infty} e^{-x^2} dx \cdot \int_0^{\infty} e^{-y^2} dy \\ &= \int_{x=0}^{\infty} \int_{y=0}^{\infty} e^{-x^2-y^2} dx dy \\ &= \int_{\phi=0}^{\pi/2} \left(\int_{\rho=0}^{\infty} e^{-\rho^2} \rho d\rho \right) d\phi \\ &= \frac{\pi}{2} \int_0^{\infty} \frac{d}{d\rho} \left(-\frac{1}{2} e^{-\rho^2} \right) d\rho = \frac{\pi}{4}. \end{aligned}$$

Thus $I = \frac{\sqrt{\pi}}{2}$.

§7.4.4 Integration in $\mathbb{R}^3$

To integrate over a region V in $\mathbb{R}^3$, we use similar ideas to that of the previous section. Let

$$\int_V f(\mathbf{x}) dV = \lim_{\epsilon \rightarrow 0} \sum_{i,j,k} f(x_i, y_j, z_k) \delta V_{ijk},$$

where the *volume element* satisfies

$$dV = dx dy dz.$$

We can do the integrals in any order (again Fubini's theorem).

Example 7.4.12

Consider the region V bound by planes $x + y + z = 1$ and $x = 0, y = 0$ and $z = 0$. We will find the volume (integrating 1 over the region).

We have

$$\begin{aligned}\int_V dV &= \int_{x=0}^1 \left(\int_{y=0}^{1-x} \left(\int_{z=0}^{1-x-y} dz \right) dy \right) dx \\ &= \int_{x=0}^1 \int_{y=0}^{1-x} (1-x-y) dy dx \\ &= \frac{1}{6}.\end{aligned}$$

If we wanted to compute say the center of mass, then assuming it had constant density say $\rho = 1$, the centre of mass $\mathbf{X}$ is

$$\mathbf{X} = \frac{1}{M} \int_V \rho \mathbf{x} dV = \frac{1}{4} \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix}$$

We can write down the change of variables for three dimensional integrals.

Proposition 7.4.13

Let $x = x(u, v, w)$, $y = y(u, v, w)$ and $z = z(u, v, w)$ be a continuously differentiable bijection with continuously differentiable inverse that maps the volume V' to V . Then

$$\int_V f(x, y, z) dx dy dz = \int_{V'} f(x(u, v, w), y(u, v, w), z(u, v, w)) |J| du dv dw,$$

where

$$J = \frac{\partial(x, y, z)}{\partial(u, v, w)}$$

Again the short version is $dx dy dz = |J| du dv dw$.

Example 7.4.14

In cylindrical polars $(u, v, w) = (\rho, \phi, z)$,

$$dV = \rho d\rho d\phi dz,$$

and $|J| = \rho$.

In spherical polars $(u, v, w) = (r, \theta, \phi)$,

$$dV = r^2 \sin \theta dr d\theta d\phi,$$

and $|J| = r^2 \sin \theta$.

Example 7.4.15

Suppose we wanted to calculate the volume of the ball of radius R , $V = \{(x, y, z) \mid x^2 + y^2 + z^2 \leq R^2\}$.

We could try a ‘bare hands’ approach in Cartesian coordinates.

$$\begin{aligned}
 \int_V dV &= \int_{z=-R}^R \left(\int_{y=-\sqrt{R^2-z^2}}^{\sqrt{R^2-z^2}} \left(\int_{x=-\sqrt{R^2-z^2-y^2}}^{\sqrt{R^2-z^2-y^2}} dx \right) dy \right) dz \\
 &= \int_{z=-R}^R \left[\int_{y=-\sqrt{R^2-z^2}}^{\sqrt{R^2-z^2}} 2\sqrt{R^2-z^2-y^2} dy \right] dz \\
 &= \int_{z=-R}^R \left[y\sqrt{R^2-z^2-y^2} + (R^2-z^2) \tan^{-1} \left(\frac{y}{\sqrt{R^2-z^2-y^2}} \right) \right]_{-\sqrt{R^2-z^2}}^{\sqrt{R^2-z^2}} dz \\
 &= \int_{-R}^R \pi(R^2-z^2) dz = \frac{4\pi R^3}{3}.
 \end{aligned}$$

Alternatively, since we have even a limited amount of self respect, we can use spherical polars. We have $V' = \{(r, \theta, \phi) \mid 0 \leq r \leq R, 0 \leq \theta \leq \pi, 0 \leq \phi < 2\pi\}$. Then

$$\begin{aligned}
 \int_V dV &= \int_{\phi=0}^{2\pi} \left[\int_{\theta=0}^{\pi} \left[\int_{r=0}^R r^2 \sin \theta dr \right] d\theta \right] d\phi \\
 &= \int_{\theta=0}^{\pi} \frac{2\pi R^3}{3} \sin \theta d\theta = \frac{4\pi R^3}{3}.
 \end{aligned}$$

And this is clearly much nicer.

Example 7.4.16

Consider a ball of radius a with a cylinder of radius $b < a$ removed. The symmetry suggests that we use cylindrical polar coordinates. In Cartesian coordinates, we would have

$$V = \{(x, y, z) \mid x^2 + y^2 + z^2 \leq a^2, x^2 + y^2 \geq b^2\},$$

but in cylindrical polars we would have

$$V' = \{(\rho, \phi, z) \mid b \leq \rho \leq a, 0 \leq z^2 + \rho^2 \leq a^2, 0 \leq \phi < 2\pi\}.$$

So we have

$$\begin{aligned}
 \int_V dV &= \int_{\rho=b}^a \left[\int_{\phi=0}^{2\pi} \left[\int_{z=-\sqrt{a^2-\rho^2}}^{\sqrt{a^2-\rho^2}} dz \right] d\phi \right] \rho d\rho \\
 &= 2\pi \int_b^a 2\rho \sqrt{a^2-\rho^2} d\rho \\
 &= \frac{4\pi}{3} (a^2 - b^2)^{3/2}.
 \end{aligned}$$

§7.4.5 Integration Over Surfaces

We have now integrated over curves, over regions of the plane, and over volumes. The remaining object to integrate over is a *surface* in $\mathbb{R}^3$, and this is where things get in-

teresting – surface integrals are the key ingredient in the integral theorems that we are building towards.

Surfaces and Their Boundaries

A two dimensional surface in $\mathbb{R}^3$ can be defined *implicitly* using a function $f : \mathbb{R}^3 \rightarrow \mathbb{R}$, by setting

$$S = \{\mathbf{x} \in \mathbb{R}^3 \mid f(\mathbf{x}) = 0\}.$$

We saw before that ∇f is normal to the level sets of f , so the normal to S at $\mathbf{x}$ is parallel to $\nabla f(\mathbf{x})$. In analogy with what we did for curves, we say the surface is **regular** if $\nabla f(\mathbf{x}) \neq \mathbf{0}$ on S , which rules out any ‘spikes’ or ‘creases’.

Example 7.4.17 (The Sphere)

Take $f(\mathbf{x}) = x^2 + y^2 + z^2 - 1$, so that

$$S = \{(x, y, z) \mid x^2 + y^2 + z^2 - 1 = 0\}$$

is the unit sphere. Then $\nabla f = 2\mathbf{x}$, which is never zero on S , and is indeed normal to the sphere at $\mathbf{x}$.

Some surfaces have a **boundary**, which we write as ∂S . For example, the hemisphere

$$S = \{(x, y, z) \mid x^2 + y^2 + z^2 = 1, z \geq 0\}$$

has boundary the circle

$$\partial S = \{(x, y, z) \mid x^2 + y^2 = 1, z = 0\}.$$

In this course, a surface will either have no boundary at all, or its boundary will be made up of piecewise smooth curves. If S has no boundary (like the sphere), we say that S is a **closed** surface.

Just as it was useful to parameterize curves, it is useful to parameterize surfaces. We do this using *two* coordinates (u, v) , writing

$$S = \{\mathbf{x} = \mathbf{x}(u, v) \mid (u, v) \in D\},$$

where D is some region in the (u, v) -plane.

Example 7.4.18 (Parameterizing the Hemisphere)

For the upper unit hemisphere we can use the angles from spherical polar coordinates as our parameters, writing

$$S = \left\{ \mathbf{x}(\theta, \phi) = \begin{pmatrix} \sin \theta \cos \phi \\ \sin \theta \sin \phi \\ \cos \theta \end{pmatrix} \mid 0 \leq \theta \leq \frac{\pi}{2}, 0 \leq \phi < 2\pi \right\}.$$

Holding v fixed and varying u traces out a curve in S with tangent vector $\partial \mathbf{x} / \partial u$, and similarly for v . So $\partial \mathbf{x} / \partial u$ and $\partial \mathbf{x} / \partial v$ are both tangent to S , and (provided they are linearly independent) their cross product is *normal* to S . With this in mind, we say the parameterization is **regular** if

$$\frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} \neq \mathbf{0}$$

for all $(u, v) \in D$, and in that case we obtain a unit normal

$$\mathbf{n} = \frac{\frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v}}{\left| \frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} \right|},$$

which varies smoothly over the (smooth parts of the) surface.

Of course, $-\mathbf{n}$ is also a perfectly good unit normal, so there is a choice to be made here. A surface for which a consistent choice of unit normal can be made over all of S is called **orientable**, and the choice of normal is an **orientation**².

An orientation of S also induces an orientation on the boundary curve ∂S : we make the convention that ∂S is traversed so that the normal vectors near the boundary point out of your *left-hand side* as you walk along it. Equivalently, this is the ‘right-hand rule’: if the thumb of your right hand points along $\mathbf{n}$, your fingers curl in the direction of ∂S .

The Area Element

Now let's integrate. Take a regular parameterized surface $S = \{\mathbf{x}(u, v) \mid (u, v) \in D\}$. We might naively try to define the integral of f over S as the integral of $f(\mathbf{x}(u, v))$ over the region D , but this can't be right – a small patch of area $\delta u \delta v$ in D does not generally correspond to a patch of the same area on S , and different parameterizations would give different answers.

Instead, let's see what a small patch actually looks like. Perturbing the coordinates one at a time,

$$\begin{aligned}\mathbf{x}(u + \delta u, v) - \mathbf{x}(u, v) &= \frac{\partial \mathbf{x}}{\partial u} \delta u + o(\delta u), \\ \mathbf{x}(u, v + \delta v) - \mathbf{x}(u, v) &= \frac{\partial \mathbf{x}}{\partial v} \delta v + o(\delta v).\end{aligned}$$

So to first order, the small rectangle $[u, u + \delta u] \times [v, v + \delta v]$ in D is mapped to a small *parallelogram* on S spanned by the vectors $\frac{\partial \mathbf{x}}{\partial u} \delta u$ and $\frac{\partial \mathbf{x}}{\partial v} \delta v$. Recalling from ‘Vectors & Matrices’ that the area of a parallelogram is the magnitude of the cross product of its sides, this patch has area

$$\left| \frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} \right| \delta u \delta v.$$

²Not every surface is orientable – the Möbius band famously has only one side, and if you slide a normal vector all the way around the band it comes back pointing the other way. We will only work with orientable surfaces in this course.

This tells us exactly what the correct ‘scaling factor’ is, and we make the following definition.

Definition 7.4.19 (Surface Integral)

Let $S = \{\mathbf{x}(u, v) \mid (u, v) \in D\}$ be a regular parameterized surface. The **scalar area element** on S is

$$dS = \left| \frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} \right| du dv,$$

and for $f : \mathbb{R}^3 \rightarrow \mathbb{R}$ we define

$$\int_S f(\mathbf{x}) dS = \int_D f(\mathbf{x}(u, v)) \left| \frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} \right| du dv.$$

In particular, taking $f = 1$ gives the *area* of the surface S .

Example 7.4.20 (Area of a Hemisphere)

Let S be the hemisphere of radius R , parameterized by

$$\mathbf{x}(\theta, \phi) = \begin{pmatrix} R \sin \theta \cos \phi \\ R \sin \theta \sin \phi \\ R \cos \theta \end{pmatrix} = R \mathbf{e}_r, \quad 0 \leq \theta \leq \frac{\pi}{2}, \quad 0 \leq \phi < 2\pi.$$

Differentiating (or just recalling the scale factors for spherical polars),

$$\frac{\partial \mathbf{x}}{\partial \theta} = R \mathbf{e}_\theta, \quad \frac{\partial \mathbf{x}}{\partial \phi} = R \sin \theta \mathbf{e}_\phi,$$

and since $\mathbf{e}_\theta \times \mathbf{e}_\phi = \mathbf{e}_r$ is a unit vector,

$$dS = R^2 \sin \theta d\theta d\phi.$$

The area of the hemisphere is then

$$\int_S dS = \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} R^2 \sin \theta d\theta d\phi = 2\pi R^2,$$

as expected.

As with curves, we should pause and check that our definition doesn’t depend on the parameterization we happened to pick.

Proposition 7.4.21

The integral $\int_S f(\mathbf{x}) dS$ is independent of the (regular) parameterization of S used.

Proof. Suppose $\mathbf{x} = \mathbf{x}(u, v)$ for $(u, v) \in D$ and $\mathbf{x} = \tilde{\mathbf{x}}(\tilde{u}, \tilde{v})$ for $(\tilde{u}, \tilde{v}) \in \tilde{D}$ are two parameterizations of S . Then there is a relationship between the coordinates,

$\mathbf{x}(u, v) = \tilde{\mathbf{x}}(\tilde{u}(u, v), \tilde{v}(u, v))$, and by the chain rule

$$\begin{aligned} \frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} &= \left(\frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{u}} \frac{\partial \tilde{u}}{\partial u} + \frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{v}} \frac{\partial \tilde{v}}{\partial u} \right) \times \left(\frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{u}} \frac{\partial \tilde{u}}{\partial v} + \frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{v}} \frac{\partial \tilde{v}}{\partial v} \right) \\ &= \left(\frac{\partial \tilde{u}}{\partial u} \frac{\partial \tilde{v}}{\partial v} - \frac{\partial \tilde{u}}{\partial v} \frac{\partial \tilde{v}}{\partial u} \right) \left(\frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{u}} \times \frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{v}} \right) \\ &= \frac{\partial(\tilde{u}, \tilde{v})}{\partial(u, v)} \left(\frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{u}} \times \frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{v}} \right), \end{aligned}$$

where the cross terms vanished since $\mathbf{a} \times \mathbf{a} = \mathbf{0}$. So the two normal vectors differ exactly by a factor of the Jacobian of the change of coordinates $(u, v) \mapsto (\tilde{u}, \tilde{v})$.

Then using the change of variables formula for double integrals,

$$\begin{aligned} \int_{\tilde{D}} f(\tilde{\mathbf{x}}(\tilde{u}, \tilde{v})) \left| \frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{u}} \times \frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{v}} \right| d\tilde{u} d\tilde{v} &= \int_D f(\mathbf{x}(u, v)) \left| \frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{u}} \times \frac{\partial \tilde{\mathbf{x}}}{\partial \tilde{v}} \right| \left| \frac{\partial(\tilde{u}, \tilde{v})}{\partial(u, v)} \right| du dv \\ &= \int_D f(\mathbf{x}(u, v)) \left| \frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} \right| du dv, \end{aligned}$$

so both parameterizations give the same integral. $\square$

Flux Integrals

For vector fields, the natural thing to integrate over a surface involves the *normal* direction.

Definition 7.4.22 (Vector Area Element and Flux)

On a regular parameterized surface S with unit normal $\mathbf{n}$, the **vector area element** is

$$d\mathbf{S} = \frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} du dv = \mathbf{n} dS.$$

For a vector field $\mathbf{F}$, the **flux** of $\mathbf{F}$ through S is

$$\int_S \mathbf{F} \cdot d\mathbf{S} = \int_S \mathbf{F} \cdot \mathbf{n} dS.$$

Note that the flux depends on the orientation: swapping $\mathbf{n}$ for $-\mathbf{n}$ flips the sign. When S is a closed surface, the convention is to take $\mathbf{n}$ to be the *outward* pointing normal.

To see why this is a sensible quantity to consider, suppose that a fluid has velocity $\mathbf{u}(\mathbf{x})$, and we want to know how much fluid crosses a surface S per unit time. Over a small patch δS of the surface, only the component of $\mathbf{u}$ *normal* to the patch actually carries fluid across it – flow tangent to the surface just slides along it. So in time δt the volume of fluid crossing the patch is $(\mathbf{u} \cdot \mathbf{n})\delta S \delta t$, and the total volume crossing S per unit time is exactly the flux $\int_S \mathbf{u} \cdot d\mathbf{S}$.

Example 7.4.23 (Flux Through a Sphere)

Let S be the sphere of radius R centred at the origin with outward normal, and let $\mathbf{F}(\mathbf{x}) = \mathbf{x}$. Using spherical polars as before,

$$d\mathbf{S} = \mathbf{e}_r R^2 \sin \theta \, d\theta \, d\phi,$$

and on the sphere $\mathbf{F} = R\mathbf{e}_r$, so $\mathbf{F} \cdot d\mathbf{S} = R^3 \sin \theta \, d\theta \, d\phi$. Then

$$\int_S \mathbf{F} \cdot d\mathbf{S} = \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} R^3 \sin \theta \, d\theta \, d\phi = 4\pi R^3,$$

which is notably three times the volume of the ball – a fact that will stop looking like a coincidence once we meet the divergence theorem.

Example 7.4.24 (Flux Through a Hemisphere)

Let S be the upper hemisphere of radius R with upward-pointing normal, and take $\mathbf{F} = z\mathbf{e}_z$. On S we have $z = R \cos \theta$ and $\mathbf{e}_z \cdot \mathbf{e}_r = \cos \theta$, so

$$\begin{aligned} \int_S \mathbf{F} \cdot d\mathbf{S} &= \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} (R \cos \theta)(\cos \theta) R^2 \sin \theta \, d\theta \, d\phi \\ &= 2\pi R^3 \left[-\frac{\cos^3 \theta}{3} \right]_0^{\pi/2} = \frac{2\pi R^3}{3}. \end{aligned}$$

§7.5 Div, Curl and the Laplacian

So far the only way we have of differentiating fields is the gradient, which takes a scalar field and produces a vector field. In this section we complete the toolkit: we will meet two ways of differentiating a *vector* field – the divergence and the curl – along with a natural second-order operator, the Laplacian. These operators are the stars of the rest of the course.

§7.5.1 The Divergence and Curl

Recall that in Cartesian coordinates the gradient operator can be written as

$$\nabla = \mathbf{e}_i \frac{\partial}{\partial x_i},$$

a ‘vector of derivatives’. Treating ∇ formally as a vector, there are two natural products we can form with a vector field $\mathbf{F}$: a dot product and a cross product.

Definition 7.5.1 (Divergence)

For a vector field $\mathbf{F} : \mathbb{R}^3 \rightarrow \mathbb{R}^3$, we define the **divergence** of $\mathbf{F}$ to be $\nabla \cdot \mathbf{F}$, which in Cartesian coordinates is

$$\nabla \cdot \mathbf{F} = \frac{\partial F_i}{\partial x_i} = \frac{\partial F_1}{\partial x_1} + \frac{\partial F_2}{\partial x_2} + \frac{\partial F_3}{\partial x_3}.$$

Note that the divergence of a vector field is a *scalar* field. To see where the Cartesian expression comes from, note that in Cartesian coordinates the basis vectors are constant, so

$$\nabla \cdot \mathbf{F} = \left(\mathbf{e}_i \frac{\partial}{\partial x_i} \right) \cdot (F_j \mathbf{e}_j) = \underbrace{(\mathbf{e}_i \cdot \mathbf{e}_j)}_{\delta_{ij}} \frac{\partial F_j}{\partial x_i} = \frac{\partial F_i}{\partial x_i}.$$

This warning matters: in curvilinear coordinates the basis vectors themselves depend on position and must also be differentiated, so the divergence is *not* just ‘ $\partial F_u / \partial u + \dots$ ’. We will sort out what happens in general coordinates at the end of this section.

Definition 7.5.2 (Curl)

For a vector field $\mathbf{F} : \mathbb{R}^3 \rightarrow \mathbb{R}^3$, we define the **curl** of $\mathbf{F}$ to be $\nabla \times \mathbf{F}$, which in Cartesian coordinates has components

$$[\nabla \times \mathbf{F}]_i = \epsilon_{ijk} \frac{\partial F_k}{\partial x_j}.$$

The curl of a vector field is another vector field. Again the Cartesian expression follows from a short computation:

$$\nabla \times \mathbf{F} = \left(\mathbf{e}_j \frac{\partial}{\partial x_j} \right) \times (F_k \mathbf{e}_k) = (\mathbf{e}_j \times \mathbf{e}_k) \frac{\partial F_k}{\partial x_j} = \epsilon_{ijk} \frac{\partial F_k}{\partial x_j} \mathbf{e}_i.$$

It is often convenient to remember this as a ‘formal determinant’,

$$\nabla \times \mathbf{F} = \det \begin{pmatrix} \mathbf{e}_1 & \mathbf{e}_2 & \mathbf{e}_3 \\ \frac{\partial}{\partial x_1} & \frac{\partial}{\partial x_2} & \frac{\partial}{\partial x_3} \\ F_1 & F_2 & F_3 \end{pmatrix}.$$

Unlike the gradient and divergence, the curl is genuinely a three-dimensional construction – it relies on the cross product, which doesn’t generalise naively to other dimensions.

Let’s compute some simple examples, which will also suggest how to *think* about these operators.

Example 7.5.3 (A Radial Field)

Let $\mathbf{F}(\mathbf{x}) = \mathbf{x}$. Then in Cartesian coordinates,

$$\nabla \cdot \mathbf{F} = \frac{\partial x_i}{\partial x_i} = \delta_{ii} = 3, \quad [\nabla \times \mathbf{F}]_i = \epsilon_{ijk} \frac{\partial x_k}{\partial x_j} = \epsilon_{ijk} \delta_{kj} = 0.$$

So a field pointing radially outwards has positive divergence and no curl.

Example 7.5.4 (A Rotating Field)

Let $\mathbf{F}(\mathbf{x}) = (-y, x, 0)$, the velocity field of a rigid rotation about the z -axis. Then

$$\nabla \cdot \mathbf{F} = 0, \quad \nabla \times \mathbf{F} = \det \begin{pmatrix} \mathbf{e}_1 & \mathbf{e}_2 & \mathbf{e}_3 \\ \partial_x & \partial_y & \partial_z \\ -y & x & 0 \end{pmatrix} = 2\mathbf{e}_3.$$

So a rotating field has no divergence, but its curl points along the axis of rotation

(with magnitude twice the angular speed).

These examples are entirely representative. If we think of $\mathbf{F}$ as the velocity field of a fluid, then a positive divergence at a point means the fluid is (locally) flowing *away* from that point, so the point acts like a *source*; negative divergence gives a *sink*. A field with $\nabla \cdot \mathbf{F} = 0$ everywhere models an incompressible fluid. Meanwhile the curl measures the *local rotation* of the fluid: if you dropped a tiny paddle wheel into the flow at $\mathbf{x}$ with its axis along $\hat{\mathbf{k}}$, it would spin at a rate proportional to $\hat{\mathbf{k}} \cdot (\nabla \times \mathbf{F})$. We will be able to make both of these statements precise once we have the integral theorems.

Finally, we can compose our operators to get a second-order operator.

Definition 7.5.5 (Laplacian)

For a scalar field $f : \mathbb{R}^3 \rightarrow \mathbb{R}$, the **Laplacian** of f is

$$\nabla^2 f = \nabla \cdot (\nabla f),$$

which in Cartesian coordinates is

$$\nabla^2 f = \frac{\partial^2 f}{\partial x_i \partial x_i} = \frac{\partial^2 f}{\partial x_1^2} + \frac{\partial^2 f}{\partial x_2^2} + \frac{\partial^2 f}{\partial x_3^2}.$$

The Laplacian shows up all over mathematical physics – in the heat equation, the wave equation, Laplace’s equation and Poisson’s equation, some of which we will meet later in these notes.

We can also apply the Laplacian to a *vector* field. In Cartesian coordinates we simply apply it to each component,

$$\nabla^2 \mathbf{F} = (\nabla^2 F_i) \mathbf{e}_i,$$

but this recipe fails in curvilinear coordinates (where the basis vectors move). The coordinate-independent statement is the following.

Proposition 7.5.6

In Cartesian coordinates, $\nabla^2 \mathbf{F} = \nabla(\nabla \cdot \mathbf{F}) - \nabla \times (\nabla \times \mathbf{F})$.

Proof. We compute the curl of the curl in index notation:

$$[\nabla \times (\nabla \times \mathbf{F})]_i = \epsilon_{ijk} \frac{\partial}{\partial x_j} \left(\epsilon_{klm} \frac{\partial F_m}{\partial x_l} \right)$$

$$\begin{aligned}
&= \epsilon_{kij}\epsilon_{klm} \frac{\partial^2 F_m}{\partial x_j \partial x_l} \\
&= (\delta_{il}\delta_{jm} - \delta_{im}\delta_{jl}) \frac{\partial^2 F_m}{\partial x_j \partial x_l} \\
&= \frac{\partial}{\partial x_i} \left(\frac{\partial F_j}{\partial x_j} \right) - \frac{\partial^2 F_i}{\partial x_j \partial x_j} \\
&= [\nabla(\nabla \cdot \mathbf{F})]_i - \nabla^2 F_i,
\end{aligned}$$

using the identity $\epsilon_{kij}\epsilon_{klm} = \delta_{il}\delta_{jm} - \delta_{im}\delta_{jl}$ from ‘Vectors & Matrices’. Rearranging gives the result. $\square$

Since the right-hand side $\nabla(\nabla \cdot \mathbf{F}) - \nabla \times (\nabla \times \mathbf{F})$ makes sense in any coordinate system, we take it as the *definition* of $\nabla^2 \mathbf{F}$ in general.

§7.5.2 Identities in Index Notation

Just as ordinary differentiation has a product rule, our new operators satisfy a family of ‘Leibniz identities’. These are used constantly, and proving a few of them is excellent practice with the index notation.

Proposition 7.5.7 (Leibniz Identities)

For scalar fields f, g and vector fields $\mathbf{F}, \mathbf{G}$, we have

- (i) $\nabla(fg) = f\nabla g + g\nabla f$,
- (ii) $\nabla \cdot (f\mathbf{F}) = (\nabla f) \cdot \mathbf{F} + f(\nabla \cdot \mathbf{F})$,
- (iii) $\nabla \times (f\mathbf{F}) = (\nabla f) \times \mathbf{F} + f(\nabla \times \mathbf{F})$,
- (iv) $\nabla \cdot (\mathbf{F} \times \mathbf{G}) = (\nabla \times \mathbf{F}) \cdot \mathbf{G} - \mathbf{F} \cdot (\nabla \times \mathbf{G})$,
- (v) $\nabla \times (\mathbf{F} \times \mathbf{G}) = \mathbf{F}(\nabla \cdot \mathbf{G}) - \mathbf{G}(\nabla \cdot \mathbf{F}) + (\mathbf{G} \cdot \nabla)\mathbf{F} - (\mathbf{F} \cdot \nabla)\mathbf{G}$,
- (vi) $\nabla(\mathbf{F} \cdot \mathbf{G}) = \mathbf{F} \times (\nabla \times \mathbf{G}) + \mathbf{G} \times (\nabla \times \mathbf{F}) + (\mathbf{F} \cdot \nabla)\mathbf{G} + (\mathbf{G} \cdot \nabla)\mathbf{F}$.

Here $\mathbf{F} \cdot \nabla$ denotes the differential operator $F_j \frac{\partial}{\partial x_j}$, so that

$$[(\mathbf{F} \cdot \nabla)\mathbf{G}]_i = F_j \frac{\partial G_i}{\partial x_j}.$$

Be careful to distinguish the operator $\mathbf{F} \cdot \nabla$ from the scalar field $\nabla \cdot \mathbf{F}$ – they are certainly not the same thing!

Proof. All of these identities are statements about fields, so they can be checked in any coordinate system we like – and we will naturally use Cartesian coordinates, where the basis vectors are constant. We prove (ii), (iv) and (v); the others are entirely similar (and are good exercises).

For (ii), by the ordinary product rule,

$$\nabla \cdot (f\mathbf{F}) = \frac{\partial}{\partial x_i} (fF_i) = \frac{\partial f}{\partial x_i} F_i + f \frac{\partial F_i}{\partial x_i} = (\nabla f) \cdot \mathbf{F} + f(\nabla \cdot \mathbf{F}).$$

For (iv),

$$\begin{aligned}
 \nabla \cdot (\mathbf{F} \times \mathbf{G}) &= \frac{\partial}{\partial x_i} (\epsilon_{ijk} F_j G_k) \\
 &= \epsilon_{ijk} \frac{\partial F_j}{\partial x_i} G_k + \epsilon_{ijk} F_j \frac{\partial G_k}{\partial x_i} \\
 &= \left(\epsilon_{kij} \frac{\partial F_j}{\partial x_i} \right) G_k - F_j \left(\epsilon_{jik} \frac{\partial G_k}{\partial x_i} \right) \\
 &= (\nabla \times \mathbf{F}) \cdot \mathbf{G} - \mathbf{F} \cdot (\nabla \times \mathbf{G}),
 \end{aligned}$$

where we just cycled and swapped indices of ϵ , picking up a sign in the second term.

For (v), we use the ϵ - δ identity:

$$\begin{aligned}
 [\nabla \times (\mathbf{F} \times \mathbf{G})]_i &= \epsilon_{ijk} \frac{\partial}{\partial x_j} (\epsilon_{klm} F_l G_m) \\
 &= \epsilon_{kij} \epsilon_{klm} \left(\frac{\partial F_l}{\partial x_j} G_m + F_l \frac{\partial G_m}{\partial x_j} \right) \\
 &= (\delta_{il} \delta_{jm} - \delta_{im} \delta_{jl}) \left(\frac{\partial F_l}{\partial x_j} G_m + F_l \frac{\partial G_m}{\partial x_j} \right) \\
 &= \frac{\partial F_i}{\partial x_j} G_j + F_i \frac{\partial G_j}{\partial x_j} - \frac{\partial F_j}{\partial x_j} G_i - F_j \frac{\partial G_i}{\partial x_j} \\
 &= [(\mathbf{G} \cdot \nabla) \mathbf{F}]_i + [\mathbf{F}(\nabla \cdot \mathbf{G})]_i - [\mathbf{G}(\nabla \cdot \mathbf{F})]_i - [(\mathbf{F} \cdot \nabla) \mathbf{G}]_i,
 \end{aligned}$$

as required. $\square$

There are also two identities involving *second* derivatives which are so important that they deserve their own proposition. They say, slightly cryptically, that ‘curl grad is zero’ and ‘div curl is zero’.

Proposition 7.5.8

For any (twice continuously differentiable) scalar field f and vector field $\mathbf{F}$,

$$\nabla \times (\nabla f) = \mathbf{0} \quad \text{and} \quad \nabla \cdot (\nabla \times \mathbf{F}) = 0.$$

Proof. Both proofs use the same trick: a symmetric object contracted with an antisymmetric one gives zero. For the first,

$$[\nabla \times (\nabla f)]_i = \epsilon_{ijk} \frac{\partial}{\partial x_j} \frac{\partial f}{\partial x_k} = \epsilon_{ijk} \frac{\partial^2 f}{\partial x_j \partial x_k}.$$

Now ϵ_{ijk} is antisymmetric under swapping $j \leftrightarrow k$, while $\frac{\partial^2 f}{\partial x_j \partial x_k}$ is symmetric (partial derivatives commute). Relabelling the dummy indices,

$$\epsilon_{ijk} \frac{\partial^2 f}{\partial x_j \partial x_k} = \epsilon_{ikj} \frac{\partial^2 f}{\partial x_k \partial x_j} = -\epsilon_{ijk} \frac{\partial^2 f}{\partial x_j \partial x_k},$$

so the expression equals its own negative and must vanish. Identically,

$$\nabla \cdot (\nabla \times \mathbf{F}) = \epsilon_{ijk} \frac{\partial^2 F_k}{\partial x_i \partial x_j} = 0$$

by antisymmetry of ϵ_{ijk} in (i, j) . □

This proposition gives us a useful vocabulary. We say $\mathbf{F}$ is **irrotational** if $\nabla \times \mathbf{F} = \mathbf{0}$, and **solenoidal** if $\nabla \cdot \mathbf{F} = 0$. The proposition then says:

- (i) every conservative field $\mathbf{F} = \nabla f$ is irrotational;
- (ii) every field of the form $\mathbf{F} = \nabla \times \mathbf{A}$ is solenoidal. We call such an $\mathbf{A}$ a **vector potential** for $\mathbf{F}$.

Remarkably, both statements have converses if the domain of $\mathbf{F}$ is topologically nice enough: an irrotational field on a simply connected domain is conservative (we will prove this using Stokes' theorem), and a solenoidal field on a suitable domain (one where every closed surface can be shrunk to a point, such as all of $\mathbb{R}^3$) has a vector potential.

In practice, checking $\nabla \times \mathbf{F} = \mathbf{0}$ is by far the easiest way to show a field is conservative, so this is a result worth internalising.

§7.5.3 Div and Curl in Orthogonal Curvilinear Coordinates

We now settle the question of what the divergence and curl look like in a general orthogonal curvilinear coordinate system (u, v, w) , with scale factors h_u, h_v, h_w and right-handed orthonormal basis $\{\mathbf{e}_u, \mathbf{e}_v, \mathbf{e}_w\}$. The subtlety, as mentioned before, is that the basis vectors vary from point to point, and naive componentwise differentiation is wrong.

Rather than grinding through derivatives of basis vectors, there is a rather slick route using two small observations. First, recall that

$$\nabla u = \frac{1}{h_u} \mathbf{e}_u,$$

which is just the formula for the gradient in curvilinear coordinates applied to the function $f = u$. Second, since the basis is right-handed and orthonormal, $\mathbf{e}_u = \mathbf{e}_v \times \mathbf{e}_w$, so

$$\mathbf{e}_u = h_v h_w \nabla v \times \nabla w,$$

and similarly for cyclic permutations of (u, v, w) .

Proposition 7.5.9 (Divergence in Curvilinear Coordinates)

If $\mathbf{F} = F_u \mathbf{e}_u + F_v \mathbf{e}_v + F_w \mathbf{e}_w$, then

$$\nabla \cdot \mathbf{F} = \frac{1}{h_u h_v h_w} \left[\frac{\partial}{\partial u} (h_v h_w F_u) + \frac{\partial}{\partial v} (h_u h_w F_v) + \frac{\partial}{\partial w} (h_u h_v F_w) \right].$$

Proof. Consider the first term $F_u \mathbf{e}_u = (F_u h_v h_w) \nabla v \times \nabla w$. Using the Leibniz identity for $\nabla \cdot (f \mathbf{G})$,

$$\nabla \cdot (F_u \mathbf{e}_u) = \nabla (F_u h_v h_w) \cdot (\nabla v \times \nabla w) + F_u h_v h_w \nabla \cdot (\nabla v \times \nabla w).$$

But by the identity for the divergence of a cross product, along with ‘curl grad is zero’,

$$\nabla \cdot (\nabla v \times \nabla w) = (\nabla \times \nabla v) \cdot \nabla w - \nabla v \cdot (\nabla \times \nabla w) = 0,$$

so the second term dies. For the first term, $\nabla v \times \nabla w = \mathbf{e}_u / (h_v h_w)$, and taking the $\mathbf{e}_u$ component of the gradient,

$$\nabla(F_u h_v h_w) \cdot \frac{\mathbf{e}_u}{h_v h_w} = \frac{1}{h_u h_v h_w} \frac{\partial}{\partial u} (h_v h_w F_u).$$

Adding the corresponding expressions for the $\mathbf{e}_v$ and $\mathbf{e}_w$ terms (which follow by cyclic symmetry) gives the result. $\square$

Proposition 7.5.10 (Curl in Curvilinear Coordinates)

With $\mathbf{F}$ as above,

$$\nabla \times \mathbf{F} = \frac{1}{h_u h_v h_w} \det \begin{pmatrix} h_u \mathbf{e}_u & h_v \mathbf{e}_v & h_w \mathbf{e}_w \\ \frac{\partial}{\partial u} & \frac{\partial}{\partial v} & \frac{\partial}{\partial w} \\ h_u F_u & h_v F_v & h_w F_w \end{pmatrix}.$$

Proof. This time write $F_u \mathbf{e}_u = (h_u F_u) \nabla u$. Then by the Leibniz identity for the curl of a product, and ‘curl grad is zero’ once more,

$$\nabla \times (F_u \mathbf{e}_u) = \nabla(h_u F_u) \times \nabla u + (h_u F_u) \underbrace{\nabla \times \nabla u}_{=0} = \nabla(h_u F_u) \times \frac{\mathbf{e}_u}{h_u}.$$

Expanding the gradient in the curvilinear basis,

$$\begin{aligned} \nabla(h_u F_u) \times \frac{\mathbf{e}_u}{h_u} &= \left(\frac{1}{h_u} \frac{\partial(h_u F_u)}{\partial u} \mathbf{e}_u + \frac{1}{h_v} \frac{\partial(h_u F_u)}{\partial v} \mathbf{e}_v + \frac{1}{h_w} \frac{\partial(h_u F_u)}{\partial w} \mathbf{e}_w \right) \times \frac{\mathbf{e}_u}{h_u} \\ &= \frac{1}{h_w h_u} \frac{\partial(h_u F_u)}{\partial w} \mathbf{e}_v - \frac{1}{h_u h_v} \frac{\partial(h_u F_u)}{\partial v} \mathbf{e}_w, \end{aligned}$$

using $\mathbf{e}_v \times \mathbf{e}_u = -\mathbf{e}_w$ and $\mathbf{e}_w \times \mathbf{e}_u = \mathbf{e}_v$. These are precisely the terms involving $h_u F_u$ in the expansion of the determinant, and the other columns follow by cyclic symmetry. $\square$

Corollary 7.5.11 (Laplacian in Curvilinear Coordinates)

For a scalar field f ,

$$\nabla^2 f = \frac{1}{h_u h_v h_w} \left[\frac{\partial}{\partial u} \left(\frac{h_v h_w}{h_u} \frac{\partial f}{\partial u} \right) + \frac{\partial}{\partial v} \left(\frac{h_u h_w}{h_v} \frac{\partial f}{\partial v} \right) + \frac{\partial}{\partial w} \left(\frac{h_u h_v}{h_w} \frac{\partial f}{\partial w} \right) \right].$$

Proof. Apply the divergence formula to $\nabla f = \frac{1}{h_u} \frac{\partial f}{\partial u} \mathbf{e}_u + \frac{1}{h_v} \frac{\partial f}{\partial v} \mathbf{e}_v + \frac{1}{h_w} \frac{\partial f}{\partial w} \mathbf{e}_w$. $\square$

It is worth recording the two special cases that get used over and over.

Example 7.5.12 (Cylindrical Polar Coordinates)

In cylindrical polars (ρ, ϕ, z) , where $(h_\rho, h_\phi, h_z) = (1, \rho, 1)$,

$$\begin{aligned}\nabla \cdot \mathbf{F} &= \frac{1}{\rho} \frac{\partial}{\partial \rho} (\rho F_\rho) + \frac{1}{\rho} \frac{\partial F_\phi}{\partial \phi} + \frac{\partial F_z}{\partial z}, \\ \nabla \times \mathbf{F} &= \frac{1}{\rho} \det \begin{pmatrix} \mathbf{e}_\rho & \rho \mathbf{e}_\phi & \mathbf{e}_z \\ \frac{\partial}{\partial \rho} & \frac{\partial}{\partial \phi} & \frac{\partial}{\partial z} \\ F_\rho & \rho F_\phi & F_z \end{pmatrix}, \\ \nabla^2 f &= \frac{1}{\rho} \frac{\partial}{\partial \rho} \left(\rho \frac{\partial f}{\partial \rho} \right) + \frac{1}{\rho^2} \frac{\partial^2 f}{\partial \phi^2} + \frac{\partial^2 f}{\partial z^2}.\end{aligned}$$

Example 7.5.13 (Spherical Polar Coordinates)

In spherical polars (r, θ, ϕ) , where $(h_r, h_\theta, h_\phi) = (1, r, r \sin \theta)$,

$$\begin{aligned}\nabla \cdot \mathbf{F} &= \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 F_r) + \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta} (\sin \theta F_\theta) + \frac{1}{r \sin \theta} \frac{\partial F_\phi}{\partial \phi}, \\ \nabla \times \mathbf{F} &= \frac{1}{r^2 \sin \theta} \det \begin{pmatrix} \mathbf{e}_r & r \mathbf{e}_\theta & r \sin \theta \mathbf{e}_\phi \\ \frac{\partial}{\partial r} & \frac{\partial}{\partial \theta} & \frac{\partial}{\partial \phi} \\ F_r & r F_\theta & r \sin \theta F_\phi \end{pmatrix}, \\ \nabla^2 f &= \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial f}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial f}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 f}{\partial \phi^2}.\end{aligned}$$

Example 7.5.14

Let's put these formulas to work.

- (i) Consider $f(\mathbf{x}) = 1/r$ in spherical polars, away from the origin. Then

$$\nabla^2 f = \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \cdot \left(-\frac{1}{r^2} \right) \right) = 0,$$

so $1/r$ is a solution of Laplace's equation on $\mathbb{R}^3 \setminus \{0\}$ – a fact which underpins much of the theory of gravity and electrostatics, as we will see.

- (ii) Consider the rotating field from before, which in cylindrical polars is $\mathbf{F} = \rho \mathbf{e}_\phi$. Then

$$\nabla \times \mathbf{F} = \frac{1}{\rho} \det \begin{pmatrix} \mathbf{e}_\rho & \rho \mathbf{e}_\phi & \mathbf{e}_z \\ \frac{\partial}{\partial \rho} & \frac{\partial}{\partial \phi} & \frac{\partial}{\partial z} \\ 0 & \rho^2 & 0 \end{pmatrix} = \frac{1}{\rho} \cdot 2\rho \mathbf{e}_z = 2\mathbf{e}_z,$$

matching our earlier Cartesian computation.

§7.6 The Integral Theorems

We have arrived at the heart of the course. The fundamental theorem of calculus says that

$$\int_a^b f'(x) \, dx = f(b) - f(a),$$

that is, integrating the derivative of a function over an interval only requires knowing the function on the *boundary* of the interval. The integral theorems of vector calculus

are all statements of exactly this shape: the integral of some derivative of a field over a region equals an integral of the field itself over the *boundary* of the region. There is one theorem for each type of region – planar regions, surfaces, and volumes.

§7.6.1 Green's Theorem

We begin in the plane.

Theorem 7.6.1 (Green's Theorem)

Let $P = P(x, y)$ and $Q = Q(x, y)$ be continuously differentiable on a planar region $A \cup \partial A$, where the boundary ∂A is piecewise smooth. Then

$$\oint_{\partial A} P \, dx + Q \, dy = \int_A \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} \right) \, dA,$$

where ∂A is traversed so that A lies to the *left* (anticlockwise, for a simple region).

We will prove Green's theorem (along with the other integral theorems) in §7.6.4, but we can quickly convince ourselves it's plausible by checking it on a rectangle $A = [a, b] \times [c, d]$. There,

$$\begin{aligned} \int_A \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} \right) \, dA &= \int_c^d \left(\int_a^b \frac{\partial Q}{\partial x} \, dx \right) \, dy - \int_a^b \left(\int_c^d \frac{\partial P}{\partial y} \, dy \right) \, dx \\ &= \int_c^d [Q(b, y) - Q(a, y)] \, dy + \int_a^b [P(x, c) - P(x, d)] \, dx, \end{aligned}$$

using the fundamental theorem of calculus on each inner integral. But this is exactly $\oint_{\partial A} P \, dx + Q \, dy$: the four terms are the contributions of the four sides of the rectangle, traversed anticlockwise (say, the P integral along the top edge runs from $x = b$ back to $x = a$, giving the $-P(x, d)$ term). One can then imagine building up an arbitrary region out of many small rectangles – the boundary contributions of adjacent rectangles cancel along shared edges, leaving only the outer boundary.

A cute application of Green's theorem is computing areas using only line integrals.

Example 7.6.2 (Area of an Ellipse)

Take $P = -\frac{1}{2}y$ and $Q = \frac{1}{2}x$. Then $\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} = 1$, so Green's theorem says

$$\text{area}(A) = \int_A \, dA = \frac{1}{2} \oint_{\partial A} x \, dy - y \, dx.$$

Now let A be the ellipse $\frac{x^2}{a^2} + \frac{y^2}{b^2} \leq 1$, with ∂A parameterized by $t \mapsto (a \cos t, b \sin t)$

for $t \in [0, 2\pi]$. Then

$$\text{area}(A) = \frac{1}{2} \int_0^{2\pi} (ab \cos^2 t + ab \sin^2 t) \, dt = \pi ab.$$

§7.6.2 Stokes' Theorem

Green's theorem relates a double integral over a flat region to an integral over its boundary. Stokes' theorem is the version for a *curved* surface in $\mathbb{R}^3$, and it tells us that the derivative being integrated is precisely the curl.

Theorem 7.6.3 (Stokes' Theorem)

Let $\mathbf{F}$ be a continuously differentiable vector field, and let S be an orientable, piecewise regular surface with piecewise smooth boundary ∂S . Then

$$\int_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S} = \oint_{\partial S} \mathbf{F} \cdot d\mathbf{x},$$

where the orientation of ∂S is compatible with the choice of normal on S , as described previously (the normal is on your left as you traverse ∂S ; equivalently, use the right-hand rule).

Again, this is the fundamental theorem of calculus in disguise: the integral of the 'derivative' $\nabla \times \mathbf{F}$ over S is determined by the values of $\mathbf{F}$ on the boundary ∂S . The only difference from the one dimensional case is that the boundary is now a curve rather than a pair of points, so 'evaluating on the boundary' means integrating around it.

An immediate consequence: if S is a *closed* surface then $\partial S = \emptyset$, so

$$\int_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S} = 0$$

for any closed surface S . Notice also that the theorem implies the (perhaps surprising) fact that $\int_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S}$ depends only on the boundary curve ∂S – any two surfaces sharing the same boundary give the same integral.

Example 7.6.4 (Verifying Stokes' Theorem on a Spherical Cap)

Let S be the cap of the unit sphere given in spherical polars by

$$S = \{\mathbf{x}(\theta, \phi) = \mathbf{e}_r \mid 0 \leq \theta \leq \alpha, 0 \leq \phi < 2\pi\},$$

and consider

$$\mathbf{F}(\mathbf{x}) = \begin{pmatrix} -x^2 y \\ 0 \\ 0 \end{pmatrix}, \quad \text{so that} \quad \nabla \times \mathbf{F} = \begin{pmatrix} 0 \\ 0 \\ x^2 \end{pmatrix}.$$

On S we have $d\mathbf{S} = \mathbf{e}_r \sin \theta \, d\theta \, d\phi$ and $x = \sin \theta \cos \phi$, and since $\mathbf{e}_z \cdot \mathbf{e}_r = \cos \theta$,

$$\begin{aligned} \int_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S} &= \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\alpha} (\sin \theta \cos \phi)^2 \cos \theta \sin \theta \, d\theta \, d\phi \\ &= \pi \int_0^{\alpha} \sin^3 \theta \cos \theta \, d\theta = \frac{\pi}{4} \sin^4 \alpha. \end{aligned}$$

Now the boundary: ∂S is the circle $t \mapsto (\sin \alpha \cos t, \sin \alpha \sin t, \cos \alpha)$ for $t \in [0, 2\pi]$, so

$$d\mathbf{x} = \sin \alpha \begin{pmatrix} -\sin t \\ \cos t \\ 0 \end{pmatrix} dt,$$

and on this circle $-x^2 y = -\sin^3 \alpha \cos^2 t \sin t$. Then

$$\oint_{\partial S} \mathbf{F} \cdot d\mathbf{x} = \sin^4 \alpha \int_0^{2\pi} (-\cos^2 t \sin t)(-\sin t) \, dt = \frac{\pi}{4} \sin^4 \alpha,$$

in agreement with Stokes' theorem.

Stokes' theorem lets us tie up a loose end from our discussion of conservative fields: it links the vanishing of circulations to the vanishing of the curl.

Proposition 7.6.5

Let $\mathbf{F}$ be a continuously differentiable vector field. Then $\oint_C \mathbf{F} \cdot d\mathbf{x} = 0$ for every closed curve C if and only if $\nabla \times \mathbf{F} = \mathbf{0}$.

Proof. ($\Leftarrow$) Given a closed curve C , take any surface S with $\partial S = C$ (for the curves we work with this can always be done). Then by Stokes' theorem,

$$\oint_C \mathbf{F} \cdot d\mathbf{x} = \int_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S} = 0.$$

($\Rightarrow$) Suppose for contradiction that $\nabla \times \mathbf{F} \neq \mathbf{0}$, so there is a point $\mathbf{x}_0$ and a unit vector $\hat{\mathbf{k}}$ with

$$\hat{\mathbf{k}} \cdot (\nabla \times \mathbf{F})(\mathbf{x}_0) = \lambda > 0.$$

Since $\nabla \times \mathbf{F}$ is continuous, there is $\delta > 0$ such that

$$\hat{\mathbf{k}} \cdot (\nabla \times \mathbf{F})(\mathbf{x}) > \frac{\lambda}{2} \quad \text{whenever } |\mathbf{x} - \mathbf{x}_0| < \delta.$$

Now let S be a small flat disc centred at $\mathbf{x}_0$, contained in this ball, lying in the plane through $\mathbf{x}_0$ with normal $\hat{\mathbf{k}}$. Applying Stokes' theorem to its boundary circle,

$$0 = \oint_{\partial S} \mathbf{F} \cdot d\mathbf{x} = \int_S (\nabla \times \mathbf{F}) \cdot \hat{\mathbf{k}} dS > \frac{\lambda}{2} \int_S dS > 0,$$

a contradiction. □

The same sort of argument gives us a coordinate-free way of *seeing* the curl, making precise the ‘paddle wheel’ picture from the last section. Let S_ϵ be a flat disc of radius ϵ , centred at $\mathbf{x}_0$, with unit normal $\hat{\mathbf{k}}$. Then

$$\int_{S_\epsilon} (\nabla \times \mathbf{F}) \cdot d\mathbf{S} = (\nabla \times \mathbf{F})(\mathbf{x}_0) \cdot \hat{\mathbf{k}} \text{area}(S_\epsilon) + \underbrace{\int_{S_\epsilon} [(\nabla \times \mathbf{F})(\mathbf{x}) - (\nabla \times \mathbf{F})(\mathbf{x}_0)] \cdot d\mathbf{S}}_{o(\text{area}(S_\epsilon)) \text{ by continuity}},$$

so dividing by the area and using Stokes' theorem,

$$(\nabla \times \mathbf{F})(\mathbf{x}_0) \cdot \hat{\mathbf{k}} = \lim_{\epsilon \rightarrow 0} \frac{1}{\text{area}(S_\epsilon)} \oint_{\partial S_\epsilon} \mathbf{F} \cdot d\mathbf{x}.$$

In other words, the component of the curl in the direction $\hat{\mathbf{k}}$ is the *infinitesimal circulation per unit area* about the axis $\hat{\mathbf{k}}$.

§7.6.3 The Divergence Theorem

The final theorem of the trio concerns volumes, and the relevant derivative is the divergence.

Theorem 7.6.6 (Divergence Theorem)

Let $\mathbf{F}$ be a continuously differentiable vector field, and let V be a volume whose boundary ∂V is a piecewise regular surface, with normal pointing *out* of V . Then

$$\int_V \nabla \cdot \mathbf{F} dV = \int_{\partial V} \mathbf{F} \cdot d\mathbf{S}.$$

That is, the total flux of $\mathbf{F}$ out of a region equals the integral of the divergence over that region – the divergence really does measure ‘net outflow’.

There is also a two dimensional version: if D is a planar region with piecewise smooth boundary ∂D , then

$$\int_D \nabla \cdot \mathbf{F} \, dA = \oint_{\partial D} \mathbf{F} \cdot \mathbf{n} \, ds,$$

where $\mathbf{n}$ is the outward unit normal to the boundary curve and ds is the arc length element.

Example 7.6.7 (Verifying the Divergence Theorem on a Cylinder)

Let V be the solid cylinder given in cylindrical polars by $0 \leq \rho \leq R$, $-h \leq z \leq h$, and take $\mathbf{F}(\mathbf{x}) = \mathbf{x}$, so $\nabla \cdot \mathbf{F} = 3$. The left-hand side is

$$\int_V \nabla \cdot \mathbf{F} \, dV = 3 \operatorname{vol}(V) = 6\pi R^2 h.$$

The boundary has three pieces: the curved side $S_R = \{\rho = R\}$, and the top and bottom discs $S_{\pm} = \{z = \pm h\}$. On S_R we have $d\mathbf{S} = \mathbf{e}_\rho R \, d\phi \, dz$ and $\mathbf{x} \cdot \mathbf{e}_\rho = \rho = R$, so

$$\int_{S_R} \mathbf{F} \cdot d\mathbf{S} = \int_{z=-h}^h \int_{\phi=0}^{2\pi} R^2 \, d\phi \, dz = 4\pi R^2 h.$$

On $S_{\pm}$ we have $d\mathbf{S} = \pm \mathbf{e}_z \rho \, d\rho \, d\phi$ and $\mathbf{x} \cdot (\pm \mathbf{e}_z) = \pm z = h$ on each disc, so each contributes

$$\int_{S_{\pm}} \mathbf{F} \cdot d\mathbf{S} = \int_{\phi=0}^{2\pi} \int_{\rho=0}^R h\rho \, d\rho \, d\phi = \pi R^2 h.$$

The total flux is $4\pi R^2 h + 2\pi R^2 h = 6\pi R^2 h$, as expected.

Exactly as with the curl, the divergence theorem characterises solenoidal fields, and gives a coordinate-free description of the divergence.

Proposition 7.6.8

Let $\mathbf{F}$ be continuously differentiable. Then $\int_S \mathbf{F} \cdot d\mathbf{S} = 0$ for every closed surface S if and only if $\nabla \cdot \mathbf{F} = 0$.

Proof. ($\Leftarrow$) is immediate from the divergence theorem applied to the volume enclosed by S . For ($\Rightarrow$), suppose $(\nabla \cdot \mathbf{F})(\mathbf{x}_0) = \lambda > 0$ at some point (if negative, the argument is identical). By continuity there is $\delta > 0$ with $\nabla \cdot \mathbf{F} > \lambda/2$ on the ball $|\mathbf{x} - \mathbf{x}_0| < \delta$. Taking V to be this ball,

$$0 = \int_{\partial V} \mathbf{F} \cdot d\mathbf{S} = \int_V \nabla \cdot \mathbf{F} \, dV > \frac{\lambda}{2} \operatorname{vol}(V) > 0,$$

a contradiction. □

Similarly, if V_ϵ is a ball of radius ϵ centred at $\mathbf{x}_0$, then by continuity

$$\int_{V_\epsilon} \nabla \cdot \mathbf{F} \, dV = (\nabla \cdot \mathbf{F})(\mathbf{x}_0) \operatorname{vol}(V_\epsilon) + o(\operatorname{vol}(V_\epsilon)),$$

so by the divergence theorem

$$(\nabla \cdot \mathbf{F})(\mathbf{x}_0) = \lim_{\epsilon \rightarrow 0} \frac{1}{\operatorname{vol}(V_\epsilon)} \int_{\partial V_\epsilon} \mathbf{F} \cdot d\mathbf{S},$$

that is, the divergence is the *infinitesimal flux per unit volume*. A point of positive divergence really is a ‘source’ of the field.

§7.6.4 Proving the Integral Theorems

We now pay our debts. The strategy is: prove the divergence theorem directly, deduce Green’s theorem from its two dimensional version, and then deduce Stokes’ theorem from Green’s theorem.

Proof of the Divergence Theorem. By linearity it suffices to prove the theorem separately for fields pointing along each coordinate axis, so first suppose $\mathbf{F} = F_z(x, y, z)\mathbf{e}_z$. Then the claim is that

$$\int_V \frac{\partial F_z}{\partial z} dV = \int_{\partial V} F_z \mathbf{e}_z \cdot d\mathbf{S}. \quad (\dagger)$$

Suppose first that V is a ‘nice’ volume, by which we mean that we can split the boundary as $\partial V = S_+ \cup S_-$, where S_+ collects the parts of the boundary whose outward normal has positive $\mathbf{e}_z$ component and S_- those with negative $\mathbf{e}_z$ component, and each is a graph over the projection A of V onto the (x, y) -plane^a. That is,

$$S_{\pm} = \left\{ \begin{pmatrix} x \\ y \\ g_{\pm}(x, y) \end{pmatrix} \mid (x, y) \in A \right\},$$

for some functions $g_- \leq g_+$. Then integrating in z first and using the fundamental theorem of calculus,

$$\begin{aligned} \int_V \frac{\partial F_z}{\partial z} dV &= \int_A \left(\int_{z=g_-(x,y)}^{g_+(x,y)} \frac{\partial F_z}{\partial z} dz \right) dx dy \\ &= \int_A [F_z(x, y, g_+(x, y)) - F_z(x, y, g_-(x, y))] dx dy. \end{aligned}$$

Now for the right-hand side of $(\dagger)$. Using (x, y) as parameters on $S_{\pm}$,

$$\frac{\partial \mathbf{x}}{\partial x} \times \frac{\partial \mathbf{x}}{\partial y} = \begin{pmatrix} 1 \\ 0 \\ \partial g_{\pm}/\partial x \end{pmatrix} \times \begin{pmatrix} 0 \\ 1 \\ \partial g_{\pm}/\partial y \end{pmatrix} = \begin{pmatrix} -\partial g_{\pm}/\partial x \\ -\partial g_{\pm}/\partial y \\ 1 \end{pmatrix},$$

which has positive $\mathbf{e}_z$ component. Since we need the normal to point *out* of V – upwards on S_+ but downwards on S_- – we get

$$d\mathbf{S} = \pm \begin{pmatrix} -\partial g_{\pm}/\partial x \\ -\partial g_{\pm}/\partial y \\ 1 \end{pmatrix} dx dy \quad \text{on } S_{\pm}.$$

Dotting with $F_z \mathbf{e}_z$, only the third component survives:

$$\int_{\partial V} F_z \mathbf{e}_z \cdot d\mathbf{S} = \int_A F_z(x, y, g_+(x, y)) dx dy - \int_A F_z(x, y, g_-(x, y)) dx dy,$$

which matches the left-hand side, establishing $(\dagger)$ for nice volumes. A general volume can be cut up into finitely many nice pieces; summing $(\dagger)$ over the pieces, the flux

integrals over the internal cut surfaces cancel in pairs (each internal surface is shared by two pieces with opposite outward normals), leaving exactly the integral over ∂V .

The same argument with the roles of the axes exchanged gives

$$\int_V \frac{\partial F_x}{\partial x} dV = \int_{\partial V} F_x \mathbf{e}_x \cdot d\mathbf{S}, \quad \int_V \frac{\partial F_y}{\partial y} dV = \int_{\partial V} F_y \mathbf{e}_y \cdot d\mathbf{S},$$

and adding the three identities gives the divergence theorem. $\square$

^aSome boundaries also have vertical portions where the outward normal is horizontal; these contribute nothing to either side of ($\dagger$), so we can safely ignore them.

The two dimensional divergence theorem is proved in exactly the same way (splitting ∂D into upper and lower graphs over an interval), and we will take it as established. From it, Green's theorem follows almost immediately.

Proof of Green's Theorem. Given P and Q , consider the planar vector field

$$\mathbf{F} = \begin{pmatrix} Q(x, y) \\ -P(x, y) \end{pmatrix}, \quad \text{so} \quad \nabla \cdot \mathbf{F} = \frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y}.$$

By the two dimensional divergence theorem,

$$\int_A \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} \right) dA = \oint_{\partial A} \mathbf{F} \cdot \mathbf{n} ds.$$

Parameterize ∂A by arc length, traversed with A on the left. The unit tangent is $\mathbf{t} = (x'(s), y'(s))$, and the *outward* unit normal is $\mathbf{t}$ rotated clockwise by $\pi/2$,

$$\mathbf{n} = \begin{pmatrix} y'(s) \\ -x'(s) \end{pmatrix}.$$

Then

$$\oint_{\partial A} \mathbf{F} \cdot \mathbf{n} ds = \oint_{\partial A} \left(Q \frac{dy}{ds} + P \frac{dx}{ds} \right) ds = \oint_{\partial A} P dx + Q dy,$$

as required. $\square$

Proof of Stokes' Theorem. Let $S = \{\mathbf{x}(u, v) \mid (u, v) \in A\}$ be a regular parameterized surface, so that ∂S is the image of ∂A . The idea is to 'pull back' everything to the (u, v) -plane and apply Green's theorem there. Define

$$P(u, v) = \mathbf{F}(\mathbf{x}(u, v)) \cdot \frac{\partial \mathbf{x}}{\partial u}, \quad Q(u, v) = \mathbf{F}(\mathbf{x}(u, v)) \cdot \frac{\partial \mathbf{x}}{\partial v}.$$

Then along any curve in A and its image in S ,

$$P du + Q dv = \mathbf{F} \cdot \left(\frac{\partial \mathbf{x}}{\partial u} du + \frac{\partial \mathbf{x}}{\partial v} dv \right) = \mathbf{F} \cdot d\mathbf{x},$$

so

$$\oint_{\partial A} P du + Q dv = \oint_{\partial S} \mathbf{F} \cdot d\mathbf{x}.$$

Now we compute the integrand of Green's theorem. By the chain and product rules,

$$\frac{\partial Q}{\partial u} = \frac{\partial x_j}{\partial u} \frac{\partial F_i}{\partial x_j} \frac{\partial x_i}{\partial v} + F_i \frac{\partial^2 x_i}{\partial u \partial v}, \quad \frac{\partial P}{\partial v} = \frac{\partial x_j}{\partial v} \frac{\partial F_i}{\partial x_j} \frac{\partial x_i}{\partial u} + F_i \frac{\partial^2 x_i}{\partial v \partial u}.$$

The second derivative terms cancel when we subtract, leaving

$$\begin{aligned} \frac{\partial Q}{\partial u} - \frac{\partial P}{\partial v} &= \frac{\partial F_i}{\partial x_j} \left(\frac{\partial x_j}{\partial u} \frac{\partial x_i}{\partial v} - \frac{\partial x_j}{\partial v} \frac{\partial x_i}{\partial u} \right) \\ &= (\delta_{jp} \delta_{iq} - \delta_{jq} \delta_{ip}) \frac{\partial F_i}{\partial x_j} \frac{\partial x_p}{\partial u} \frac{\partial x_q}{\partial v} \\ &= \epsilon_{kji} \epsilon_{kpq} \frac{\partial F_i}{\partial x_j} \frac{\partial x_p}{\partial u} \frac{\partial x_q}{\partial v} \\ &= \left(\epsilon_{kji} \frac{\partial F_i}{\partial x_j} \right) \left(\epsilon_{kpq} \frac{\partial x_p}{\partial u} \frac{\partial x_q}{\partial v} \right) \\ &= [\nabla \times \mathbf{F}]_k \left[\frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} \right]_k \\ &= (\nabla \times \mathbf{F}) \cdot \left(\frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} \right). \end{aligned}$$

So by Green's theorem,

$$\begin{aligned} \oint_{\partial S} \mathbf{F} \cdot d\mathbf{x} &= \int_A \left(\frac{\partial Q}{\partial u} - \frac{\partial P}{\partial v} \right) du dv \\ &= \int_A (\nabla \times \mathbf{F}) \cdot \left(\frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v} \right) du dv = \int_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S}, \end{aligned}$$

which is Stokes' theorem. (One can check that the orientation conventions match up: traversing ∂A anticlockwise corresponds exactly to traversing ∂S compatibly with the normal $\frac{\partial \mathbf{x}}{\partial u} \times \frac{\partial \mathbf{x}}{\partial v}$.) $\square$

§7.6.5 Conservative Fields Revisited

Way back when we discussed line integrals, we showed that exact differentials are closed, and claimed that the converse holds on simply connected domains. With Stokes' theorem in hand we can finally prove this, in the language of vector fields: recall that $\mathbf{F} \cdot d\mathbf{x}$ being closed corresponds precisely to $\nabla \times \mathbf{F} = \mathbf{0}$, and being exact corresponds to $\mathbf{F} = \nabla f$.

Theorem 7.6.9

Let $\Omega \subseteq \mathbb{R}^3$ be open and simply connected, and let $\mathbf{F}$ be a continuously differentiable vector field on Ω with $\nabla \times \mathbf{F} = \mathbf{0}$. Then $\mathbf{F}$ is conservative: there exists a scalar field f with $\mathbf{F} = \nabla f$ on Ω .

Proof. Fix a base point $\mathbf{x}_0 \in \Omega$, and define

$$f(\mathbf{x}) = \int_{C(\mathbf{x})} \mathbf{F} \cdot d\mathbf{x}',$$

where $C(\mathbf{x})$ is any piecewise smooth curve in Ω from $\mathbf{x}_0$ to $\mathbf{x}$.

First we check this is well defined. If C_1 and C_2 are two such curves, then $C_1 - C_2$ is a closed loop in Ω . Since Ω is simply connected, this loop can be continuously shrunk to a point within Ω , and the shrinking process sweeps out a surface $S \subseteq \Omega$ with $\partial S = C_1 - C_2$. By Stokes' theorem,

$$\int_{C_1} \mathbf{F} \cdot d\mathbf{x}' - \int_{C_2} \mathbf{F} \cdot d\mathbf{x}' = \oint_{C_1 - C_2} \mathbf{F} \cdot d\mathbf{x}' = \int_S (\nabla \times \mathbf{F}) \cdot d\mathbf{S} = 0,$$

so the definition of f does not depend on the choice of curve.

Now we check $\nabla f = \mathbf{F}$. Fix $\mathbf{x} \in \Omega$ and a small $\mathbf{h}$, and choose the path to $\mathbf{x} + \mathbf{h}$ to be a path to $\mathbf{x}$ followed by the straight line segment from $\mathbf{x}$ to $\mathbf{x} + \mathbf{h}$ (which lies in Ω for $|\mathbf{h}|$ small, as Ω is open). Then

$$f(\mathbf{x} + \mathbf{h}) - f(\mathbf{x}) = \int_0^1 \mathbf{F}(\mathbf{x} + t\mathbf{h}) \cdot \mathbf{h} dt = \mathbf{F}(\mathbf{x}) \cdot \mathbf{h} + o(\mathbf{h}),$$

using the continuity of $\mathbf{F}$. Comparing with the definition of the gradient, $\nabla f = \mathbf{F}$. $\square$

So on a simply connected domain,

$$\mathbf{F} \text{ conservative} \iff \nabla \times \mathbf{F} = \mathbf{0} \iff \oint_C \mathbf{F} \cdot d\mathbf{x} = 0 \text{ for all closed } C.$$

The hypothesis on the domain really is needed: the field

$$\mathbf{F} = \frac{1}{x^2 + y^2} \begin{pmatrix} -y \\ x \\ 0 \end{pmatrix}$$

is irrotational on $\mathbb{R}^3$ minus the z -axis (a domain which is *not* simply connected), but its circulation around the unit circle in the (x, y) -plane is $2\pi \neq 0$, so it cannot be conservative there. Looking down the z -axis, the domain has a 'hole', and the circle C below cannot be shrunk to a point without crossing it.

There is an analogous result for the divergence, which we state without proof: if $\nabla \cdot \mathbf{F} = 0$ on a domain in which every closed surface can be shrunk to a point (such as $\mathbb{R}^3$ itself, or $\mathbb{R}^3$ minus the z -axis – but *not* $\mathbb{R}^3$ minus the origin), then $\mathbf{F} = \nabla \times \mathbf{A}$ for some vector potential $\mathbf{A}$.

§7.7 Maxwell's Equations

Having assembled all this machinery, it would be a shame not to use it. In this section we take a brief tour of electromagnetism, which is governed by a system of partial differential

equations – Maxwell’s equations – written entirely in the language of vector calculus. Almost everything we have developed will make an appearance.

§7.7.1 Conservation Laws

Before writing down Maxwell’s equations, we make a general observation. Many equations of mathematical physics take the form

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J} = 0,$$

where $\rho(\mathbf{x}, t)$ is the *density* of some quantity (mass, electric charge, energy, ...) and $\mathbf{J}(\mathbf{x}, t)$ is its *current density*, describing how the quantity flows. An equation of this form is called a **conservation law**, and the name is justified by the following computation. Suppose that ρ and $|\mathbf{J}|$ decay rapidly as $|\mathbf{x}| \rightarrow \infty$, and define the total charge

$$Q = \int_{\mathbb{R}^3} \rho(\mathbf{x}, t) \, dV.$$

Then, differentiating under the integral and using the conservation law and then the divergence theorem,

$$\begin{aligned} \frac{dQ}{dt} &= \int_{\mathbb{R}^3} \frac{\partial \rho}{\partial t} \, dV = - \int_{\mathbb{R}^3} \nabla \cdot \mathbf{J} \, dV \\ &= - \lim_{R \rightarrow \infty} \int_{|\mathbf{x}| \leq R} \nabla \cdot \mathbf{J} \, dV = - \lim_{R \rightarrow \infty} \int_{|\mathbf{x}|=R} \mathbf{J} \cdot d\mathbf{S} = 0, \end{aligned}$$

since $\mathbf{J}$ decays rapidly. So the total charge Q is constant in time – charge is *conserved*. The same argument on a finite volume V says that the rate of change of the charge inside V equals minus the flux of $\mathbf{J}$ out through ∂V : charge only changes by flowing through the boundary.

§7.7.2 The Equations

Electromagnetism concerns two vector fields: the electric field $\mathbf{E}(\mathbf{x}, t)$ and the magnetic field $\mathbf{B}(\mathbf{x}, t)$. These are produced by (and act upon) electric charges, described by the charge density $\rho(\mathbf{x}, t)$ and current density $\mathbf{J}(\mathbf{x}, t)$. The dynamics are governed by **Maxwell’s equations**:

$$\nabla \cdot \mathbf{E} = \frac{\rho}{\epsilon_0}, \tag{M1}$$

$$\nabla \cdot \mathbf{B} = 0, \tag{M2}$$

$$\nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = \mathbf{0}, \tag{M3}$$

$$\nabla \times \mathbf{B} - \mu_0 \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} = \mu_0 \mathbf{J}. \tag{M4}$$

Here ϵ_0 and μ_0 are constants (the permittivity and permeability of free space), which satisfy the rather suggestive relation

$$\frac{1}{\mu_0 \epsilon_0} = c^2,$$

where $c \approx 3 \times 10^8 \, \text{m s}^{-1}$ is the speed of light. We will see why shortly.

As a first check of consistency, take the divergence of (M4). Since ‘div curl is zero’,

$$0 = \nabla \cdot (\nabla \times \mathbf{B}) = \mu_0 \epsilon_0 \frac{\partial}{\partial t} (\nabla \cdot \mathbf{E}) + \mu_0 \nabla \cdot \mathbf{J} = \mu_0 \left(\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J} \right),$$

using (M1). So Maxwell’s equations *force* the conservation law

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J} = 0,$$

that is, electric charge is automatically conserved.

§7.7.3 Integral Forms

Each of Maxwell’s equations has an equivalent integral formulation, obtained using our integral theorems, and each integral form has a satisfying physical reading.

Integrating (M1) over a volume V and applying the divergence theorem gives **Gauss’ law**,

$$\int_{\partial V} \mathbf{E} \cdot d\mathbf{S} = \frac{Q}{\epsilon_0},$$

where Q is the total charge inside V : the flux of the electric field out of any closed surface measures the charge enclosed.

Doing the same to (M2),

$$\int_{\partial V} \mathbf{B} \cdot d\mathbf{S} = 0,$$

so there is no net magnetic flux through any closed surface. In other words, there are no ‘magnetic charges’ – you cannot have a magnet with only a north pole.

Integrating (M3) over a (fixed) surface S and applying Stokes’ theorem gives **Faraday’s law**,

$$\oint_{\partial S} \mathbf{E} \cdot d\mathbf{x} = -\frac{d}{dt} \int_S \mathbf{B} \cdot d\mathbf{S}.$$

A changing magnetic flux through S induces a circulation of the electric field around the boundary – this is the principle behind electrical generators, where turning a magnet drives a current around a wire.

Finally, integrating (M4) over a surface and applying Stokes’ theorem gives **Ampère’s law** (with Maxwell’s correction),

$$\oint_{\partial S} \mathbf{B} \cdot d\mathbf{x} = \mu_0 \int_S \mathbf{J} \cdot d\mathbf{S} + \mu_0 \epsilon_0 \frac{d}{dt} \int_S \mathbf{E} \cdot d\mathbf{S}.$$

So a current flowing through a wire generates a magnetic field circulating around the wire (and so does a changing electric flux).

§7.7.4 Electromagnetic Waves

Here is the payoff of writing everything with div and curl. Consider empty space, where $\rho = 0$ and $\mathbf{J} = \mathbf{0}$. Recall that the vector Laplacian satisfies

$$\nabla^2 \mathbf{F} = \nabla(\nabla \cdot \mathbf{F}) - \nabla \times (\nabla \times \mathbf{F}).$$

Applying this to $\mathbf{E}$ and using Maxwell's equations repeatedly,

$$\begin{aligned} \nabla^2 \mathbf{E} &= \nabla \underbrace{(\nabla \cdot \mathbf{E})}_{=0 \text{ by (M1)}} - \nabla \times (\nabla \times \mathbf{E}) \\ &= \nabla \times \frac{\partial \mathbf{B}}{\partial t} \quad \text{by (M3)} \\ &= \frac{\partial}{\partial t}(\nabla \times \mathbf{B}) \\ &= \mu_0 \epsilon_0 \frac{\partial^2 \mathbf{E}}{\partial t^2} \quad \text{by (M4)}. \end{aligned}$$

That is,

$$\nabla^2 \mathbf{E} - \frac{1}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} = \mathbf{0},$$

which is the *wave equation* for waves travelling at speed c . An identical computation (using (M2) and swapping the roles of (M3) and (M4)) gives

$$\nabla^2 \mathbf{B} - \frac{1}{c^2} \frac{\partial^2 \mathbf{B}}{\partial t^2} = \mathbf{0}.$$

So in a vacuum, disturbances of the electric and magnetic fields propagate as waves at the speed of light. This is no coincidence: light *is* an electromagnetic wave, and this computation – essentially Maxwell's own – was the first theoretical evidence for that fact.

§7.7.5 Electrostatics and Potentials

Now suppose instead that all fields and sources are independent of time. Then Maxwell's equations decouple into a pair of systems,

$$\begin{cases} \nabla \cdot \mathbf{E} = \rho/\epsilon_0 \\ \nabla \times \mathbf{E} = \mathbf{0} \end{cases} \quad \begin{cases} \nabla \cdot \mathbf{B} = 0 \\ \nabla \times \mathbf{B} = \mu_0 \mathbf{J}, \end{cases}$$

one governing *electrostatics* and one *magnetostatics*.

Look at the electric system. Since $\mathbf{E}$ is irrotational on the simply connected domain $\mathbb{R}^3$, our theory of conservative fields says $\mathbf{E} = -\nabla\phi$ for some scalar field ϕ , called the **electric potential** (the sign is a physics convention). Substituting into the first equation,

$$\nabla^2 \phi = -\frac{\rho}{\epsilon_0}.$$

Similarly, since $\mathbf{B}$ is solenoidal on $\mathbb{R}^3$, it has a vector potential: $\mathbf{B} = \nabla \times \mathbf{A}$.

So electrostatics boils down to solving the equation $\nabla^2 \phi = -\rho/\epsilon_0$ – an instance of *Poisson's equation*, the subject of the next section.

§7.8 Poisson's Equation and Laplace's Equation

As we've just seen, a great many problems in mathematical physics reduce to solving

$$\nabla^2 \phi = F$$

on some domain $\Omega \subseteq \mathbb{R}^n$ (for us, $n = 2$ or 3), for a given 'source' function F . This is called **Poisson's equation**, and in the special case $F \equiv 0$ it is called **Laplace's equation**. The same equation describes electric and gravitational potentials, steady-state temperature distributions, and much else besides.

§7.8.1 Boundary Value Problems

On its own, Poisson's equation has far too many solutions (we can add to ϕ any solution of Laplace's equation), so a well-posed problem must come with *boundary conditions*. Two kinds are standard. The **Dirichlet problem** prescribes the values of ϕ on the boundary:

$$\nabla^2 \phi = F \text{ in } \Omega, \quad \phi = f \text{ on } \partial\Omega.$$

The **Neumann problem** prescribes the normal derivative:

$$\nabla^2 \phi = F \text{ in } \Omega, \quad \frac{\partial \phi}{\partial n} = g \text{ on } \partial\Omega,$$

where $\frac{\partial \phi}{\partial n} = \mathbf{n} \cdot \nabla \phi$ and $\mathbf{n}$ is the outward normal. If Ω is unbounded (say $\Omega = \mathbb{R}^3$), the boundary condition is replaced by a decay condition as $|\mathbf{x}| \rightarrow \infty$. In both cases we require ϕ and $\nabla \phi$ to extend continuously to the boundary.

Example 7.8.1

Let's solve

$$\nabla^2 \phi = r \text{ in } \{r < a\}, \quad \phi = 1 \text{ on } \{r = a\},$$

where r is the spherical radial coordinate. Since the problem is spherically symmetric, we guess a solution of the form $\phi = \phi(r)$, and use the radial part of the spherical polar Laplacian:

$$\frac{1}{r^2} \frac{d}{dr} \left(r^2 \frac{d\phi}{dr} \right) = r \implies \frac{d}{dr} \left(r^2 \frac{d\phi}{dr} \right) = r^3.$$

Integrating twice, the general spherically symmetric solution is

$$\phi(r) = \frac{r^3}{12} + A - \frac{B}{r}.$$

But a term B/r blows up at the origin, which lies inside our domain, so we must take $B = 0$ for ϕ to be a genuine solution on all of $\{r < a\}$. The boundary condition $\phi(a) = 1$ then fixes $A = 1 - a^3/12$, giving

$$\phi(r) = 1 + \frac{1}{12} (r^3 - a^3).$$

There is something slightly dishonest about 'guessing' that ϕ depends only on r – how do we know we haven't missed other, non-symmetric solutions? The answer is the following uniqueness theorem, which is itself a lovely application of the divergence theorem.

§7.8.2 Uniqueness

The divergence theorem gives us a surprisingly quick proof that the boundary conditions above pin down the solution essentially uniquely.

Theorem 7.8.2 (Uniqueness for Poisson's Equation)

The solution of the Dirichlet problem for Poisson's equation, if it exists, is unique. The solution of the Neumann problem is unique up to adding a constant.

Proof. Suppose ϕ_1 and ϕ_2 both solve the problem, and let $\psi = \phi_1 - \phi_2$. By linearity, ψ satisfies the corresponding *homogeneous* problem:

$$\nabla^2 \psi = 0 \text{ in } \Omega, \quad \psi = 0 \text{ (resp. } \frac{\partial \psi}{\partial n} = 0) \text{ on } \partial\Omega.$$

Now consider the quantity

$$I[\psi] = \int_{\Omega} |\nabla \psi|^2 \, dV \geq 0.$$

Using the Leibniz identity $\nabla \cdot (\psi \nabla \psi) = \nabla \psi \cdot \nabla \psi + \psi \nabla^2 \psi$ and $\nabla^2 \psi = 0$,

$$\begin{aligned} I[\psi] &= \int_{\Omega} \nabla \cdot (\psi \nabla \psi) \, dV - \int_{\Omega} \psi \nabla^2 \psi \, dV \\ &= \int_{\partial\Omega} \psi \nabla \psi \cdot \mathbf{dS} = \int_{\partial\Omega} \psi \frac{\partial \psi}{\partial n} \, dS, \end{aligned}$$

by the divergence theorem. But on $\partial\Omega$ either $\psi = 0$ (Dirichlet) or $\partial\psi/\partial n = 0$ (Neumann), so in both cases $I[\psi] = 0$. Since the integrand $|\nabla \psi|^2$ is non-negative and continuous, this forces $\nabla \psi = \mathbf{0}$ throughout Ω , so ψ is constant.

In the Dirichlet case $\psi = 0$ on the boundary, so the constant is zero and $\phi_1 = \phi_2$. In the Neumann case no such conclusion is available, and indeed adding a constant to any solution gives another. $\square$

So in the previous example, the spherically symmetric solution we found is *the* solution. This ‘guess cleverly, then invoke uniqueness’ strategy is extremely common, and we will use it repeatedly below.

Example 7.8.3 (Inside a Charged Shell)

Suppose a charge density is zero for $r < a$ (and arbitrary but spherically symmetric outside). What is the electric field in the cavity $r < a$? The potential satisfies

$$\nabla^2 \phi = 0 \text{ in } \{r < a\}, \quad \phi = \text{const on } \{r = a\}$$

(the boundary value is constant by symmetry). But a constant function solves this Dirichlet problem, so by uniqueness it is the only solution. Hence $\mathbf{E} = -\nabla \phi = \mathbf{0}$: there is no electric field anywhere inside the shell. This is a version of Newton's shell theorem, here obtained with essentially no computation.

§7.8.3 Gauss' Flux Method

For source terms with spherical or cylindrical symmetry, the divergence theorem gives a wonderfully efficient way of solving Poisson's equation, known as **Gauss' flux method**.

Suppose we want to solve $\nabla^2 \phi = F$ on $\mathbb{R}^3$ where $F = F(r)$ is spherically symmetric. By symmetry (and uniqueness!) we look for $\phi = \phi(r)$, for which

$$\nabla \phi = \phi'(r) \mathbf{e}_r.$$

Integrate $\nabla \cdot (\nabla \phi) = F$ over the ball $|\mathbf{x}| < R$ and apply the divergence theorem:

$$\int_{|\mathbf{x}|=R} \nabla \phi \cdot d\mathbf{S} = \int_{|\mathbf{x}|<R} F dV =: Q(R),$$

where we think of $Q(R)$ as the 'total charge' (or mass, etc.) inside radius R . On the sphere $|\mathbf{x}| = R$ we have $d\mathbf{S} = \mathbf{e}_r R^2 \sin \theta d\theta d\varphi$, so $\nabla \phi \cdot d\mathbf{S} = \phi'(R) dS$, and $\phi'(R)$ is constant over the sphere. Hence

$$Q(R) = \phi'(R) \int_{|\mathbf{x}|=R} dS = 4\pi R^2 \phi'(R),$$

which rearranges to the key formula

$$\phi'(R) = \frac{Q(R)}{4\pi R^2}, \quad \text{i.e.} \quad \nabla \phi = \frac{Q(r)}{4\pi r^2} \mathbf{e}_r.$$

The flux through a sphere only sees the charge *inside* it.

Example 7.8.4 (A Uniformly Charged Ball)

Let's find the electric field of a ball of uniform charge density ρ_0 and radius a . The potential satisfies $\nabla^2 \phi = -\rho(r)/\epsilon_0$ where $\rho = \rho_0$ for $r \leq a$ and 0 beyond. The enclosed charge is

$$Q(r) = \begin{cases} \frac{4}{3}\pi r^3 \rho_0 & r \leq a, \\ \frac{4}{3}\pi a^3 \rho_0 = Q & r > a, \end{cases}$$

where Q is the total charge. By Gauss' flux method (applied to $-\epsilon_0 \phi$),

$$\mathbf{E} = -\nabla \phi = \frac{1}{4\pi \epsilon_0} \frac{Q(r)}{r^2} \mathbf{e}_r = \begin{cases} \frac{\rho_0 r}{3\epsilon_0} \mathbf{e}_r & r \leq a, \\ \frac{Q}{4\pi \epsilon_0 r^2} \mathbf{e}_r & r > a. \end{cases}$$

Two features are worth noting. Outside the ball, the field is exactly that of a *point charge* Q at the origin – the details of the charge distribution are invisible. And

letting $a \rightarrow 0$ with Q fixed, we obtain the field of a point charge,

$$\mathbf{E} = \frac{Q}{4\pi\epsilon_0 r^2} \mathbf{e}_r,$$

which is the inverse square law. The same mathematics with ϕ the gravitational potential and $\nabla^2 \phi = 4\pi G\rho$ gives Newton's inverse square law of gravitation, and shows that a spherical planet attracts as if all its mass were concentrated at its centre.

The corresponding computation for cylindrically symmetric sources, integrating over a cylinder of radius R and height h (the flat ends contribute nothing since $\nabla\phi = \phi'(\rho)\mathbf{e}_\rho$ is horizontal), gives

$$2\pi R h \phi'(R) = \int_V F \, dV \implies \phi'(\rho) = \frac{1}{\rho} \int_0^\rho s F(s) \, ds.$$

For example, an infinite wire with charge λ per unit length produces a field decaying like $1/\rho$, not $1/\rho^2$.

§7.8.4 Harmonic Functions

Solutions of Laplace's equation $\nabla^2 \phi = 0$ are important enough to have their own name: they are called **harmonic** functions. Harmonic functions have some rather striking rigidity properties, and the divergence theorem is the key to all of them.

Theorem 7.8.5 (Mean Value Property)

If ϕ is harmonic on a domain $\Omega \subseteq \mathbb{R}^3$, then for any $\mathbf{a} \in \Omega$ and any $r > 0$ small enough that the closed ball $|\mathbf{x} - \mathbf{a}| \leq r$ lies in Ω ,

$$\phi(\mathbf{a}) = \frac{1}{4\pi r^2} \int_{|\mathbf{x}-\mathbf{a}|=r} \phi(\mathbf{x}) \, dS.$$

In words: the value of a harmonic function at a point equals its *average* over any sphere centred at that point.

Proof. Let $F(r)$ denote the average on the right-hand side. Parameterizing the sphere with spherical polar angles, $\mathbf{x} = \mathbf{a} + r\mathbf{e}_r$ and $dS = r^2 \sin \theta \, d\theta \, d\varphi$, so the factors of r^2 cancel:

$$F(r) = \frac{1}{4\pi} \int_{\varphi=0}^{2\pi} \int_{\theta=0}^{\pi} \phi(\mathbf{a} + r\mathbf{e}_r) \sin \theta \, d\theta \, d\varphi.$$

Note that as $r \rightarrow 0$, $F(r) \rightarrow \phi(\mathbf{a})$ by continuity. Now differentiate with respect to r , using $\frac{d}{dr} \phi(\mathbf{a} + r\mathbf{e}_r) = \mathbf{e}_r \cdot \nabla \phi(\mathbf{a} + r\mathbf{e}_r)$:

$$\begin{aligned} F'(r) &= \frac{1}{4\pi} \int_{\varphi=0}^{2\pi} \int_{\theta=0}^{\pi} \mathbf{e}_r \cdot \nabla \phi(\mathbf{a} + r\mathbf{e}_r) \sin \theta \, d\theta \, d\varphi \\ &= \frac{1}{4\pi r^2} \int_{|\mathbf{x}-\mathbf{a}|=r} \nabla \phi \cdot d\mathbf{S} \end{aligned}$$

$$= \frac{1}{4\pi r^2} \int_{|\mathbf{x}-\mathbf{a}|<r} \nabla^2 \phi \, dV = 0,$$

where we recognised the integral as a flux integral, applied the divergence theorem, and used that ϕ is harmonic. So F is constant, and since $F(r) \rightarrow \phi(\mathbf{a})$ as $r \rightarrow 0$, we get $F(r) = \phi(\mathbf{a})$ for all valid r . $\square$

Theorem 7.8.6 (Maximum Principle)

If ϕ is harmonic on a (connected) domain Ω , then ϕ has no strict local maximum in the interior of Ω . Moreover, if ϕ attains its maximum value at an interior point, then ϕ is constant.

Proof. Suppose ϕ attains a maximum at an interior point $\mathbf{a}$, so $\phi(\mathbf{a}) \geq \phi(\mathbf{x})$ for all $\mathbf{x} \in \Omega$. Pick $\epsilon > 0$ small enough that the ball $|\mathbf{x} - \mathbf{a}| \leq \epsilon$ lies inside Ω . By the mean value property,

$$0 = \frac{1}{4\pi\epsilon^2} \int_{|\mathbf{x}-\mathbf{a}|=\epsilon} (\phi(\mathbf{a}) - \phi(\mathbf{x})) \, dS.$$

The integrand is continuous and non-negative, so it must vanish identically: $\phi = \phi(\mathbf{a})$ on the whole sphere. Since ϵ was arbitrary (below some threshold), ϕ is constant on a ball around $\mathbf{a}$.

Now take any other point $\mathbf{y} \in \Omega$. Connect $\mathbf{a}$ to $\mathbf{y}$ by a chain of overlapping balls inside Ω , each centred at a point of the previous ball. Applying the argument above repeatedly along the chain, ϕ is constant on each ball, so $\phi(\mathbf{y}) = \phi(\mathbf{a})$. Hence ϕ is constant on Ω . $\square$

Corollary 7.8.7

If ϕ is harmonic on a bounded domain Ω and continuous up to the boundary, then

$$\max_{\Omega \cup \partial\Omega} \phi = \max_{\partial\Omega} \phi,$$

that is, ϕ attains its maximum on the boundary. (Applying this to $-\phi$, the same holds for the minimum.)

This gives another proof of uniqueness for the Dirichlet problem: the difference of two solutions is harmonic and zero on the boundary, so its max and min are both zero.

§7.9 Cartesian Tensors

To finish the course, we are going to revisit a foundational question: what actually *is* a vector? We have been writing vectors as columns of components, but the components depend on a choice of basis, while the vector itself – an arrow in space – does not. Making this precise leads to the notion of a *tensor*, which simultaneously generalises scalars, vectors and matrices, and which gives the right language for many physical laws. Throughout this section we work exclusively with *Cartesian* coordinates, that is, right-handed orthonormal bases of $\mathbb{R}^3$, and we use the summation convention relentlessly.

§7.9.1 Changing Coordinates

Let $\{\mathbf{e}_i\}$ and $\{\mathbf{e}'_i\}$ be two right-handed orthonormal bases of $\mathbb{R}^3$. A vector $\mathbf{x}$ can be expanded in either basis,

$$\mathbf{x} = x_j \mathbf{e}_j = x'_j \mathbf{e}'_j,$$

and we would like to relate the two sets of components. Since the bases are orthonormal, $\mathbf{e}_i \cdot \mathbf{e}_j = \delta_{ij}$ and $\mathbf{e}'_i \cdot \mathbf{e}'_j = \delta_{ij}$, so dotting the expansion with $\mathbf{e}'_i$,

$$x'_i = \mathbf{e}'_i \cdot \mathbf{x} = (\mathbf{e}'_i \cdot \mathbf{e}_j) x_j.$$

So if we define the 3×3 array

$$R_{ij} = \mathbf{e}'_i \cdot \mathbf{e}_j,$$

then the components transform according to

$$x'_i = R_{ij} x_j.$$

Dotting instead with $\mathbf{e}_i$ gives the inverse relationship $x_i = R_{ji} x'_j$.

What kind of matrix is R ? Substituting one relation into the other,

$$x_i = R_{ji} x'_j = R_{ji} R_{jk} x_k,$$

and since this holds for every vector $\mathbf{x}$, we must have $R_{ji} R_{jk} = \delta_{ik}$, that is,

$$R^\top R = R R^\top = I,$$

so R is an *orthogonal* matrix. Moreover, using $\mathbf{e}_j = R_{ij} \mathbf{e}'_i$ and the right-handedness of both bases,

$$1 = \mathbf{e}_1 \cdot (\mathbf{e}_2 \times \mathbf{e}_3) = R_{i1} R_{j2} R_{k3} \mathbf{e}'_i \cdot (\mathbf{e}'_j \times \mathbf{e}'_k) = R_{i1} R_{j2} R_{k3} \epsilon_{ijk} = \det R,$$

so $\det R = 1$ and R is a *rotation* matrix. To summarise: under a change of right-handed orthonormal basis, the components of a vector transform as $v'_i = R_{ij} v_j$ for a rotation matrix R .

Contrast this with a *scalar* quantity, like the dot product of two vectors. If $\sigma = \mathbf{a} \cdot \mathbf{b} = a_i b_i$, then in the new basis

$$\sigma' = a'_i b'_i = R_{ip} a_p R_{iq} b_q = \delta_{pq} a_p b_q = a_p b_p = \sigma,$$

using orthogonality of R . So scalars don't transform at all – as had better be the case, since $\mathbf{a} \cdot \mathbf{b}$ has a geometric meaning independent of coordinates.

Now consider a *linear map*. Let $\mathbf{n}$ be a fixed unit vector and let T be the orthogonal projection onto the plane normal to $\mathbf{n}$,

$$T(\mathbf{x}) = \mathbf{x} - (\mathbf{x} \cdot \mathbf{n}) \mathbf{n}.$$

Writing $\mathbf{y} = T(\mathbf{x})$ in components, $y_i = (\delta_{ij} - n_i n_j) x_j$, so with respect to the basis $\{\mathbf{e}_i\}$ the map is described by the array

$$T_{ij} = \delta_{ij} - n_i n_j.$$

In a second basis, the same formula holds with primes, and using $n'_i = R_{ip} n_p$ and $\delta_{ij} = R_{ip} R_{jq} \delta_{pq}$,

$$T'_{ij} = \delta_{ij} - n'_i n'_j = R_{ip} R_{jq} (\delta_{pq} - n_p n_q) = R_{ip} R_{jq} T_{pq}.$$

So the components of a linear map transform with *two* copies of R . There is a clear pattern emerging, and it leads us to the central definition of the section.

§7.9.2 Tensors and Their Rank

Guided by how vectors themselves transform, we make the following definition.

Definition 7.9.1 (Cartesian Tensor)

A **(Cartesian) tensor of rank n** is an object with components $T_{ij\dots k}$ (n indices) with respect to each right-handed orthonormal basis, which transform under a change of basis according to

$$T'_{ij\dots k} = R_{ip}R_{jq}\cdots R_{kr}T_{pq\dots r},$$

where $R_{ij} = \mathbf{e}'_i \cdot \mathbf{e}_j$.

So a tensor of rank 0 is a scalar, a tensor of rank 1 is a vector, and our discussion above shows that linear maps are tensors of rank 2. The point of the definition is that a tensor is a genuinely basis-independent object: its components in any one basis determine its components in every other, by a fixed rule.

Let's build up a stock of examples.

Example 7.9.2 (Outer Products)

If $\mathbf{u}, \mathbf{v}, \dots, \mathbf{w}$ are n vectors, then

$$T_{ij\dots k} = u_i v_j \cdots w_k$$

defines a tensor of rank n , since each factor transforms with its own copy of R :

$$T'_{ij\dots k} = u'_i v'_j \cdots w'_k = R_{ip}u_p R_{jq}v_q \cdots R_{kr}w_r = R_{ip}R_{jq}\cdots R_{kr}T_{pq\dots r}.$$

(Not every tensor is of this special form, but sums of such tensors give everything.)

Example 7.9.3 (The Kronecker Delta)

The symbol δ_{ij} is defined by the same rule in every basis, so $\delta'_{ij} = \delta_{ij}$. Is this consistent with the tensor transformation law? We need

$$R_{ip}R_{jq}\delta_{pq} = R_{ip}R_{jp} = \delta_{ij} = \delta'_{ij},$$

which holds by orthogonality. So δ is a rank 2 tensor whose components are the same in every basis.

Example 7.9.4 (The Levi-Civita Symbol)

Similarly, ϵ_{ijk} is defined identically in every basis, and

$$R_{ip}R_{jq}R_{kr}\epsilon_{pqr} = (\det R)\epsilon_{ijk} = \epsilon_{ijk},$$

using the standard determinant identity and $\det R = 1$. So ϵ is a rank 3 tensor. (Note the role of right-handedness here: if we allowed reflections, $\det R = -1$ and ϵ would pick up a sign.)

Example 7.9.5 (The Conductivity Tensor)

Tensors arise naturally in physics whenever one vector quantity depends linearly on another. For instance, in many materials an applied electric field $\mathbf{E}$ produces a current density $\mathbf{J}$ depending linearly on $\mathbf{E}$:

$$J_i = \sigma_{ij} E_j,$$

where σ_{ij} is the **electrical conductivity tensor** of the material. (For an isotropic material $\sigma_{ij} = \sigma \delta_{ij}$ and $\mathbf{J}$ is parallel to $\mathbf{E}$; in a crystal, current may flow more easily in some directions than others, and $\mathbf{J}$ need not be parallel to $\mathbf{E}$.)

The array σ_{ij} really is a tensor. Both $\mathbf{J}$ and $\mathbf{E}$ are vectors, so

$$\sigma'_{ij} E'_j = J'_i = R_{ip} J_p = R_{ip} \sigma_{pq} E_q = R_{ip} \sigma_{pq} R_{jq} E'_j,$$

where in the last step we used $E_q = R_{jq} E'_j$. Since $\mathbf{E}$ is arbitrary, $\sigma'_{ij} = R_{ip} R_{jq} \sigma_{pq}$.

Remark. Having indices does not make something a tensor! We could define an array A_{ij} of numbers in one particular basis and declare $A'_{ij} = 0$ in every other basis – this is a perfectly well-defined indexed object, but it does not obey the transformation law. The transformation law is the entire content of being a tensor.

§7.9.3 Operations on Tensors

Tensors of the same rank can be added and multiplied by scalars componentwise, and the results are again tensors (the transformation law is linear in the components). More interestingly, there are two operations that change rank.

Definition 7.9.6 (Tensor Product)

If U has rank m and V has rank n , their **tensor product** $U \otimes V$ is the rank $m + n$ tensor with components

$$(U \otimes V)_{ij \dots k pq \dots r} = U_{ij \dots k} V_{pq \dots r}.$$

That this is a tensor is checked exactly as for outer products of vectors – each factor brings its own copies of R .

Definition 7.9.7 (Contraction)

If T has rank $n \geq 2$, the **contraction** of T on a pair of indices (say the first two) is the rank $n - 2$ tensor with components

$$\delta_{ij} T_{ijk \dots l} = T_{iik \dots l}.$$

To see that contraction lowers the rank by exactly two (rather than breaking the tensor property altogether), we transform:

$$T'_{iik \dots l} = R_{ip} R_{iq} R_{kr} \dots R_{ls} T_{pqr \dots s} = \delta_{pq} R_{kr} \dots R_{ls} T_{pqr \dots s} = R_{kr} \dots R_{ls} T_{ppr \dots s},$$

using orthogonality to kill the two contracted copies of R . The surviving indices transform correctly.

Contraction is everywhere once you look for it: the trace T_{ii} of a rank 2 tensor is a scalar, the dot product $a_i b_i$ is a contraction of the tensor product $a_i b_j$, and matrix multiplication $(ST)_{ik} = S_{ij} T_{jk}$ is a contraction of $S \otimes T$.

There is also a very useful criterion for *recognising* tensors, which saves us from checking the transformation law by hand.

Proposition 7.9.8

A rank 2 array T_{ij} (defined in each basis) is a tensor if and only if the map

$$(\mathbf{a}, \mathbf{b}) \mapsto T_{ij} a_i b_j$$

defines a bilinear map $\mathbb{R}^3 \times \mathbb{R}^3 \rightarrow \mathbb{R}$ independent of the choice of basis (that is, a bilinear *scalar*). The analogous statement holds for higher ranks with multilinear maps.

Proof. If T is a tensor, then $T_{ij} a_i b_j$ is a full contraction of the rank 4 tensor $T_{ij} a_k b_l$, hence a scalar. Conversely, suppose $t(\mathbf{a}, \mathbf{b}) = T_{ij} a_i b_j$ is a basis-independent bilinear map. Then $T_{ij} = t(\mathbf{e}_i, \mathbf{e}_j)$, and changing basis with $\mathbf{e}'_i = R_{ip} \mathbf{e}_p$ (which follows from $R_{ip} = \mathbf{e}'_i \cdot \mathbf{e}_p$),

$$T'_{ij} = t(\mathbf{e}'_i, \mathbf{e}'_j) = t(R_{ip} \mathbf{e}_p, R_{jq} \mathbf{e}_q) = R_{ip} R_{jq} t(\mathbf{e}_p, \mathbf{e}_q) = R_{ip} R_{jq} T_{pq},$$

using bilinearity. □

Theorem 7.9.9 (Quotient Theorem)

Suppose $T_{i \dots j p \dots q}$ is an array of numbers defined in each Cartesian coordinate system, such that whenever $u_{p \dots q}$ is a tensor (of rank m), the array

$$v_{i \dots j} = T_{i \dots j p \dots q} u_{p \dots q}$$

is also a tensor (of rank n). Then T is a tensor of rank $n + m$.

The name comes from thinking of T as the ‘quotient’ v/u . This is exactly the argument we made for the conductivity tensor, done once and for all.

Proof. It suffices to consider tensors of the special form $u_{p \dots q} = c_p \dots d_q$ for vectors $\mathbf{c}, \dots, \mathbf{d}$. By hypothesis

$$v_{i \dots j} = T_{i \dots j p \dots q} c_p \dots d_q$$

is a tensor, so contracting fully with further arbitrary vectors $\mathbf{a}, \dots, \mathbf{b}$,

$$T_{i \dots j p \dots q} a_i \dots b_j c_p \dots d_q$$

is a scalar, independent of basis. But this expression is multilinear in $(\mathbf{a}, \dots, \mathbf{b}, \mathbf{c}, \dots, \mathbf{d})$, so by the multilinear map criterion above, T is a tensor. □

§7.9.4 Symmetric, Antisymmetric and Isotropic Tensors

We say a tensor T is **symmetric** in a pair of indices if swapping them leaves the components unchanged, e.g. $T_{ij \dots} = T_{ji \dots}$, and **antisymmetric** if swapping them flips the

sign. Crucially, these are properties of the *tensor*, not of the basis used: if $T_{ij} = T_{ji}$, then

$$T'_{ij} = R_{ip}R_{jq}T_{pq} = R_{ip}R_{jq}T_{qp} = T'_{ji},$$

by relabelling dummy indices, and similarly for antisymmetry. A tensor is **totally symmetric** (or antisymmetric) if it is so in every pair of indices; δ_{ij} and $a_i a_j a_k$ are totally symmetric, while ϵ_{ijk} is totally antisymmetric.

Any rank 2 tensor splits into symmetric and antisymmetric parts,

$$T_{ij} = \underbrace{\frac{1}{2}(T_{ij} + T_{ji})}_{S_{ij}} + \underbrace{\frac{1}{2}(T_{ij} - T_{ji})}_{A_{ij}}.$$

Counting components: S_{ij} has 6 independent components and A_{ij} has 3 (the entries above the diagonal), which adds up to the 9 components of a general rank 2 tensor. The count of 3 is suspicious – it suggests the antisymmetric part is secretly a *vector*, and indeed it is.

Proposition 7.9.10

Every rank 2 tensor T_{ij} can be written uniquely as

$$T_{ij} = S_{ij} + \epsilon_{ijk}\omega_k,$$

where S_{ij} is symmetric and $\omega_k = \frac{1}{2}\epsilon_{kpq}T_{pq}$.

Proof. Taking $S_{ij} = \frac{1}{2}(T_{ij} + T_{ji})$, we need only show $\epsilon_{ijk}\omega_k$ recovers the antisymmetric part. Indeed,

$$\epsilon_{ijk}\omega_k = \frac{1}{2}\epsilon_{ijk}\epsilon_{kpq}T_{pq} = \frac{1}{2}(\delta_{ip}\delta_{jq} - \delta_{iq}\delta_{jp})T_{pq} = \frac{1}{2}(T_{ij} - T_{ji}) = A_{ij}.$$

Uniqueness follows since the symmetric and antisymmetric parts of a tensor are determined by T (symmetrise or antisymmetrise both sides), and ω is determined by A . $\square$

Example 7.9.11 (Strain and Rotation in an Elastic Body)

Here is a physical situation where performing this decomposition is genuinely informative. Suppose an elastic body deforms, with the point $\mathbf{x}$ moving to $\mathbf{x} + \mathbf{u}(\mathbf{x})$ for a small displacement field $\mathbf{u}$. Two nearby points originally separated by $\delta\mathbf{x}$ end up separated by

$$\delta\mathbf{x} + \mathbf{u}(\mathbf{x} + \delta\mathbf{x}) - \mathbf{u}(\mathbf{x}), \quad \text{where} \quad u_i(\mathbf{x} + \delta\mathbf{x}) - u_i(\mathbf{x}) = \frac{\partial u_i}{\partial x_j}\delta x_j + o(\delta\mathbf{x}).$$

Decompose the tensor $\partial u_i/\partial x_j$ as above:

$$\frac{\partial u_i}{\partial x_j} = e_{ij} + \epsilon_{ijk}\omega_k, \quad e_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right), \quad \omega_k = -\frac{1}{2}[\nabla \times \mathbf{u}]_k.$$

Then

$$u_i(\mathbf{x} + \delta\mathbf{x}) - u_i(\mathbf{x}) = e_{ij}\delta x_j + [\delta\mathbf{x} \times \boldsymbol{\omega}]_i + o(\delta\mathbf{x}).$$

The antisymmetric part contributes a small *rotation* of the body about the axis ω , which doesn't deform the body at all. The actual stretching and shearing is captured entirely by the symmetric part e_{ij} , which is called the **linear strain tensor**.

For symmetric rank 2 tensors we can say more, by borrowing a theorem from linear algebra.

Proposition 7.9.12 (Principal Axes)

If T_{ij} is a symmetric rank 2 tensor, then there is a basis in which its components are diagonal. The corresponding coordinate axes are called the **principal axes** of the tensor.

Proof. A real symmetric matrix can be diagonalised by an orthogonal matrix, which we may take to have determinant 1 (flip the sign of a column if necessary). The change of basis formula for matrices, $T' = RTR^\top$, is componentwise exactly the transformation law $T'_{ij} = R_{ip}R_{jq}T_{pq}$ for rank 2 tensors, so applying that rotation as our change of basis diagonalises the components. $\square$

Finally, we single out the tensors that look the same in *every* basis.

Definition 7.9.13 (Isotropic Tensor)

A tensor is **isotropic** if its components are the same in every (right-handed, orthonormal) basis, that is,

$$R_{ip}R_{jq} \cdots R_{kr}T_{pq \cdots r} = T_{ij \cdots k} \quad \text{for every rotation } R.$$

We have already met the key examples: every scalar is isotropic, and so are δ_{ij} and ϵ_{ijk} . Remarkably, in three dimensions this is essentially a complete list.

Theorem 7.9.14 (Classification of Isotropic Tensors)

In $\mathbb{R}^3$, up to scalar multiples:

- (i) every rank 0 tensor is isotropic;
- (ii) the only isotropic tensor of rank 1 is $\mathbf{0}$;
- (iii) the isotropic tensors of rank 2 are $\alpha\delta_{ij}$;
- (iv) the isotropic tensors of rank 3 are $\beta\epsilon_{ijk}$;
- (v) the isotropic tensors of rank 4 are

$$\alpha\delta_{ij}\delta_{kl} + \beta\delta_{ik}\delta_{jl} + \gamma\delta_{il}\delta_{jk};$$

and every isotropic tensor of higher rank is a linear combination of products of δ 's and ϵ 's.

Proof (Sketch). The idea is to test the isotropy condition against enough specific rotations. We illustrate ranks 1 and 2.

For rank 1: suppose $v_i = R_{ij}v_j$ for all rotations R . Taking R to be the rotation by π about the x_3 -axis, which sends $(v_1, v_2, v_3) \mapsto (-v_1, -v_2, v_3)$, we get $v_1 = v_2 = 0$. Rotating by π about the x_1 -axis then forces $v_3 = 0$.

For rank 2: let R be the rotation by $\pi/2$ about the x_3 -axis,

$$R = \begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Then isotropy gives $T_{13} = R_{1p}R_{3q}T_{pq} = T_{23}$ but also $T_{23} = R_{2p}R_{3q}T_{pq} = -T_{13}$, so $T_{13} = T_{23} = 0$, and similarly all off-diagonal entries vanish. Moreover $T_{11} = R_{1p}R_{1q}T_{pq} = T_{22}$, and using rotations about the other axes, $T_{11} = T_{22} = T_{33}$. Hence $T_{ij} = \alpha\delta_{ij}$.

Higher ranks proceed with the same technique, only with more indices to chase. $\square$

Isotropic tensors give a beautiful trick for evaluating certain integrals without doing any real work.

Proposition 7.9.15

Let f be a function of $r = |\mathbf{x}|$ only. Then

$$T_{ij\dots k} = \int_{|\mathbf{x}| < R} f(r) x_i x_j \cdots x_k \, dV$$

is an isotropic tensor (as is the corresponding integral over all of $\mathbb{R}^3$, when it converges).

Proof. T is a tensor (each basis gives an array, and one can check the multilinear criterion). For isotropy, transform and substitute $y_i = R_{ip}x_p$ in the integral: a rotation has $|\det| = 1$, so dV is unchanged, and both $f(r)$ and the ball $|\mathbf{x}| < R$ are rotation-invariant. Hence

$$T'_{ij\dots k} = \int_{|\mathbf{x}| < R} f(r) R_{ip}x_p R_{jq}x_q \cdots R_{kr}x_r \, dV = \int_{|\mathbf{y}| < R} f(r) y_i y_j \cdots y_k \, dV = T_{ij\dots k},$$

as required. $\square$

Example 7.9.16

Let's compute

$$T_{ij} = \int_{\mathbb{R}^3} e^{-r^5} x_i x_j \, dV.$$

By the proposition, T_{ij} is isotropic of rank 2, so $T_{ij} = \alpha\delta_{ij}$ for some scalar α – and to find α we need only compute *one* number, which we do by contracting:

$$3\alpha = T_{ii} = \int_{\mathbb{R}^3} e^{-r^5} r^2 \, dV = 4\pi \int_0^\infty e^{-r^5} r^4 \, dr = 4\pi \left[-\frac{e^{-r^5}}{5} \right]_0^\infty = \frac{4\pi}{5}.$$

Hence $T_{ij} = \frac{4\pi}{15}\delta_{ij}$, and we have computed nine integrals for the price of one.

§7.9.5 Tensor Calculus

Just as scalar and vector fields assign a scalar or vector to each point of space, a **tensor field** of rank n assigns a rank n tensor $T_{ij\dots k}(\mathbf{x})$ to each point. Our differential operators interact with tensor fields in a very clean way, and the starting observation is that *differentiation itself transforms like a tensor index*.

Since $x'_i = R_{ij}x_j$ and equivalently $x_j = R_{ij}x'_i$, we have $\partial x_j / \partial x'_i = R_{ij}$, so by the chain rule

$$\frac{\partial}{\partial x'_i} = \frac{\partial x_j}{\partial x'_i} \frac{\partial}{\partial x_j} = R_{ij} \frac{\partial}{\partial x_j}.$$

Proposition 7.9.17

If $T_{i\dots j}$ is a rank n tensor field, then

$$\frac{\partial}{\partial x_p} \cdots \frac{\partial}{\partial x_q} T_{i\dots j}(\mathbf{x}) \quad (m \text{ derivatives})$$

is a rank $n + m$ tensor field.

Proof. Under a change of basis, using the transformation law for T and for each derivative,

$$\begin{aligned} \frac{\partial}{\partial x'_p} \cdots \frac{\partial}{\partial x'_q} T'_{i\dots j} &= R_{pa} \frac{\partial}{\partial x_a} \cdots R_{qb} \frac{\partial}{\partial x_b} (R_{ic} \cdots R_{jd} T_{c\dots d}) \\ &= R_{pa} \cdots R_{qb} R_{ic} \cdots R_{jd} \frac{\partial}{\partial x_a} \cdots \frac{\partial}{\partial x_b} T_{c\dots d}, \end{aligned}$$

where we could pull the (constant!) matrices R out of the derivatives. $\square$

Note the parenthetical remark: this argument works precisely because in Cartesian coordinates the change of basis matrix is constant. (This is why this topic is called *Cartesian* tensors – in general curvilinear coordinates, differentiation of tensor fields is much more subtle.)

This proposition packages up several facts we already knew: ∇f is a vector field (rank $0 + 1$), $\nabla \cdot \mathbf{F} = \partial F_i / \partial x_i$ is a scalar field (a contraction of the rank 2 field $\partial F_j / \partial x_i$), and $[\nabla \times \mathbf{F}]_i = \epsilon_{ijk} \partial F_k / \partial x_j$ is a vector field (contract ϵ with $\partial F_k / \partial x_j$ twice).

The divergence theorem also upgrades to tensor fields, and the proof is a pleasant application of what we know.

Theorem 7.9.18 (Divergence Theorem for Tensor Fields)

For a tensor field $T_{ij\dots k\dots l}$ and a volume V with piecewise regular boundary,

$$\int_V \frac{\partial}{\partial x_k} T_{ij\dots k\dots l} \, dV = \int_{\partial V} T_{ij\dots k\dots l} n_k \, dS,$$

where $\mathbf{n}$ is the outward unit normal, and the contraction may be on any chosen index.

Proof. Fix constant vectors $\mathbf{a}, \mathbf{b}, \dots, \mathbf{c}$ and consider the vector field with components

$$v_k = a_i b_j \cdots c_l T_{ij \dots k \dots l},$$

contracting every index of T except the k . Applying the ordinary divergence theorem to $\mathbf{v}$,

$$\begin{aligned} a_i b_j \cdots c_l \int_V \frac{\partial}{\partial x_k} T_{ij \dots k \dots l} dV &= \int_V \frac{\partial v_k}{\partial x_k} dV \\ &= \int_{\partial V} v_k n_k dS = a_i b_j \cdots c_l \int_{\partial V} T_{ij \dots k \dots l} n_k dS. \end{aligned}$$

Since $\mathbf{a}, \mathbf{b}, \dots, \mathbf{c}$ were arbitrary, the two multilinear forms agree, so the tensors themselves are equal. $\square$

§7.9.6 The Inertia Tensor

We end with the classic example of a rank 2 tensor in physics. Consider a rigid body occupying a volume V with mass density $\rho(\mathbf{x})$, rotating with angular velocity $\boldsymbol{\omega}$ about an axis through the origin. Each point of the body moves with velocity $\mathbf{v} = \boldsymbol{\omega} \times \mathbf{x}$, so the total angular momentum about the origin is

$$\mathbf{L} = \int_V \rho(\mathbf{x}) \mathbf{x} \times \mathbf{v} dV = \int_V \rho(\mathbf{x}) \mathbf{x} \times (\boldsymbol{\omega} \times \mathbf{x}) dV.$$

Expanding the triple product in index notation,

$$[\mathbf{x} \times (\boldsymbol{\omega} \times \mathbf{x})]_i = \epsilon_{ijk} x_j \epsilon_{klm} \omega_l x_m = (\delta_{il} \delta_{jm} - \delta_{im} \delta_{jl}) x_j \omega_l x_m = (x_k x_k) \omega_i - x_i x_j \omega_j,$$

so

$$L_i = \left[\int_V \rho(\mathbf{x}) (x_k x_k \delta_{ij} - x_i x_j) dV \right] \omega_j = I_{ij} \omega_j,$$

where we define the **inertia tensor** of the body,

$$I_{ij} = \int_V \rho(\mathbf{x}) (x_k x_k \delta_{ij} - x_i x_j) dV.$$

So angular momentum depends *linearly* on angular velocity, but – unlike its familiar one dimensional counterpart $L = I\omega$ – the angular momentum need not be parallel to the rotation axis. That I_{ij} really is a tensor follows from the quotient theorem (or directly, since $x_k x_k \delta_{ij} - x_i x_j$ is built from tensors and the integral transforms as in our isotropy proposition).

Since I_{ij} is manifestly symmetric, the principal axes theorem applies: every rigid body has three perpendicular *principal axes* for which the inertia tensor is diagonal, and rotation about a principal axis gives $\mathbf{L}$ parallel to $\boldsymbol{\omega}$.

Example 7.9.19 (Inertia Tensor of an Ellipsoid)

Let V be the solid ellipsoid

$$V = \left\{ \mathbf{x} \mid \frac{x_1^2}{a^2} + \frac{x_2^2}{b^2} + \frac{x_3^2}{c^2} \leq 1 \right\}$$

with uniform density ρ_0 and mass $M = \frac{4}{3}\pi\rho_0 abc$.

To evaluate the integrals, use ‘scaled’ spherical polar coordinates

$$x_1 = ar \sin \theta \cos \varphi, \quad x_2 = br \sin \theta \sin \varphi, \quad x_3 = cr \cos \theta,$$

with $r \in [0, 1]$, which have Jacobian $|J| = abc r^2 \sin \theta$.

First, the off-diagonal terms. For $i \neq j$, the integrand $x_i x_j$ is odd under flipping the sign of one coordinate while the region and density are symmetric, so

$$I_{ij} = - \int_V \rho_0 x_i x_j \, dV = 0, \quad i \neq j.$$

So the coordinate axes are principal axes – as we’d expect, they are the axes of symmetry of the ellipsoid. For the diagonal terms,

$$\begin{aligned} I_{33} &= \int_V \rho_0 (x_1^2 + x_2^2) \, dV \\ &= \rho_0 abc \int_{\varphi=0}^{2\pi} \int_{\theta=0}^{\pi} \int_{r=0}^1 r^2 \sin^2 \theta (a^2 \cos^2 \varphi + b^2 \sin^2 \varphi) r^2 \sin \theta \, dr \, d\theta \, d\varphi \\ &= \frac{\rho_0 abc}{5} \cdot \pi (a^2 + b^2) \int_{\theta=0}^{\pi} \sin^3 \theta \, d\theta \\ &= \frac{\rho_0 abc}{5} \cdot \pi (a^2 + b^2) \cdot \frac{4}{3} = \frac{M}{5} (a^2 + b^2), \end{aligned}$$

using $\int_0^{2\pi} \cos^2 \varphi \, d\varphi = \int_0^{2\pi} \sin^2 \varphi \, d\varphi = \pi$ and $\int_0^{\pi} \sin^3 \theta \, d\theta = \frac{4}{3}$. By symmetry,

$$I_{11} = \frac{M}{5} (b^2 + c^2), \quad I_{22} = \frac{M}{5} (a^2 + c^2),$$

so

$$I = \frac{M}{5} \begin{pmatrix} b^2 + c^2 & 0 & 0 \\ 0 & a^2 + c^2 & 0 \\ 0 & 0 & a^2 + b^2 \end{pmatrix}.$$

Example 7.9.20 (Inertia Tensor of a Ball, the Slick Way)

For a uniform ball of radius R and mass $M = \frac{4}{3}\pi\rho_0 R^3$, we could set $a = b = c = R$ above, but isotropy gives a cleaner route. The region and density are rotation-invariant, so I_{ij} is an isotropic rank 2 tensor: $I_{ij} = \alpha \delta_{ij}$. Contracting,

$$3\alpha = I_{ii} = \int_{|\mathbf{x}| \leq R} \rho_0 (3r^2 - r^2) \, dV = 2\rho_0 \int_{|\mathbf{x}| \leq R} r^2 \, dV = 2\rho_0 \cdot 4\pi \int_0^R r^4 \, dr = \frac{8\pi\rho_0 R^5}{5},$$

so $\alpha = \frac{8\pi\rho_0 R^5}{15} = \frac{2}{5}MR^2$, giving

$$I_{ij} = \frac{2}{5}MR^2 \delta_{ij}.$$

Every axis through the centre of a ball is a principal axis, with the familiar moment of inertia $\frac{2}{5}MR^2$.

And with that, we have reached the end of the course. From arc lengths to inertia tensors, the recurring themes have been the same: differential operators built from ∇ , integrals over curves, surfaces and volumes, the integral theorems binding the two together, and index notation quietly doing most of the heavy lifting.

8 Vectors and Matrices

Vectors and Matrices covers topics in both algebra and geometry, and the ways in which they relate to one another. Starting from the complex numbers, we will work our way up through vectors in three dimensions, vectors in general, and then to linear maps and the matrices that represent them – along the way meeting determinants, eigenvalues, and the various canonical forms a matrix can be put into. The approaches used throughout are quite varied in their nature (they can be abstract or concrete, conceptual or computational, and so on), and being able to switch fluently between these viewpoints is one of the main skills this course develops.

This article constitutes my notes for the ‘Vectors and Matrices’ course, held in Michaelmas 2020 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§8.1 Complex Numbers

The complex numbers arose through the study of polynomials, but there is hardly an area of modern mathematics where they are not of use, with applications stretching from number theory to geometry to quantum mechanics.

§8.1.1 Defining the Complex Numbers

We are going to start right at the beginning, though some familiarity with complex numbers is assumed. We will construct the set of complex numbers, denoted by $\mathbb{C}$, from the real numbers $\mathbb{R}$ by adjoining an element i with the property that $i^2 = -1$.

Definition 8.1.1 (Complex Numbers)

A **complex number** is a number $z \in \mathbb{C}$ of the form $z = x + yi$ with $x, y \in \mathbb{R}$ such that $i^2 = -1$.

We call $x = \operatorname{Re}(z)$ the **real part**, and $y = \operatorname{Im}(z)$ the **imaginary part** of z .

The reals are a subset of the complex numbers, as for $x \in \mathbb{R}$, we have $x + 0i \in \mathbb{C}$.

Basic Operations

With the complex numbers defined, we have to come up with some things to do with them. We can add, subtract, multiply and divide complex numbers in a sensible way, and indeed they form a *field* (we will elaborate on this later).

Definition 8.1.2 (Basic Operations in $\mathbb{C}$)

Let $z_1 = x_1 + y_1i$ and $z_2 = x_2 + y_2i$ be two complex numbers. Then we define **addition** and **multiplication** as

$$z_1 + z_2 = (x_1 + x_2) + (y_1 + y_2)i,$$

$$z_1 \times z_2 = (x_1x_2 - y_1y_2) + (x_1y_2 + x_2y_1)i.$$

We can see from this definition that the operation of multiplication respects our original requirement that $i^2 = -1$. From these definitions we can also immediately define **subtraction** and **division** as the inverse operations of these, with

$$\begin{aligned} z_1 - z_2 &= (x_1 - x_2) + (y_1 - y_2)i \\ \frac{z_1}{z_2} &= \frac{x_1 + y_1i}{x_2 + y_2i} \cdot \frac{x_2 - y_2i}{x_2 - y_2i} = \left(\frac{x_1x_2 + y_1y_2}{x_2^2 + y_2^2} \right) + \left(\frac{x_2y_1 - x_1y_2}{x_2^2 + y_2^2} \right)i. \end{aligned}$$

From the definitions of addition and multiplication, it is clear that both operations are commutative and associative. Indeed, as we also have inverse operations, the complex numbers form groups.

Proposition 8.1.3 ($\mathbb{C}$ is a Group)

$\mathbb{C}$ with the operation $+$ is an abelian group with identity 0, and $\mathbb{C} \setminus \{0\}$ with the operation $\times$ is an abelian group with identity 1.

Proof Sketch. Check definitions and verify that $+$ and $\times$ are indeed associative. $\square$

Another useful operation is the *complex conjugate*.

Definition 8.1.4 (Complex Conjugation)

For a complex number $z = x + iy$, we define its **complex conjugate** to be $\bar{z} = z^* = x - iy$.

Complex conjugation allows us to extract the real and imaginary parts of a complex number, with

$$\operatorname{Re}(z) = \frac{z + \bar{z}}{2}, \quad \text{and} \quad \operatorname{Im}(z) = \frac{z - \bar{z}}{2i}.$$

For complex numbers z_1 and z_2 , we have $\overline{\bar{z}} = z$, $\overline{z_1 + z_2} = \bar{z}_1 + \bar{z}_2$ and $\overline{z_1 z_2} = \bar{z}_1 \cdot \bar{z}_2$.

Aside: The History of Complex Numbers

The complex numbers arose through the study of polynomials, and their serious study really began in the study of the *cubic* polynomials of the form¹

$$x^3 - 3px - 2q = 0.$$

The sixteenth century mathematicians del Ferro, Tartaglia and Cardano discovered that this equation could be solved explicitly, with the result being published in Cardano's 1545 work *Ars Magna* (where he mentioned del Ferro as a first author, and noted that Tartaglia had independently found the same result). The solution they had obtained was

$$x = \sqrt[3]{q + \sqrt{q^2 - p^3}} + \sqrt[3]{q - \sqrt{q^2 - p^3}}.$$

For example, for the cubic $x^3 - 12x - 20$ we obtain the solution $x = \sqrt[3]{16} + \sqrt[3]{2}$.

¹This form of a cubic equation is a 'depressed', and any general cubic can be expressed in this form.

Some 30 years later, Rafael Bombelli discussed one particular cubic in his work *l'Algebra*. He looked at $x^3 - 15x - 4 = 0$. One might observe (through mere trial and error) that $x = 4$ is a solution, but using Cardano's formula, we obtain the solution

$$x = \sqrt[3]{2 + \sqrt{-121}} + \sqrt[3]{2 - \sqrt{-121}}.$$

Indeed, Bombelli noticed this and gave an explanation for how these two solutions were essentially the same, even with the presence of the rather puzzling term $\sqrt{-121}$. His explanation essentially began by noting that if we wrote $\sqrt{-121} = 11i$, then we could find that

$$\begin{aligned}\sqrt[3]{2 + \sqrt{-121}} &= 2 + ni \\ \sqrt[3]{2 - \sqrt{-121}} &= 2 - ni,\end{aligned}$$

and adding would then result in $2 + ni + 2 - ni = 4$, our other solution.

Inherent in this explanation was an expectation that this i would obey many of the same rules of arithmetic that we would expect of, say, a real number. After this work, contributions from mathematicians such as Descartes, Wallis, de Moivre, Euler, Wessel, Argand, Hamilton, Gauss, Cauchy and many others began to build up a rich theory of the complex numbers, later developing the field of complex analysis, all centered on this construction of some i with the property that $i^2 = -1$.

Looking again at the solutions to polynomials it turns out that the complex numbers are sufficient to solve *every* polynomial equation. This result is known as the 'Fundamental Theorem of Algebra', and was proved in the 18th century. We will use it frequently in this course, but you will have to wait until a later course to see a proof.

Theorem 8.1.5 (Fundamental Theorem of Algebra)

Let $p(z)$ be a polynomial of degree $n \geq 1$ with complex coefficients. Then $p(z) = 0$ has precisely n (not necessarily distinct) complex roots, counted with multiplicity.

The Argand Diagram

There is a geometric way to interpret complex numbers and the way that they operate. We can plot a complex number $z = x + yi$ on the **Argand diagram** or **complex plane** by associating it with a point (x, y) . We call the x axis the 'real' axis, and the y axis the 'imaginary' axis.

From the complex number written $z = x + yi$, we can plot it in rectangular coordinates. However, it can also be useful to plot it using polar coordinates. With this in mind, we introduce some useful definitions.

Definition 8.1.6 (Modulus)

For a complex number $z = x + yi$, we define its **modulus** to be $r = |z|$ such that $r \geq 0$ and $r^2 = |z|^2 = x^2 + y^2$.

Indeed, this definition matches the distance from the origin of the Argand diagram to the point (x, y) .

Definition 8.1.7 (Argument)

For a non-zero complex number z , we define its **argument** to be $\theta = \arg(z)$, a real number such that $z = r(\cos \theta + i \sin \theta)$. We say this is the **polar form** of z .

From this, we get that for $z = x + yi$,

$$\cos \theta = \frac{x}{\sqrt{x^2 + y^2}}, \quad \sin \theta = \frac{y}{\sqrt{x^2 + y^2}}, \quad \text{and} \quad \tan \theta = \frac{y}{x}.$$

An important point to note is that $\arg(z)$ is only defined up to multiples of 2π , as mapping $\theta \mapsto \theta + 2\pi$ leaves z unchanged. So, to make θ unique (which is often useful), we typically restrict its range. For example, if we restrict $-\pi < \theta \leq \pi$, we get the **principal value** of θ .

Using the Argand diagram, there is a geometric way to define addition, multiplication and complex conjugation. Addition and subtraction correspond to parallelograms constructed as shown.

Complex conjugation corresponds to reflection in the real axis.

Multiplication is slightly more complex. If we have two complex numbers in polar form, $z_1 = r_1(\cos \theta_1 + i \sin \theta_1)$ and $z_2 = r_2(\cos \theta_2 + i \sin \theta_2)$, then expanding and applying the angle sum identities gives $z_1 z_2 = r_1 r_2(\cos(\theta_1 + \theta_2) + i \sin(\theta_1 + \theta_2))$. This gives the following.

Proposition 8.1.8 (Moduli Multiply and Arguments Add)

For complex numbers z_1 and z_2 , we have $\arg(z_1 z_2) = \arg(z_1) + \arg(z_2)$ and $|z_1 z_2| = |z_1| \cdot |z_2|$.

This is shown in the diagram below.

To see how useful a geometric perspective can be, consider the following result.

Proposition 8.1.9 (Triangle Inequality)

For complex numbers z_1 and z_2 , $|z_1 + z_2| \leq |z_1| + |z_2|$.

Algebraic Proof. We have $|z_1 + z_2|^2 = (z_1 + z_2)\overline{(z_1 + z_2)} = |z_1|^2 + z_1\overline{z_2} + \overline{z_1}z_2 + |z_2|^2$, so it suffices to show that $z_1\overline{z_2} + \overline{z_1}z_2 \leq 2|z_1||z_2|$. To show this, we have

$$\begin{aligned} z_1\overline{z_2} + \overline{z_1}z_2 &\leq 2|z_1||z_2| \\ \iff \frac{z_1\overline{z_2} + \overline{z_1}z_2}{2} &\leq |z_1||\overline{z_2}| \\ \iff \operatorname{Re}(z_1\overline{z_2}) &\leq |z_1\overline{z_2}|, \end{aligned}$$

which is true. □

Now put everything on an Argand diagram and stare at it for a minute.

Geometric Proof. The shortest distance between 0 and $z_1 + z_2$ is $|z_1 + z_2|$. This is a side length of the triangle at 0, z_1 and $z_1 + z_2$, and this must be shorter than the

other two sides of the triangle, which has length $|z_1| + |z_2|$. This gives the triangle inequality. $\square$

Alternate forms of the triangle inequality are

$$|z_2 - z_1| \geq |z_2| - |z_1|, \quad \text{and} \quad |z_2 - z_1| \geq |z_1| - |z_2|.$$

One of these tends to be trivially true, however, due to one side being negative. Still, we can combine these into a single statement

$$|z_2 - z_1| \geq ||z_2| - |z_1||.$$

We will end our discussion with the following theorem which will repeatedly appear.

Theorem 8.1.10 (De Moivre's Theorem)

For $n \in \mathbb{Z}$ and $\theta \in \mathbb{R}$, we have

$$(\cos \theta + i \sin \theta)^n = \cos n\theta + i \sin n\theta,$$

where $z^0 = 1$ for non-zero z .

Proof Sketch. Use induction and angle sum identities. A different proof will be given after exponential functions are defined. $\square$

§8.1.2 Exponential and Trigonometric Functions

We define the functions $\exp$, $\cos$ and $\sin$ on the complex numbers by

$$\begin{aligned} \exp(z) &= \sum_{n=0}^{\infty} \frac{1}{n!} z^n = e^z \\ \cos(z) &= \frac{1}{2}(e^{iz} + e^{-iz}) = 1 - \frac{1}{2!}z^2 + \frac{1}{4!}z^4 - \dots \\ \sin(z) &= \frac{1}{2i}(e^{iz} - e^{-iz}) = z - \frac{1}{3!}z^3 + \frac{1}{5!}z^5 - \dots \end{aligned}$$

These functions are defined by **power series**, which will be explored more in Analysis. They converge for all z , and can be manipulated and rearranged as you may expect.

Aside: Power Series (Preview of Analysis I)

A **power series** about a point x_0 is a sum of the form

$$\sum_{n=0}^{\infty} a_n(x - x_0)^n,$$

where $a_n \in \mathbb{C}$. A power series is said to **converge** at a point x if the finite sums $\sum_{n=0}^N a_n(x - x_0)^n$ tend to a limit as $N \rightarrow \infty$. With each power series there is a **radius of convergence** ρ such that if $|x - x_0| < \rho$, then the power series converges absolutely. If $|x - x_0| > \rho$, then the series does not converge. If $|x - x_0| = \rho$, then it may or may not converge. In the functions defined above, the radius of convergence is infinity.

We can manipulate power series as you might expect. Notably, we can differentiate term by term (and the radius of convergence will stay the same), and we can add and multiply power series if we are in the radius of convergence of both.

Power series will be discussed in detail in Analysis I.

These definitions reduce to familiar definitions when $z \in \mathbb{R}$. Indeed, if we differentiate the series, we get

$$\frac{d}{dx} \exp(x) = \exp(x), \quad \frac{d}{dx} \cos(x) = -\sin(x), \quad \frac{d}{dx} \sin(x) = \cos(x),$$

and $\exp(0) = 1$, $\cos(0) = 1$, $\sin(0) = 0$, which together uniquely defines these functions over the reals. However, the behavior over $\mathbb{C}$ is somewhat richer.

Proposition 8.1.11 (Properties of the Complex Exponential)

For $z = x + yi$,

- (i) $e^z = e^x(\cos y + i \sin y)$.
- (ii) e^z can take on all values in $\mathbb{C}$ except 0.
- (iii) $e^z = 1$ if and only if $z = 2n\pi i$ for $n \in \mathbb{Z}$.

Proof. (i) $e^{x+iy} = e^x e^{iy}$, and $e^{iy} = \cos y + i \sin y$.

(ii) $|e^z| = |e^x|$, which takes on all positive real values, and $\arg(e^z) = y$, which takes on all real values.

(iii) $e^z = 1 \iff e^x = 1$ and $\cos y = 1$, $\sin y = 0$ which gives $x = 0$ and $y = 2n\pi$ as required. $\square$

Returning to polar form, we can write

$$z = r(\cos \theta + i \sin \theta) = re^{i\theta},$$

where $r = |z|$ and $\theta = \arg(z)$. Then De Moivre's theorem follows immediately from $(e^{i\theta})^n = e^{in\theta}$.

§8.1.3 Roots of Unity

An important application of these results are *roots of unity*, which answers the question 'find all z such that $z^n = 1$ '.

Definition 8.1.12 (Roots of Unity)

An n th root of unity is a complex number z such that $z^n = 1$.

Proposition 8.1.13 (Finding Roots of Unity)

The n th roots of unity are

$$z = e^{2k\pi i/n} = \cos \frac{2\pi k}{n} + i \sin \frac{2\pi k}{n},$$

where $k \in \{0, 1, \dots, n-1\}$.

Proof. Writing z in polar form, these are easy to find. We have $z = re^{i\theta}$, then

$$z^n = r^n e^{in\theta} = 1,$$

so $r = 1$, and $\theta = \frac{2k\pi}{n}$ for some $k \in \mathbb{Z}$. This gives n distinct solutions. $\square$

To get a feel for this, we can plot the cases for $n = 2, 3, 4$ and 5 on an Argand diagram. This hints at a geometric interpretation of the roots of unity.

Figure 8.1: n th roots of unity on an Argand diagram

Proposition 8.1.14 (Geometric Interpretation of Roots of Unity)

The n th roots of unity correspond to the vertices of a regular n -gon, inscribed within the unit circle with a vertex at 1.

Proof. Follows directly from roots of unity written in polar form. $\square$

§8.1.4 Logarithms and Complex Powers

Over $\mathbb{R}$, the exponential function is one to one. This means that we can quite easily define the inverse function, the logarithm, on the positive reals (the image of the exponential over $\mathbb{R}$).

This is not true over $\mathbb{C}$, as the complex exponential function is many to one. For example, $e^{3\pi i/2} = e^{7\pi i/2} = -i$. However, we do know that if we have $e^{i\theta} = e^{i\gamma}$, then θ and γ differ by a multiple of 2π ². Thus we can define a *multi-valued* logarithm function.

The Complex Logarithm

To see how to define the logarithm over $\mathbb{C}$, let z be any non-zero complex number. Then if we let $\theta = \arg(z)$ with $-\pi < \theta \leq \pi$, then we can write

$$z = re^{i\theta} = e^{\log r} e^{i\theta + 2n\pi i} = e^{\log r + i(\theta + 2n\pi)},$$

for any $n \in \mathbb{Z}$.

Definition 8.1.15 (Complex Logarithm)

For a complex number z , we define the **complex logarithm** $\log z$ to be the multi-valued function

$$\log z = \log r + i(\theta + 2n\pi),$$

where $r = |z|$, $\theta = \arg(z)$ with $-\pi < \theta \leq \pi$ and $n \in \mathbb{Z}$.

Example 8.1.16 (Calculating Complex Logarithms)

Let $z = \frac{5}{2} + \frac{5\sqrt{3}i}{2}$. We will find $\log z$. We have $|z| = 5$, and the principal value is $\arg(z) = \pi/3$. Thus we have

$$\log z = \log 5 + i(\pi/3 + 2n\pi), \quad n \in \mathbb{Z}.$$

Sometimes we will want single-valued behavior from the complex logarithm, and we can define the **principal logarithm** so that we fix $n = 0$. A warning though: if this is done, not all of the familiar properties of the logarithm still hold.³

Complex Powers

The multi-valued nature of the logarithm carries into the notion of taking powers of complex numbers. For real numbers, we can define $x^a = e^{a \ln x}$ for $x > 0$. We can do the same for complex numbers.

Definition 8.1.17 (Complex Powers)

We define **complex powers** for $z, \alpha \in \mathbb{C}$ with $z \neq 0$ to be the multi-valued

$$z^\alpha = e^{\alpha \log z}.$$

²This comes from the argument of a complex number only being defined up to a multiple of 2π

³When taking the principal logarithm, we are really taking a *branch* of the multi-valued logarithm function. This corresponds with taking a slice of the Riemann surface that $\log z$ defines. This gives some weird behavior as we move past certain sets of points (singular points) which breaks many of the identities that we use frequently for the real valued logarithm.

This is not *always* multi valued. For example, if $\alpha \in \mathbb{Z}$, then z^α is unique. If $\alpha \in \mathbb{Q}$, then there will be only finitely many values. However, in most cases there will be infinitely many values.

Example 8.1.18 (Calculating i^i)

We have

$$\begin{aligned} i^i &= e^{i \log i} \\ &= e^{i \log 1 + i(\pi/2 + 2n\pi)} \\ &= e^{-(2n+1/2)\pi}, \end{aligned}$$

for any $n \in \mathbb{Z}$. Notably $i^i \in \mathbb{R}$.

§8.1.5 Transformations, Lines and Circles

Consider the following transformations on $\mathbb{C}$.

- $z \mapsto z + \alpha$, translation by $\alpha \in \mathbb{C}$.
- $z \mapsto \lambda z$, scaling by $\lambda \in \mathbb{R}$,
- $z \mapsto e^{i\theta} z$, rotation by $\theta \in \mathbb{R}$.
- $z \mapsto \bar{z}$, reflection in the real axis.
- $z \mapsto \frac{1}{z}$, inversion.

Using these transformations, we can think geometrically to do things like find equations of various geometric objects.

First we will find the general point on a line in $\mathbb{C}$ through z_0 , parallel to $w \in \mathbb{C}$ where $w \neq 0$.

We can write $z = z_0 + \lambda w$ for $\lambda \in \mathbb{R}$. To eliminate λ , we can take the conjugate $\bar{z} = \bar{z}_0 + \lambda \bar{w}$, and then multiplying by w and subtracting we obtain $\bar{w}z - w\bar{z} = \bar{w}z_0 - w\bar{z}_0$.

Similarly, we can find the general point on a circle with a center $c \in \mathbb{C}$ and positive real radius ρ .

A general point on this circle can be written $z = c + \rho e^{i\alpha}$, $\alpha \in \mathbb{R}$. To get rid of α , note that we could instead write $|z - c| = \rho$.

We can unify these two forms in the following way.

Proposition 8.1.19 (Circles and Lines in $\mathbb{C}$)

The equation of any line, and of any circle, may be written respectively as

$$\bar{B}z + B\bar{z} + C = 0 \quad \text{and} \quad z\bar{z} + \bar{B}z + B\bar{z} + C = 0$$

for some complex B and real C .

In particular, the first is a line in the direction iB , and the second (if $|B|^2 > C$) is a circle with centre $-B$ and radius $\sqrt{|B|^2 - C}$.

Proof. For the line, we found above that a general line through z_0 parallel to w satisfies $\bar{w}z - w\bar{z} = \bar{w}z_0 - w\bar{z}_0$. The right-hand side is a constant, and both sides are purely imaginary (each is equal to the negative of its own conjugate). Multiplying through by i , we can write this as $\bar{B}z + B\bar{z} + C = 0$ where $B = -iw$ and $C \in \mathbb{R}$, and then the direction of the line is $w = iB$ (rescaling to absorb factors). This process is reversible, so every equation of this form with $B \neq 0$ gives a line.

For the circle, expanding $|z - c|^2 = \rho^2$ gives

$$z\bar{z} - \bar{c}z - c\bar{z} + |c|^2 - \rho^2 = 0,$$

which is of the stated form with $B = -c$ and $C = |c|^2 - \rho^2 \in \mathbb{R}$. Conversely, given such an equation we can complete the square to get $|z + B|^2 = |B|^2 - C$, a circle with centre $-B$ and radius $\sqrt{|B|^2 - C}$, provided $|B|^2 > C$. $\square$

§8.2 Vectors in Three Dimensions

Fundamentally, vectors are mathematical objects that we can add together and take multiples of, in both cases obtaining another vector. We will consider vectors in a general setting later on, but in this chapter we will consider vectors in $\mathbb{R}^3$, three dimensional space. Specifically, we will take a geometric approach, thinking of vectors as position vectors and using Euclidean notions of points, lines, planes, etc.

We begin by choosing a point O as the origin. Then points A and B have position vectors

$$\mathbf{a} = \overrightarrow{OA}, \quad \mathbf{b} = \overrightarrow{OB}.$$

The vectors have length $|\mathbf{a}| = |\overrightarrow{OA}|$, the distance between O and A . We also let $\mathbf{0}$ denote the position vector of O .

§8.2.1 Vector Addition and Scalar Multiplication

The most important operations on vectors (in $\mathbb{R}^3$ and in general) are vector addition and scalar multiplication. We define these geometrically as follows.

Definition 8.2.1 (Scalar Multiplication in $\mathbb{R}^3$)

Given $\mathbf{a}$, the position vector for a point A , and a scalar $\lambda \in \mathbb{R}$, we define **scalar multiplication** $\lambda\mathbf{a}$ to be the position vector for the point A' on the line OA such that

$$|\lambda\mathbf{a}| = |OA'| = |\lambda||\mathbf{a}|,$$

with the vector being in the direction $\overrightarrow{OA}$ if λ is positive, and in the opposite direction otherwise.

If two vectors are scalar multiples of each other, then we say that they are **parallel**. Specifically, we write $\mathbf{a} \parallel \mathbf{b}$ if and only if $\mathbf{a} = \lambda\mathbf{b}$ or $\mathbf{b} = \lambda\mathbf{a}$ for some $\lambda \in \mathbb{R}$. Notably, $\mathbf{a} \parallel \mathbf{0}$ for all vectors $\mathbf{a}$.

Definition 8.2.2 (Vector Addition in $\mathbb{R}^3$)

Given $\mathbf{a}$ and $\mathbf{b}$, position vectors of points A and B , if $\mathbf{a} \parallel \mathbf{b}$, we construct the parallelogram $OACB$, and define **vector addition** $\mathbf{a} + \mathbf{b} = \mathbf{c}$.

If $\mathbf{a} \parallel \mathbf{b}$, then writing $\mathbf{a} = \alpha\mathbf{u}$ and $\mathbf{b} = \beta\mathbf{u}$ where $\mathbf{u}$ is a unit vector, then $\mathbf{a} + \mathbf{b} = (\alpha + \beta)\mathbf{u}$.

Given some set of vectors $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k$, we can form a **linear combination**

$$\lambda_1\mathbf{v}_1 + \lambda_2\mathbf{v}_2 + \dots + \lambda_k\mathbf{v}_k,$$

where $\lambda_i \in \mathbb{R}$. With this in mind, we can consider the set of all vectors that can be formed as a linear combination of some vectors.

Definition 8.2.3 (Span)

For vectors $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k$, we define their **span** to be the set

$$\text{span}\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k\} = \{\lambda_1 \mathbf{v}_1 + \lambda_2 \mathbf{v}_2 + \dots + \lambda_k \mathbf{v}_k \mid \lambda_i \in \mathbb{R}\}.$$

If two vectors $\mathbf{a} \nparallel \mathbf{b}$, then $\text{span}\{\mathbf{a}, \mathbf{b}\}$ is a plane through OAB .

Vector addition and scalar multiplication obey some basic properties that you should keep in mind, as they will be used again when we define vectors in a general sense.

Proposition 8.2.4 (Basic Properties of Vector Operations)

For any vectors $\mathbf{a}, \mathbf{b}$ and $\mathbf{c}$,

- (i) Vectors along with vector addition form an abelian group.
- (ii) $\lambda(\mathbf{a} + \mathbf{b}) = \lambda\mathbf{a} + \lambda\mathbf{b}$.
- (iii) $(\lambda + \mu)\mathbf{a} = \lambda\mathbf{a} + \mu\mathbf{a}$.
- (iv) $\lambda(\mu\mathbf{a}) = (\lambda\mu)\mathbf{a}$.

Proof Sketch. Check geometric definitions. Checking associativity of vector addition will require the construction of a parallelepiped. $\square$

§8.2.2 The Dot Product

We saw in the previous section how to add vectors, and how to multiply a vector by a scalar. In the next two sections, we will consider how to multiply a vector and a vector. We will first define the *scalar* or *dot product*. Consider two vectors $\mathbf{a}$ and $\mathbf{b}$, with the angle between them being θ as shown.

Definition 8.2.5 (Dot Product)

For two vectors $\mathbf{a}$ and $\mathbf{b}$, and θ the angle between them as shown, we define the **scalar** or **dot product** as

$$\mathbf{a} \cdot \mathbf{b} = |\mathbf{a}||\mathbf{b}| \cos \theta.$$

[Note that θ is defined unless $\mathbf{a}$ or $\mathbf{b}$ is zero, but then $|\mathbf{a}| = 0$ or $|\mathbf{b}| = 0$ and $\mathbf{a} \cdot \mathbf{b} = 0$.]

The scalar product encodes the angle between vectors, and in particular it gives us a test for perpendicularity. We say vectors $\mathbf{a}$ and $\mathbf{b}$ are **orthogonal** or **perpendicular** if and only if $\mathbf{a} \cdot \mathbf{b} = 0$. This corresponds with $\theta = \pm\pi/2$, or with either $|\mathbf{a}| = 0$ or $|\mathbf{b}| = 0$.

There is a geometric interpretation of the dot product. Fundamentally, the dot product is a *projection*. For $\mathbf{a} \neq \mathbf{0}$, the quantity $|\mathbf{b}| \cos \theta$ is the component of $\mathbf{b}$ when projected along the direction of $\mathbf{a}$.

Proposition 8.2.6 (Basic Properties of the Dot Product)

For any vectors $\mathbf{a}$ and $\mathbf{b}$,

- (i) $\mathbf{a} \cdot \mathbf{b} = \mathbf{b} \cdot \mathbf{a}$.
- (ii) $\mathbf{a} \cdot \mathbf{a} = |\mathbf{a}|^2 \geq 0$, and $\mathbf{a} \cdot \mathbf{a} = 0$ if and only if $\mathbf{a} = \mathbf{0}$.
- (iii) $(\lambda \mathbf{a}) \cdot \mathbf{b} = \lambda(\mathbf{a} \cdot \mathbf{b}) = \mathbf{a} \cdot (\lambda \mathbf{b})$.
- (iv) $\mathbf{a} \cdot (\mathbf{b} + \mathbf{c}) = \mathbf{a} \cdot \mathbf{b} + \mathbf{a} \cdot \mathbf{c}$.

Proof. Properties (i) to (iii) follow directly from the definition of the dot product. Property (iv) follows from the geometric interpretation of the dot product shown above. $\square$

§8.2.3 The Cross Product

The next operation only works with vectors in three dimensions, and is the *vector* or *cross product*. As before, consider two vectors $\mathbf{a}$ and $\mathbf{b}$, and let θ be measured as shown with respect to $\hat{\mathbf{n}}$, a unit normal to the plane spanned by $\mathbf{a}$ and $\mathbf{b}$.

Definition 8.2.7 (Cross Product)

For two vectors $\mathbf{a}$ and $\mathbf{b}$ with angle θ measured as shown, we define the **vector** or **cross product** as

$$\mathbf{a} \times \mathbf{b} = |\mathbf{a}||\mathbf{b}| \sin \theta \hat{\mathbf{n}},$$

where $\hat{\mathbf{n}}$ is a unit vector perpendicular to the plane spanned by $\mathbf{a}$ and $\mathbf{b}$.

[$\hat{\mathbf{n}}$ is defined up to a sign if $\mathbf{a} \nparallel \mathbf{b}$, but changing the sign changes θ to $2\pi - \theta$, and thus leaves $\mathbf{a} \times \mathbf{b}$ unchanged. When $\hat{\mathbf{n}}$ is not defined ($\mathbf{a} \parallel \mathbf{b}$ or θ not defined), $\mathbf{a} \times \mathbf{b} = \mathbf{0}$.]

The geometric interpretation of the cross product is that $|\mathbf{a} \times \mathbf{b}|$ is the area of the parallelogram as shown.

The direction of $\mathbf{a} \times \mathbf{b}$ gives the orientation of this parallelogram in space.

For an alternate geometric interpretation, fix a vector $\mathbf{a}$ and consider some vector $\mathbf{x}$ with $\mathbf{x} \perp \mathbf{a}$. Then the transformation $\mathbf{x} \mapsto \mathbf{a} \times \mathbf{x}$ corresponds with scaling $\mathbf{x}$ by $|\mathbf{a}|$ and rotating by $\pi/2$ in the plane perpendicular to $\mathbf{a}$.

Proposition 8.2.8 (Basic Properties of the Cross Product)

For vectors $\mathbf{a}$, $\mathbf{b}$ and $\mathbf{c}$,

- (i) $\mathbf{a} \times \mathbf{b} = -(\mathbf{b} \times \mathbf{a})$.
- (ii) $(\lambda \mathbf{a}) \times \mathbf{b} = \lambda(\mathbf{a} \times \mathbf{b})$.
- (iii) $\mathbf{a} \times (\mathbf{b} + \mathbf{c}) = \mathbf{a} \times \mathbf{b} + \mathbf{a} \times \mathbf{c}$.
- (iv) $\mathbf{a} \times \mathbf{b} = \mathbf{0}$ if and only if $\mathbf{a} \parallel \mathbf{b}$.
- (v) $\mathbf{a} \times \mathbf{b} \perp \mathbf{a}, \mathbf{b}$, so $\mathbf{a} \cdot (\mathbf{a} \times \mathbf{b}) = \mathbf{b} \cdot (\mathbf{a} \times \mathbf{b}) = 0$.

Proof Sketch. Check definitions. □

§8.2.4 Orthonormal Bases and Components

So far we have considered vectors in a purely geometric sense. But just as a coordinate system can be used to reason about geometry, basis (and by extension components) can be used to reason about vectors. We will look at bases again in a more general setting later on, but for now we will focus on vectors in three dimensions.

When we use a cartesian coordinate system, we pick a set of axes and using them, we can describe the position of any point. In a similar way, a *basis* is a set of vectors that span the space. That is, any vector can be written as a linear combination of vectors in the set. However we also have an additional requirement: this linear combination must be unique.

Definition 8.2.9 (Basis – Informal)

We say that a set of vectors is a **basis** if any vector can be uniquely written as a linear combination of vectors in the set.

Before we continue, it's helpful when working with vectors in three dimensions (and in other settings) to pick basis vectors in a certain way. We introduce the following definition.

Definition 8.2.10 (Orthonormal)

We say that a set of vectors $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n\}$ is **orthonormal** if they are all unit

vectors and are orthogonal to each other. That is, if $|\mathbf{v}_i| = 1$ and

$$\mathbf{v}_i \cdot \mathbf{v}_j = \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{if } i \neq j. \end{cases}$$

for all $1 \leq i, j \leq n$.

Now choose vectors $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ that are **orthonormal**. Then the set $\{\mathbf{e}_i\}$ is a basis, so for any vector $\mathbf{a}$, we can write

$$\mathbf{a} = \sum_i a_i \mathbf{e}_i = a_1 \mathbf{e}_1 + a_2 \mathbf{e}_2 + a_3 \mathbf{e}_3,$$

and each coefficient is uniquely defined by $a_i = \mathbf{e}_i \cdot \mathbf{a}$. Note that this only works because of our orthonormal condition.

Recalling that dot products correspond to projections, we can see that this really is analogous to a cartesian coordinate system.

Once we have specified the basis vectors $\{\mathbf{e}_i\}$, we can then identify the vector $\mathbf{a}$ by its **components**, writing

$$\mathbf{a} = (a_1, a_2, a_3), \quad \text{or} \quad \mathbf{a} = \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix},$$

which is a **row** or **column** vector respectively⁴.

An advantage of writing vectors in this form is that we can work directly with the components of vectors, rather than using a purely geometric approach.

Dot Product in Components

For two vectors $\mathbf{a} = (a_1, a_2, a_3)$ and $\mathbf{b} = (b_1, b_2, b_3)$, their dot product is

$$\mathbf{a} \cdot \mathbf{b} = (a_1, a_2, a_3) \cdot (b_1, b_2, b_3) = a_1 b_1 + a_2 b_2 + a_3 b_3.$$

This comes directly from writing $\mathbf{a}$ and $\mathbf{b}$ in terms of $\mathbf{e}_i$, and using the orthonormality condition.

We can use this to directly calculate the length of the vector, with

$$\mathbf{a} \cdot \mathbf{a} = |\mathbf{a}|^2 = a_1^2 + a_2^2 + a_3^2.$$

⁴The difference will be important when we move onto matrices.

Cross Product in Components

The cross product is orientation dependent, so it helps to choose the basis in a specific way. Usually, we pick a **right-handed** bases, which is one that satisfies

$$\begin{aligned}\mathbf{e}_1 \times \mathbf{e}_2 &= \mathbf{e}_3 \\ \mathbf{e}_2 \times \mathbf{e}_3 &= \mathbf{e}_1 \\ \mathbf{e}_3 \times \mathbf{e}_1 &= \mathbf{e}_2,\end{aligned}$$

and note that just one of these implies all of the others. Then we can calculate the cross product of two vectors in component form.

$$\begin{aligned}\mathbf{a} \times \mathbf{b} &= (a_1\mathbf{e}_1 + a_2\mathbf{e}_2 + a_3\mathbf{e}_3) \times (b_1\mathbf{e}_1 + b_2\mathbf{e}_2 + b_3\mathbf{e}_3) \\ &= (a_2b_3 - a_3b_2)\mathbf{e}_1 + (a_3b_1 - a_1b_3)\mathbf{e}_2 + (a_1b_2 - a_2b_1)\mathbf{e}_3.\end{aligned}$$

Example 8.2.11 (Computing a Cross Product)

The following is an example of computing a cross product using vector components.

$$\begin{aligned}\mathbf{a} \times \mathbf{b} &= \begin{pmatrix} 2 \\ 0 \\ -1 \end{pmatrix} \times \begin{pmatrix} 7 \\ -3 \\ 5 \end{pmatrix} \\ &= \begin{pmatrix} 0 \times 5 - (-3) \times (-1) \\ 7 \times (-1) - 2 \times 5 \\ 2 \times (-3) - 7 \times 0 \end{pmatrix} \\ &= \begin{pmatrix} -3 \\ -17 \\ -6 \end{pmatrix}.\end{aligned}$$

Later on in this chapter, we will develop some more tools for working efficiently with components.

§8.2.5 Triple Products

Scalar Triple Product

Given three vectors, we define the *scalar triple product* as follows.

Definition 8.2.12 (Scalar Triple Product)

Let $\mathbf{a}, \mathbf{b}, \mathbf{c}$ be vectors. The **scalar triple product** of $\mathbf{a}, \mathbf{b}, \mathbf{c}$ is

$$\begin{aligned}[\mathbf{a}, \mathbf{b}, \mathbf{c}] &= \mathbf{a} \cdot (\mathbf{b} \times \mathbf{c}) = \mathbf{b} \cdot (\mathbf{c} \times \mathbf{a}) = \mathbf{c} \cdot (\mathbf{a} \times \mathbf{b}) \\ &= -\mathbf{a} \cdot (\mathbf{c} \times \mathbf{b}) = -\mathbf{b} \cdot (\mathbf{a} \times \mathbf{c}) = -\mathbf{c} \cdot (\mathbf{b} \times \mathbf{a}).\end{aligned}$$

The most natural interpretation of the scalar triple product is as the ‘signed’ volume of the parallelepiped formed by $\mathbf{a}, \mathbf{b}, \mathbf{c}$.

In the sketch above (where we assume $\theta, \phi < \pi/2$), we have

$$|\mathbf{c}| |\mathbf{a} \times \mathbf{b}| \cos \phi = \underbrace{|\mathbf{a}| |\mathbf{b}| \sin \theta}_{\text{base area}} \cdot \underbrace{|\mathbf{c}| \cos \phi}_{\text{height}},$$

which is the volume as shown.

We do have a sign, and indeed we have that $\mathbf{c} \cdot (\mathbf{a} \times \mathbf{b}) > 0$ implies that $\mathbf{a}, \mathbf{b}, \mathbf{c}$ is a right handed set. Also $\mathbf{c} \cdot (\mathbf{a} \times \mathbf{b}) = 0$ if and only if $\mathbf{a}, \mathbf{b}, \mathbf{c}$ are coplanar (corresponding with the parallelepiped having zero volume).

We can compute the scalar triple product using components. For $\mathbf{a} = (a_1, a_2, a_3)$, $\mathbf{b} = (b_1, b_2, b_3)$, $\mathbf{c} = (c_1, c_2, c_3)$, then we have

$$\begin{aligned} \mathbf{a} \cdot (\mathbf{b} \times \mathbf{c}) &= a_1 b_2 c_3 - a_1 b_3 c_2 \\ &\quad + a_2 b_3 c_1 - a_2 b_1 c_3 \\ &\quad + a_3 b_1 c_2 - a_3 b_2 c_1 \\ &= \begin{vmatrix} a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{vmatrix}, \end{aligned}$$

which is a determinant (we shall study these in Section 5).

Vector Triple Product

Another slightly less used product on three vectors is the *vector triple product*.

Definition 8.2.13 (Vector Triple Product)

For vectors $\mathbf{a}, \mathbf{b}, \mathbf{c}$, we define the **vector triple product** to be

$$\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = (\mathbf{a} \cdot \mathbf{c})\mathbf{b} - (\mathbf{a} \cdot \mathbf{b})\mathbf{c}.$$

We will prove this identity later on, but note that this product is not associative. As the cross product is anticommutative, we do have

$$\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = -(\mathbf{b} \times \mathbf{c}) \times \mathbf{a}.$$

There's not really a sensible geometric interpretation of the vector triple product, but it is used in other vector formulas as it can shorten certain expressions.

§8.2.6 Lines, Planes & Vector Equations

We defined vectors as position vectors from an origin O , but with the introduction of vector addition, we can also use vectors to describe the displacement between two points,

$$\mathbf{u} = \overrightarrow{QP} = \mathbf{p} - \mathbf{q}.$$

With this description of displacement vectors, we can define geometric objects such as lines and planes using equations involving vectors.

Lines

A general point on a line through $\mathbf{a}$ in the direction of $\mathbf{u} \neq \mathbf{0}$ can be written as

$$\mathbf{r} = \mathbf{a} + \lambda \mathbf{u}, \quad \lambda \in \mathbb{R}.$$

This is known as the **parametric form** of the line. Note the similarity between this equation and the one for a line in the complex plane.

To eliminate the parameter from this equation, we can take the cross product with $\mathbf{u}$

$$\begin{aligned} \mathbf{u} \times \mathbf{r} &= \mathbf{u} \times (\mathbf{a} + \lambda \mathbf{u}) \\ &= \mathbf{u} \times \mathbf{a} \\ \implies \mathbf{u} \times (\mathbf{r} - \mathbf{a}) &= \mathbf{0}. \end{aligned}$$

With this in mind, consider also the related equation $\mathbf{u} \times \mathbf{r} = \mathbf{c}$ with $\mathbf{u}, \mathbf{c} \neq \mathbf{0}$. From this, $\mathbf{u} \cdot \mathbf{c} = \mathbf{u} \cdot (\mathbf{u} \times \mathbf{r}) = 0$, so if $\mathbf{u} \cdot \mathbf{c} \neq 0$, this is inconsistent and there are no solutions. Otherwise, if $\mathbf{u} \cdot \mathbf{c} = 0$, then $\mathbf{u} \times (\mathbf{u} \times \mathbf{c}) = -|\mathbf{u}|^2 \mathbf{c}$, so $\mathbf{a} = \frac{-1}{|\mathbf{u}|^2} (\mathbf{u} \times \mathbf{c})$ is one solution. Then $\mathbf{r} = \mathbf{a} + \lambda \mathbf{u}$ is the general solution.

Planes

A general point on a plane Π through $\mathbf{a}$ with directions $\mathbf{u}, \mathbf{v}$ in the plane ($\mathbf{u} \nparallel \mathbf{v}$) is

$$\mathbf{r} = \mathbf{a} + \lambda \mathbf{u} + \mu \mathbf{v}, \quad \lambda, \mu \in \mathbb{R}.$$

An alternative form comes from considering a normal to the plane, $\mathbf{n} = \mathbf{u} \times \mathbf{v} (\neq \mathbf{0})$. With this, we get

$$\begin{aligned} \mathbf{n} \cdot \mathbf{r} &= \mathbf{n} \cdot \mathbf{a} \\ \implies \mathbf{n} \cdot (\mathbf{r} - \mathbf{a}) &= 0. \end{aligned}$$

For a geometric interpretation of this, note that $\mathbf{r} - \mathbf{a}$ is the displacement in the direction of the plane, and thus should be perpendicular to $\mathbf{n}$, a normal to the plane.

Other Vector Equations

To handle other vector equations, a general strategy is to manipulate equations and dot/cross with constant vectors.

Example 8.2.14 (Vector Equation of a Sphere)

We will attempt to find a geometric interpretation of the vector equation

$$|\mathbf{r}|^2 + \mathbf{r} \cdot \mathbf{a} = k,$$

with $\mathbf{a}$, k constant.

Here, we can ‘complete the square’ to get

$$\left| \mathbf{r} + \frac{1}{2}\mathbf{a} \right|^2 = k + \frac{1}{4}|\mathbf{a}|^2,$$

which is a sphere with center $-\frac{1}{2}\mathbf{a}$ and radius $(k + \frac{1}{4}|\mathbf{a}|^2)^{1/2}$, if $k > -\frac{1}{4}|\mathbf{a}|^2$. If this is not the case, then there are no solutions.

Example 8.2.15 (Arbitrary Vector Equation)

We will solve the vector equation

$$\mathbf{r} + \mathbf{a} \times (\mathbf{b} \times \mathbf{r}) = \mathbf{c},$$

where $\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$ are given.

We will use the ‘dot and cross stuff’ approach. We use the vector triple product identity to rewrite this as

$$\mathbf{r} + (\mathbf{a} \cdot \mathbf{r})\mathbf{b} - (\mathbf{a} \cdot \mathbf{b})\mathbf{r} = \mathbf{c}. \quad (\dagger)$$

Then dotting with $\mathbf{a}$ we get

$$\begin{aligned}\mathbf{a} \cdot \mathbf{r} + (\mathbf{a} \cdot \mathbf{r})(\mathbf{b} \cdot \mathbf{a}) - (\mathbf{a} \cdot \mathbf{b})(\mathbf{a} \cdot \mathbf{r}) &= \mathbf{c} \cdot \mathbf{a} \\ \implies \mathbf{a} \cdot \mathbf{r} &= \mathbf{c} \cdot \mathbf{a}. \quad (\dagger\dagger)\end{aligned}$$

Taking a dot product has ‘lost information’, so we substitute $(\dagger\dagger)$ into $(\dagger)$ to get

$$(1 - \mathbf{a} \cdot \mathbf{b})\mathbf{r} = \mathbf{c} - (\mathbf{a} \cdot \mathbf{c})\mathbf{b}.$$

If $\mathbf{a} \cdot \mathbf{b} \neq 1$, then we can rearrange to get our solution

$$\mathbf{r} = \frac{1}{1 - \mathbf{a} \cdot \mathbf{b}}(\mathbf{c} - (\mathbf{a} \cdot \mathbf{c})\mathbf{b}),$$

which is a point.

If $\mathbf{a} \cdot \mathbf{b} = 1$, then $\mathbf{c} - (\mathbf{a} \cdot \mathbf{c})\mathbf{b} \neq \mathbf{0}$ would cause the equation to be inconsistent. So if $\mathbf{c} - (\mathbf{a} \cdot \mathbf{c})\mathbf{b} = \mathbf{0}$, then $(\dagger)$ can be rewritten

$$(\mathbf{a} \cdot \mathbf{r} - \mathbf{a} \cdot \mathbf{c})\mathbf{b} = \mathbf{0},$$

of which the set of solutions is given by $(\dagger\dagger)$, a plane.

§8.2.7 Index Notation & The Summation Convention

Returning to the component approach that we began to develop earlier, we will now introduce some machinery for working with components algebraically in a more streamlined way. The notation may look like mere bookkeeping at first, but it makes otherwise painful vector identities almost mechanical to prove.

Components, δ and ε

Begin by writing vectors $\mathbf{a}$, $\mathbf{b}$, ... in terms of components a_i, b_i with respect to an orthonormal, right-handed basis $\{\mathbf{e}_i\}$. In the following discussion, the indices $i, j, k, l, p, q, \dots$ will take on values $1, 2, 3$ ⁵.

Using indices, we can take some vector $\mathbf{c} = \alpha\mathbf{a} + \beta\mathbf{b}$ and express the components as $c_i = [\alpha\mathbf{a} + \beta\mathbf{b}]_i = \alpha a_i + \beta b_i$, for $i = 1, 2, 3$ (a **free variable**). Using the same notation, we can write things like

$$\mathbf{a} \cdot \mathbf{b} = \sum_i a_i b_i,$$

and

$$\begin{aligned}\mathbf{x} &= \mathbf{a} + (\mathbf{b} \cdot \mathbf{c})\mathbf{d} \\ \iff x_j &= a_j + \left(\sum_k b_k c_k \right) d_j, \quad \text{for } j = 1, 2, 3.\end{aligned}$$

⁵This corresponds to the number of basis vectors, and the approach used will naturally generalize to indices taking on more values.

Definition 8.2.16 (Kronecker Delta Symbol)

We define the **Kronecker delta** symbol to be

$$\delta_{ij} = \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{if } i \neq j. \end{cases}$$

With this definition, we get $\mathbf{e}_i \cdot \mathbf{e}_j = \delta_{ij}$, which encodes our orthonormality condition from before. Then

$$\begin{aligned} \mathbf{a} \cdot \mathbf{b} &= \left(\sum_i a_i \mathbf{e}_i \right) \cdot \left(\sum_j b_j \mathbf{e}_j \right) \\ &= \sum_{ij} a_i b_j \mathbf{e}_i \cdot \mathbf{e}_j \\ &= \sum_{ij} a_i b_j \delta_{ij} \\ &= \sum_i a_i b_i. \end{aligned}$$

Definition 8.2.17 (Levi-Civita Symbol)

We define the **Levi-Civita symbol** such that

$$\varepsilon_{ijk} = \begin{cases} +1 & \text{if } (i \ j \ k) \text{ is an even permutation of } (1 \ 2 \ 3), \\ -1 & \text{if } (i \ j \ k) \text{ is an odd permutation of } (1 \ 2 \ 3), \\ 0 & \text{otherwise} \end{cases}$$

For example,

$$\begin{aligned} \varepsilon_{123} &= \varepsilon_{231} = \varepsilon_{312} = +1, \\ \varepsilon_{321} &= \varepsilon_{213} = \varepsilon_{132} = -1, \\ \varepsilon_{ijk} &= 0 \text{ if any of } i, j, k \text{ repeat.} \end{aligned}$$

The Levi-Civita symbol is **totally antisymmetric**, in that exchanging a pair of indices produces a change in sign.

With this definition, in our right-handed orthonormal basis we have

$$\mathbf{e}_i \times \mathbf{e}_j = \sum_k \varepsilon_{ijk} \mathbf{e}_k,$$

for example

$$\mathbf{e}_2 \times \mathbf{e}_1 = \sum_k \varepsilon_{21k} \mathbf{e}_k = \varepsilon_{213} \mathbf{e}_3 = -\mathbf{e}_3.$$

So we can compute the cross product of two vectors as

$$\mathbf{a} \times \mathbf{b} = \left(\sum_i a_i \mathbf{e}_i \right) \times \left(\sum_j b_j \mathbf{e}_j \right)$$

$$\begin{aligned}
&= \sum_{ij} a_i b_j \mathbf{e}_i \times \mathbf{e}_j \\
&= \sum_{ijk} a_i b_j \varepsilon_{ijk} \mathbf{e}_k \\
&\iff (\mathbf{a} \times \mathbf{b})_k = \sum_{ij} \varepsilon_{ijk} a_i b_j.
\end{aligned}$$

For example, $(\mathbf{a} \times \mathbf{b})_3 = \sum_{ij} \varepsilon_{ij3} a_i b_j = \varepsilon_{123} a_1 b_2 + \varepsilon_{213} a_2 b_1 = a_1 b_2 - a_2 b_1$, as we had before.

Summation Convention

With components and index notation, indices that appear twice in a given term are usually summed over. In the **summation convention**, we omit the sigma ($\sum$) signs for repeated indices, and the sums are implicitly understood.

Example 8.2.18 (Examples of the Summation Convention)

The following all use the summation convention.

- (i) $a_i \delta_{ij} = a_1 \delta_{1j} + a_2 \delta_{2j} + a_3 \delta_{3j} = a_j$.
- (ii) $\mathbf{a} \cdot \mathbf{b} = a_i b_i$.
- (iii) $(\mathbf{a} \times \mathbf{b})_i = \varepsilon_{ijk} a_j b_k$.
- (iv) $\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c}) = \varepsilon_{ijk} a_i b_j c_k$.
- (v) $\delta_{ii} = \delta_{11} + \delta_{22} + \delta_{33} = 3$.
- (vi) $[(\mathbf{a} \cdot \mathbf{c})\mathbf{b} - (\mathbf{a} \cdot \mathbf{b})\mathbf{c}]_i = (\mathbf{a} \cdot \mathbf{c})b_i - (\mathbf{a} \cdot \mathbf{b})c_i = a_j c_j b_i - a_k b_k c_i$.

We can explicitly define the rules of the summation convention as follows.

Definition 8.2.19 (Summation Convention Rules)

When using the summation convention, we have the following rules.

- (i) An index occurring exactly once in any given term must appear once in every term of an equation, and it can take any value – a **free index**.
- (ii) Any index occurring exactly *twice* in a given term is summed over – a **repeated**, **contracted** or **dummy index**.
- (iii) No index can occur more than twice in a given term.

Let's have a look at applying the summation convention to prove the vector triple product identity we stated earlier.

Proposition 8.2.20 (Vector Triple Product Identity)

For vectors $\mathbf{a}, \mathbf{b}, \mathbf{c}$, we have

$$\mathbf{a} \times (\mathbf{b} \times \mathbf{c}) = (\mathbf{a} \cdot \mathbf{c})\mathbf{b} - (\mathbf{a} \cdot \mathbf{b})\mathbf{c}.$$

Proof. We have

$$\begin{aligned} [\mathbf{a} \times (\mathbf{b} \times \mathbf{c})]_i &= \varepsilon_{ijk} a_j (\mathbf{b} \times \mathbf{c})_k \\ &= \varepsilon_{ijk} a_j \varepsilon_{kpq} b_p c_q \\ &= (\varepsilon_{ijk} \varepsilon_{pqk}) a_j b_p c_q, \end{aligned}$$

now $\varepsilon_{ijk} \varepsilon_{pqk} = \delta_{ip} \delta_{jq} - \delta_{iq} \delta_{jp}$ (we will prove this later on), hence

$$\begin{aligned} [\mathbf{a} \times (\mathbf{b} \times \mathbf{c})]_i &= (\delta_{ip} \delta_{jq}) a_j b_p c_q - (\delta_{iq} \delta_{jp}) a_j b_p c_q \\ &= [(\mathbf{a} \cdot \mathbf{c}) \mathbf{b} - (\mathbf{a} \cdot \mathbf{b}) \mathbf{c}]_i, \end{aligned}$$

as required. □

εε Identities

We will finish this section by looking at εε identities, which can be used in various computations involving δ and ε symbols.

- $\varepsilon_{ijk} \varepsilon_{pqk} = \delta_{ip} \delta_{jq} - \delta_{iq} \delta_{jp} = \varepsilon_{kij} \varepsilon_{kpq}$.

To check this, note that RHS and LHS are antisymmetric under $i \leftrightarrow j$, $p \leftrightarrow q$, so both vanish if i & j or p & q take the same value. Now it suffices to check examples $i = p = 1, j = q = 2$, where LHS and RHS are both +1, or $i = q = 1, j = p = 2$, where LHS and RHS are both −1. All other index choices giving non-zero results work similarly.

- $\varepsilon_{ijk} \varepsilon_{pjk} = 2\delta_{ip}$.

This comes from the above identity, where the LHS becomes $\delta_{ip} \delta_{jj} - \delta_{ij} \delta_{jp} = 3\delta_{ip} - \delta_{ip} = 2\delta_{ip}$.

- $\varepsilon_{ijk} \varepsilon_{ijk} = 6$.

This follows directly from the previous result, with $i = p$. Then $2\delta_{ii} = 6$.

§8.3 Vectors in a General Setting, $\mathbb{R}^n$ and $\mathbb{C}^n$

In the previous chapter, we studied vectors as they occur when considering position vectors in three dimensions. However, vectors are more general objects, which we will see in this chapter. First, we will consider how to immediately generalise vectors from $\mathbb{R}^3$ (as in the previous chapter) to $\mathbb{R}^n$.

§8.3.1 Vectors in $\mathbb{R}^n$

By regarding vectors as sets of components, it's easy to generalize from 3 to n dimensions.

Definition 8.3.1 ($\mathbb{R}^n$ Space)

We define $\mathbb{R}^n$ to be the set of n -tuples of real numbers,

$$\mathbb{R}^n = \{(x_1, x_2, \dots, x_n) \mid x_i \in \mathbb{R}\}.$$

We also define **vector addition** and **scalar multiplication** as

$$(x_1, \dots, x_n) + (y_1, \dots, y_n) = (x_1 + y_1, \dots, x_n + y_n),$$

$$\text{and } \lambda(x_1, \dots, x_n) = (\lambda x_1, \dots, \lambda x_n).$$

As before, we can take arbitrary linear combinations and we also get a notion of parallelism, where $\mathbf{x} \parallel \mathbf{y}$ if and only if $\mathbf{x} = \lambda \mathbf{y}$ or $\mathbf{y} = \lambda \mathbf{x}$ for $\lambda \in \mathbb{R}$.

We also still have a dot product, but in more general settings, such operations are normally referred to as *inner products*.

Definition 8.3.2 (Inner Product)

The inner product on $\mathbb{R}^n$ is defined by

$$\mathbf{x} \cdot \mathbf{y} = \sum_i x_i y_i = x_1 y_1 + x_2 y_2 + \dots + x_n y_n.$$

Proposition 8.3.3 (Properties of the Inner Product)

In $\mathbb{R}^n$, the inner product satisfies

- (i) *Symmetric.* $\mathbf{x} \cdot \mathbf{y} = \mathbf{y} \cdot \mathbf{x}$.
- (ii) *Bilinear.* $(\lambda \mathbf{x} + \lambda' \mathbf{x}') \cdot \mathbf{y} = \lambda \mathbf{x} \cdot \mathbf{y} + \lambda' \mathbf{x}' \cdot \mathbf{y}$.
- (iii) *Positive Definite.* $\mathbf{x} \cdot \mathbf{x} = \sum_i x_i^2 \geq 0$, and is equal 0 if and only if $\mathbf{x} = \mathbf{0}$.

Also, if we return back to vectors in three-dimensions, we had an equivalent definition of the dot product as

$$\mathbf{x} \cdot \mathbf{y} = |\mathbf{x}| |\mathbf{y}| \cos \theta,$$

where θ is the angle between the vectors. Using this as a definition of the inner product in $\mathbb{R}^n$, we get a definition for the angle between vectors.

When we look at vector spaces in general, we will define the inner product in general to be any operation that satisfies these properties.

We also have the notions of length and orthogonality, much the same as in three-dimensions.

Definition 8.3.4 (Length/Norm)

For $\mathbf{x} \in \mathbb{R}^n$, we define its **length** or **norm** to be $|\mathbf{x}| \geq 0$ with $|\mathbf{x}|^2 = \mathbf{x} \cdot \mathbf{x}$.

Definition 8.3.5 (Orthogonality)

We say two vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ are **orthogonal** if and only if $\mathbf{x} \cdot \mathbf{y} = 0$.

When working in $\mathbb{R}^n$, we typically use a set of basis vectors known as the **standard basis**. They are

$$\mathbf{e}_1 = (1, 0, 0, \dots, 0),$$

$$\mathbf{e}_2 = (0, 1, 0, \dots, 0),$$

$$\begin{aligned} & \vdots \\ \mathbf{e}_n &= (0, 0, 0, \dots, 1). \end{aligned}$$

Then we have

$$\mathbf{x} = \sum_i x_i \mathbf{e}_i,$$

and $\mathbf{e}_i \cdot \mathbf{e}_j = \delta_{ij}$, so this basis is orthonormal.

Cauchy-Schwarz and the Triangle Inequality

We will now state an inequality about the inner product of two vectors in $\mathbb{R}^n$.

Proposition 8.3.6 (Cauchy-Schwarz Inequality)

For all vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, we have

$$|\mathbf{x} \cdot \mathbf{y}| \leq |\mathbf{x}| \cdot |\mathbf{y}|,$$

with equality if and only if $\mathbf{x} \parallel \mathbf{y}$.

Proof. If $\mathbf{y} = \mathbf{0}$, then we are done. Otherwise, consider

$$\begin{aligned} |\mathbf{x} - \lambda \mathbf{y}|^2 &= (\mathbf{x} - \lambda \mathbf{y}) \cdot (\mathbf{x} - \lambda \mathbf{y}) \\ &= |\mathbf{x}|^2 - 2\lambda \mathbf{x} \cdot \mathbf{y} + \lambda^2 |\mathbf{y}|^2 \geq 0 \end{aligned}$$

for any $\lambda \in \mathbb{R}$. This is a real quadratic in λ with at most one real root, so its discriminant satisfies

$$(-2\mathbf{x} \cdot \mathbf{y})^2 - 4|\mathbf{x}|^2 |\mathbf{y}|^2 \leq 0,$$

which rearranges to give $|\mathbf{x} \cdot \mathbf{y}| \leq |\mathbf{x}| |\mathbf{y}|$. Equality holds if and only if the discriminant is zero, that is, if $\mathbf{x} = \lambda \mathbf{y}$ for some λ , as required. $\square$

As vectors in $\mathbb{R}^n$ are just sets of components, we can state this inequality in terms of real numbers. For sequences of real numbers (a_i) and (b_i) , we have

$$\left(\sum_{i=1}^n a_i b_i \right)^2 \leq \left(\sum_{i=1}^n a_i^2 \right) \left(\sum_{i=1}^n b_i^2 \right),$$

where we have equality if and only if $\frac{a_i}{b_i}$ is a constant for all i where $a_i b_i \neq 0$.

We also have the triangle inequality, similar to the one stated in Section 1.

Proposition 8.3.7 (Triangle Inequality)

For all $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$,

$$|\mathbf{x} + \mathbf{y}| \leq |\mathbf{x}| + |\mathbf{y}|$$

Proof. We have

$$\begin{aligned} |\mathbf{x} + \mathbf{y}|^2 &= |\mathbf{x}|^2 + 2\mathbf{x} \cdot \mathbf{y} + |\mathbf{y}|^2 \\ &\leq |\mathbf{x}|^2 + 2|\mathbf{x}| \cdot |\mathbf{y}| + |\mathbf{y}|^2 \\ &= (|\mathbf{x}| + |\mathbf{y}|)^2, \end{aligned}$$

as required. □

A comment about $\mathbb{R}^n$ and $\mathbb{R}^3$

The definition we gave for the inner product on $\mathbb{R}^n$ can be written as

$$\mathbf{a} \cdot \mathbf{b} = \delta_{ij} a_i b_j,$$

for $\mathbf{a}, \mathbf{b} \in \mathbb{R}^n$ where we use the summation convention. For $n = 3$, this matches with the compact definition of the dot product we gave previously.

However, in three dimensions we also had a compact definition of the cross product with

$$(\mathbf{a} \times \mathbf{b})_i = \varepsilon_{ijk} a_j b_k.$$

In $\mathbb{R}^n$ however, we have $\varepsilon_{ij\dots k}$ where there are n indices (we will look at this again in Section 5). This is totally antisymmetric, so we cannot use ε to define a vector-valued product for any n except 3.

In $\mathbb{R}^2$ however, we have ε_{ij} where $\varepsilon_{12} = -\varepsilon_{21} = 1$, and we can define an additional scalar product

$$[\mathbf{a}, \mathbf{b}] = \varepsilon_{ij} a_i b_j = a_1 b_2 - a_2 b_1.$$

This corresponds with the signed area of a parallelogram, and $|[\mathbf{a}, \mathbf{b}]| = |\mathbf{a}||\mathbf{b}|\sin\theta$. Compare this with $[\mathbf{a}, \mathbf{b}, \mathbf{c}] = \varepsilon_{ijk} a_i b_j c_k$, the signed volume of the parallelepiped in three dimensions we defined earlier.

§8.3.2 Vector Spaces

We will now go one step further and define what a vector is in a much more general sense. This will be done by defining the properties that vectors have, rather than what they are themselves.

Definition 8.3.8 (Vector Space)

Let V be a set of objects called **vectors** with operations $\mathbf{v} + \mathbf{w} \in V$ defined for all $\mathbf{v}, \mathbf{w} \in V$, and $\lambda \mathbf{v} \in V$ for all $\mathbf{v} \in V$ and $\lambda \in F$, where F is some field.

Then V is a **vector space** if

- (i) V with $+$ is an abelian group.
- (ii) $\lambda(\mathbf{v} + \mathbf{w}) = \lambda\mathbf{v} + \lambda\mathbf{w}$.
- (iii) $(\lambda + \mu)\mathbf{v} = \lambda\mathbf{v} + \mu\mathbf{v}$.

$$(iv) \lambda(\mu \mathbf{v}) = (\lambda\mu)\mathbf{v}.$$

$$(v) 1\mathbf{v} = \mathbf{v}.$$

In this course, we will deal only with the fields $\mathbb{R}$ and $\mathbb{C}$. If $F = \mathbb{R}$, then we call V a **real vector space**, and if $F = \mathbb{C}$, then we call it a **complex vector space**.

Example 8.3.9 (Example of a Real Vector Space)

Let V be the set of all functions $f : [0, 1] \rightarrow \mathbb{R}$ where $f(0) = f(1) = 0$ and f is smooth. Then V is a real vector space.

Indeed we have

$$\begin{aligned} (f + g)(x) &= f(x) + g(x), \\ (\lambda f)(x) &= \lambda(f(x)). \end{aligned}$$

The other properties can be checked as required.

We can also define a *subspace* in the natural way.

Definition 8.3.10 (Subspace)

A **subspace** of a vector space V is a subset $U \subseteq V$ that is also a vector space.

Note that a non-empty subset is a subspace if and only if $\mathbf{v}, \mathbf{w} \in U$ implies $\lambda\mathbf{v} + \mu\mathbf{w} \in U$ where λ, μ are some arbitrary scalars.

For any vectors $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_r \in V$, their span

$$\text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_r\} = \{\lambda_1\mathbf{v}_1 + \dots + \lambda_r\mathbf{v}_r \mid \lambda_i \in \mathbb{R} \text{ or } \mathbb{C}\}.$$

is a subspace. Also note that V and $\{\mathbf{0}\}$ are both subspaces of a vector space V .

Linear Dependence & Independence

We will now think about whether sets of vectors are independent.

Definition 8.3.11 (Linear Dependence/Independence)

For $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_r \in V$, some vector space, consider the **linear relation**

$$\lambda_1\mathbf{v}_1 + \lambda_2\mathbf{v}_2 + \dots + \lambda_r\mathbf{v}_r = \mathbf{0} \quad (\dagger)$$

If $(\dagger)$ implies that $\lambda_i = 0$ for all i , then these vectors form a **linearly independent** set. If $(\dagger)$ holds with some $\lambda_i \neq 0$, then they form a **linearly dependent** set.

Example 8.3.12 (Example of a Linearly Dependent Set)

In $\mathbb{R}^2$, the set $\left\{ \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \begin{pmatrix} 0 \\ 2 \end{pmatrix} \right\}$ is linearly dependent, since

$$0 \begin{pmatrix} 1 \\ 0 \end{pmatrix} + 2 \begin{pmatrix} 0 \\ 1 \end{pmatrix} - 1 \begin{pmatrix} 0 \\ 2 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix},$$

which is a non-trivial linear relation.

Any set containing $\mathbf{0}$ is linearly dependent, since $\lambda\mathbf{0} = \mathbf{0}$ for any $\lambda \neq 0$.

In $\mathbb{R}^3$, the set of vectors $\{\mathbf{a}, \mathbf{b}, \mathbf{c}\}$ are linearly independent if $\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c}) \neq 0$, since if $\alpha\mathbf{a} + \beta\mathbf{b} + \gamma\mathbf{c} = \mathbf{0}$, then dotting with $\mathbf{b} \times \mathbf{c}$ gives $\alpha\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c}) = 0 \implies \alpha = 0$, and β, γ similarly.

Inner Products

A real vector space can have an additional structure that we can define by axioms.

Definition 8.3.13 (Inner Product)

For a real vector space V and $\mathbf{v}, \mathbf{w} \in V$, an **inner product** denoted by

$$\mathbf{v} \cdot \mathbf{w} \quad \text{or} \quad (\mathbf{v}, \mathbf{w}) \in \mathbb{R}$$

is a map that is symmetric, bilinear, and positive definite.

If these conditions hold, then we get things like the Cauchy-Schwarz inequality and a norm as by the previous argument.

Example 8.3.14 (Inner Product on a Real Vector Space)

Consider the real vector space of functions $V = \{f : [0, 1] \rightarrow \mathbb{R} \mid f \text{ smooth, and } f(0) = f(1) = 0\}$. We can define the inner product as

$$(f, g) = \int_0^1 f(x)g(x) \, dx,$$

which satisfies the conditions specified above. Then we have

$$|(f, g)| \leq \|f\| \cdot \|g\|,$$

that is,

$$\left| \int_0^1 f(x)g(x) \, dx \right| \leq \left(\int_0^1 f(x)^2 \, dx \right)^{1/2} \left(\int_0^1 g(x)^2 \, dx \right)^{1/2}.$$

We can also say something about linear independence from an inner product.

Lemma 8.3.15

In any real vector space V with an inner product, if $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_r$ are non-zero and orthogonal vectors, then they are linearly independent.

Proof. If $\sum_i \alpha_i \mathbf{v}_i = \mathbf{0}$, then $(\mathbf{v}_j, \sum_i \alpha_i \mathbf{v}_i) = 0$ for a fixed j , so $\alpha_j(\mathbf{v}_j, \mathbf{v}_j) = 0$, and thus $\alpha_j = 0$. $\square$

§8.3.3 Basis and Dimension

We can generalize the notion of a basis to an arbitrary vector space.

Definition 8.3.16 (Basis)

For a vector space V , a **basis** is a set $B = \{\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n\}$ such that

- (i) B spans V , that is, any $\mathbf{v} \in V$ can be written $\mathbf{v} = \sum_{i=1}^n v_i \mathbf{e}_i$.
- (ii) B is linearly independent.

The linear independence implies that the coefficients v_i in (i) are unique. We say that v_i are the components of $\mathbf{v}$ with respect to the basis B .

Example 8.3.17 (Standard Basis)

The standard basis for $\mathbb{R}^n$ consists of the vectors

$$\mathbf{e}_1 = \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix}, \quad \mathbf{e}_2 = \begin{pmatrix} 0 \\ 1 \\ \vdots \\ 0 \end{pmatrix}, \quad \dots, \quad \mathbf{e}_n = \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 1 \end{pmatrix}.$$

This is a basis since it satisfies the definition as $\mathbf{x} \in \mathbb{R}^n$, we have

$$\mathbf{x} = \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix} = x_1 \mathbf{e}_1 + \dots + x_n \mathbf{e}_n,$$

and $\mathbf{x} = \mathbf{0}$ if and only if $x_1 = x_2 = \dots = x_n = 0$.

Of course in the example above we just used one particular base. For example in $\mathbb{R}^2$ another basis consists of $\{(1, 0), (1, 1)\}$.

Theorem 8.3.18 (The Basis Theorem)

If $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$ and $\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$ are both bases of a vector space V , then $n = m$.

Proof. We can find coefficients A_{ai} and B_{ia} such that $\mathbf{f}_a = \sum_i A_{ai} \mathbf{e}_i$ and $\mathbf{e}_i = \sum_a B_{ia} \mathbf{f}_a$. So we have that

$$\begin{aligned} \mathbf{f}_a &= \sum_i A_{ai} \left(\sum_b B_{ib} \mathbf{f}_b \right) \\ &= \sum_b \left(\sum_i A_{ai} B_{ib} \right) \mathbf{f}_b, \end{aligned}$$

but coefficients with respect to a basis are unique, hence

$$\sum_i A_{ai} B_{ib} = \delta_{ab}.$$

Similarly, $\sum_a B_{ia}A_{aj} = \delta_{ij}$. Finally,

$$\begin{aligned}\sum_{ia} A_{ai}B_{ia} &= \sum_a \delta_{aa} = m \\ &= \sum_i \delta_{ii} = n,\end{aligned}$$

hence $n = m$. □

This theorem allows us to state the following definition.

Definition 8.3.19 (Dimension)

The **dimension** of a vector space V , written $\dim V$, is the size of its basis.

Note that $\mathbb{R}^n$ has dimension n .

The steps in the proof of the basis theorem are within the scope of the course, but you will not be expected to prove this theorem without prompts (it is non-examinable in the schedules). The same applies with the following.

Proposition 8.3.20

Let V be a vector space with finite subsets $Y = \{\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_m\}$ that spans V , and $X = \{\mathbf{u}_1, \dots, \mathbf{u}_k\}$ that is linearly independent. Then $k \leq n \leq m$ where $n = \dim V$. Also

- (i) A basis can be formed from subsets of Y ,
- (ii) A basis can be obtained from X by adding additional vectors (from Y if necessary).

Proof. (i) If Y is linearly independent, then it's a basis and $m = n = \dim V$. If Y is not linearly independent, then

$$\sum_{i=1}^m \lambda_i \mathbf{w}_i = \mathbf{0}, \quad \text{with some } \lambda_i \neq 0.$$

Take $\lambda_m \neq 0$ without loss of generality, then $\mathbf{w}_m = -\frac{1}{\lambda_m} \sum_{i=1}^{m-1} \lambda_i \mathbf{w}_i$, so $\text{span } Y = \text{span } Y'$, with $Y' = \{\mathbf{w}_1, \dots, \mathbf{w}_{m-1}\}$. This can be repeated until a basis is obtained.

- (ii) If X spans V then it's a basis and $k = n = \dim V$. If not, then there exists $\mathbf{u}_{k+1} \in V$ not in $\text{span } X$. But then $\sum_{i=1}^{k+1} \mu_i \mathbf{u}_i = \mathbf{0}$ implies $\mu_{k+1} = 0$, thus $X' = \{\mathbf{u}_1, \dots, \mathbf{u}_{k+1}\}$ is linearly independent. Furthermore, we can choose $\mathbf{u}_{k+1} \in Y$ as otherwise $Y \subseteq \text{span } X \implies \text{span } Y \subseteq \text{span } X \implies \text{span } X = V$. We can repeat this process until we obtain a basis (and this must stop since Y is a finite set). □

Not every vector space has a finite dimension, but in this course we will deal only with vector spaces that do, save for the occasional example.

Example 8.3.21 (Example of an Infinite Dimensional Vector Space)

Consider the vector space

$$V = \{f : [0, 1] \rightarrow \mathbb{R} \mid f \text{ smooth}, f(0) = f(1) = 0\}.$$

Then consider $S_n(x) = \sqrt{2} \sin(n\pi x)$, $n = 1, 2, \dots$. These belong to V and

$$(S_n, S_m) = 2 \int_0^1 \sin(n\pi x) \sin(m\pi x) dx = \delta_{mn},$$

so they are all linearly independent. But we have infinitely many of them, so V is infinite dimensional.

§8.3.4 Vectors in $\mathbb{C}^n$

So far we have looked at real vector spaces, and particularly at $\mathbb{R}^n$. We can define a similar vector space over the complex numbers.

Definition 8.3.22 ($\mathbb{C}^n$ Space)

We define $\mathbb{C}^n$ to be the set of n -tuples of complex numbers,

$$\mathbb{C}^n = \{(z_1, z_2, \dots, z_n) \mid z_j \in \mathbb{C}\}.$$

We also define **addition** and scalar multiplication with

$$(z_1, \dots, z_n) + (w_1, \dots, w_n) = (z_1 + w_1, \dots, z_n + w_n) \\ \text{and } \lambda(z_1, \dots, z_n) = (\lambda z_1, \dots, \lambda z_n)$$

Note that we could have used real scalars and have gotten a real vector space, but having a complex vector space is more natural.

The distinction between real and complex vector spaces is important. For example, if we have $\mathbf{z} = (z_1, \dots, z_n) \in \mathbb{C}^n$, with $z_j = x_j + iy_j$ then

$$\mathbf{z} = \sum_j x_j \mathbf{e}_j + \sum_j y_j \mathbf{f}_j, \quad \text{where } \mathbf{f}_j = i\mathbf{e}_j,$$

is a real linear combination, and thus $\{\mathbf{e}_1, \dots, \mathbf{e}_n, \mathbf{f}_1, \dots, \mathbf{f}_n\}$ is a basis for $\mathbb{C}^n$ as a real vector space, and it has dimension $2n$. However, taking $\mathbb{C}^n$ as defined before, it is of dimension n which is clearly different.

From now on we will view $\mathbb{C}^n$ as a complex vector space unless we say otherwise.

Complex Inner Product

We can define an inner product on $\mathbb{C}^n$.

Definition 8.3.23 (Complex Inner Product)

For $\mathbf{z}, \mathbf{w} \in \mathbb{C}^n$, we define the inner product to be

$$(\mathbf{z}, \mathbf{w}) = \sum_j \bar{z}_j w_j = \bar{z}_1 w_1 + \cdots + \bar{z}_n w_n.$$

Proposition 8.3.24 (Properties of the Complex Inner Product)

The complex inner product satisfies

- (i) *Hermitian*. $(\mathbf{w}, \mathbf{z}) = \overline{(\mathbf{z}, \mathbf{w})}$.
- (ii) *Linear/anti-linear*. $(\mathbf{z}, \lambda \mathbf{w} + \lambda' \mathbf{w}') = \lambda(\mathbf{z}, \mathbf{w}) + \lambda'(\mathbf{z}, \mathbf{w}')$ and $(\lambda \mathbf{z} + \lambda' \mathbf{z}', \mathbf{w}) = \bar{\lambda}(\mathbf{z}, \mathbf{w}) + \bar{\lambda}'(\mathbf{z}', \mathbf{w})$.
- (iii) *Positive definite*. $(\mathbf{z}, \mathbf{z}) = \sum_j |z_j|^2$, which is real, non-negative and zero if and only if $\mathbf{z} = \mathbf{0}$.

Proof Sketch. Check definitions. □

We also define the *length* or *norm* of $\mathbf{z}$ to be $|\mathbf{z}| \geq 0$ with $|\mathbf{z}|^2 = (\mathbf{z}, \mathbf{z})$.

We can also say that $\mathbf{z}, \mathbf{w} \in \mathbb{C}^n$ are orthogonal if $(\mathbf{z}, \mathbf{w}) = 0$. With this, note that the standard basis for $\mathbb{C}^n$ is orthonormal.

§8.4 Matrices and Linear Maps

Vector spaces have two basic operations: addition and scalar multiplication. The prominence of these operations makes thinking about functions that preserve this structure quite useful. Such functions are called linear maps, and in the setting of finite dimensional vector spaces we have a useful way of studying them: matrices. In this chapter we will study both ideas and how they link together.

§8.4.1 Linear Maps

Let's begin by defining what we mean exactly by a linear map.

Definition 8.4.1 (Linear Map)

A **linear map** or **linear transformation** is a function $T : V \rightarrow W$ between two vector spaces V and W such that

$$T(\lambda \mathbf{x} + \mu \mathbf{y}) = \lambda T(\mathbf{x}) + \mu T(\mathbf{y}),$$

for all $\mathbf{x}, \mathbf{y} \in V$ and $\lambda, \mu \in \mathbb{R}$ or $\mathbb{C}$ ^a.

^aDepending on whether we are working with real or complex vector spaces.

From this definition, it is immediately clear that a linear map is completely determined by its action on a set of basis vectors.

Let's have a look at some examples of linear maps that appear in geometry.

Example 8.4.2 (Geometric Linear Maps)

The following are all examples of linear maps.

- (i) A rotation is an example of a linear map. In $\mathbb{R}^2$, a rotation about $\mathbf{0}$ through an angle θ is defined by

$$\begin{aligned}\mathbf{e}_1 &\mapsto \mathbf{e}'_1 = \cos \theta \mathbf{e}_1 + \sin \theta \mathbf{e}_2 \\ \mathbf{e}_2 &\mapsto \mathbf{e}'_2 = -\sin \theta \mathbf{e}_1 + \cos \theta \mathbf{e}_2\end{aligned}$$

In $\mathbb{R}^3$, a rotation about an axis given by $\mathbf{e}_3$ is defined as above, but with $\mathbf{e}_3 \mapsto \mathbf{e}'_3 = \mathbf{e}_3$.

- (ii) A projection onto a plane through the origin with unit normal $\hat{\mathbf{n}}$ is a linear map, defined by

$$\mathbf{x} \mapsto \mathbf{x}' = \mathbf{x}_{\perp} = \mathbf{x} - (\mathbf{x} \cdot \hat{\mathbf{n}})\hat{\mathbf{n}}.$$

Similarly, the reflection about that plane is a linear map, defined by

$$\mathbf{x} \mapsto \mathbf{x}' = \mathbf{x} - 2(\mathbf{x} \cdot \hat{\mathbf{n}})\hat{\mathbf{n}}$$

- (iii) A dilation along the basis vectors with scale factors α, β, γ is a linear map, defined by

$$\mathbf{e}_1 \mapsto \mathbf{e}'_1 = \alpha \mathbf{e}_1, \quad \mathbf{e}_2 \mapsto \mathbf{e}'_2 = \beta \mathbf{e}_2, \quad \mathbf{e}_3 \mapsto \mathbf{e}'_3 = \gamma \mathbf{e}_3.$$

- (iv) For orthogonal unit vectors $\mathbf{a}, \mathbf{b} \in \mathbb{R}^3$ and $\lambda \in \mathbb{R}$, we can define a *shear* to be the linear map

$$\mathbf{x} \mapsto \mathbf{x}' = \mathbf{x} + \lambda \mathbf{a}(\mathbf{x} \cdot \mathbf{b}).$$

This displaces each point in the direction of $\mathbf{a}$, by an amount proportional to how far along $\mathbf{b}$ the point lies.

When we have a linear map $T : V \rightarrow W$, it can be helpful to think about what vectors in the vector space W are in the image of this function, and also what in V will just be

sent to $\mathbf{0}$. Because we deal with these so commonly, we introduce standard terms.

Definition 8.4.3 (Image and Kernel)

If $T : V \rightarrow W$ is a linear map, we say that its **image** is the set

$$\text{img}(T) = \{\mathbf{x}' \in W \mid \mathbf{x}' = T(\mathbf{x}) \text{ for some } \mathbf{x} \in V\},$$

and its **kernel** is the set

$$\ker(T) = \{\mathbf{x} \in V \mid T(\mathbf{x}) = \mathbf{0}\}.$$

Proposition 8.4.4 (Image and Kernel are Subspaces)

If $T : V \rightarrow W$ is a linear map, then $\ker(T)$ is a subspace of V and $\text{img}(T)$ is a subspace of W .

Proof Sketch. Use the properties of T as a linear map to check definitions. $\square$

These subspaces have a special property relating to their dimension. We call the dimension of the image the **rank** and dimension of the kernel as the **nullity** of a linear map. Then we have the following result (the proof of which is non-examinable).

Theorem 8.4.5 (Rank-Nullity Theorem)

For a linear map $T : V \rightarrow W$, we have $\text{rank}(T) + \text{null}(T) = \dim V$.

Proof. Let $\mathbf{e}_1, \dots, \mathbf{e}_k$ be a basis for $\ker(T)$. Extend this by adding in $\mathbf{e}_{k+1}, \dots, \mathbf{e}_n$ to get a basis for V . We claim that $B = \{T(\mathbf{e}_{k+1}), \dots, T(\mathbf{e}_n)\}$ is a basis for $\text{img}(T)$ (from which the result would follow).

First we have that B spans $\text{img}(T)$, since for any $\mathbf{x} = \sum_{i=1}^n x_i \mathbf{e}_i \in V$, $T(\mathbf{x}) = \sum_{i=k+1}^n x_i T(\mathbf{e}_i)$. Also, B is linearly independent since $\sum_{i=k+1}^n \lambda_i T(\mathbf{e}_i) = \mathbf{0}$ implies that $T(\sum_{i=k+1}^n \lambda_i \mathbf{e}_i) = \mathbf{0}$. But then that linear combination must be in the kernel, so we must have $\lambda_i = 0$, as $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$ are linearly independent. Thus B is a basis, as required. $\square$

§8.4.2 Matrices

In the examples above, we described linear maps by giving their action on basis vectors, or by giving an explicit formula for the image of a general vector $\mathbf{x}$. We are now going to introduce *matrices*, which give us a uniform (and highly computable) way of doing this.

Let $T : \mathbb{R}^n \rightarrow \mathbb{R}^m$ be a linear map, and write $\mathbf{x}' = T(\mathbf{x})$. Taking the standard basis $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$ of $\mathbb{R}^n$, we can write any $\mathbf{x} \in \mathbb{R}^n$ as $\mathbf{x} = \sum_j x_j \mathbf{e}_j$. Then by linearity,

$$\mathbf{x}' = T\left(\sum_j x_j \mathbf{e}_j\right) = \sum_j x_j T(\mathbf{e}_j),$$

so taking components in $\mathbb{R}^m$,

$$x'_i = \sum_j [T(\mathbf{e}_j)]_i x_j.$$

This motivates the following definition.

Definition 8.4.6 (Matrix of a Linear Map)

Let $T : \mathbb{R}^n \rightarrow \mathbb{R}^m$ be a linear map. The **matrix** of T (with respect to the standard bases) is the $m \times n$ array of numbers $A = \{A_{ij}\}$ with entries

$$A_{ij} = [T(\mathbf{e}_j)]_i,$$

that is, the j th column of A is the image of the j th basis vector. We write

$$A = \begin{pmatrix} A_{11} & \cdots & A_{1n} \\ \vdots & \ddots & \vdots \\ A_{m1} & \cdots & A_{mn} \end{pmatrix},$$

where A_{ij} is the entry in row i and column j , and we define the action of A on a vector by $\mathbf{x}' = A\mathbf{x}$ where $x'_i = \sum_j A_{ij}x_j$, or with the summation convention just $x'_i = A_{ij}x_j$.

The fact that *the columns of the matrix are the images of the basis vectors* is worth internalising – it is how one actually writes down matrices in practice, and we will use it constantly. The same definitions work with $\mathbb{C}^n$ and $\mathbb{C}^m$ (or indeed between any vector spaces with a choice of basis, as we will see when changing bases in Section 7).

Let's use this to write down matrices for the geometric linear maps we met before, working in $\mathbb{R}^2$ and $\mathbb{R}^3$.

Example 8.4.7 (Matrices of Geometric Maps) (i) A rotation about $\mathbf{0}$ through angle θ in $\mathbb{R}^2$ sends $\mathbf{e}_1 \mapsto \cos \theta \mathbf{e}_1 + \sin \theta \mathbf{e}_2$ and $\mathbf{e}_2 \mapsto -\sin \theta \mathbf{e}_1 + \cos \theta \mathbf{e}_2$. Putting these images in as columns, the matrix of the rotation is

$$R(\theta) = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}.$$

In $\mathbb{R}^3$, a rotation by θ about the $\mathbf{e}_3$ axis fixes $\mathbf{e}_3$, giving

$$R = \begin{pmatrix} \cos \theta & -\sin \theta & 0 \\ \sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

(ii) A reflection in the plane through the origin with unit normal $\hat{\mathbf{n}}$ is $\mathbf{x} \mapsto \mathbf{x} - 2(\mathbf{x} \cdot \hat{\mathbf{n}})\hat{\mathbf{n}}$, which in components reads $x'_i = x_i - 2x_j n_j n_i$. So the matrix has entries

$$H_{ij} = \delta_{ij} - 2n_i n_j.$$

(iii) A dilation with scale factors α, β, γ along the coordinate axes has matrix

$$\begin{pmatrix} \alpha & 0 & 0 \\ 0 & \beta & 0 \\ 0 & 0 & \gamma \end{pmatrix}.$$

(iv) The shear $\mathbf{x} \mapsto \mathbf{x} + \lambda \mathbf{a}(\mathbf{x} \cdot \mathbf{b})$ with $\mathbf{a} = \mathbf{e}_1$, $\mathbf{b} = \mathbf{e}_2$ has matrix

$$S_\lambda = \begin{pmatrix} 1 & \lambda & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

which displaces points in the $\mathbf{e}_1$ direction by an amount proportional to their $\mathbf{e}_2$ component. The picture to have in mind (in the plane, with $\lambda = 1/2$) is the following, with the unit square being tilted into a parallelogram.

It's also worth knowing what a rotation about a *general* axis looks like, and index notation makes the derivation quite pleasant.

Proposition 8.4.8 (Rotation About a General Axis)

Let R be the rotation through angle θ about an axis through the origin in the direction of the unit vector $\hat{\mathbf{n}}$ (in the positive sense given by the right-hand rule). Then

$$\mathbf{x}' = \mathbf{x} \cos \theta + (1 - \cos \theta)(\hat{\mathbf{n}} \cdot \mathbf{x})\hat{\mathbf{n}} + \sin \theta (\hat{\mathbf{n}} \times \mathbf{x}),$$

or in components, $x'_i = R_{ij}x_j$ where

$$R_{ij} = \cos \theta \delta_{ij} + (1 - \cos \theta)n_i n_j - \sin \theta \varepsilon_{ijk} n_k.$$

Proof. We resolve $\mathbf{x}$ into a part parallel to the axis, $(\hat{\mathbf{n}} \cdot \mathbf{x})\hat{\mathbf{n}}$, and a part perpendicular to it, $\mathbf{x}_\perp = \mathbf{x} - (\hat{\mathbf{n}} \cdot \mathbf{x})\hat{\mathbf{n}}$. The parallel part is unchanged by the rotation. The perpendicular part rotates by θ in the plane perpendicular to $\hat{\mathbf{n}}$, which is spanned by the orthogonal pair $\mathbf{x}_\perp$ and $\hat{\mathbf{n}} \times \mathbf{x}$ (which have the same length). So $\mathbf{x}_\perp \mapsto \cos \theta \mathbf{x}_\perp + \sin \theta (\hat{\mathbf{n}} \times \mathbf{x})$, and adding the parallel part back gives

$$\mathbf{x}' = (\hat{\mathbf{n}} \cdot \mathbf{x})\hat{\mathbf{n}} + \cos \theta (\mathbf{x} - (\hat{\mathbf{n}} \cdot \mathbf{x})\hat{\mathbf{n}}) + \sin \theta (\hat{\mathbf{n}} \times \mathbf{x}),$$

which rearranges to the stated result. The component form follows by writing

$$(\hat{\mathbf{n}} \times \mathbf{x})_i = \varepsilon_{ijk} n_j x_k = -\varepsilon_{ijk} x_j n_k.$$

□

§8.4.3 Matrix Algebra

Since matrices represent linear maps, the natural operations on linear maps (adding them, scaling them, and composing them) give us corresponding operations on matrices.

Definition 8.4.9 (Matrix Addition and Scalar Multiplication)

For $m \times n$ matrices A, B and a scalar λ , we define $A + B$ and λA to be the $m \times n$ matrices with entries

$$(A + B)_{ij} = A_{ij} + B_{ij}, \quad (\lambda A)_{ij} = \lambda A_{ij}.$$

These represent the maps $\mathbf{x} \mapsto A\mathbf{x} + B\mathbf{x}$ and $\mathbf{x} \mapsto \lambda(A\mathbf{x})$ respectively.

Composition is more interesting, and gives us *matrix multiplication*. Suppose A is an $n \times \ell$ matrix representing $S : \mathbb{R}^\ell \rightarrow \mathbb{R}^n$, and B is an $m \times n$ matrix representing $T : \mathbb{R}^n \rightarrow \mathbb{R}^m$. Then the composite $T \circ S : \mathbb{R}^\ell \rightarrow \mathbb{R}^m$ sends

$$x''_i = B_{ik} x'_k = B_{ik} (A_{kj} x_j) = (B_{ik} A_{kj}) x_j,$$

using the summation convention. So the composite is represented by the $m \times \ell$ matrix BA with entries as follows.

Definition 8.4.10 (Matrix Multiplication)

For an $m \times n$ matrix B and an $n \times \ell$ matrix A , the **product** BA is the $m \times \ell$ matrix with entries

$$(BA)_{ij} = \sum_{k=1}^n B_{ik} A_{kj},$$

that is, the (i, j) entry of BA is the i th row of B dotted with the j th column of A .

Note that the product is only defined when the number of columns of B matches the number of rows of A – exactly the condition needed for the maps to compose. Matrix multiplication inherits its properties from composition of functions: it is associative, $A(BC) = (AB)C$, and distributes over addition. What it is *not* is commutative.

Example 8.4.11 (Matrix Multiplication is Not Commutative)

Take

$$A = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}. \quad \text{Then} \quad AB = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix} \neq \begin{pmatrix} 1 & 1 \\ 1 & 2 \end{pmatrix} = BA.$$

Geometrically this should not be a surprise – performing two shears in different directions, the order genuinely matters.

We write I for the **identity matrix**, with entries $I_{ij} = \delta_{ij}$, which represents the identity map and satisfies $AI = IA = A$.

There are a few more operations on matrices which don't come from composing linear maps, but which we will use constantly.

Definition 8.4.12 (Transpose)

If A is an $m \times n$ matrix, its **transpose** A^T is the $n \times m$ matrix with entries

$$(A^T)_{ij} = A_{ji}.$$

Proposition 8.4.13 (Properties of the Transpose)

For matrices A and B of appropriate sizes,

- (i) $(A^T)^T = A$,
- (ii) $(AB)^T = B^T A^T$,
- (iii) if $\mathbf{x}$ is a column vector, then $\mathbf{x}^T$ is a row vector, and $\mathbf{x}^T \mathbf{y} = \mathbf{x} \cdot \mathbf{y}$ for $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$.

Proof. (i) and (iii) are immediate from the definitions. For (ii), we compute using the summation convention:

$$((AB)^T)_{ij} = (AB)_{ji} = A_{jk} B_{ki} = (B^T)_{ik} (A^T)_{kj} = (B^T A^T)_{ij},$$

where we are free to reorder the (scalar!) factors in the middle. $\square$

Over the complex numbers, the natural analogue of the transpose also conjugates the entries.

Definition 8.4.14 (Hermitian Conjugate)

For a complex matrix A , its **Hermitian conjugate** is

$$A^\dagger = \overline{(A^T)} = \overline{A}^T,$$

that is, $(A^\dagger)_{ij} = \overline{A_{ji}}$. As with the transpose, $(AB)^\dagger = B^\dagger A^\dagger$.

The Hermitian conjugate interacts with the complex inner product on $\mathbb{C}^n$ in the same way the transpose interacts with the dot product: $(\mathbf{z}, \mathbf{w}) = \mathbf{z}^\dagger \mathbf{w}$.

These operations pick out some particularly important classes of square matrices.

Definition 8.4.15 (Symmetric and Hermitian Matrices)

A square matrix A is **symmetric** if $A^T = A$, and **antisymmetric** if $A^T = -A$. A complex square matrix is **Hermitian** if $A^\dagger = A$, and **skew-Hermitian** if $A^\dagger = -A$.

Note the diagonal entries of an antisymmetric matrix are all zero, the diagonal entries of a Hermitian matrix are real, and those of a skew-Hermitian matrix are purely imaginary. Hermitian matrices will play a starring role when we study eigenvalues in Section 6.

Definition 8.4.16 (Trace)

The **trace** of an $n \times n$ matrix A is the sum of its diagonal entries,

$$\text{tr}(A) = A_{ii} = A_{11} + A_{22} + \cdots + A_{nn}.$$

Proposition 8.4.17 (Cyclic Property of Trace)

For $n \times n$ matrices A and B , $\text{tr}(AB) = \text{tr}(BA)$.

Proof. $\text{tr}(AB) = (AB)_{ii} = A_{ik}B_{ki} = B_{ki}A_{ik} = (BA)_{kk} = \text{tr}(BA)$. $\square$

Example 8.4.18 (Trace of a Reflection)

For the reflection matrix $H_{ij} = \delta_{ij} - 2n_i n_j$, we get

$$\text{tr}(H) = H_{ii} = \delta_{ii} - 2n_i n_i = 3 - 2|\hat{\mathbf{n}}|^2 = 1,$$

independent of the choice of plane – a first hint that the trace captures something basis-independent about the underlying map, a fact we will return to.

There is a useful way of decomposing an arbitrary square matrix using these notions. Any $n \times n$ matrix B can be split into symmetric and antisymmetric parts,

$$B_{ij} = \underbrace{\frac{1}{2}(B_{ij} + B_{ji})}_{S_{ij}} + \underbrace{\frac{1}{2}(B_{ij} - B_{ji})}_{A_{ij}},$$

and the symmetric part can be further split off from its trace, writing $S_{ij} = \frac{1}{n} \text{tr}(S) \delta_{ij} + T_{ij}$ where $\text{tr}(T) = 0$. Altogether,

$$B = \underbrace{\frac{1}{n} \text{tr}(B) I}_{\text{isotropic}} + \underbrace{\left(\frac{1}{2}(B + B^T) - \frac{1}{n} \text{tr}(B) I \right)}_{\text{symmetric, traceless}} + \underbrace{\frac{1}{2}(B - B^T)}_{\text{antisymmetric}}.$$

In three dimensions, the antisymmetric part has only three independent entries, and can be packaged as a vector: setting $A_{ij} = \varepsilon_{ijk} \omega_k$ gives

$$A = \begin{pmatrix} 0 & \omega_3 & -\omega_2 \\ -\omega_3 & 0 & \omega_1 \\ \omega_2 & -\omega_1 & 0 \end{pmatrix},$$

and then $A\mathbf{x} = -\boldsymbol{\omega} \times \mathbf{x}$ where $\boldsymbol{\omega} = (\omega_1, \omega_2, \omega_3)$. This decomposition appears throughout applied mathematics (for instance in describing the local behaviour of fluid flows, where the three parts correspond to expansion, strain, and rotation).

§8.4.4 Inverses, Orthogonal and Unitary Matrices

We now consider when the linear map represented by a matrix can be undone.

Definition 8.4.19 (Inverse)

Let A be an $m \times n$ matrix. An $n \times m$ matrix B is a **left inverse** of A if $BA = I$, and a **right inverse** if $AB = I$. If A is square and has both, then they coincide, since

$$B = B(AC) = (BA)C = C,$$

and we write A^{-1} for this **inverse** of A , satisfying $AA^{-1} = A^{-1}A = I$. A square

matrix with an inverse is called **invertible** or **non-singular**.

Not every square matrix is invertible – the zero matrix clearly isn't, and neither is the matrix of a projection (having squashed the component along $\hat{\mathbf{n}}$, there is no way to recover it). We will find a clean criterion for invertibility in the next section, using determinants. For now, we note the basic properties.

Proposition 8.4.20

If A and B are invertible $n \times n$ matrices, then

- (i) $(A^{-1})^{-1} = A$,
- (ii) $(AB)^{-1} = B^{-1}A^{-1}$,
- (iii) $(A^T)^{-1} = (A^{-1})^T$.

Proof. (i) is immediate. For (ii), $(B^{-1}A^{-1})(AB) = B^{-1}(A^{-1}A)B = B^{-1}B = I$. For (iii), transposing $AA^{-1} = I$ gives $(A^{-1})^T A^T = I$. $\square$

In two dimensions we can just write the inverse down: if $ad - bc \neq 0$ then

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix}^{-1} = \frac{1}{ad - bc} \begin{pmatrix} d & -b \\ -c & a \end{pmatrix},$$

as can be checked by multiplying out. The quantity $ad - bc$ appearing here is the *determinant*, which is the subject of the next section.

We finish with two classes of matrices whose inverses are essentially free.

Definition 8.4.21 (Orthogonal and Unitary Matrices)

A real $n \times n$ matrix R is **orthogonal** if

$$R^T R = R R^T = I, \quad \text{i.e.} \quad R^{-1} = R^T.$$

A complex $n \times n$ matrix U is **unitary** if

$$U^\dagger U = U U^\dagger = I, \quad \text{i.e.} \quad U^{-1} = U^\dagger.$$

The condition $R^T R = I$ says, in components, $R_{ki} R_{kj} = \delta_{ij}$ – that is, *the columns of R are orthonormal* (and by considering $R R^T = I$, so are the rows). Similarly the columns of a unitary matrix are orthonormal with respect to the complex inner product. This gives orthogonal matrices their geometric significance.

Proposition 8.4.22 (Orthogonal Matrices Preserve the Dot Product)

A real $n \times n$ matrix R is orthogonal if and only if

$$(R\mathbf{x}) \cdot (R\mathbf{y}) = \mathbf{x} \cdot \mathbf{y} \quad \text{for all } \mathbf{x}, \mathbf{y} \in \mathbb{R}^n.$$

In particular, orthogonal matrices preserve lengths and angles.

Proof. If R is orthogonal, then $(R\mathbf{x}) \cdot (R\mathbf{y}) = (R\mathbf{x})^T (R\mathbf{y}) = \mathbf{x}^T R^T R \mathbf{y} = \mathbf{x}^T \mathbf{y} = \mathbf{x} \cdot \mathbf{y}$. Conversely, if the dot product is preserved then taking $\mathbf{x} = \mathbf{e}_i$ and $\mathbf{y} = \mathbf{e}_j$ gives $(R^T R)_{ij} = (R\mathbf{e}_i) \cdot (R\mathbf{e}_j) = \delta_{ij}$, so $R^T R = I$. □

In fact, preserving lengths alone is enough: if $|R\mathbf{x}| = |\mathbf{x}|$ for all $\mathbf{x}$, then the identity $\mathbf{x} \cdot \mathbf{y} = \frac{1}{2}(|\mathbf{x} + \mathbf{y}|^2 - |\mathbf{x}|^2 - |\mathbf{y}|^2)$ shows the dot product is preserved as well, so the length-preserving matrices are precisely the orthogonal ones.

Example 8.4.23 (Rotations and Reflections are Orthogonal) (i) The reflection matrix $H_{ij} = \delta_{ij} - 2n_i n_j$ satisfies

$$\begin{aligned} (HH^T)_{ij} &= H_{ik} H_{jk} = (\delta_{ik} - 2n_i n_k)(\delta_{jk} - 2n_j n_k) \\ &= \delta_{ij} - 2n_i n_j - 2n_j n_i + 4n_i n_j (n_k n_k) = \delta_{ij}, \end{aligned}$$

using $n_k n_k = 1$. So H is orthogonal (as it must be – reflections certainly preserve lengths and angles). Note also $H^T = H$, so $H^{-1} = H$: reflecting twice does nothing.

(ii) For the rotation $R(\theta, \hat{\mathbf{n}})$ about a general axis, the component formula from before gives $R_{ji}(\theta, \hat{\mathbf{n}}) = R_{ij}(-\theta, \hat{\mathbf{n}})$, i.e. R^T is the rotation by $-\theta$. So $R^T R = I$, and rotations are orthogonal too.

We will return to orthogonal and unitary matrices repeatedly: in the next section we will see what determinants say about them, in Section 6 they will be the key to diagonalising symmetric and Hermitian matrices, and in Section 7 we will study them as groups of transformations in their own right.

§8.5 Determinants and Inverses

We saw at the end of the last section that a 2×2 matrix is invertible exactly when the quantity $ad - bc$ is non-zero. In this section we will develop the analogous quantity for $n \times n$ matrices – the *determinant*. As promised in the introduction, we will take two points of view: we need to be able to *compute* determinants, but we also want to understand what they *mean*. The meaning comes first: the determinant measures how the linear map scales volume.

§8.5.1 Motivation: Scaling Areas and Volumes

Consider a linear map $T : \mathbb{R}^2 \rightarrow \mathbb{R}^2$ with matrix M . The unit square spanned by $\mathbf{e}_1, \mathbf{e}_2$ is mapped to the parallelogram spanned by $M\mathbf{e}_1$ and $M\mathbf{e}_2$, which has signed area

$$[M\mathbf{e}_1, M\mathbf{e}_2] = \varepsilon_{ij} (M\mathbf{e}_1)_i (M\mathbf{e}_2)_j = \varepsilon_{ij} M_{i1} M_{j2} = M_{11} M_{22} - M_{21} M_{12},$$

recalling the two dimensional alternating symbol ε_{ij} from Section 3. By linearity, *every* region has its area scaled by this same factor.

Similarly, a linear map of $\mathbb{R}^3$ sends the unit cube to the parallelepiped spanned by the images of the basis vectors, which has signed volume given by the scalar triple product

$$[Me_1, Me_2, Me_3] = \varepsilon_{ijk} M_{i1} M_{j2} M_{k3}.$$

These are the determinants in two and three dimensions, and the general definition is the natural extension of this pattern to n indices. To write it down we need the Levi-Civita symbol with n indices, and for that we need a brief word about permutations.

§8.5.2 Permutations and the ε Symbol in n Dimensions

Recall (from Groups) that a **permutation** of $\{1, 2, \dots, n\}$ is a bijection from the set to itself, and that the permutations form a group S_n of order $n!$ under composition. A **transposition** is a permutation swapping two elements and fixing the rest. Every permutation σ can be written as a product of transpositions, and while such an expression is far from unique, the parity of the number of transpositions used is an invariant of σ . We define the **sign** $\varepsilon(\sigma) = (-1)^k$ where σ is a product of k transpositions, and call σ **even** or **odd** according to whether $\varepsilon(\sigma)$ is $+1$ or -1 . The sign is multiplicative: $\varepsilon(\sigma\tau) = \varepsilon(\sigma)\varepsilon(\tau)$, and $\varepsilon(\sigma^{-1}) = \varepsilon(\sigma)$.

Definition 8.5.1 (Levi-Civita Symbol in n Dimensions)

The **Levi-Civita** or **alternating symbol** with n indices is defined by

$$\varepsilon_{ij\dots l} = \begin{cases} +1 & \text{if } i, j, \dots, l \text{ is an even permutation of } 1, 2, \dots, n, \\ -1 & \text{if } i, j, \dots, l \text{ is an odd permutation of } 1, 2, \dots, n, \\ 0 & \text{otherwise (if any index repeats).} \end{cases}$$

In particular, $\varepsilon_{\sigma(1)\sigma(2)\dots\sigma(n)} = \varepsilon(\sigma)$ for any $\sigma \in S_n$, and exchanging any pair of indices changes the sign.

Just as in three dimensions, we can combine n vectors in $\mathbb{R}^n$ or $\mathbb{C}^n$ into a scalar.

Definition 8.5.2 (Alternating Form)

Given vectors $\mathbf{v}_1, \dots, \mathbf{v}_n \in \mathbb{R}^n$ or $\mathbb{C}^n$, their **alternating form** is

$$[\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n] = \varepsilon_{ij\dots l} (\mathbf{v}_1)_i (\mathbf{v}_2)_j \cdots (\mathbf{v}_n)_l = \sum_{\sigma \in S_n} \varepsilon(\sigma) (\mathbf{v}_1)_{\sigma(1)} (\mathbf{v}_2)_{\sigma(2)} \cdots (\mathbf{v}_n)_{\sigma(n)}.$$

For $n = 2$ this is the signed area $[\mathbf{a}, \mathbf{b}] = a_1 b_2 - a_2 b_1$, and for $n = 3$ it is the scalar triple product. The key properties, which follow directly from the corresponding properties of ε , are the following.

Proposition 8.5.3 (Properties of the Alternating Form) (i) *Multilinearity.* The form is linear in each argument separately, e.g.

$$[\alpha \mathbf{u} + \beta \mathbf{w}, \mathbf{v}_2, \dots, \mathbf{v}_n] = \alpha [\mathbf{u}, \mathbf{v}_2, \dots, \mathbf{v}_n] + \beta [\mathbf{w}, \mathbf{v}_2, \dots, \mathbf{v}_n].$$

(ii) *Total antisymmetry.* $[\mathbf{v}_{\sigma(1)}, \dots, \mathbf{v}_{\sigma(n)}] = \varepsilon(\sigma)[\mathbf{v}_1, \dots, \mathbf{v}_n]$; in particular exchanging two arguments changes the sign, and the form vanishes if two arguments are equal.

(iii) *Normalisation.* $[\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n] = 1$.

Proof Sketch. (i) and (iii) are immediate from the definition. For (ii), it suffices to check a single transposition (as these generate S_n and the sign is multiplicative), and exchanging two arguments amounts to relabelling the summation variable $\sigma \mapsto \sigma\tau$, which flips the sign of each term. $\square$

A consequence of multilinearity and antisymmetry which will do a lot of work for us: if one of the vectors is a linear combination of the others, the form vanishes. In fact, we can say more.

Proposition 8.5.4

$[\mathbf{v}_1, \dots, \mathbf{v}_n] \neq 0$ if and only if $\mathbf{v}_1, \dots, \mathbf{v}_n$ are linearly independent.

Proof. If the vectors are linearly dependent, then one of them, say $\mathbf{v}_p$, is a linear combination of the others. Substituting this combination in and expanding by multilinearity, each resulting term has a repeated argument, so vanishes by antisymmetry.

Conversely, if the vectors are linearly independent then they form a basis of $\mathbb{R}^n$ (being n of them), so each standard basis vector can be expanded as $\mathbf{e}_i = U_{ai}\mathbf{v}_a$ for some coefficients U_{ai} . Then by multilinearity and antisymmetry,

$$1 = [\mathbf{e}_1, \dots, \mathbf{e}_n] = U_{a1}U_{b2} \cdots U_{cn}[\mathbf{v}_a, \mathbf{v}_b, \dots, \mathbf{v}_c] = U_{a1}U_{b2} \cdots U_{cn} \varepsilon_{ab \cdots c} [\mathbf{v}_1, \dots, \mathbf{v}_n],$$

so $[\mathbf{v}_1, \dots, \mathbf{v}_n]$ cannot be zero. $\square$

§8.5.3 The Determinant

We can now make our main definition.

Definition 8.5.5 (Determinant)

The **determinant** of an $n \times n$ matrix M is the alternating form of its columns $\mathbf{C}_a = M\mathbf{e}_a$,

$$\begin{aligned} \det M &= [M\mathbf{e}_1, M\mathbf{e}_2, \dots, M\mathbf{e}_n] = \varepsilon_{ij \cdots l} M_{i1} M_{j2} \cdots M_{ln} \\ &= \sum_{\sigma \in S_n} \varepsilon(\sigma) M_{\sigma(1)1} M_{\sigma(2)2} \cdots M_{\sigma(n)n}. \end{aligned}$$

We also write $\det M = |M|$, displaying the array between vertical bars.

By our earlier discussion, $\det M$ is precisely the factor by which the map $\mathbf{x} \mapsto M\mathbf{x}$ scales signed volume. The proposition above then immediately gives us the link to invertibility that we were looking for:

$$\det M \neq 0 \iff \text{the columns of } M \text{ are linearly independent} \iff \text{img } M = \mathbb{R}^n,$$

and by rank-nullity this is also equivalent to $\ker M = \{\mathbf{0}\}$. (We will construct the inverse explicitly below.)

Example 8.5.6 (Small Determinants)

For $n = 2$ we recover

$$\begin{vmatrix} a & b \\ c & d \end{vmatrix} = ad - bc,$$

and for $n = 3$, expanding the sum over the six permutations of S_3 ,

$$\begin{vmatrix} M_{11} & M_{12} & M_{13} \\ M_{21} & M_{22} & M_{23} \\ M_{31} & M_{32} & M_{33} \end{vmatrix} = M_{11}M_{22}M_{33} + M_{12}M_{23}M_{31} + M_{13}M_{21}M_{32} \\ - M_{11}M_{23}M_{32} - M_{12}M_{21}M_{33} - M_{13}M_{22}M_{31}.$$

Also, if M is diagonal (or indeed upper or lower triangular), the only permutation contributing a non-zero term is the identity, so $\det M = M_{11}M_{22} \cdots M_{nn}$.

The determinant doesn't care whether we work with rows or columns.

Proposition 8.5.7 ($\det M^T = \det M$)

For any $n \times n$ matrix M , we have

$$\det M = \sum_{\sigma \in S_n} \varepsilon(\sigma) M_{1\sigma(1)} M_{2\sigma(2)} \cdots M_{n\sigma(n)} = \det(M^T).$$

Proof. Take a term $M_{\sigma(1)1} M_{\sigma(2)2} \cdots M_{\sigma(n)n}$ of the defining sum. Reordering the factors so that the *row* indices are in increasing order, it becomes $M_{1\rho(1)} M_{2\rho(2)} \cdots M_{n\rho(n)}$ where $\rho = \sigma^{-1}$. Since $\varepsilon(\sigma^{-1}) = \varepsilon(\sigma)$, and summing over σ is the same as summing over $\rho = \sigma^{-1}$, the two sums coincide. $\square$

Row and Column Operations

The properties of the alternating form translate directly into how the determinant behaves under *row and column operations*, and this gives an efficient way of computing determinants. Writing $\mathbf{C}_a$ for the columns (everything below applies equally to rows, using $\det M = \det M^T$):

- *Scaling*: if $\mathbf{C}_a \mapsto \lambda \mathbf{C}_a$ for a single fixed a , then $\det M \mapsto \lambda \det M$, by multilinearity. Note in particular that $\det(\lambda M) = \lambda^n \det M$ – the determinant is very much not linear in M .
- *Exchanges*: if two columns are exchanged, then $\det M \mapsto -\det M$, by antisymmetry.

- *Operations*: if $\mathbf{C}_a \mapsto \mathbf{C}_a + \lambda \mathbf{C}_b$ with $b \neq a$, then $\det M$ is *unchanged*, since the extra term is a determinant with a repeated column.

Example 8.5.8 (Computing a Determinant with Row and Column Operations)

Let's compute, for $a \in \mathbb{C}$,

$$\det A = \begin{vmatrix} 1 & 1 & a \\ a & 1 & 1 \\ 1 & a & 1 \end{vmatrix}.$$

Subtracting the third column from the first ($\mathbf{C}_1 \mapsto \mathbf{C}_1 - \mathbf{C}_3$), and then taking out the common factor,

$$\det A = \begin{vmatrix} 1-a & 1 & a \\ a-1 & 1 & 1 \\ 0 & a & 1 \end{vmatrix} = (1-a) \begin{vmatrix} 1 & 1 & a \\ -1 & 1 & 1 \\ 0 & a & 1 \end{vmatrix}.$$

Now $\mathbf{C}_2 \mapsto \mathbf{C}_2 - \mathbf{C}_3$ followed by taking out $(1-a)$ again gives

$$\det A = (1-a)^2 \begin{vmatrix} 1 & 1 & a \\ -1 & 0 & 1 \\ 0 & -1 & 1 \end{vmatrix},$$

and finally adding the second and third rows to the first ($\mathbf{R}_1 \mapsto \mathbf{R}_1 + \mathbf{R}_2 + \mathbf{R}_3$),

$$\det A = (1-a)^2 \begin{vmatrix} 0 & 0 & a+2 \\ -1 & 0 & 1 \\ 0 & -1 & 1 \end{vmatrix} = (1-a)^2(a+2),$$

where the last determinant is found by expanding the sum directly (only one permutation contributes). We will use this particular matrix again shortly when solving linear systems.

The Determinant of a Product

The single most important algebraic property of the determinant is that it is *multiplicative*. This is geometrically obvious – composing two maps composes their volume-scaling factors – but it deserves an honest proof. We first record a small generalisation of the definition.

Lemma 8.5.9

For an $n \times n$ matrix M ,

$$\varepsilon_{i_1 i_2 \dots i_n} M_{i_1 a_1} M_{i_2 a_2} \dots M_{i_n a_n} = (\det M) \varepsilon_{a_1 a_2 \dots a_n}.$$

Proof. The left hand side is totally antisymmetric under exchanging any pair of the free indices $a_1, \dots, a_n$ (exchanging a_p and a_q can be undone by relabelling the summed indices $i_p \leftrightarrow i_q$, at the cost of a sign from ε). Any totally antisymmetric n -index object is a multiple of $\varepsilon_{a_1 \dots a_n}$, and setting $a_j = j$ shows that the constant of proportionality is $\det M$. $\square$

Theorem 8.5.10 (Determinants are Multiplicative)

For $n \times n$ matrices M and N ,

$$\det(MN) = \det M \det N.$$

Proof. Directly from the definition and the lemma,

$$\begin{aligned} \det(MN) &= \varepsilon_{i_1 \dots i_n} (MN)_{i_1 1} \cdots (MN)_{i_n n} \\ &= \varepsilon_{i_1 \dots i_n} M_{i_1 k_1} N_{k_1 1} \cdots M_{i_n k_n} N_{k_n n} \\ &= (\varepsilon_{i_1 \dots i_n} M_{i_1 k_1} \cdots M_{i_n k_n}) N_{k_1 1} \cdots N_{k_n n} \\ &= (\det M) \varepsilon_{k_1 \dots k_n} N_{k_1 1} \cdots N_{k_n n} = \det M \det N. \square \end{aligned}$$

Corollary 8.5.11 (i) If M is invertible, then $\det(M^{-1}) = (\det M)^{-1}$.

(ii) If R is orthogonal, then $\det R = \pm 1$.

(iii) If U is unitary, then $|\det U| = 1$.

Proof. (i) $\det(M^{-1}) \det(M) = \det(M^{-1}M) = \det I = 1$.

(ii) $R^T R = I$ gives $(\det R)^2 = \det(R^T) \det(R) = 1$.

(iii) $U^\dagger U = I$ gives $\overline{\det U} \det U = 1$, since $\det(U^\dagger) = \det(\overline{U}^T) = \overline{\det U}$. $\square$

In $\mathbb{R}^3$ this splits the orthogonal matrices into two families: the rotations, with $\det R = 1$ (preserving orientation), and the reflections, with $\det R = -1$ (reversing it). We will pick this thread up again in Section 7.

§8.5.4 Minors, Cofactors and the Laplace Expansion

The next tool both organises hand computation of determinants and leads directly to the formula for the inverse.

Definition 8.5.12 (Minors and Cofactors)

Let M be an $n \times n$ matrix. The **minor** M^{ia} is the determinant of the $(n-1) \times (n-1)$ matrix obtained from M by deleting row i and column a . The **cofactor** of the entry M_{ia} is

$$\Delta_{ia} = (-1)^{i+a} M^{ia}.$$

Theorem 8.5.13 (Laplace Expansion)

For an $n \times n$ matrix M and any fixed column a (or fixed row i),

$$\det M = \sum_{i=1}^n M_{ia} \Delta_{ia} = \sum_{a=1}^n M_{ia} \Delta_{ia}.$$

Proof. Expanding column a as $\mathbf{C}_a = \sum_i M_{ia} \mathbf{e}_i$ and using multilinearity,

$$\det M = [\mathbf{C}_1, \dots, \mathbf{C}_a, \dots, \mathbf{C}_n] = \sum_i M_{ia} [\mathbf{C}_1, \dots, \mathbf{e}_i, \dots, \mathbf{C}_n],$$

so it remains to identify $[\mathbf{C}_1, \dots, \mathbf{e}_i, \dots, \mathbf{C}_n]$ with the cofactor Δ_{ia} . In this determinant, column a is $\mathbf{e}_i$; adding suitable multiples of column a to the others, we may assume every other entry of row i is zero without changing the value. Now move column a to the last position ($n - a$ adjacent exchanges) and row i to the last position ($n - i$ adjacent exchanges), picking up a sign $(-1)^{(n-a)+(n-i)} = (-1)^{i+a}$. The result is a block matrix

$$(-1)^{i+a} \begin{vmatrix} \tilde{M} & \mathbf{0} \\ * & 1 \end{vmatrix} = (-1)^{i+a} \det \tilde{M},$$

where $\tilde{M}$ is M with row i and column a deleted – here the block determinant reduces to $\det \tilde{M}$ since any permutation not fixing the last index contributes zero. This is exactly $(-1)^{i+a} M^{ia} = \Delta_{ia}$. The row version follows from $\det M = \det M^T$. $\square$

Example 8.5.14 (Laplace Expansion in Practice)

Expanding along columns or rows with many zeros keeps the computation short. For instance, expanding along the second column,

$$\begin{vmatrix} 2 & 0 & 2 \\ 3 & 2 & 1 \\ 2 & 0 & 1 \end{vmatrix} = -0 + 2 \begin{vmatrix} 2 & 2 \\ 2 & 1 \end{vmatrix} - 0 = 2(2 - 4) = -4.$$

In practice one uses row and column operations to create zeros, and then expands.

Example 8.5.15 (A Vandermonde-type Determinant)

As a slightly more substantial example, let us show

$$\begin{vmatrix} 1 & a & a^2 \\ 1 & b & b^2 \\ 1 & c & c^2 \end{vmatrix} = (a - b)(b - c)(c - a).$$

Subtracting row 2 from row 1, and row 3 from row 2,

$$\begin{vmatrix} 0 & a - b & a^2 - b^2 \\ 0 & b - c & b^2 - c^2 \\ 1 & c & c^2 \end{vmatrix} = (a - b)(b - c) \begin{vmatrix} 0 & 1 & a + b \\ 0 & 1 & b + c \\ 1 & c & c^2 \end{vmatrix},$$

and expanding along the first column gives

$$(a - b)(b - c) \cdot 1 \cdot \begin{vmatrix} 1 & a + b \\ 1 & b + c \end{vmatrix} = (a - b)(b - c)(c - a).$$

§8.5.5 The Adjugate and the Inverse

Here is the key observation: in the Laplace expansion $\det M = \sum_i M_{ia}\Delta_{ia}$, what happens if we expand the entries of one column against the cofactors of a *different* column?

Lemma 8.5.16

For an $n \times n$ matrix M ,

$$\sum_i M_{ib}\Delta_{ia} = (\det M) \delta_{ab}.$$

Proof. If $a = b$ this is the Laplace expansion. If $a \neq b$, then $\sum_i M_{ib}\Delta_{ia} = [\mathbf{C}_1, \dots, \mathbf{C}_b, \dots, \mathbf{C}_n]$ with $\mathbf{C}_b$ appearing in position a – but $\mathbf{C}_b$ also appears in its own position b , so this is a determinant with a repeated column, which vanishes. $\square$

Definition 8.5.17 (Adjugate)

The **adjugate** of M is the transpose of the matrix of cofactors,

$$(\operatorname{adj} M)_{ai} = \Delta_{ia}.$$

With this notation, the lemma says precisely that $(\operatorname{adj} M)M = (\det M)I$, giving us the general formula for the inverse.

Theorem 8.5.18 (Inverse via the Adjugate)

If $\det M \neq 0$, then M is invertible with

$$M^{-1} = \frac{1}{\det M} \operatorname{adj} M, \quad \text{that is,} \quad (M^{-1})_{ai} = \frac{\Delta_{ia}}{\det M}.$$

Conversely, if $\det M = 0$ then M has no inverse.

Proof. The formula follows from Lemma 8.5.16 (and the analogous row version gives $M \operatorname{adj} M = (\det M)I$ as well). If $\det M = 0$, then for any B we have $\det(BM) = \det B \det M = 0 \neq \det I$, so no inverse can exist. $\square$

Example 8.5.19 (Inverting a 3×3 Matrix)

Consider the shear matrix from the previous section,

$$S_\lambda = \begin{pmatrix} 1 & \lambda & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

This is triangular, so $\det S_\lambda = 1$. Computing the cofactors, the only non-trivial one is $\Delta_{21} = -\lambda$, and we find

$$S_\lambda^{-1} = \begin{pmatrix} 1 & -\lambda & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} = S_{-\lambda},$$

which is geometrically obvious: to undo a shear, shear back the other way.

While the adjugate formula is theoretically clean, as a computational method it is dreadful: computing an $n \times n$ determinant from cofactors takes on the order of $n!$ operations. For actually solving equations, the method of choice is *Gaussian elimination*, discussed below, which takes on the order of n^3 operations.

§8.5.6 Systems of Linear Equations

Much of the theory we have built up comes together in the problem of solving simultaneous linear equations. A system of n equations in n unknowns $x_1, \dots, x_n$ can be packaged as

$$A\mathbf{x} = \mathbf{b},$$

where A is an $n \times n$ matrix of coefficients and $\mathbf{b} \in \mathbb{R}^n$ is given. We say the system is **homogeneous** if $\mathbf{b} = \mathbf{0}$, and **inhomogeneous** otherwise.

Thinking of A as a linear map makes the structure of the solutions transparent. There are three possibilities.

- (i) If $\det A \neq 0$, then A^{-1} exists and there is a *unique* solution

$$\mathbf{x} = A^{-1}\mathbf{b}$$

for any $\mathbf{b}$ (which is $\mathbf{x} = \mathbf{0}$ in the homogeneous case).

- (ii) If $\det A = 0$ and $\mathbf{b} \notin \text{img } A$, then there are *no* solutions – the system is inconsistent.
 (iii) If $\det A = 0$ and $\mathbf{b} \in \text{img } A$, then there are *infinitely many* solutions, of the form

$$\mathbf{x} = \mathbf{x}_0 + \mathbf{u},$$

where $\mathbf{x}_0$ is any *particular solution* (so $A\mathbf{x}_0 = \mathbf{b}$) and $\mathbf{u}$ ranges over $\ker A$. Writing $\mathbf{u}_1, \dots, \mathbf{u}_k$ for a basis of the kernel (where $k = \text{null } A > 0$), the general solution is $\mathbf{x} = \mathbf{x}_0 + \sum_j \mu_j \mathbf{u}_j$ for scalars μ_j .

To see that these are the only possibilities: if $\mathbf{x}$ and $\mathbf{x}_0$ are both solutions, then $A(\mathbf{x} - \mathbf{x}_0) = \mathbf{0}$, so any two solutions differ by an element of the kernel. And $\det A \neq 0$ if and only if $\text{rank } A = n$, if and only if (by rank-nullity) $\ker A = \{\mathbf{0}\}$.

You may notice the structure of case (iii) – particular solution plus general solution of the homogeneous problem – is precisely the ‘particular integral plus complementary function’ pattern familiar from linear differential equations. This is no coincidence: both are instances of solving a linear equation.

Example 8.5.20 (A Family of Linear Systems)

Let us solve $A\mathbf{x} = \mathbf{b}$ where

$$A = \begin{pmatrix} 1 & 1 & a \\ a & 1 & 1 \\ 1 & a & 1 \end{pmatrix}, \quad \mathbf{b} = \begin{pmatrix} 1 \\ c \\ 1 \end{pmatrix}, \quad a, c \in \mathbb{R}.$$

We computed earlier that $\det A = (1 - a)^2(a + 2)$.

Case $a \neq 1, -2$. Here $\det A \neq 0$, so for every c there is the unique solution $\mathbf{x} = A^{-1}\mathbf{b}$. Geometrically, the three planes described by the rows meet in a single point.

Case $a = 1$. All three rows become $(1, 1, 1)$, so

$$\text{img } A = \text{span} \left\{ \begin{pmatrix} 1 \\ 1 \\ 1 \end{pmatrix} \right\}, \quad \ker A = \text{span} \left\{ \begin{pmatrix} -1 \\ 1 \\ 0 \end{pmatrix}, \begin{pmatrix} -1 \\ 0 \\ 1 \end{pmatrix} \right\}.$$

If $c \neq 1$ then $\mathbf{b} \notin \text{img } A$ and there are no solutions. If $c = 1$, then $\mathbf{x}_0 = (1, 0, 0)$ is a particular solution, and the general solution is

$$\mathbf{x} = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} + \lambda \begin{pmatrix} -1 \\ 1 \\ 0 \end{pmatrix} + \mu \begin{pmatrix} -1 \\ 0 \\ 1 \end{pmatrix},$$

which is a plane (all three planes coincide).

Case $a = -2$. Solving $A\mathbf{u} = \mathbf{0}$ directly gives $\ker A = \text{span}\{(1, 1, 1)\}$, and $\text{img } A$ is spanned by $(1, -2, 1)$ and $(1, 1, -2)$. One can check $\mathbf{b} \in \text{img } A$ if and only if $c = -2$, in which case $\mathbf{x}_0 = (1, 0, 0)$ is a particular solution^a and the general solution is the line $\mathbf{x} = \mathbf{x}_0 + \lambda(1, 1, 1)$. For $c \neq -2$ there are no solutions.

^aFound by inspection: any single solution will do.

Geometric Interpretation

In $\mathbb{R}^3$, each row of the system $A\mathbf{x} = \mathbf{b}$ is the equation of a plane, $\mathbf{R}_i \cdot \mathbf{x} = b_i$, with normal $\mathbf{R}_i$ (assuming $\mathbf{R}_i \neq \mathbf{0}$). Solving the system means intersecting the three planes, and the possibilities line up with the rank of A :

- If $\text{rank } A = 3$, the three normals are linearly independent and the planes meet in exactly one point.
- If $\text{rank } A = 2$, the normals span a plane. For the homogeneous problem the solution set is a line. In the inhomogeneous case, the planes may intersect in a common line, or may form a ‘sheaf’ – intersecting pairwise in three parallel lines, like a triangular prism – with no common point (no solutions).
- If $\text{rank } A = 1$, the normals are all parallel. The planes are parallel, and there are solutions only if they all coincide, in which case the solution set is that plane.

The two rank 2 configurations are worth visualising. Viewing the planes edge-on (looking along the direction of the would-be common line), they appear as three lines: either all passing through one point, or forming a triangle.

a common line (end-on)

a sheaf (end-on)

§8.5.7 Gaussian Elimination

Finally, let’s discuss how solving linear systems actually gets done. The method is **Gaussian elimination**: use one equation to eliminate a variable from the others, and

repeat. It applies to any system of m equations in n unknowns,

$$A_{11}x_1 + A_{12}x_2 + \cdots + A_{1n}x_n = d_1, \quad \dots, \quad A_{m1}x_1 + \cdots + A_{mn}x_n = d_m.$$

Assuming $A_{11} \neq 0$ (reordering the equations if necessary), we can subtract multiples of the first equation from the others to eliminate x_1 from all of them. Then we use the (new) second equation to eliminate x_2 from those below it, and so on. Whenever a leading coefficient vanishes we reorder to fix it, and the process halts when no equations with non-zero coefficients remain. We are left with a system in *echelon form*:

$$\begin{aligned} A_{11}x_1 + A_{12}x_2 + \cdots + \cdots + A_{1n}x_n &= d_1 \\ A_{22}^{(2)}x_2 + \cdots + \cdots + A_{2n}^{(2)}x_n &= d_2^{(2)} \\ &\vdots \\ A_{rr}^{(r)}x_r + \cdots + A_{rn}^{(r)}x_n &= d_r^{(r)} \\ 0 &= d_{r+1}^{(r)} \\ &\vdots \\ 0 &= d_m^{(r)}, \end{aligned}$$

where the superscripts track how many times a coefficient has been updated, and the leading coefficients $A_{ii}^{(i)}$ are non-zero. The number r of non-trivial equations remaining is exactly $\text{rank } A$, and reading off the possibilities:

- (i) If some $d_j^{(r)} \neq 0$ for $j > r$, the system is inconsistent – *no solutions* (it is *overdetermined*).
- (ii) If $r = n$ and the leftover equations all read $0 = 0$, we can solve the n th equation for x_n , substitute back into the $(n-1)$ th to find x_{n-1} , and so on – a *unique solution*, found by *back substitution*.
- (iii) If $r < n$ and the leftover equations read $0 = 0$, then $x_{r+1}, \dots, x_n$ can be chosen freely and the remaining variables are determined – *infinitely many solutions* (the system is *underdetermined*).

Example 8.5.21 (Gaussian Elimination in Action)

Consider the system

$$\begin{aligned} 3x_1 + 2x_2 + x_3 &= 3 \\ 6x_1 + 3x_2 + 3x_3 &= 0 \\ 6x_1 + 2x_2 + 4x_3 &= 6. \end{aligned}$$

Subtracting twice the first equation from the second and third,

$$\begin{aligned} 3x_1 + 2x_2 + x_3 &= 3 \\ -x_2 + x_3 &= -6 \\ -2x_2 + 2x_3 &= 0, \end{aligned}$$

and then subtracting twice the second from the third leaves $0 = 12$. The system is inconsistent, and there are no solutions.

Gaussian elimination also gives an efficient way to compute determinants: for a square matrix, the elimination steps are row operations which leave the determinant unchanged, apart from row exchanges which flip its sign. The end result is upper triangular, so

$$\det A = (-1)^k A_{11} A_{22}^{(2)} \cdots A_{nn}^{(n)},$$

where k is the number of row exchanges used. In particular $\det A \neq 0$ if and only if the elimination reaches $r = n$, tying together our earlier characterisations.

§8.5.8 Matrix Rank

We defined the rank of a linear map as the dimension of its image. For a matrix, there are two natural candidate notions, and it is a small theorem that they agree.

Definition 8.5.22 (Column and Row Rank)

The **column rank** of a matrix A is the maximum number of linearly independent columns of A , i.e. the dimension of the span of the columns. The **row rank** is defined analogously using rows.

Since the columns of A are the images $A\mathbf{e}_j$ of the basis vectors, the column rank is precisely $\text{rank } A = \dim \text{img } A$.

Theorem 8.5.23 (Row Rank Equals Column Rank)

For any $m \times n$ matrix A , the row rank and column rank are equal.

Proof. Let r be the row rank of A , and let $\mathbf{v}_1^T, \dots, \mathbf{v}_r^T$ be a maximal linearly independent set of rows. Then every row of A is a linear combination of these, say

$$\mathbf{r}_i^T = \sum_{k=1}^r C_{ik} \mathbf{v}_k^T$$

for some coefficients C_{ik} . Looking at the j th component of this equation,

$$A_{ij} = \sum_{k=1}^r C_{ik} (\mathbf{v}_k)_j,$$

which says that the j th column of A is the linear combination $\sum_k (\mathbf{v}_k)_j \mathbf{c}_k$ of the r fixed vectors $\mathbf{c}_k = (C_{1k}, \dots, C_{mk})^T$. Hence the column span has dimension at most r , i.e. column rank $\leq$ row rank. Applying the same argument to A^T gives the reverse inequality. $\square$

§8.6 Eigenvalues and Eigenvectors

This section is about the core question raised in the introduction: given a linear map, what does it act on in a really simple way? For most vectors $\mathbf{x}$, applying a matrix

A moves them somewhere with no obvious relation to where they started. But some special vectors are simply *scaled* – the map doesn't turn them at all. Understanding these special directions turns out to essentially unlock the structure of the whole map.

§8.6.1 Definitions and the Characteristic Polynomial

Let's make precise the notion of a direction which a linear map simply scales.

Definition 8.6.1 (Eigenvectors and Eigenvalues)

Let A be an $n \times n$ matrix acting on $V = \mathbb{R}^n$ or $\mathbb{C}^n$. A vector $\mathbf{v} \in V$ with $\mathbf{v} \neq \mathbf{0}$ is an **eigenvector** of A with **eigenvalue** λ if

$$A\mathbf{v} = \lambda\mathbf{v}.$$

Note that we insist $\mathbf{v} \neq \mathbf{0}$ (every scalar would be an eigenvalue for $\mathbf{0}$, which would tell us nothing), but $\lambda = 0$ is allowed – an eigenvector with eigenvalue 0 is just a non-zero vector of the kernel.

Geometrically, an eigenvector picks out an *invariant line* through the origin: a typical vector $\mathbf{x}$ gets moved off its own direction by A , but an eigenvector $\mathbf{v}$ stays on the dashed line below, merely stretched by a factor of λ .

How do we find eigenvalues? The equation $A\mathbf{v} = \lambda\mathbf{v}$ rearranges to $(A - \lambda I)\mathbf{v} = \mathbf{0}$, which asks for a non-zero vector in the kernel of $A - \lambda I$. By the theory of the last section, such a vector exists precisely when $\det(A - \lambda I) = 0$. We have proven:

Proposition 8.6.2

λ is an eigenvalue of A if and only if

$$\det(A - \lambda I) = 0.$$

This is called the **characteristic equation** of A .

Definition 8.6.3 (Characteristic Polynomial)

The **characteristic polynomial** of an $n \times n$ matrix A is

$$\chi_A(t) = \det(A - tI).$$

The eigenvalues of A are exactly the roots of χ_A .

Expanding the determinant, $\chi_A(t) = c_0 + c_1t + \cdots + c_nt^n$ is a polynomial of degree n in t . This simple observation, combined with the fundamental theorem of algebra from Section 1, already tells us a surprising amount.

Proposition 8.6.4 (Properties of the Characteristic Polynomial)

Let A be an $n \times n$ matrix with characteristic polynomial $\chi_A(t) = c_0 + c_1t + \cdots + c_nt^n$, and let $\lambda_1, \dots, \lambda_n$ be the roots of χ_A counted with multiplicity. Then

- (i) A has n eigenvalues counted with multiplicity (and in particular, working over $\mathbb{C}$, at least one);
- (ii) $\text{tr}(A) = \lambda_1 + \lambda_2 + \cdots + \lambda_n$;
- (iii) $\det(A) = \lambda_1\lambda_2 \cdots \lambda_n$;
- (iv) if A is real, the non-real eigenvalues come in complex conjugate pairs.

Proof. Since $c_n = (-1)^n \neq 0$, χ_A has degree exactly n , and (i) follows from the fundamental theorem of algebra. Writing

$$\chi_A(t) = (-1)^n(t - \lambda_1)(t - \lambda_2) \cdots (t - \lambda_n),$$

we can compare coefficients with the determinant expansion. The terms of degree n and $n - 1$ in $\det(A - tI)$ can only arise from the product of diagonal entries $(A_{11} - t) \cdots (A_{nn} - t)$ (any other permutation omits at least two diagonal entries), so

$$c_{n-1} = (-1)^{n-1}(A_{11} + \cdots + A_{nn}) = (-1)^{n-1} \text{tr}(A),$$

while expanding the factorised form gives $c_{n-1} = (-1)^{n-1}(\lambda_1 + \cdots + \lambda_n)$. This proves (ii). For (iii), set $t = 0$: $\chi_A(0) = \det A$, and the factorised form gives $\chi_A(0) = \lambda_1 \cdots \lambda_n$. Finally, if A is real then the c_i are real, so $\chi_A(\lambda) = 0$ implies $\chi_A(\bar{\lambda}) = \overline{\chi_A(\lambda)} = 0$, giving (iv). $\square$

Let's compute some examples, which will also serve to illustrate the various things that can happen.

Example 8.6.5 (Finding Eigenvalues and Eigenvectors) (i) Take $A = \begin{pmatrix} 2 & i \\ -i & 2 \end{pmatrix}$ acting on $\mathbb{C}^2$. The characteristic equation is

$$\det \begin{pmatrix} 2 - \lambda & i \\ -i & 2 - \lambda \end{pmatrix} = (2 - \lambda)^2 - 1 = 0,$$

so $\lambda = 1$ or 3 . For $\lambda = 1$, solving $(A - I)\mathbf{v} = \mathbf{0}$ gives $\mathbf{v} = \alpha \begin{pmatrix} 1 \\ i \end{pmatrix}$, and for $\lambda = 3$

we get $\mathbf{v} = \beta \begin{pmatrix} 1 \\ -i \end{pmatrix}$, for any non-zero α, β .

(ii) Take the shear $A = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$. Then $\chi_A(t) = (1 - t)^2$, so $\lambda = 1$ is the only eigenvalue, with multiplicity two. But solving $(A - I)\mathbf{v} = \mathbf{0}$ forces $v_2 = 0$, so the only eigenvectors are $\mathbf{v} = \alpha \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ – there is only *one* linearly independent eigenvector. (Geometrically: a shear fixes its horizontal axis and genuinely tilts every other direction.)

(iii) Take the rotation $U = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}$. Then

$$\chi_U(t) = t^2 - 2t \cos \theta + 1,$$

which has roots $\lambda = e^{\pm i\theta}$ – for θ not a multiple of π there are *no real* eigenvalues (as expected: a genuine rotation of the plane preserves no direction), but over $\mathbb{C}$ there are two, with eigenvectors $\begin{pmatrix} 1 \\ \mp i \end{pmatrix}$.

§8.6.2 Eigenspaces and Multiplicities

For a given eigenvalue, the set of all associated eigenvectors (together with $\mathbf{0}$) forms a subspace, since it is a kernel.

Definition 8.6.6 (Eigenspace)

For an eigenvalue λ of A , the **eigenspace** is

$$E_\lambda = \{\mathbf{v} : A\mathbf{v} = \lambda\mathbf{v}\} = \ker(A - \lambda I).$$

There are now two different ways to count ‘how many times’ λ occurs as an eigenvalue, and their interplay is the crux of this section.

Definition 8.6.7 (Algebraic and Geometric Multiplicity)

Let λ be an eigenvalue of A .

- The **algebraic multiplicity** M_λ is the multiplicity of λ as a root of $\chi_A(t)$, i.e. the largest k such that $(t - \lambda)^k$ divides $\chi_A(t)$.
- The **geometric multiplicity** m_λ is $\dim E_\lambda = \text{null}(A - \lambda I)$, the maximum number of linearly independent eigenvectors with eigenvalue λ .

If $M_\lambda > 1$ we say the eigenvalue is **degenerate** or **repeated**.

It is a fact (which we will be able to prove once we can change bases, in Section 7) that

$$1 \leq m_\lambda \leq M_\lambda,$$

that is, the geometric multiplicity never exceeds the algebraic one. The shear above shows the inequality can be strict: there $M_1 = 2$ but $m_1 = 1$.

Example 8.6.8 (Multiplicities) (i) Let

$$A = \begin{pmatrix} -2 & 2 & -3 \\ 2 & 1 & -6 \\ -1 & -2 & 0 \end{pmatrix}.$$

Computing, $\chi_A(t) = -(t - 5)(t + 3)^2$, so the eigenvalues are 5 and -3 with

$M_5 = 1$, $M_{-3} = 2$. Solving $(A - 5I)\mathbf{v} = \mathbf{0}$ gives

$$E_5 = \text{span} \left\{ \begin{pmatrix} 1 \\ 2 \\ -1 \end{pmatrix} \right\},$$

while for $\lambda = -3$ the system $(A + 3I)\mathbf{v} = \mathbf{0}$ reduces to the single equation $v_1 + 2v_2 - 3v_3 = 0$, so

$$E_{-3} = \text{span} \left\{ \begin{pmatrix} -2 \\ 1 \\ 0 \end{pmatrix}, \begin{pmatrix} 3 \\ 0 \\ 1 \end{pmatrix} \right\}.$$

Hence $m_5 = M_5 = 1$ and $m_{-3} = M_{-3} = 2$: three linearly independent eigenvectors in total.

(ii) Let

$$B = \begin{pmatrix} -3 & -1 & 1 \\ -1 & -3 & 1 \\ -2 & -2 & 0 \end{pmatrix}.$$

Here $\chi_B(t) = -(t+2)^3$, so $\lambda = -2$ with $M_{-2} = 3$. But $(B + 2I)\mathbf{v} = \mathbf{0}$ reduces to the single equation $v_1 + v_2 - v_3 = 0$, giving

$$E_{-2} = \text{span} \left\{ \begin{pmatrix} -1 \\ 1 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} \right\},$$

so $m_{-2} = 2 < 3 = M_{-2}$. There are only two independent eigenvectors to be found.

- (iii) For a reflection H in a plane through the origin with unit normal $\hat{\mathbf{n}}$: clearly $H\hat{\mathbf{n}} = -\hat{\mathbf{n}}$, and $H\mathbf{u} = \mathbf{u}$ for any $\mathbf{u}$ in the plane. So the eigenvalues are -1 , with $E_{-1} = \text{span}\{\hat{\mathbf{n}}\}$, and 1 , with E_1 the plane itself: $M_{-1} = m_{-1} = 1$ and $M_1 = m_1 = 2$.
- (iv) For a rotation R through θ about the axis $\hat{\mathbf{n}}$ in $\mathbb{R}^3$: the axis satisfies $R\hat{\mathbf{n}} = \hat{\mathbf{n}}$, giving eigenvalue 1 , and restricting to the plane perpendicular to the axis we get a two dimensional rotation, contributing complex eigenvalues $e^{\pm i\theta}$ as computed above.

§8.6.3 Linear Independence and Diagonalisation

The importance of having ‘enough’ eigenvectors is the following: if the eigenvectors of A form a *basis*, then in that basis the map just scales each basis direction, and its matrix is diagonal. Working with diagonal matrices is a delight – powers, inverses and polynomials of them can be simply read off – so we would very much like to know when this happens.

The first main result is that eigenvectors for different eigenvalues never interfere with one another.

Proposition 8.6.9 (Independence of Eigenvectors)

Let $\mathbf{v}_1, \dots, \mathbf{v}_r$ be eigenvectors of A with eigenvalues $\lambda_1, \dots, \lambda_r$. If the eigenvalues are distinct, then the eigenvectors are linearly independent.

Proof. Suppose we have a linear relation $\sum_{j=1}^r \alpha_j \mathbf{v}_j = \mathbf{0}$. Fix any k , and apply the matrix

$$\prod_{j \neq k} (A - \lambda_j I)$$

to both sides. Each eigenvector $\mathbf{v}_i$ with $i \neq k$ is annihilated by its own factor $(A - \lambda_i I)$, while $\mathbf{v}_k$ just picks up scalars, leaving

$$\alpha_k \prod_{j \neq k} (\lambda_k - \lambda_j) \mathbf{v}_k = \mathbf{0}.$$

The product of the (non-zero!) factors $\lambda_k - \lambda_j$ is non-zero, and $\mathbf{v}_k \neq \mathbf{0}$, so $\alpha_k = 0$. As k was arbitrary, the relation was trivial. $\square$

Corollary 8.6.10

Let $\lambda_1, \dots, \lambda_r$ be the distinct eigenvalues of A , and let B_i be a basis of the eigenspace E_{λ_i} . Then the union $B = B_1 \cup B_2 \cup \dots \cup B_r$ is linearly independent.

Proof. A general linear combination of the elements of B can be grouped as $\mathbf{w}_1 + \dots + \mathbf{w}_r$ with $\mathbf{w}_i \in E_{\lambda_i}$. If this sum is $\mathbf{0}$, then applying $\prod_{j \neq k} (A - \lambda_j I)$ exactly as in the proposition^a shows each $\mathbf{w}_k = \mathbf{0}$. But $\mathbf{w}_k$ is a linear combination of the basis B_k , so all its coefficients vanish. $\square$

^aThe argument only used that $\mathbf{w}_i$ is an eigenvector or zero.

Definition 8.6.11 (Diagonalisable)

An $n \times n$ matrix A is **diagonalisable** if there is an invertible matrix P with

$$P^{-1}AP = D = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_n),$$

a diagonal matrix. (We will see in Section 7 that this says exactly that A represents the same map as D , but with respect to a different basis.)

Proposition 8.6.12 (Diagonalisability Criterion)

For an $n \times n$ matrix A , the following are equivalent:

- (i) there is a basis of $V = \mathbb{C}^n$ consisting of eigenvectors $\mathbf{v}_1, \dots, \mathbf{v}_n$ of A ;
- (ii) A is diagonalisable, and indeed $P^{-1}AP = D$ where the columns of P are the eigenvectors $\mathbf{v}_i$ and the diagonal entries of D are the corresponding eigenvalues.

Proof. The key computation: for any matrix P with columns $\mathbf{v}_i$, the columns of AP are $A\mathbf{v}_i$, while the columns of PD are $\lambda_i \mathbf{v}_i$. So

$$AP = PD \iff A\mathbf{v}_i = \lambda_i \mathbf{v}_i \text{ for each } i.$$

If we have a basis of eigenvectors, take these as the columns of P ; then P is invertible (its columns are linearly independent) and $P^{-1}AP = D$. Conversely if $P^{-1}AP = D$ with P invertible, the columns of P are n linearly independent eigenvectors, hence a basis. $\square$

Combining this with Corollary 8.6.10, we get workable criteria.

Theorem 8.6.13 (Tests for Diagonalisability)

Let A be an $n \times n$ matrix.

- (i) If A has n distinct eigenvalues, then A is diagonalisable.
- (ii) In general, A is diagonalisable over $\mathbb{C}$ if and only if $m_\lambda = M_\lambda$ for every eigenvalue λ .

Proof. For (i), the n corresponding eigenvectors are linearly independent by the proposition above, and n linearly independent vectors in $\mathbb{C}^n$ form a basis.

For (ii), take bases of all the eigenspaces; by Corollary 8.6.10 their union is linearly independent, and it has $\sum_\lambda m_\lambda$ elements. If $m_\lambda = M_\lambda$ for all λ , then since $\sum_\lambda M_\lambda = n$ (the characteristic polynomial has n roots with multiplicity over $\mathbb{C}$), this union is a basis of eigenvectors. Conversely, if $m_\mu < M_\mu$ for some μ , then the maximum possible number of linearly independent eigenvectors is $\sum_\lambda m_\lambda < n$, so no eigenvector basis exists. $\square$

Note carefully that (i) is sufficient but not necessary – the identity matrix has just one eigenvalue but is already diagonal!

Example 8.6.14 (Diagonalising a Matrix)

Returning to the matrix

$$A = \begin{pmatrix} -2 & 2 & -3 \\ 2 & 1 & -6 \\ -1 & -2 & 0 \end{pmatrix}$$

from before, we found eigenvalues $5, -3, -3$ with three independent eigenvectors. Assembling them into the columns of

$$P = \begin{pmatrix} 1 & -2 & 3 \\ 2 & 1 & 0 \\ -1 & 0 & 1 \end{pmatrix}, \quad \text{with} \quad P^{-1} = \frac{1}{8} \begin{pmatrix} 1 & 2 & -3 \\ -2 & 4 & 6 \\ 1 & 2 & 5 \end{pmatrix},$$

we get $P^{-1}AP = \text{diag}(5, -3, -3)$: the matrix is diagonalisable even though its eigenvalues are not distinct.

On the other hand, the matrix B from the same example has $m_{-2} = 2 < 3 = M_{-2}$, so B is *not* diagonalisable. (There is also a slicker way to see this: if B were diagonalisable, then $P^{-1}BP = -2I$ would give $B = P(-2I)P^{-1} = -2I$, which is false.) Similarly the shear $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$ is not diagonalisable.

§8.6.4 Hermitian and Symmetric Matrices

We now specialise to Hermitian matrices ($A^\dagger = A$), which include the real symmetric matrices ($A^T = A$). These matrices turn out to have astonishingly good eigenvalue behaviour, and they appear everywhere – notably as the matrices of quadratic forms below, and (though beyond this course) as the observables of quantum mechanics.

The key observation is that for a Hermitian matrix, using the complex inner product $(\mathbf{v}, \mathbf{w}) = \mathbf{v}^\dagger \mathbf{w}$ on $\mathbb{C}^n$,

$$(A\mathbf{v})^\dagger \mathbf{w} = \mathbf{v}^\dagger A^\dagger \mathbf{w} = \mathbf{v}^\dagger (A\mathbf{w}),$$

i.e. A can be moved from one side of the inner product to the other.

Theorem 8.6.15 (Eigenvalues and Eigenvectors of Hermitian Matrices)

Let A be an $n \times n$ Hermitian matrix. Then

- (i) every eigenvalue of A is real;
- (ii) eigenvectors with distinct eigenvalues are orthogonal;
- (iii) if A is real (and hence symmetric), the eigenvectors in (ii) can be chosen to be real.

Proof. (i) Let $A\mathbf{v} = \lambda\mathbf{v}$ with $\mathbf{v} \neq \mathbf{0}$. Then

$$\lambda \mathbf{v}^\dagger \mathbf{v} = \mathbf{v}^\dagger (A\mathbf{v}) = (A\mathbf{v})^\dagger \mathbf{v} = \bar{\lambda} \mathbf{v}^\dagger \mathbf{v},$$

and since $\mathbf{v}^\dagger \mathbf{v} = |\mathbf{v}|^2 \neq 0$, we get $\lambda = \bar{\lambda}$.

(ii) Let $A\mathbf{v} = \lambda\mathbf{v}$ and $A\mathbf{w} = \mu\mathbf{w}$ with $\lambda \neq \mu$ (both real by (i)). Then

$$\mu \mathbf{v}^\dagger \mathbf{w} = \mathbf{v}^\dagger (A\mathbf{w}) = (A\mathbf{v})^\dagger \mathbf{w} = \lambda \mathbf{v}^\dagger \mathbf{w},$$

so $(\lambda - \mu)\mathbf{v}^\dagger \mathbf{w} = 0$, forcing $\mathbf{v}^\dagger \mathbf{w} = 0$.

(iii) Given $A\mathbf{v} = \lambda\mathbf{v}$ with A and λ real, write $\mathbf{v} = \mathbf{u} + i\mathbf{u}'$ with $\mathbf{u}, \mathbf{u}' \in \mathbb{R}^n$. Taking real and imaginary parts of the (linear) eigenvector equation, $A\mathbf{u} = \lambda\mathbf{u}$ and $A\mathbf{u}' = \lambda\mathbf{u}'$, and at least one of $\mathbf{u}, \mathbf{u}'$ is non-zero. $\square$

If a Hermitian matrix has distinct eigenvalues, this hands us an *orthogonal* basis of eigenvectors, which we can normalise to be orthonormal. The remarkable fact – and the main theorem about Hermitian matrices – is that this works even when there are repeated eigenvalues.

To handle the repeated case we want to turn bases of eigenspaces into *orthonormal* bases, and there is a standard procedure for doing exactly that.

Proposition 8.6.16 (Gram-Schmidt Orthogonalisation)

Let $\mathbf{w}_1, \dots, \mathbf{w}_r$ be linearly independent vectors in $\mathbb{R}^n$ or $\mathbb{C}^n$. Define, iteratively,

$$\mathbf{v}_1 = \mathbf{w}_1, \quad \mathbf{v}_k = \mathbf{w}_k - \sum_{j=1}^{k-1} \frac{(\mathbf{v}_j, \mathbf{w}_k)}{(\mathbf{v}_j, \mathbf{v}_j)} \mathbf{v}_j.$$

Then the $\mathbf{v}_i$ are non-zero, pairwise orthogonal, and span the same subspace as the $\mathbf{w}_i$. Normalising each $\mathbf{v}_i$ then yields an orthonormal basis of that subspace.

Proof Sketch. At each step we subtract from $\mathbf{w}_k$ its components along the previously constructed directions, so a direct computation gives $(\mathbf{v}_j, \mathbf{v}_k) = 0$ for $j < k$. Each $\mathbf{v}_k$ is non-zero since $\mathbf{w}_k$ is not in the span of $\mathbf{w}_1, \dots, \mathbf{w}_{k-1}$. $\square$

The geometry of a single step is exactly the projection picture from Section 2: we remove from $\mathbf{w}_2$ its projection onto $\mathbf{v}_1$, and what is left over is orthogonal to $\mathbf{v}_1$.

Theorem 8.6.17 (Unitary Diagonalisation of Hermitian Matrices)

Every $n \times n$ Hermitian matrix A is diagonalisable, and moreover the basis of eigenvectors $\mathbf{u}_1, \dots, \mathbf{u}_n$ can be chosen orthonormal. Equivalently, there is a *unitary* matrix U (whose columns are the $\mathbf{u}_i$) with

$$U^\dagger A U = D = \text{diag}(\lambda_1, \dots, \lambda_n),$$

with all λ_i real. If A is real and symmetric, U can be taken real, i.e. *orthogonal*: $Q^T A Q = D$ with $Q^T Q = I$.

Proof (Non-Examinable). We induct on n , the case $n = 1$ being trivial. Let λ_1 be an eigenvalue of A (one exists, by the fundamental theorem of algebra) with normalised eigenvector $\mathbf{u}_1$. Extend $\mathbf{u}_1$ to a basis of $\mathbb{C}^n$ and apply Gram-Schmidt to obtain an orthonormal basis $\mathbf{u}_1, \mathbf{w}_2, \dots, \mathbf{w}_n$; let P be the unitary matrix with these as columns. Then the first column of $P^\dagger A P$ is $P^\dagger A \mathbf{u}_1 = \lambda_1 P^\dagger \mathbf{u}_1 = \lambda_1 \mathbf{e}_1$, and moreover $P^\dagger A P$ is still Hermitian, so its first row is also $\lambda_1 \mathbf{e}_1^T$. That is,

$$P^\dagger A P = \begin{pmatrix} \lambda_1 & \mathbf{0}^T \\ \mathbf{0} & C \end{pmatrix},$$

where C is an $(n-1) \times (n-1)$ Hermitian matrix. By induction there is a unitary $\tilde{Q}$ with $\tilde{Q}^\dagger C \tilde{Q}$ diagonal, and bordering $\tilde{Q}$ with a 1 in the top-left corner gives a unitary Q for which $(PQ)^\dagger A (PQ)$ is diagonal. Since products of unitary matrices are unitary, we are done; the columns of PQ are the required orthonormal eigenvectors. In the real symmetric case, all eigenvalues are real and every step can be carried out with real vectors and orthogonal matrices. $\square$

Example 8.6.18 (Orthogonal Diagonalisation with a Repeated Eigenvalue)

Let

$$A = \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix},$$

which is real and symmetric. The characteristic polynomial is $\chi_A(t) = -(t+1)^2(t-2)$, so the eigenvalues are $-1, -1, 2$. For $\lambda = 2$ we find the eigenvector $(1, 1, 1)$, and for $\lambda = -1$ the eigenspace is the plane $v_1 + v_2 + v_3 = 0$, e.g. spanned by

$$\mathbf{w}_1 = \begin{pmatrix} 1 \\ -1 \\ 0 \end{pmatrix}, \quad \mathbf{w}_2 = \begin{pmatrix} 1 \\ 0 \\ -1 \end{pmatrix}.$$

These are not orthogonal to each other, so we apply Gram-Schmidt within the eigenspace: keep $\mathbf{u}_1 = \frac{1}{\sqrt{2}}(1, -1, 0)$, and replace $\mathbf{w}_2$ by

$$\mathbf{w}'_2 = \mathbf{w}_2 - (\mathbf{u}_1 \cdot \mathbf{w}_2)\mathbf{u}_1 = \begin{pmatrix} 1/2 \\ 1/2 \\ -1 \end{pmatrix}, \quad \text{normalised to} \quad \mathbf{u}_2 = \frac{1}{\sqrt{6}} \begin{pmatrix} 1 \\ 1 \\ -2 \end{pmatrix}.$$

Together with $\mathbf{u}_3 = \frac{1}{\sqrt{3}}(1, 1, 1)$, we have an orthonormal basis of eigenvectors (note $\mathbf{u}_1, \mathbf{u}_2 \perp \mathbf{u}_3$ automatically, being in eigenspaces of different eigenvalues). So with

$$Q = \begin{pmatrix} 1/\sqrt{2} & 1/\sqrt{6} & 1/\sqrt{3} \\ -1/\sqrt{2} & 1/\sqrt{6} & 1/\sqrt{3} \\ 0 & -2/\sqrt{6} & 1/\sqrt{3} \end{pmatrix},$$

an orthogonal matrix, we get $Q^T A Q = \text{diag}(-1, -1, 2)$.

Remark. Hermitian matrices are not the end of the story: a complex matrix can be unitarily diagonalised if and only if it is **normal**, meaning $AA^\dagger = A^\dagger A$. This class includes Hermitian, skew-Hermitian and unitary matrices (and their real cousins) all at once, but we won't pursue this further here.

§8.6.5 Quadratic Forms

One of the payoffs of orthogonal diagonalisation is a complete understanding of *quadratic forms* – expressions like $2x_1^2 - 4x_1x_2 + 5x_2^2$ in which every term has degree two. These arise throughout mathematics and physics: as conics and quadric surfaces, as second-order terms in Taylor expansions, as moments of inertia, and so on.

Definition 8.6.19 (Quadratic Form)

A **quadratic form** on $\mathbb{R}^n$ is a function $\mathcal{F} : \mathbb{R}^n \rightarrow \mathbb{R}$ of the form

$$\mathcal{F}(\mathbf{x}) = \mathbf{x}^T A \mathbf{x} = A_{ij} x_i x_j,$$

where A is a real symmetric $n \times n$ matrix.

There is no loss of generality in taking A symmetric: an antisymmetric matrix B satisfies $\mathbf{x}^T B \mathbf{x} = 0$ (as $\mathbf{x}^T B \mathbf{x}$ is a scalar equal to its own transpose $-\mathbf{x}^T B \mathbf{x}$), so only the

symmetric part of a general matrix contributes to the form.⁶

Since A is real symmetric, Theorem 8.6.17 provides an orthogonal Q with $Q^T A Q = D = \text{diag}(\lambda_1, \dots, \lambda_n)$. Substituting $\mathbf{x} = Q\mathbf{x}'$, i.e. $\mathbf{x}' = Q^T \mathbf{x}$,

$$\mathcal{F}(\mathbf{x}) = (Q\mathbf{x}')^T A (Q\mathbf{x}') = (\mathbf{x}')^T (Q^T A Q) \mathbf{x}' = \lambda_1 x_1'^2 + \lambda_2 x_2'^2 + \dots + \lambda_n x_n'^2.$$

In other words: *in the right orthonormal coordinates, every quadratic form is a weighted sum of squares*, with the eigenvalues of A as weights. The new coordinate axes – the directions of the orthonormal eigenvectors $\mathbf{u}_i$ – are called the **principal axes** of the form.

Example 8.6.20 (Diagonalising a Quadratic Form)

Consider $\mathcal{F}(\mathbf{x}) = 2x_1^2 - 4x_1x_2 + 5x_2^2$. We have $\mathcal{F}(\mathbf{x}) = \mathbf{x}^T A \mathbf{x}$ with

$$A = \begin{pmatrix} 2 & -2 \\ -2 & 5 \end{pmatrix}$$

(note the off-diagonal entries are each *half* the cross-term coefficient). The eigenvalues of A are 1 and 6, with orthonormal eigenvectors

$$\mathbf{u}_1 = \frac{1}{\sqrt{5}} \begin{pmatrix} 2 \\ 1 \end{pmatrix}, \quad \mathbf{u}_2 = \frac{1}{\sqrt{5}} \begin{pmatrix} -1 \\ 2 \end{pmatrix}.$$

So setting $x_1' = \frac{1}{\sqrt{5}}(2x_1 + x_2)$ and $x_2' = \frac{1}{\sqrt{5}}(-x_1 + 2x_2)$, the form becomes

$$\mathcal{F} = x_1'^2 + 6x_2'^2.$$

In particular the level set $\mathcal{F} = 1$ is an ellipse, with principal axes along $\mathbf{u}_1$ and $\mathbf{u}_2$ and semi-axes 1 and $1/\sqrt{6}$.

The signs of the eigenvalues determine the character of the form. If all $\lambda_i > 0$ the form is **positive definite** (like $|\mathbf{x}|^2$); if the signs are mixed, the level sets change character entirely. In $\mathbb{R}^2$, the level set $\mathcal{F} = k$ ($k > 0$) is an ellipse if $\lambda_1, \lambda_2 > 0$ and a hyperbola if $\lambda_1 \lambda_2 < 0$; in $\mathbb{R}^3$, positive eigenvalues give ellipsoids, while mixed signs give hyperboloids (of one or two sheets, according to the sign pattern and k).

Example 8.6.21 (A Hyperboloid)

Take the matrix A with entries $A_{ij} = 1 - \delta_{ij}$ from the previous subsection, so

$$\mathcal{F}(\mathbf{x}) = 2x_1x_2 + 2x_2x_3 + 2x_3x_1 = -x_1'^2 - x_2'^2 + 2x_3'^2$$

⁶Over $\mathbb{C}$, the analogous object is a *Hermitian form* $F(\mathbf{z}) = \mathbf{z}^\dagger A \mathbf{z}$ with A Hermitian; the computation $\overline{F(\mathbf{z})} = (\mathbf{z}^\dagger A \mathbf{z})^\dagger = \mathbf{z}^\dagger A \mathbf{z}$ shows that Hermitian forms take real values.

in principal axes coordinates. The surface $\mathcal{F} = 1$, i.e. $2x_3'^2 = 1 + x_1'^2 + x_2'^2$, is a hyperboloid of two sheets (rotationally symmetric about the x_3' axis), while $\mathcal{F} = -1$ gives $x_1'^2 + x_2'^2 = 1 + 2x_3'^2$, a hyperboloid of one sheet.

§8.6.6 Quadrics and Conics

Allowing linear terms as well as quadratic ones, we arrive at the general notion of a quadric.

Definition 8.6.22 (Quadric)

A **quadric** in $\mathbb{R}^n$ is the solution set of

$$Q(\mathbf{x}) = \mathbf{x}^T A \mathbf{x} + \mathbf{b}^T \mathbf{x} + c = 0,$$

where $A \neq 0$ is a real symmetric $n \times n$ matrix, $\mathbf{b} \in \mathbb{R}^n$ and $c \in \mathbb{R}$.

If A is invertible, we can absorb the linear term by completing the square: setting $\mathbf{y} = \mathbf{x} + \frac{1}{2}A^{-1}\mathbf{b}$ (a translation of the origin), a short computation gives

$$\mathbf{y}^T A \mathbf{y} = \mathbf{x}^T A \mathbf{x} + \mathbf{b}^T \mathbf{x} + \frac{1}{4}\mathbf{b}^T A^{-1} \mathbf{b},$$

so $Q(\mathbf{x}) = 0$ becomes $\mathbf{y}^T A \mathbf{y} = k$ where $k = \frac{1}{4}\mathbf{b}^T A^{-1} \mathbf{b} - c$. Diagonalising as before, every quadric with $\det A \neq 0$ is – after a translation and a rotation of coordinates, which change nothing geometrically – a level set of a sum of squares:

$$\lambda_1 x_1^2 + \lambda_2 x_2^2 + \cdots + \lambda_n x_n^2 = k.$$

Conics

In $\mathbb{R}^2$ quadrics are curves, called **conics**, and we can classify them completely. Suppose first $\det A \neq 0$, so as above the conic is $\lambda_1 x_1^2 + \lambda_2 x_2^2 = k$ in suitable coordinates.

- If $\lambda_1, \lambda_2 > 0$: an *ellipse* for $k > 0$, a single point for $k = 0$, and empty for $k < 0$.
- If $\lambda_1 > 0 > \lambda_2$: a *hyperbola* for $k \neq 0$ (with the two orientations for the two signs of k), and for $k = 0$ a *pair of lines* through the origin, since $\lambda_1 x_1^2 - |\lambda_2| x_2^2$ factorises.

If $\det A = 0$, then exactly one eigenvalue vanishes (as $A \neq 0$), say $\lambda_2 = 0$, and the translation trick above is unavailable. In principal axis coordinates the equation reads

$$\lambda_1 x_1'^2 + b_1' x_1' + b_2' x_2' + c = 0.$$

Completing the square in x_1' removes the b_1' term. If $b_2' \neq 0$, absorbing the constant into x_2' then leaves

$$\lambda_1 x_1''^2 + b_2' x_2'' = 0,$$

a *parabola*. If $b_2' = 0$, we instead get $\lambda_1 x_1''^2 + c' = 0$, which is a pair of parallel lines, a single line, or empty, according to the sign of c'/λ_1 .

So, up to translations and rotations, a conic is an ellipse, a hyperbola, a parabola, or a degenerate case (points and lines). The three non-degenerate conics have standard forms

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \quad (\text{ellipse}), \quad \frac{x^2}{a^2} - \frac{y^2}{b^2} = 1 \quad (\text{hyperbola}), \quad y^2 = 4ax \quad (\text{parabola}).$$

The Focus-Directrix Property

The name ‘conic’ comes from the fact that these curves are the sections of a cone by planes – and there is also a beautiful unified description in terms of a focus and directrix, which is the form in which conics appear in Dynamics and Relativity when studying planetary orbits.

Fix a constant $e > 0$ (the **eccentricity**), a point F (the **focus**), and a line (the **directrix**). Consider the locus of points P whose distance from F is e times the distance from the directrix. Taking $F = (ae, 0)$ and the directrix $x = a/e$ (with $a > 0$), the condition is

$$\sqrt{(x - ae)^2 + y^2} = e \left| \frac{a}{e} - x \right|.$$

Squaring and simplifying,

$$\frac{x^2}{a^2} + \frac{y^2}{a^2(1 - e^2)} = 1.$$

For $e < 1$ this is an ellipse with semi-minor axis $b = a\sqrt{1 - e^2}$ (with $e \rightarrow 0$ approaching a circle); for $e > 1$ the second denominator is negative and we get the hyperbola $\frac{x^2}{a^2} - \frac{y^2}{a^2(e^2 - 1)} = 1$; and a similar computation with $e = 1$, focus $(a, 0)$ and directrix $x = -a$ gives the parabola $y^2 = 4ax$. So the eccentricity interpolates between all three non-degenerate conics.

In polar coordinates centred on the focus, all three cases combine into the single equation

$$r = \frac{\ell}{1 + e \cos \theta},$$

where $\ell = a|1 - e^2|$ (for the parabola, $\ell = 2a$). Note that r stays bounded when $e < 1$, while for $e \geq 1$ the denominator can vanish and the curve escapes to infinity – exactly the distinction between bound (elliptic) and unbound (parabolic, hyperbolic) orbits.

§8.7 Changing Basis, Canonical Forms and Symmetries

In this final section, we tie together several loose threads. We have repeatedly used expressions of the form $P^{-1}AP$, promising that they mean ‘the same map, written with respect to a different basis’ – it is time to make this precise. Once we can change basis freely, the natural question becomes: given a linear map, how simple can we make its matrix look? The answers (diagonal matrices where possible, and *Jordan blocks* where not) are some of the most useful results in linear algebra. We will finish with the Cayley-Hamilton theorem, and a look at matrix groups of symmetries.

§8.7.1 Change of Basis

Let’s first set up the matrix of a linear map with respect to *arbitrary* bases, generalising what we did in Section 4 for standard bases.

Let $T : V \rightarrow W$ be a linear map between real or complex vector spaces with $\dim V = n$ and $\dim W = m$, and choose bases $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$ of V and $\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$ of W . The **matrix of T with respect to these bases** is the $m \times n$ matrix A defined by

$$T(\mathbf{e}_i) = \sum_a \mathbf{f}_a A_{ai},$$

i.e. column i of A holds the components of $T(\mathbf{e}_i)$ with respect to the basis $\{\mathbf{f}_a\}$. This is set up exactly so that the abstract statement $\mathbf{y} = T(\mathbf{x})$ becomes the matrix statement $y_a = A_{ai}x_i$ on components: indeed

$$T\left(\sum_i x_i \mathbf{e}_i\right) = \sum_i x_i T(\mathbf{e}_i) = \sum_a \left(\underbrace{\sum_i A_{ai}x_i}_{y_a}\right) \mathbf{f}_a.$$

Now suppose we pick *new* bases $\{\mathbf{e}'_i\}$ of V and $\{\mathbf{f}'_a\}$ of W . The relationship between old and new is captured by **change of basis matrices** P ($n \times n$) and Q ($m \times m$), defined by

$$\mathbf{e}'_i = \sum_j \mathbf{e}_j P_{ji}, \quad \mathbf{f}'_a = \sum_b \mathbf{f}_b Q_{ba},$$

so the columns of P are the new basis vectors written in terms of the old (and similarly for Q). Both are invertible, since they map a basis to a basis.

Theorem 8.7.1 (Change of Basis Formula)

Let A be the matrix of T with respect to $\{\mathbf{e}_i\}$, $\{\mathbf{f}_a\}$, and A' its matrix with respect to $\{\mathbf{e}'_i\}$, $\{\mathbf{f}'_a\}$. Then

$$A' = Q^{-1}AP.$$

Proof. We compute $T(\mathbf{e}'_i)$ in two ways. Directly from the definitions,

$$T(\mathbf{e}'_i) = T\left(\sum_j \mathbf{e}_j P_{ji}\right) = \sum_j T(\mathbf{e}_j) P_{ji} = \sum_{j,a} \mathbf{f}_a A_{aj} P_{ji},$$

while using the matrix with respect to the new bases,

$$T(\mathbf{e}'_i) = \sum_b \mathbf{f}'_b A'_{bi} = \sum_{a,b} \mathbf{f}_a Q_{ab} A'_{bi}.$$

Comparing coefficients of the basis vectors $\mathbf{f}_a$ (whose coefficients are unique),

$$(AP)_{ai} = (QA')_{ai},$$

so $AP = QA'$ and $A' = Q^{-1}AP$. $\square$

It is also instructive to see how *components of vectors* transform. If $\mathbf{x} = \sum_i x_i \mathbf{e}_i = \sum_j x'_j \mathbf{e}'_j$, then substituting the definition of $\mathbf{e}'_j$ and comparing coefficients gives

$$x_i = \sum_j P_{ij} x'_j, \quad \text{i.e.} \quad X = PX' \text{ and } X' = P^{-1}X,$$

writing X, X' for the column vectors of components. (Note the slight inversion: the *new* components are obtained using P^{-1} .) Then from $Y = AX$ we get $QY' = APX'$, so $Y' = (Q^{-1}AP)X'$ – the change of basis formula again.

Example 8.7.2 (Changing Bases)

Define $T : V \rightarrow W$ with $\dim V = 2$, $\dim W = 3$ by

$$T(\mathbf{e}_1) = \mathbf{f}_1 + 2\mathbf{f}_2 - \mathbf{f}_3, \quad T(\mathbf{e}_2) = -\mathbf{f}_1 + 2\mathbf{f}_2 + \mathbf{f}_3, \quad \text{so} \quad A = \begin{pmatrix} 1 & -1 \\ 2 & 2 \\ -1 & 1 \end{pmatrix}.$$

Now take new bases $\mathbf{e}'_1 = \mathbf{e}_1 - \mathbf{e}_2$, $\mathbf{e}'_2 = \mathbf{e}_1 + \mathbf{e}_2$ and $\mathbf{f}'_1 = \mathbf{f}_1 - \mathbf{f}_3$, $\mathbf{f}'_2 = \mathbf{f}_2$, $\mathbf{f}'_3 = \mathbf{f}_1 + \mathbf{f}_3$, so

$$P = \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}, \quad Q = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 0 \\ -1 & 0 & 1 \end{pmatrix}, \quad Q^{-1} = \frac{1}{2} \begin{pmatrix} 1 & 0 & -1 \\ 0 & 2 & 0 \\ 1 & 0 & 1 \end{pmatrix}.$$

The change of basis formula gives

$$A' = Q^{-1}AP = \begin{pmatrix} 2 & 0 \\ 0 & 4 \\ 0 & 0 \end{pmatrix},$$

and indeed one can check directly that $T(\mathbf{e}'_1) = 2\mathbf{f}_1 - 2\mathbf{f}_3 = 2\mathbf{f}'_1$ and $T(\mathbf{e}'_2) = 4\mathbf{f}_2 = 4\mathbf{f}'_2$. A good choice of basis has made the map look about as simple as possible.

§8.7.2 Similar Matrices

The most important case of the change of basis formula is $V = W$ with $\{\mathbf{e}_i\} = \{\mathbf{f}_i\}$ and $\{\mathbf{e}'_i\} = \{\mathbf{f}'_i\}$, so that $Q = P$ and

$$A' = P^{-1}AP.$$

Definition 8.7.3 (Similar Matrices)

Two $n \times n$ matrices A and B are **similar** if $B = P^{-1}AP$ for some invertible matrix

P .

Similarity is an equivalence relation, and by the discussion above, two matrices are similar precisely when they represent *the same linear map with respect to different bases*. Anything intrinsic to the underlying map must therefore be shared by all matrices similar to it. Here are the key examples, which we have already met.

Proposition 8.7.4 (Invariants Under Similarity)

If A and B are similar, then

- (i) $\det B = \det A$,
- (ii) $\operatorname{tr} B = \operatorname{tr} A$,
- (iii) $\chi_B(t) = \chi_A(t)$, so A and B have the same eigenvalues with the same algebraic multiplicities.

Proof. Let $B = P^{-1}AP$.

- (i) $\det B = \det(P^{-1}) \det A \det P = \det A$, using multiplicativity.
- (ii) $\operatorname{tr} B = \operatorname{tr}(P^{-1}(AP)) = \operatorname{tr}((AP)P^{-1}) = \operatorname{tr} A$, using the cyclic property.
- (iii) Since $tI = P^{-1}(tI)P$, we have

$$\chi_B(t) = \det(P^{-1}AP - tI) = \det(P^{-1}(A - tI)P) = \det(A - tI) = \chi_A(t). \quad \square$$

So the determinant, trace and characteristic polynomial are genuinely properties of the linear map, not of the particular matrix chosen to represent it. (The converse fails, incidentally: matrices with the same characteristic polynomial need not be similar – compare I and the shear $\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$.)

As promised in Section 6, we can now prove the relationship between the two multiplicities.

Proposition 8.7.5 (Geometric vs Algebraic Multiplicity)

For any eigenvalue λ of an $n \times n$ matrix A , we have $1 \leq m_\lambda \leq M_\lambda$.

Proof. Let $m = m_\lambda$, and choose a basis $\mathbf{v}_1, \dots, \mathbf{v}_m$ of the eigenspace E_λ , extended to a basis $\mathbf{v}_1, \dots, \mathbf{v}_n$ of $\mathbb{C}^n$. Let P be the (invertible) matrix with these as columns. Since $A\mathbf{v}_i = \lambda\mathbf{v}_i$ for $i \leq m$, the first m columns of $\tilde{A} = P^{-1}AP$ are $\lambda\mathbf{e}_1, \dots, \lambda\mathbf{e}_m$, so $\tilde{A}$ has the block form

$$\tilde{A} = \begin{pmatrix} \lambda I_m & B \\ 0 & C \end{pmatrix}$$

for some blocks B and C . Then, expanding the determinant repeatedly along the first columns,

$$\chi_A(t) = \chi_{\tilde{A}}(t) = \det \begin{pmatrix} (\lambda - t)I_m & B \\ 0 & C - tI \end{pmatrix} = (\lambda - t)^m \chi_C(t),$$

so $(t - \lambda)^m$ divides $\chi_A(t)$, i.e. $M_\lambda \geq m$. $\square$

§8.7.3 Canonical Forms

We saw that a diagonalisable matrix is exactly one that is similar to a diagonal matrix. What is the simplest form we can reach when a matrix is *not* diagonalisable? For 2×2 matrices we can answer this completely.

Theorem 8.7.6 (Canonical Forms for 2×2 Matrices)

Any 2×2 complex matrix A is similar to exactly one of the following:

$$\begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix} \ (\lambda_1 \neq \lambda_2), \quad \begin{pmatrix} \lambda & 0 \\ 0 & \lambda \end{pmatrix}, \quad \begin{pmatrix} \lambda & 1 \\ 0 & \lambda \end{pmatrix}.$$

Proof. Over $\mathbb{C}$, the characteristic polynomial χ_A has two roots, counted with multiplicity. We consider the possible cases.

- (i) If the roots $\lambda_1 \neq \lambda_2$ are distinct, then the corresponding eigenvectors are linearly independent, and taking P with the eigenvectors as columns diagonalises A , giving the first form.
- (ii) If there is a repeated root λ with $m_\lambda = 2$, then $E_\lambda = \mathbb{C}^2$, and any basis diagonalises: A is similar to λI . (In fact then $A = P(\lambda I)P^{-1} = \lambda I$ already.)
- (iii) If there is a repeated root λ with $m_\lambda = 1$, then A is not diagonalisable, and we claim it is similar to the third matrix. Since $A \neq \lambda I$, we can pick a vector $\mathbf{w}$ with

$$\mathbf{u} = (A - \lambda I)\mathbf{w} \neq \mathbf{0}.$$

Now, here is the trick: since $\chi_A(t) = (t - \lambda)^2$, the Cayley-Hamilton theorem (proven independently below – or verified directly in the 2×2 case) gives $(A - \lambda I)^2 = \chi_A(A) = 0$, so

$$(A - \lambda I)\mathbf{u} = (A - \lambda I)^2\mathbf{w} = \mathbf{0},$$

i.e. $\mathbf{u}$ is an eigenvector. Then $\{\mathbf{u}, \mathbf{w}\}$ is linearly independent (as $\mathbf{w}$ is not an eigenvector but $\mathbf{u}$ is), and on this basis

$$A\mathbf{u} = \lambda\mathbf{u}, \quad A\mathbf{w} = \mathbf{u} + \lambda\mathbf{w},$$

which is precisely the third matrix, with respect to the basis $\{\mathbf{u}, \mathbf{w}\}$.

Finally, no two of the three forms are similar to each other (compare characteristic polynomials, and diagonalisability), so the case is uniquely determined by A . $\square$

Example 8.7.7 (Finding a Canonical Form)

Let

$$A = \begin{pmatrix} 1 & 4 \\ -1 & 5 \end{pmatrix}, \quad \text{so} \quad \chi_A(t) = t^2 - 6t + 9 = (t - 3)^2.$$

The eigenvalue 3 is repeated, and $A \neq 3I$, so we are in the third case. Take $\mathbf{w} = (1, 0)^T$; then

$$\mathbf{u} = (A - 3I)\mathbf{w} = \begin{pmatrix} -2 & 4 \\ -1 & 2 \end{pmatrix} \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} -2 \\ -1 \end{pmatrix},$$

which is indeed an eigenvector of A . With

$$P = \begin{pmatrix} -2 & 1 \\ -1 & 0 \end{pmatrix} \quad \text{we get} \quad P^{-1}AP = \begin{pmatrix} 3 & 1 \\ 0 & 3 \end{pmatrix}.$$

What happens for larger matrices? The building blocks are the $k \times k$ **Jordan blocks**

$$J_k(\lambda) = \begin{pmatrix} \lambda & 1 & & \\ & \lambda & \ddots & \\ & & \ddots & 1 \\ & & & \lambda \end{pmatrix} = \lambda I + N,$$

where N has 1s just above the diagonal and 0s elsewhere. The matrix N acts on the standard basis by $\mathbf{e}_k \mapsto \mathbf{e}_{k-1} \mapsto \cdots \mapsto \mathbf{e}_1 \mapsto \mathbf{0}$ (so $N^k = 0$), and one checks that $J_k(\lambda)$ has characteristic polynomial $(\lambda - t)^k$ with $M_\lambda = k$ but $m_\lambda = 1$: it is the ‘most non-diagonalisable’ matrix with a single eigenvalue.

Theorem 8.7.8 (Jordan Normal Form)

Any $n \times n$ complex matrix is similar to a block diagonal matrix

$$\begin{pmatrix} J_{n_1}(\lambda_1) & & \\ & \ddots & \\ & & J_{n_r}(\lambda_r) \end{pmatrix},$$

where $n_1 + \cdots + n_r = n$, the λ_i are eigenvalues (possibly with repeats among different blocks), and the collection of blocks is unique up to reordering. A matrix is diagonalisable if and only if all its blocks are 1×1 .

The proof is well beyond this course (it belongs to Linear Algebra, and Groups, Rings and Modules, in Part IB), but the statement is worth knowing: it completely classifies complex matrices up to similarity, and the 2×2 theorem above is exactly its two dimensional case.

§8.7.4 The Cayley-Hamilton Theorem

If $p(t) = c_0 + c_1t + \cdots + c_k t^k$ is a polynomial and A a square matrix, we can form the matrix

$$p(A) = c_0I + c_1A + \cdots + c_k A^k.$$

Matrix polynomials – and indeed power series, such as the matrix exponential $\exp A = \sum_{r=0}^{\infty} \frac{1}{r!} A^r$ – behave pleasantly with respect to similarity and diagonalisation. Since $(P^{-1}AP)^r = P^{-1}A^rP$, we have

$$p(P^{-1}AP) = P^{-1}p(A)P,$$

and if $D = \text{diag}(\lambda_1, \dots, \lambda_n)$ then $p(D) = \text{diag}(p(\lambda_1), \dots, p(\lambda_n))$.

Now for one of the most striking results of the course: what happens if we substitute a matrix into its *own* characteristic polynomial?

Theorem 8.7.9 (Cayley-Hamilton Theorem)

Every $n \times n$ complex matrix satisfies its own characteristic equation:

$$\chi_A(A) = c_0 I + c_1 A + \cdots + c_n A^n = 0.$$

Before the proof, a warning about a tempting non-proof: it is *not* valid to argue ' $\chi_A(A) = \det(A - AI) = \det(0) = 0$ '. The expression $\chi_A(A)$ means substituting A into the polynomial $\chi_A(t)$ after expanding it out, which is not the same as plugging a matrix into the determinant.

Proof (for diagonalisable matrices). Suppose $P^{-1}AP = D = \text{diag}(\lambda_1, \dots, \lambda_n)$. Then, using the observations above,

$$\chi_A(D) = \text{diag}(\chi_A(\lambda_1), \dots, \chi_A(\lambda_n)) = 0,$$

since the λ_i are eigenvalues of A , i.e. roots of χ_A . Hence

$$\chi_A(A) = \chi_A(PDP^{-1}) = P\chi_A(D)P^{-1} = 0. \quad \square$$

Proof (general, non-examinable). Let $M = A - tI$, so that $\det M = \chi_A(t) = \sum_{r=0}^n c_r t^r$. Each entry of the adjugate $\text{adj } M$ is (up to sign) an $(n-1) \times (n-1)$ minor of M , hence a polynomial in t of degree at most $n-1$, so we can write

$$\text{adj } M = \sum_{r=0}^{n-1} B_r t^r$$

for some matrices $B_0, \dots, B_{n-1}$ independent of t . The fundamental adjugate identity $(\text{adj } M)M = (\det M)I$ then reads

$$\left(\sum_{r=0}^{n-1} B_r t^r \right) (A - tI) = \sum_{r=0}^n c_r t^r I.$$

Both sides are polynomials in t with matrix coefficients, so we may compare coefficients of each power of t :

$$c_0 I = B_0 A, \quad c_1 I = B_1 A - B_0, \quad \dots, \quad c_{n-1} I = B_{n-1} A - B_{n-2}, \quad c_n I = -B_{n-1}.$$

Now multiply the equation for $c_r I$ on the right by A^r and sum over r : the right hand sides telescope,

$$\chi_A(A) = \sum_{r=0}^n c_r A^r = B_0 A + (B_1 A^2 - B_0 A) + \cdots + (B_{n-1} A^n - B_{n-2} A^{n-1}) - B_{n-1} A^n = 0. \quad \square$$

A nice consequence: Cayley-Hamilton gives a formula for the inverse in terms of *positive* powers of A . Rearranging $\chi_A(A) = 0$,

$$-c_0 I = A(c_1 I + c_2 A + \cdots + c_n A^{n-1}),$$

and since $c_0 = \chi_A(0) = \det A$, if A is invertible then

$$A^{-1} = \frac{-1}{\det A} (c_1 I + c_2 A + \cdots + c_n A^{n-1}).$$

Example 8.7.10 (Inverting with Cayley-Hamilton)

For $A = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$, we have $\chi_A(t) = t^2 - 5t - 2$, so $A^2 - 5A - 2I = 0$, giving

$$A^{-1} = \frac{1}{2}(A - 5I) = \frac{1}{2} \begin{pmatrix} -4 & 2 \\ 3 & -1 \end{pmatrix} = \frac{1}{-2} \begin{pmatrix} 4 & -2 \\ -3 & 1 \end{pmatrix},$$

agreeing with the 2×2 inverse formula (here $\det A = -2$).

§8.7.5 Symmetries and Transformation Groups

We finish the course by returning to orthogonal matrices, now viewed as *groups of symmetries* of space. Recall from Section 4 that the orthogonal matrices are exactly the length-preserving ones.

Proposition 8.7.11 (The Orthogonal Group)

The set of $n \times n$ orthogonal matrices forms a group under matrix multiplication, the **orthogonal group** $O(n)$. The subset with determinant 1 forms a subgroup, the **special orthogonal group** $SO(n)$.

Proof. For closure, if $R^T R = S^T S = I$ then $(RS)^T(RS) = S^T(R^T R)S = S^T S = I$. The identity is orthogonal; the inverse of an orthogonal matrix is R^T , which is orthogonal since $(R^T)^T R^T = R R^T = I$; and matrix multiplication is associative. For $SO(n)$, closure follows from multiplicativity of the determinant. $\square$

Since $\det R = \pm 1$ for orthogonal R , the group $O(n)$ splits into two halves: $SO(n)$, the *rotations*, which preserve orientation (and hence signed volumes), and the remainder, the *reflections*, with determinant -1 . Any element of the second half can be written as (a fixed reflection) $\times$ (a rotation).

In two dimensions we can describe everything explicitly: requiring the columns to be orthonormal forces any element of $O(2)$ to have the form

$$\begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix} \quad \text{or} \quad \begin{pmatrix} \cos \theta & \sin \theta \\ \sin \theta & -\cos \theta \end{pmatrix},$$

the first being the rotations (determinant 1) and the second the reflections (determinant -1 , being reflections in the line at angle $\theta/2$ to the x -axis).

There is one conceptual point worth making about transformations $x'_i = R_{ij}x_j$: they admit two readings.

- *Active*: R moves the vectors of space, and x'_i are the components of the *new* vector in the old basis.
- *Passive*: nothing moves; x'_i are the components of the *same* vector with respect to a new (rotated) orthonormal basis. This is the change-of-basis reading, with $P = R^{-1} = R^T$.

Both readings are useful, and translating between them carelessly is a well-known source of sign errors.

Minkowski Space and Lorentz Transformations

The definition of ‘orthogonal’ depended on the dot product, which measures length. If we change the way we measure length, we change which matrices count as symmetries – and there is one non-standard choice of enormous physical importance.

Definition 8.7.12 (Minkowski Inner Product)

The **Minkowski inner product** on $\mathbb{R}^2$ is

$$(\mathbf{x}, \mathbf{y}) = \mathbf{x}^T J \mathbf{y}, \quad \text{where} \quad J = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

i.e. $(\mathbf{x}, \mathbf{y}) = x_0 y_0 - x_1 y_1$, indexing coordinates from 0. With this inner product, $\mathbb{R}^2$ is called **Minkowski space**: the coordinate x_0 plays the role of time and x_1 of space.

This is symmetric and bilinear, but *not* positive definite: $(\mathbf{x}, \mathbf{x}) = x_0^2 - x_1^2$ can take either sign (it is a quadratic form with eigenvalues ± 1). The analogue of the circle $|\mathbf{x}|^2 = k$ is the hyperbola $x_0^2 - x_1^2 = k$.

Which matrices preserve this inner product? We need $(M\mathbf{x}, M\mathbf{y}) = (\mathbf{x}, \mathbf{y})$ for all $\mathbf{x}, \mathbf{y}$, i.e. $\mathbf{x}^T M^T J M \mathbf{y} = \mathbf{x}^T J \mathbf{y}$ for all vectors, which forces

$$M^T J M = J,$$

in analogy with $R^T I R = I$ for orthogonal matrices. Taking determinants gives $\det M = \pm 1$ as before, and looking at the $(0, 0)$ entry of the equation gives $M_{00}^2 = 1 + M_{10}^2 \geq 1$.

Proposition 8.7.13 (Lorentz Transformations)

The matrices with $M^T J M = J$, $\det M = 1$ and $M_{00} \geq 1$ are exactly those of the form

$$M(\theta) = \begin{pmatrix} \cosh \theta & \sinh \theta \\ \sinh \theta & \cosh \theta \end{pmatrix}, \quad \theta \in \mathbb{R},$$

and they form a group – the **Lorentz group** – with $M(\theta_1)M(\theta_2) = M(\theta_1 + \theta_2)$.

Proof Sketch. The condition $M^T J M = J$ says the columns $M\mathbf{e}_0, M\mathbf{e}_1$ are ‘orthonormal’ with respect to the Minkowski product. From $(M\mathbf{e}_0, M\mathbf{e}_0) = M_{00}^2 - M_{10}^2 = 1$ with $M_{00} \geq 1$, we can write $(M_{00}, M_{10}) = (\cosh \theta, \sinh \theta)$ for a unique $\theta \in \mathbb{R}$. Then $(M\mathbf{e}_0, M\mathbf{e}_1) = 0$ and $(M\mathbf{e}_1, M\mathbf{e}_1) = -1$ force the second column to be $\pm(\sinh \theta, \cosh \theta)$, and $\det M = 1$ fixes the sign $+$. The group law follows from the addition formulae for $\cosh$ and $\sinh$, which mirror those for $\cos$ and $\sin$. $\square$

These **hyperbolic rotations** preserve each branch of the hyperbolas $x_0^2 - x_1^2 = k$, just as ordinary rotations preserve circles.

To connect with physics, substitute $v = \tanh \theta$ (so $-1 < v < 1$) and write $\gamma = (1 - v^2)^{-1/2} = \cosh \theta$. Renaming $(x_0, x_1) = (t, x)$,

$$M = \gamma \begin{pmatrix} 1 & v \\ v & 1 \end{pmatrix}, \quad \text{i.e.} \quad t' = \gamma(t + vx), \quad x' = \gamma(x + vt).$$

This is the **Lorentz boost** of special relativity, relating the time and space coordinates of observers in relative motion with velocity v , in units where the speed of light is 1 – the factor γ is responsible for time dilation and length contraction. The group law becomes the relativistic velocity addition formula

$$v_3 = \tanh(\theta_1 + \theta_2) = \frac{v_1 + v_2}{1 + v_1 v_2},$$

which in particular never exceeds the speed of light. The Lorentz transformations will be picked up in earnest in Dynamics and Relativity; for us, they are a fitting final example of how the framework of this course – vector spaces, inner products, and the matrix groups preserving them – extends beyond Euclidean geometry.

II

Part IB

About Part IB

If Part IA is about technique, Part IB is about abstraction. This is the year in which the objects you have been computing with are replaced by the axioms they satisfy, and it is by some distance the largest single jump in the degree. It is also the year with the most courses in it – fifteen chapters here, out of a longer list on offer – because the second year is where a mathematician’s tastes are supposed to start declaring themselves.

The clearest example of the shift is Linear Algebra. Vectors and Matrices spent a year in $\mathbb{R}^3$ and $\mathbb{C}^n$; Linear Algebra deletes the coordinates and starts from a vector space over an arbitrary field, and suddenly the dual space, the trace, the determinant and the Jordan normal form all become statements about linear maps rather than statements about arrays of numbers. The same thing happens to analysis. Analysis and Topology takes the ϵ - N arguments of Analysis I and asks what they actually needed; the answer is a metric, and then not even that, and by the end of the chapter you are proving compactness results in a topological space with no numbers in sight. Groups, Rings and Modules performs the same trick on Groups, generalising the integers and the polynomials into a single theory of factorisation, and then generalising vector spaces into modules so thoroughly that the classification of finitely generated modules over a Euclidean domain hands you back both the structure of finite abelian groups and the Jordan normal form as corollaries.

That triple – Linear Algebra, Analysis and Topology, Groups, Rings and Modules – is the spine of the year, and almost every Part II course leans on at least one of them.

Alongside the abstraction there is theory-building of a different kind. Complex Analysis is the outstanding course of the second year, and possibly of the degree: a short list of hypotheses about a function of a complex variable turns out to force an extraordinary amount of structure, and Cauchy’s theorem propagates through the chapter until residues, the argument principle and Rouché’s theorem all fall out of it. Complex Methods covers overlapping ground from the other direction, caring about contour integrals you can actually evaluate and conformal maps you can actually draw; reading the two chapters side by side is instructive precisely because they disagree about what a proof is for. Geometry, meanwhile, does for surfaces what Analysis and Topology does for spaces, working up through the two fundamental forms to the Theorema Egregium and the Gauss–Bonnet theorem, which is the first result in the book where a local computation and a global topological invariant are forced to agree.

The applied courses inherit Part IA’s machinery and finally put it to work. Vector Calculus’s integral theorems become Maxwell’s equations in Electromagnetism and the transport theorems in Fluid Dynamics. Methods is the workhorse of the year, and worth singling out: Fourier series, Sturm–Liouville theory, distributions and Green’s functions form a toolkit that reappears in nearly every applied course afterwards. Variational Principles reframes mechanics in terms of stationary actions, which is the language Principles of Quantum Mechanics and Statistical Physics will later use, and Quantum Mechanics itself is in large part an exercise in solving the equations that Methods taught you to solve.

Four courses here sit slightly apart. Statistics and Markov Chains take Part IA Probability seriously enough to build real theory on it – estimators, confidence intervals and hypothesis tests in one case, recurrence, invariant distributions and convergence to equilibrium in the other. Optimisation, with its convexity, duality and simplex method, and Numerical Analysis, with its interpolation, quadrature and stability theory, are the two

most computational chapters in the book. None of them is a prerequisite for a great deal, but Optimisation and Markov Chains both feed into Stochastic Financial Models, and Numerical Analysis shares more than you would expect with Topics in Analysis.

The character of the year, in short, is that objects stop being defined by what they are and start being defined by what they do. It is uncomfortable for a while, and then it becomes the only way you want to think.

9 Analysis and Topology

This course is a second course in Analysis and a first course in Topology. We will study both concrete results over $\mathbb{R}$ and $\mathbb{C}$ concerning uniform convergence and continuity, and we will also move to more abstract settings to discuss metric and topological spaces, completeness, connectedness and compactness.

This article constitutes my notes for the ‘Analysis and Topology’ course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§9.1 Uniform Convergence and Uniform Continuity

§9.1.1 Uniform Convergence

Recall the notion of convergence for a sequence in $\mathbb{R}$ or $\mathbb{C}$:

Definition 9.1.1 (Convergence of a Sequence)

A sequence $a_1, a_2, \dots \in \mathbb{R}$ is said to **converge** to the limit a if given any $\epsilon > 0$, we can find an integer N such that $|a_n - a| < \epsilon$ for all $n \geq N$. We write $a_n \rightarrow a$ as $n \rightarrow \infty$.

That is, given any ϵ , there is some point in the sequence after which the terms of the sequence are ϵ close to a .

Our aim is going to define a similar notion to make sense of $f_n \rightarrow f$, where f_n is a sequence of functions.

Definition 9.1.2 (Uniform Convergence)

A sequence of functions $f_1, f_2, \dots$ with $f_i : S \rightarrow \mathbb{R}$ is said to **converge uniformly** on S to a function $f : S \rightarrow \mathbb{R}$ if given any $\epsilon > 0$, we can find an integer N such that $|f_n(x) - f(x)| < \epsilon$ for all $n \geq N$ and any $x \in S$.

Remark. In the above definition, our N can depend only on ϵ , and must be independent of the particular choice of $x \in S$. This is why we call this *uniform* convergence – because the property has to hold uniformly across the domain.

Equivalently, we could say that for all $\varepsilon > 0$ there's some $N \in \mathbb{N}$ such that for all $n \geq N$ we have $\sup_{x \in S} |f_n(x) - f(x)| < \varepsilon$.

The above definition implies that if we fix some value of x that $f_1(x), f_2(x), \dots$ converges to $f(x)$. This implies that the function f is unique, due to the uniqueness of limits in $\mathbb{R}$ and $\mathbb{C}$. We sometimes call f the **uniform limit**.

Definition 9.1.3 (Pointwise Convergence)

We say that f_n **converges pointwise** on S to f if $f_n(x) \rightarrow f(x)$ for every $x \in S$.

Remark. In this definition our ' N ' can depend on ε and x ! This makes it a much weaker notion than uniform convergence, and clearly uniform convergence implies pointwise convergence.

Example 9.1.4 (Checking Uniform Convergence)

Consider the sequence of functions $f_n(x) = x^2 \cdot e^{-nx}$ for $n \in \mathbb{N}$ and $x \in \mathbb{R}^+$. We want to know if this sequence of functions converges uniformly on this domain.

Since pointwise convergence is implied by uniform convergence, we can first check the pointwise limit exists and use that to specify f in our definition of uniform convergence.

Fix $x \geq 0$. Then $x^2 e^{-nx} \rightarrow 0$ as $n \rightarrow \infty$. So f_n tends to 0 (the zero function) pointwise on $\mathbb{R}^+$. We can now check if f_n converges uniformly to the zero function.

We can attempt to compute the quantity

$$\sup_{x \geq 0} |f_n(x) - 0| = \sup_{x \geq 0} f_n(x).$$

One approach would be to differentiate it, which would need some care. A better way is to find an upper bound on $|f_n(x) - f(x)|$ which does not depend on x . In this case we can bound

$$0 \leq x^2 e^{-nx} = \frac{x^2}{1 + nx + n^2 x^2 / 2 + \dots} \leq \frac{2}{n^2},$$

for all $x \geq 0$. Thus $\sup_{x \geq 0} f_n(x) \leq 2/n^2 \rightarrow 0$ as $n \rightarrow \infty$. So indeed $f_n \rightarrow 0$ uniformly on $\mathbb{R}^+$.

Example 9.1.5 (Showing Uniform Convergence Doesn't Hold)

Consider the sequence of functions $f_n(x) = x^n$ for $n \in \mathbb{N}$, over the domain $[0, 1]$.

We can compute the limit as

$$x^n \rightarrow f(x) = \begin{cases} 0 & \text{if } 0 \leq x < 1, \\ 1 & \text{if } x = 1. \end{cases}$$

This implies that $\sup_{x \in [0, 1]} |f_n(x) - f(x)| = 1$. So this doesn't tend to zero, and thus the sequence of functions f_n converges pointwise but not uniformly.

The picture above shows what is going wrong – as n grows, the graph of x^n sags towards zero, but it always has to climb back up to 1 at the right endpoint. The convergence near $x = 1$ is genuinely slower, and no single N works across the whole interval.

Alternatively, we could compute $\sup_{x \in [0,1]} f_n(x) \geq f_n((1/2)^{1/n}) = 1/2$, which shows that f_n does not converge uniformly.

Remark. The statement “ $f_n \not\rightarrow f$ uniformly on the domain S ” means there exists some ε such that for all $N \in \mathbb{N}$, there’s some $n \geq N$ and $x \in S$ such that $|f_n(x) - f(x)| \geq \varepsilon$. In many cases when thinking about this, it’s almost easier just to negate the statement symbolically.

We will now see that the uniform limit function retains certain properties from the original sequence. For example, the uniform limit of continuous functions is continuous.

Theorem 9.1.6 (Continuity of the Uniform Limit)

Let $S \subseteq \mathbb{R}$ or $\mathbb{C}$. Given a sequence of functions $f_n : S \rightarrow \mathbb{R}$ (or $\mathbb{C}$), if f_n is continuous for all n , and $f_n \rightarrow f$ uniformly on S , then f is continuous.

Proof. We will show that f is continuous at some arbitrary $a \in S$. Given $\varepsilon > 0$, there exists some $n \in \mathbb{N}$ such that for $x \in S$ we have $|f_n(x) - f(x)| < \varepsilon/3$. Then since f_n is continuous, there exists $\delta > 0$ such that $|x - a| < \delta$ implies that $|f_n(x) - f_n(a)| < \varepsilon/3$. Then if $x \in S$ and $|x - a| < \delta$, we have

$$|f(x) - f(a)| \leq |f(x) - f_n(x)| + |f_n(x) - f_n(a)| + |f_n(a) - f(a)| \leq \varepsilon,$$

as required^a. □

^aThis type of proof is called a ‘ $\varepsilon/3$ ’ proof, or a 3ε proof depending on your outlook

Remark. This result *does not* hold for just pointwise convergence. For example, consider $f_n(x) = x^n$ on the interval $[0, 1]$. However, the set of points at which it can be discontinuous is relatively small. Also this result does not hold for differentiability.

Another way of viewing this result is that it gives us a case where swapping limits is okay¹, that is

$$\lim_{x \rightarrow a} \lim_{n \rightarrow \infty} f_n(x) = \lim_{x \rightarrow a} f(x) = f(a),$$

¹Generally, swapping limits is bad.

if f_n converges uniformly to f .

We can also prove that boundedness is a property preserved by the uniform limit.

Lemma 9.1.7 (Uniform Limit of Bounded Functions is Bounded)

Assume that $f_n \rightarrow f$ uniformly on some set S . If f_n is bounded for every n , then so is f .

Proof. Fix some $n \in \mathbb{N}$ such that for all $x \in S$ we have $|f_n(x) - f(x)| < 1$. Then since f_n is bounded, there is an $M \in \mathbb{R}$ such that $|f_n(x)| \leq M$ for all $x \in S$. Thus

$$|f(x)| \leq |f(x) - f_n(x)| + |f_n(x)| \leq 1 + M,$$

so f is bounded. □

Another natural property that's preserved by the uniform limit is integrability. Since we have f bounded, we can sensibly talk about the upper and lower sums, and just need to check that Riemann's criterion is satisfied.

Theorem 9.1.8 (Uniform Limit of Integrable Functions is Integrable)

Let $f_n : [a, b] \rightarrow \mathbb{R}$ be a sequence of integrable functions. If $f_n \rightarrow f$ uniformly on $[a, b]$ then f is integrable and

$$\int_a^b f_n \rightarrow \int_a^b f,$$

as $n \rightarrow \infty$.

Proof. Since every f_n is integrable, they must all be bounded and hence f is also bounded. Thus it suffices to check that Riemann's criterion is satisfied.

Given $\varepsilon > 0$, we can fix an $n \in \mathbb{N}$ such that $x \in [a, b]$ implies $|f_n(x) - f(x)| < \varepsilon$. Then since f_n is integrable, there exists a dissection $\mathcal{D} = \{x_0, x_1, \dots, x_m\}$ of $[a, b]$ such that $S_{\mathcal{D}}(f_n) - s_{\mathcal{D}}(f_n) < \varepsilon$.

Now, for each $k \in \{1, \dots, m\}$ and any $x, y \in [x_{k-1}, x_k]$, we have

$$\begin{aligned} |f(x) - f(y)| &\leq |f(x) - f_n(x)| + |f_n(x) - f_n(y)| + |f_n(y) - f(y)| \\ &\leq |f_n(x) - f_n(y)| + 2\varepsilon. \end{aligned}$$

Then noting that we can write the difference between the supremum and infimum of f in the interval $[x_{k-1}, x_k]$ as

$$\sup_{x, y \in [x_{k-1}, x_k]} |f(x) - f(y)| \leq \sup_{x, y \in [x_{k-1}, x_k]} |f_n(x) - f_n(y)| + 2\varepsilon,$$

we can multiply by $(x_k - x_{k-1})$ and sum over k to get

$$S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) \leq S_{\mathcal{D}}(f_n) - s_{\mathcal{D}}(f_n) + 2\varepsilon(b - a) \leq \varepsilon(2(b - a) + 1),$$

so f is integrable.

Finally, we can write

$$\left| \int_a^b f_n - \int_a^b f \right| \leq \int_a^b |f_n - f| \leq (b-a) \cdot \sup_{[a,b]} |f_n - f| \rightarrow 0$$

as $n \rightarrow \infty$. □

Similar to the previous theorem, this result can be viewed as giving us a case where swapping integrals (which are some form of limit) and limits is okay, so that

$$\int_a^b \lim_{n \rightarrow \infty} f_n(x) dx = \lim_{n \rightarrow \infty} \int_a^b f_n(x) dx,$$

whenever $f_n \rightarrow f$ uniformly.

From these results², we obtain some results on how we can both integrate and differentiate sufficiently nice functions term by term.

Theorem 9.1.9 (Term-wise Integration)

Let $g_n : [a, b] \rightarrow \mathbb{R}$ be a sequence of integrable functions. Then if $\sum_{n=1}^{\infty} g_n(x)$ converges uniformly on $[a, b]$, the function $x \mapsto \sum_{n=1}^{\infty} g_n(x)$ is integrable and

$$\int_a^b \sum_{n=1}^{\infty} g_n(x) dx = \sum_{n=1}^{\infty} \int_a^b g_n(x) dx.$$

Proof Sketch. Let f_n be the sequence of partial sums, and notice that f_n converging uniformly implies that we can apply the previous theorem. □

Theorem 9.1.10 (Term-wise Differentiation)

Let $g_n : [a, b] \rightarrow \mathbb{R}$ be a sequence of continuously differentiable functions. If $\sum_{j=1}^n g_j(c)$ converges for *some* $c \in [a, b]$ and $\sum_{j=1}^n g'_j$ converges uniformly as $n \rightarrow \infty$, then $\sum_{j=1}^{\infty} g_j$ converges uniformly to a continuously differentiable function g , and

$$g'(x) = \frac{d}{dx} \left(\sum_{j=1}^{\infty} g_j(x) \right) = \sum_{j=1}^{\infty} g'_j(x).$$

Proof. We are going to try and solve $g' = h$, where we let $h(x) = \sum_{k=1}^{\infty} g'_k(x)$, subject to the initial condition $g(c) = \sum_{n=1}^{\infty} g_n(c)$.

Since $\sum_{n=1}^{\infty} g'_n(x) \rightarrow h$ uniformly, and since g'_n is continuous, we know that h is continuous and thus integrable.

Now let $\lambda = \sum_{n=1}^{\infty} g_n(c)$, and define

$$g(x) = \lambda + \int_c^x h(t) dt,$$

for $x \in [a, b]$. Since h is continuous, by the fundamental theorem of calculus, g is

²The derivation is straightforward, just consider the sequence of partial sums!

differentiable with $g' = h$, and moreover, $g(c) = \lambda$.

Again by the fundamental theorem of calculus, we also have

$$g_k(x) = g_k(c) + \int_c^x g'_k(t) dt,$$

for $x \in [a, b]$ and $k \in \mathbb{N}$.

Now given $\varepsilon > 0$, there exists a positive integer N such that for $n \geq N$ we have

$$\left| \lambda - \sum_{k=1}^n g_k(c) \right| < \frac{\varepsilon}{2}, \quad \text{and} \quad \left| h(t) - \sum_{k=1}^n g'_k(t) \right| < \frac{\varepsilon}{2(b-a)},$$

for $t \in [a, b]$. Then for $x \in [a, b]$, we have

$$\begin{aligned} \left| g(x) - \sum_{k=1}^n g_k(x) \right| &= \left| \lambda + \int_c^x h(t) dt - \sum_{k=1}^n \left(g_k(c) + \int_c^x g'_k(t) dt \right) \right| \\ &\leq \left| \lambda - \sum_{k=1}^n g_k(c) \right| + \left| \int_c^x \left(h(t) - \sum_{k=1}^n g'_k(t) \right) dt \right| \\ &\leq \frac{\varepsilon}{2} + |x - c| \cdot \frac{\varepsilon}{2(b-a)} \\ &\leq \varepsilon. \end{aligned}$$

This shows that $\sum_{k=1}^n g_k(x) \rightarrow g(x)$ uniformly on $[a, b]$, and we also know that g is differentiable and $g' = h$ is continuous. $\square$

§9.1.2 The General Principle of Uniform Convergence

If a sequence $x_n \in \mathbb{R}$ is Cauchy, that is, if for all $\varepsilon > 0$ there exists a positive integer N such that $m, n \geq N$ implies $|x_m - x_n| < \varepsilon$, then the *general principle of convergence* says that the sequence converges. Said differently, terms in a sequence getting arbitrarily close together is necessary and sufficient for convergence.

A similar concept can be applied to sequences of functions.

Definition 9.1.11 (Uniformly Cauchy)

A sequence f_n of functions on a set S is **uniformly Cauchy** if for all $\varepsilon > 0$ there exists a positive integer N such that $n, m \geq N$ implies that for any $x \in S$ we have $|f_m(x) - f_n(x)| < \varepsilon$.

From this, we get an analogue of the general principle of convergence for uniform convergence.

Theorem 9.1.12 (General Principle of Uniform Convergence)

If f_n is a uniformly Cauchy sequence of functions on a set S , then it converges uniformly on S to some function f .

Proof. For any $x \in S$, the sequence of functions being uniformly Cauchy implies that the sequence of reals $f_n(x)$ is Cauchy. Thus $f_n(x)$ converges for all $x \in S$, and f_n converges pointwise to some function f .

Given $\varepsilon > 0$, there is some positive integer N such that for all $m, n \geq N$ and all $x \in S$, $|f_m(x) - f_n(x)| < \varepsilon/2$. We first fix $x \in S$, and fix $n \geq N$. Since $f_m(x) \rightarrow f(x)$ as $m \rightarrow \infty$, we can choose $m \in \mathbb{N}$ such that $|f_m(x) - f(x)| < \varepsilon/2$, and $m \geq N$. Then

$$|f_n(x) - f(x)| \leq |f_n(x) - f_m(x)| + |f_m(x) - f(x)| < \varepsilon,$$

as required, and thus f_n converges uniformly to f . $\square$

This is an incredibly important theorem, and has lots of applications. One example is proving the uniform convergence of certain power series, which we will see below.

Theorem 9.1.13 (Weierstrass M -test)

Let f_n be a sequence of functions on a set S . Assume that for every $n \in \mathbb{N}$ there is an $M_n \in \mathbb{R}^+$ such that $|f_n(x)| \leq M_n$ for all $x \in S$. If $\sum_{n=1}^{\infty} M_n$ converges, then $\sum_{n=1}^{\infty} f_n(x)$ converges uniformly on S .

Proof. Let $F_n(x) = \sum_{k=1}^n f_k(x)$ where $x \in S$ and $n \in \mathbb{N}$. For $x \in S$ and $n \geq m$ we have

$$|F_n(x) - F_m(x)| \leq \sum_{k=m+1}^n |f_k(x)| \leq \sum_{k=m+1}^n M_k.$$

Now given $\varepsilon > 0$, we can choose $N \in \mathbb{N}$ such that $\sum_{k=N+1}^{\infty} M_k < \varepsilon$. Then for every $x \in S$ and $n \geq m \geq N$, we have

$$|F_n(x) - F_m(x)| \leq \sum_{k=m+1}^{\infty} M_k < \varepsilon,$$

so F_n is uniformly Cauchy on S , and hence converges uniformly on S by the general principle of uniform convergence. $\square$

Definition 9.1.14 (Open Disk)

We define the **complex open disk** $D(a, R)$ to be the set

$$D(a, R) = \{z \in \mathbb{C} \mid |z - a| < R\}.$$

Example 9.1.15 (Uniform Convergence of $\sum_{n=1}^{\infty} z^n/n^2$)

We want to know if the power series $\sum_{n=1}^{\infty} z^n/n^2$ converges uniformly.

It's easy to check that the radius of convergence is 1, so now we consider the terms in the sequence $f_n(z) = z^n/n^2$ where $z \in D(0, 1)$.

For all such z , $|f_n(z)| \leq 1/n^2$, and since $\sum_{n=1}^{\infty} 1/n^2$ is convergent, by the M -test, this power series converges uniformly on $D(0, 1)$.

Of course, not every power series converges uniformly.

For example, the power series $\sum_{n=0}^{\infty} z^n$ has radius of convergence 1, and has bounded partial sums for $z \in D(0, 1)$. However, it converges to $1/(1 - z)$, which is not bounded (and hence the convergence can't be uniform, as otherwise boundedness would be preserved).

Despite this example, we can see that uniform convergence basically failed near the radius of convergence, and we can still recover a nice result if we just move *slightly* away, we can still get uniform convergence.

Theorem 9.1.16 (Uniform Convergence Near the Radius of Convergence)

Assume the power series $\sum_{n=0}^{\infty} c_n(z - a)^n$ has radius of convergence R . Then for any r with $0 < r < R$, the power series converges uniformly on $D(a, r)$.

Proof. Fix some $w \in \mathbb{C}$ such that $r < |w - a| < R$. We set $\rho = \frac{r}{|w - a|}$, and we note that $\rho \in (0, 1)$.

Since $\sum_{n=0}^{\infty} c_n(w - a)^n$ converges, we have $c_n(w - a)^n \rightarrow 0$ as $n \rightarrow \infty$. Thus there exists some $M \in \mathbb{R}^+$ such that $|c_n(w - a)^n| \leq M$ for all $n \in \mathbb{N}$.

Now if we take $z \in D(a, r)$ and $n \in \mathbb{N}$, we have

$$\begin{aligned} |c_n(z - a)^n| &= |c_n(w - a)^n| \cdot \left(\frac{|z - a|}{|w - a|} \right)^n \\ &\leq M \left(\frac{r}{|w - a|} \right)^n \leq M \rho^n. \end{aligned}$$

Then since $\sum_{n=0}^{\infty} M \rho^n$ is convergent, by the M -test we have $\sum_{n=0}^{\infty} c_n(z - a)^n$ converging uniformly for $z \in D(a, r)$. $\square$

This result allows us to use our results about uniform convergence to say things about power series. For example:

1. Since a power series is the uniform limit of polynomials inside the radius of convergence, and polynomials are continuous, we get that power series are also continuous inside their radius of convergence.
2. Using our term-wise differentiability result, we get that power series can be differentiated term-wise inside their radius of convergence, and that the power series $\sum_{n=0}^{\infty} c_n(z - a)^n$ has derivative $\sum_{n=1}^{\infty} c_n \cdot n(z - a)^{n-1}$.

We saw previously that it's possible for a power series to not converge uniformly on its whole open disk of convergence. However, the previous theorem showed that we could get arbitrarily close to the radius of convergence, and we'd still have *some* amount of uniform convergence.

To be exact, consider a power series $\sum_{n=0}^{\infty} c_n(z - a)^n$ with radius of convergence R . Then if we take some $w \in D(a, R)$, and fix some r such that $|w - a| < r < R$, we can find some $\delta > 0$ such that $|w - a| + \delta < r$.

Then if $|z - w| < \delta$, $|z - a| \leq |z - w| + |w - a| < \delta + |w - a| < r$, so $D(w, \delta) \subset D(a, r)$, and thus $\sum_{n=0}^{\infty} c_n(z - a)^n$ converges uniformly on $D(w, \delta)$.

This inspires a helpful definition.

Definition 9.1.17 (Open)

A subset U of $\mathbb{C}$ is **open** if for all $w \in U$ there exists $\delta > 0$ such that $D(w, \delta) \subset U$.

Definition 9.1.18 (Local Uniform Convergence)

Let U be an open subset of $\mathbb{C}$ and f_n be a sequence of functions on U . We say that f_n **converges locally uniformly** on U if for all $w \in U$ there exists some $\delta > 0$ such that f_n converges uniformly on $D(w, \delta) \subset U$.

With this the result we discussed above can be stated as follows.

Theorem 9.1.19 (Local Uniform Convergence of Power Series)

A power series centered at a with radius of convergence R converges locally uniformly on $D(a, R)$.

We will return to this when we discuss compactness later on.

§9.1.3 Uniform Continuity

Recall the standard notion of continuity.

Definition 9.1.20 (Continuity)

Let $A \subseteq \mathbb{C}$ and $f : A \rightarrow \mathbb{C}$. We say that f is **continuous at** $a \in A$ if given any $\epsilon > 0$ we can find a $\delta > 0$ such that $|f(a) - f(x)| < \epsilon$ for all $x \in A$ such that $|x - a| < \delta$.

We say that f is **continuous** if it is continuous at every $a \in A$.

In the above definition, our δ is allowed to depend on both ϵ and x .

Definition 9.1.21 (Uniform Continuity)

Let $A \subset \mathbb{C}$ and $f : A \rightarrow \mathbb{C}$. We say that f is **uniformly continuous** on A if given any $\epsilon > 0$ we can find a $\delta > 0$ such that for all $x, y \in A$ we have $|x - y| < \delta$ implying $|f(x) - f(y)| < \epsilon$.

Here, we again impose this *uniformity* constraint, that is, δ is allowed to depend on ε only.

It's easy to see that uniform continuity implies continuity, but the converse doesn't hold in general.

Example 9.1.22 (Uniformly Continuous Function)

We will show that $f(x) = 2x + 17$ is uniformly continuous over $\mathbb{R}$.

Given $\varepsilon > 0$, let $\delta = \varepsilon/2$. Then for all $x, y \in \mathbb{R}$ with $|x - y| < \delta$ we have $|f(x) - f(y)| = 2|x - y| < \varepsilon$, as required.

Example 9.1.23 (A Non-Uniformly Continuous Function)

The function $f(x) = x^2$ over $\mathbb{R}$ is continuous, but not uniformly continuous.

Consider $\varepsilon = 1$. Then given some δ , let $x = 1/\delta$ and $y = 1/\delta + \delta/2$. Then we have $|x - y| < \delta$ but $|f(x) - f(y)| = 1 + \delta^2/4 > 1 = \varepsilon$, so f is not uniformly continuous.

Here, our uniform continuity was shown to not hold by taking larger and larger x , which forced the slope of the function to get too large for a given value of δ to be sufficient. It turns out that this is the only failure point of uniform continuity, and indeed continuity implies uniform continuity when we are working over a bounded interval.

The proof of this is quite natural – we use Bolzano-Weierstrass to show that a contradiction to uniform continuity is a contradiction to continuity.³

Theorem 9.1.24 (Continuous Functions are Uniformly Continuous)

Let $f : [a, b] \rightarrow \mathbb{C}$ be continuous. Then f is uniformly continuous.

Proof. Suppose f was not uniformly continuous, that is, there exists some $\epsilon > 0$ such that for all $\delta > 0$ there is some x, y with $|x - y| < \delta$ such that $|f(x) - f(y)| \geq \epsilon$.

Taking $\delta = 1/n$, we can find some sequences $x_n, y_n \in [a, b]$ such that $|x_n - y_n| < 1/n$, and $|f(x_n) - f(y_n)| \geq \epsilon$. Then by Bolzano-Weierstrass, we can find some convergent subsequence $x_{n_j} \rightarrow x$ for some $x \in [a, b]$. But then $|x_{n_j} - y_{n_j}| < 1/n_j$ for all j , so we must have $y_{n_j} \rightarrow x$ also.

Then $|f(x_{n_j}) - f(y_{n_j})| \geq \epsilon$ for every j , which implies that $f(x_{n_j})$ and $f(y_{n_j})$ cannot converge to the same value. But then by continuity we have $f(x_{n_j}) \rightarrow f(x)$ and $f(y_{n_j}) \rightarrow f(x)$, which is a contradiction. Thus f must be uniformly continuous. $\square$

With this result, we can prove the familiar result that continuous functions are integrable.

Theorem 9.1.25 (Continuous Functions are Integrable)

Let $f : [a, b] \rightarrow \mathbb{R}$ be continuous. Then f is Riemann integrable.

³Another argument which is more direct can be made using compactness, but we will look past this for now.

Proof. Given $\epsilon > 0$, since f is uniformly continuous, there is some $\delta > 0$ such that $|f(x) - f(y)| < \epsilon/(b-a)$ whenever $|x - y| < \delta$ and $x, y \in [a, b]$.

Now choose some integer n large enough that $(b-a)/n < \delta$, and define the dissection $\mathcal{D} = \{x_0, x_1, \dots, x_n\}$ with $x_j = a + j(b-a)/n$. Then we have

$$\sup_{x \in [x_{j-1}, x_j]} f(x) - \inf_{x \in [x_{j-1}, x_j]} f(x) \leq \frac{\epsilon}{(b-a)},$$

for all $1 \leq j \leq n$, and thus

$$\begin{aligned} S_{\mathcal{D}}(f) - s_{\mathcal{D}}(f) &= \sum_{j=1}^n (x_j - x_{j-1}) \left[\sup_{x \in [x_{j-1}, x_j]} f(x) - \inf_{x \in [x_{j-1}, x_j]} f(x) \right] \\ &\leq \sum_{j=1}^n \frac{b-a}{n} \cdot \frac{\epsilon}{b-a} = \epsilon, \end{aligned}$$

and thus f is Riemann integrable. $\square$

§9.2 Metric Spaces

§9.2.1 Defining Metric Spaces

In $\mathbb{R}$ and $\mathbb{C}$, we measured the ‘closeness’ of two points x, y using $|x - y|$. We used this throughout our study of analysis both in this course and previously, and possibly the most important property of this was the triangle inequality,

$$|x - z| \leq |x - y| + |y - z|.$$

The triangle inequality acts, more or less, as saying that being close is *transitive*. That is, if x is close to y , and y is close to z , then x is close to z .

In fact, we can abstract away quite naturally from the absolute value into a more general setting in which a measure of distance has this property.

Definition 9.2.1 (Metric)

Let M be a set. A **metric** on M is a function $d : M \times M \rightarrow \mathbb{R}$ such that

- *Positivity.* For all $x, y \in M$, $d(x, y) \geq 0$, with equality if and only if $x = y$.
- *Symmetry.* For all $x, y \in M$, $d(x, y) = d(y, x)$.
- *Triangle inequality.* For all $x, y, z \in M$,

$$d(x, z) \leq d(x, y) + d(y, z).$$

Definition 9.2.2 (Metric Space)

A **metric space** is a pair (M, d) where M is a set and d is a metric on M .

Example 9.2.3 (Metric Spaces on $\mathbb{R}$)

The real line $\mathbb{R}$ is a metric space under the metric $d(x, y) = |x - y|$. In fact, any subset of $\mathbb{R}$ is a metric space with the same metric.

Example 9.2.4 (Euclidean Space $\mathbb{R}^n$)

In $\mathbb{R}^n$, we can define the **Euclidean norm** of $x \in \mathbb{R}^n$ by

$$\|x\| = \|x\|_2 = \left(\sum_{k=1}^n |x_k|^2 \right)^{\frac{1}{2}}.$$

This satisfies the triangle inequality $\|x + y\| \leq \|x\| + \|y\|$. This ‘norm’ then induces a metric on $\mathbb{R}^n$

$$d(x, y) = d_2(x, y) = \|x - y\|_2 = \left(\sum_{k=1}^n |x_k - y_k|^2 \right)^{\frac{1}{2}}.$$

This metric is the **Euclidean distance**, and with it we get a metric space $(\mathbb{R}^n, d_2)$ called **Euclidean space**. This is the standard metric space on $\mathbb{R}^n$.

Remark. We sometimes denote the n -dimensional real or complex Euclidean space by ℓ_2^n . The Euclidean norm is called the ℓ_2 -norm, and the corresponding Euclidean distance is called the ℓ_2 -metric.

Example 9.2.5 (Taxicab Metric)

It’s also possible to use the **taxicab metric** on $\mathbb{R}^n$, given by

$$d(x, y) = \sum_{k=1}^n |x_k - y_k|.$$

This is also known as the ℓ_1 -metric.

Example 9.2.6 (ℓ_∞ Metric)

In $\mathbb{R}^n$ or $\mathbb{C}^n$, we can define the ℓ_∞ norm of x by

$$\|x\|_\infty = \max_{1 \leq k \leq n} |x_k|,$$

and then we can define the **ℓ_∞ -metric** by

$$d(x, y) = \|x - y\|_\infty = \max_{1 \leq k \leq n} |x_k - y_k|.$$

We then get a metric space which we denote by ℓ_∞^n .

To get some feeling for how these three metrics on $\mathbb{R}^n$ differ, it’s instructive to look at the ‘unit circle’ $\{x \mid d(x, 0) = 1\}$ in each of them. In the plane, we get a diamond, a circle and a square respectively.

In particular, distances measured in these metrics differ, but not by much – each of these unit circles can be sandwiched between scaled copies of the others. We will return to this observation when we discuss *equivalence* of metrics.

Example 9.2.7 (Uniform Metric)

Let S be a set, and let $\ell_\infty(S)$ be the set of all bounded scalar functions on S . We define the ℓ_∞ -norm of $f \in \ell_\infty(S)$ by

$$\|f\| = \|f\|_\infty = \sup_{x \in S} |f(x)|,$$

also called the sup norm or the uniform norm. From this we can define $d(f, g) = \|f - g\|_\infty$ called the **uniform metric** on $\ell_\infty(S)$.

Example 9.2.8 (L_p -Norm)

Let $\mathcal{C}[a, b]$ be the set of all continuous functions defined on the closed and bounded interval $[a, b]$. Then for $p \geq 1$ we can define the **L_p -norm** of $f \in \mathcal{C}[a, b]$ by

$$\|f\|_p = \left(\int_a^b |f(x)|^p dx \right)^{1/p}.$$

This defines^a the **L_p -metric**, $d_p(f, g) = \|f - g\|_p$.

^aIf you want to check that d_p satisfies the metric space axioms, you do need the *Minkowski inequality*, which we will not discuss.

Example 9.2.9 (Discrete Metric)

Let M be any set. Then

$$d(x, y) = \begin{cases} 0 & \text{if } x = y, \\ 1 & \text{if } x \neq y. \end{cases}$$

defines the metric called the **discrete metric**, and (M, d) is called a **discrete metric space**.

Example 9.2.10 (Word Metric)

Let G be a group generated by $S \subset G$, where $e \notin S$ and $x \in S$ implies $x^{-1} \in S$.

Then

$$d(x, y) = \min\{n \geq 0 \mid \text{there exists } s_1, \dots, s_n \in S \text{ such that } y = xs_1 \cdots s_n\}$$

defines the **word metric**.

Example 9.2.11 (p -adic Metric)

Fix a prime $p \in \mathbb{N}$. We define

$$d(x, y) = \begin{cases} 0 & \text{if } x = y, \\ p^{-n} & \text{if } x \neq y \text{ where } x - y = p^n m \text{ with } p \nmid m. \end{cases}$$

defines a metric on $\mathbb{Z}$ called the **p -adic metric**.

§9.2.2 Subspaces

As with many mathematical objects, it can be useful to discuss the substructure to a metric space.

Definition 9.2.12 (Subspace)

Let (M, d) be a metric space and let $N \subset M$. Then d is a metric on N , and (N, d) is a **subspace** of M .

Example 9.2.13 ($\mathbb{Q}$ is a subspace of $\mathbb{R}$)

$\mathbb{Q}$ with the metric $d(x, y) = |x - y|$ is a subspace of $\mathbb{R}$.

Example 9.2.14 ($\mathcal{C}[a, b]$ is a subspace of $\ell_\infty([a, b])$)

Since every continuous function on a closed, bounded interval is bounded, it follows that $\mathcal{C}[a, b]$ is a subset of $\ell_\infty([a, b])$, so $\mathcal{C}[a, b]$ with the uniform metric is a subspace of $\ell_\infty([a, b])$.

Given two metric spaces, there is a number of natural construction of another metric space which has those two metric spaces as subspaces.

Definition 9.2.15 (Product Space)

Let (M, d) and (M', d') be metric spaces. Then each of the following defines a metric on $M \times M'$:

$$\begin{aligned} d_1((x, x'), (y, y')) &= d(x, y) + d'(x', y'), \\ d_2((x, x'), (y, y')) &= (d(x, y)^2 + d'(x', y')^2)^{1/2}, \\ d_\infty((x, x'), (y, y')) &= \max\{d(x, y), d'(x', y')\}. \end{aligned}$$

We denote the metric space $(M \times M', d_p)$ by $M \oplus_p M'$.

Remark. There is no canonical choice of which of $\{d_1, d_2, d_\infty\}$ we take as the product

metric. Indeed, it's straightforward to show that

$$d_\infty \leq d_2 \leq d_1 \leq 2d_\infty,$$

and later on when we discuss concepts such as convergence we will see that because of this fact, the exact choice of metric doesn't matter *that* much.

Of course, this construction extends naturally to any finite number of metric spaces.

§9.2.3 Convergence

Metric spaces give us a measure of closeness, and we know that in $\mathbb{R}$ and $\mathbb{C}$ that convergence is really just a notion of a sequence getting close to some 'limiting value'. Indeed, convergence as we defined it before directly translates into the language of metric spaces.

Definition 9.2.16 (Convergence)

Let (M, d) be a metric space. A sequence $a_1, a_2, \dots \in M$ is said to **converge** to the limit $a \in M$ if given any $\varepsilon > 0$, we can find an integer N such that $d(a_n, a) < \varepsilon$ for all $n \geq N$. We write $a_n \rightarrow a$ as $n \rightarrow \infty$.

A straightforward but useful thing to note is that this definition implies $a_n \rightarrow a$ if and only if $d(a_n, a) \rightarrow 0$ in $\mathbb{R}$.

Now we need to go back to all of the theorems about convergence that were proved in an earlier Analysis course and check if they still hold for a general Metric space (that is, if they don't really use the structure of $\mathbb{R}$, apart from closeness).

Lemma 9.2.17 (Uniqueness of Limits)

If $a_n \rightarrow a$ and $a_n \rightarrow b$ in a metric space M , then $a = b$.

Proof. Assume that $a \neq b$. Given any $\epsilon > 0$, we can find integers N_1 and N_2 such that

$$\begin{aligned} d(a_n, a) &\leq \epsilon, & \text{for all } n \geq N_1 \\ d(a_n, b) &\leq \epsilon, & \text{for all } n \geq N_2 \end{aligned}$$

Then letting $\epsilon = d(a, b)/3$ and taking $N = \max\{N_1, N_2\}$, we have by the triangle inequality

$$d(a, b) \leq d(a, a_n) + d(a_n, b) \leq 2\epsilon = \frac{2}{3}d(a, b)$$

for all $n \geq N$. Thus we must have $d(a, b) = 0$, and $a = b$, contradicting our assumption. $\square$

Lemma 9.2.18 (Convergence of Subsequences)

If $a_n \rightarrow a$ as $n \rightarrow \infty$ in a metric space M , and $n(1) < n(2) < \dots$, then $a_{n(j)} \rightarrow a$ as $j \rightarrow \infty$.

Proof Sketch. Take the old proof from $\mathbb{R}$ and $\mathbb{C}$ and replace the absolute values with the metric! $\square$

§9.2.4 Continuity

As with convergence, we also get a direct generalization of the notion of continuity.

Definition 9.2.19 (Continuity)

Let $f : M \rightarrow M'$ be a function between metric spaces (M, d) and (M', d') . Then for $a \in M$, we say that f is **continuous** at a if given any $\varepsilon > 0$ we can find a $\delta > 0$ such that $d'(f(x), f(a)) < \varepsilon$ for all $x \in M$ such that $d(x, a) < \delta$.

We say that f is **continuous** if f is continuous at a for all $a \in M$.

Proposition 9.2.20 (Sequence Definition of Continuity)

Let $f : M \rightarrow M'$ be a function between metric spaces, and let $a \in M$. Then f is continuous at a if and only if $x_n \rightarrow a$ in M implies that $f(x_n) \rightarrow f(a)$ in M' .

We also keep the same standard properties of continuity as before.

Proposition 9.2.21 (Sums, Products, and Reciprocals of Continuous Functions)

Let $f, g : M \rightarrow \mathbb{R}$ be scalar functions on a metric space M . Then the following hold.

- (i) If f and g are continuous at a , then so is their sum $f + g$.
- (ii) If f and g are continuous at a , then so is their product fg .
- (iii) If $N = \{x \in M \mid g(x) \neq 0\}$, then if f and g are continuous at $a \in N$, then so is f/g .

Proposition 9.2.22 (The Composition of Continuous Functions is Continuous)

Let $f : M \rightarrow M'$ and $g : M' \rightarrow M''$ with M, M', M'' all metric spaces. Then if f is continuous at $a \in M$ and g is continuous at $f(a)$, then $g \circ f$ is also continuous at a .

Example 9.2.23 (Constant Function)

Consider the constant function $f : M \rightarrow M'$ with $f(x) = b$ for some $b \in M'$. Then f is continuous.

Example 9.2.24 (Identity Function)

Consider the identity function $\text{id} : M \rightarrow M$. This is continuous at all $a \in M$, as given $\varepsilon > 0$ we can take $\delta = \varepsilon$, and if $d(x, a) < \delta$ then $d(\text{id}(x), \text{id}(a)) = d(x, a) < \delta = \varepsilon$.

Example 9.2.25 (Polynomials)

Using the examples above, we get that polynomials are always continuous.

Example 9.2.26 (Metrics are Continuous)

Let (M, d) be a metric space. Then d is a function between metric spaces, $d : M \oplus_p M \rightarrow \mathbb{R}$ (where we take some $p \in \{1, 2, \infty\}$).

Given $v = (x, x')$ and $w = (y, y') \in M \oplus_p M$, then

$$|d(v) - d(w)| = |d(x, x') - d(y, y')| \leq d(x, y) + d(x', y') = d_1(v, w) \leq 2d_p(v, w).$$

So $\delta = \varepsilon/2$ will do.

Definition 9.2.27 (Isometric and Lipschitz)

Let $f : M \rightarrow M'$ be a function between metric spaces. Then f is **isometric** if for all $x, y \in M$ we have $d'(f(x), f(y)) = d(x, y)$.

We say that f is **Lipschitz** if there exists some $c \in \mathbb{R}^+$ such that $d'(f(x), f(y)) \leq cd(x, y)$.

Definition 9.2.28 (Uniform Continuity)

Let $f : M \rightarrow M'$ be a function between metric spaces. We say that f is **uniformly continuous** if given $\varepsilon > 0$, there exists some $\delta > 0$ such that for all $x, y \in M$ with $d(x, y) < \delta$ we have $d'(f(x), f(y)) < \varepsilon$.

We can easily see that f isometric implies that it's Lipschitz, and f Lipschitz implies that it's uniformly continuous. Also, if f is isometric then it must be injective (but not necessarily surjective). If f is also surjective then we call it a **isometry**.

If there exists an isometry between two metric spaces M and M' , we say that they are **isometric**.

Example 9.2.29

Let (M, d) and (M', d') be metric spaces, and fix some $y \in M'$. Then if we define $f : M \rightarrow M \oplus_p M'$ by $f(x) = (x, y)$, we have $d_p(f(x), f(z)) = d_p((x, y), (z, y)) = d(x, z)$. So f is an isometry, and $M \times \{y\}$ is an isometric copy of M in the space $M \oplus_p M'$.

§9.2.5 The Topology of a Metric Space

While we will discuss topology and topological spaces later, it's worth looking at a few of the core ideas in the context of metric spaces.

It seems that there are some concepts in metric spaces that don't *really* rely on the metric, just about the closeness of points. The point of this section is looking to see exactly what type of relations are these, so that we can generalize them to a setting where we don't use a metric.

We begin with the familiar concept of an open ball.

Definition 9.2.30 (Open Ball)

Let M be a metric space, $x \in M$ and $r > 0$. The **open ball** in M of center x and radius r is the set $D_r(x)$ given by

$$D_r(x) = \{y \in M \mid d(x, y) < r\}.$$

The idea of open balls is a natural one, and it even fits naturally into some of our previous definitions.

For example, we say that $x_n \rightarrow x$ in M if and only if for all $\varepsilon > 0$, there is some positive integer N such that $n \geq N$ implies that $x_n \in D_\varepsilon(x)$.

Similarly, for a function $f : M \rightarrow M'$ we say that f is continuous at $x \in M$ if and only if for all $\varepsilon > 0$ there exists some $\delta > 0$ such that $f(D_\delta(x)) \subset D_\varepsilon(f(x))$.

Definition 9.2.31 (Closed Ball)

Let M be a metric space, $x \in M$ and $r > 0$. The **closed ball** in M of center x and radius r is the set $B_r(x)$ given by

$$B_r(x) = \{y \in M \mid d(x, y) \leq r\}.$$

Example 9.2.32 (Open and Closed Ball in $\mathbb{R}$)

In $\mathbb{R}$, we have $D_r(x) = (x - r, x + r)$, and $B_r(x) = [x - r, x + r]$.

We now move to define some concepts that will be a little less straightforward, but should come together later on as we discuss more topology.

Definition 9.2.33 (Neighborhood)

Let M be a metric space, and let $U \subset M$. For $x \in M$, we say that U is a **neighborhood** of x in M if there exists some $r > 0$ such that $D_r(x) \subset U$.

Definition 9.2.34 (Open)

We say that U is **open** in M if for all x in U there is some $r > 0$ such that $D_r(x) \subset U$. That is, if U is a neighborhood for all of its points.

Example 9.2.35 (Upper Half of the Complex Plane is Not Open)

Consider the set $H = \{z \in \mathbb{C} \mid \operatorname{Im} z \geq 0\}$. Then let $w \in H$, and let $\delta = \operatorname{Im} w$. If $\delta > 0$, then $D_\delta(w) \subset H$, and if $\delta = 0$, then for all $r > 0$ $D_r(w) \not\subset H$. Thus H is not open.

We commonly use the seeming tautological fact that open balls are open.

Lemma 9.2.36

Open balls are open.

Proof. Consider some open ball $D_r(x)$ in a metric space M . Then let $y \in D_r(x)$, and set $\delta = r - d(x, y)$. Then $\delta > 0$, and if $z \in D_\delta(y)$ then

$$d(z, x) \leq d(z, y) + d(y, x) < \delta + d(x, y) = r,$$

so $z \in D_r(x)$. This shows that $D_\delta(y) \subset D_r(x)$. $\square$

Corollary 9.2.37

Let M be a metric space, $U \subset M$ and $x \in M$. Then U is a neighborhood of x if and only if there exists an open subset V of M such that $x \in V \subset U$.

Proof Sketch. Check definitions. $\square$

This notion of neighborhoods and open sets is sufficient to describe both convergence and continuity in a metric space on its own.

Proposition 9.2.38 (Convergence using Open Sets & Neighborhoods)

In a metric space M , the following are equivalent.

- (i) $x_n \rightarrow x$;
- (ii) For all neighborhoods U of x in M , there exists some positive integer N such that $n \geq N$ implies $x_n \in U$;
- (iii) For all open subsets U of M with $x \in U$, there is a positive integer N such that for all $n \geq N$ we have $x_n \in U$.

Proof. (i) implies (ii). Let U be a neighborhood of x in M . Then by definition there exists some $\varepsilon > 0$ such that $D_\varepsilon(x) \subset U$. Then since $x_n \rightarrow x$, there's an $N \in \mathbb{N}$ such that $n \geq N$ implies $d(x_n, x) < \varepsilon$, that is, $x_n \in D_\varepsilon(x)$.

(ii) implies (iii). This is clear since any open set U with $x \in U$ is a neighborhood of x .

(iii) implies (i). Given some $\varepsilon > 0$, $U = D_\varepsilon(x)$ is open and $x \in U$. Then by (iii) there's an $N \in \mathbb{N}$ such that $n \geq N$ implies $x_n \in U$, that is, $d(x_n, x) < \varepsilon$. $\square$

Proposition 9.2.39 (Local Continuity using Open Sets & Neighborhoods)

Let $f : M \rightarrow M'$ be a function between metric spaces, and let $x \in M$. Then the following are equivalent:

- (i) f is continuous at x ;
- (ii) For all neighborhoods V of $f(x)$ in M' , there exists a neighborhood U of x in M such that $f(U) \subset V$;
- (iii) For all neighborhoods V of $f(x)$ in M' , $f^{-1}(V)$ is a neighborhood of x in M .

Proof. (i) implies (ii). Let V be a neighborhood of $f(x)$ in M' . Then by definition

there exists some $\varepsilon > 0$ such that $D_\varepsilon(f(x)) \subset V$. Since f is continuous at x , there exists $\delta > 0$ such that $f(D_\delta(x)) \subset D_\varepsilon(f(x))$. Then $U = D_\delta(x)$ is a neighborhood of x in M , and $f(U) \subset V$.

(ii) *implies* (iii). Let V be a neighborhood of $f(x)$ in M' . Then by (ii) there is a neighborhood U of x in M such that $f(U) \subset V$. Then $U \subset f^{-1}(V)$, and since U is a neighborhood of x in M , there is some $r > 0$ with $D_r(x) \subset U \subset f^{-1}(V)$. Thus $f^{-1}(V)$ is a neighborhood of x in M .

(iii) *implies* (i). Given $\varepsilon > 0$, $V = D_\varepsilon(f(x))$ is a neighborhood of $f(x)$ in M' . By (iii), $f^{-1}(V)$ is a neighborhood of x in M . So there exists $\delta > 0$ with $D_\delta(x) \subset f^{-1}(V)$. Then $f(D_\delta(x)) \subset V = D_\varepsilon(f(x))$. $\square$

Proposition 9.2.40 (Global Continuity using Open Sets & Neighborhoods)

Let $f : M \rightarrow M'$ be a function between metric spaces. Then the following are equivalent:

- (i) f is continuous;
- (ii) $f^{-1}(V)$ is open in M for all open subsets V of M' .

Proof. (i) *implies* (ii). Let V be open in M' . Let $x \in f^{-1}(V)$. Then $f(x) \in V$. Since V is open, there's some $\varepsilon > 0$ such that $D_\varepsilon(f(x)) \subset V$. Since f is continuous at x , there's a $\delta > 0$ such that $f(D_\delta(x)) \subset D_\varepsilon(f(x))$. Therefore $D_\delta(x) \subset f^{-1}(D_\varepsilon(f(x))) \subset f^{-1}(V)$. Thus $f^{-1}(V)$ is open in M .

(ii) *implies* (i). Let $x \in M$, and let $\varepsilon > 0$. Then $V = D_\varepsilon(f(x))$ is open in M' . By (ii) $f^{-1}(V)$ is open in M , also $x \in f^{-1}(V)$ and $f(x) \in V$. Then by definition there's a $\delta > 0$ such that $D_\delta(x) \subset f^{-1}(V)$, so $f(D_\delta(x)) \subset V = D_\varepsilon(f(x))$. $\square$

We can now write down what the *topology* of a metric space is. We are going to study topology in general later on, but we can use some properties that occur here to inform how we define things more generally afterwards.

Definition 9.2.41 (Topology of a Metric Space)

The **topology** of a metric space M is the family of all open subsets of M .

Proposition 9.2.42 (Basic Properties)

The topology of a metric space satisfies the following.

- (i) $\emptyset$ and M are open.
- (ii) If U_i is open in M for all i in some index set I , then $\bigcup_{i \in I} U_i$ is open in M .
- (iii) U, V open in M implies $U \cap V$ open in M .

Proof. Part (i). This is clear.

Part (ii). Given $x \in \bigcup_{i \in I} U_i$, then there's some $i_0 \in I$ with $x \in U_{i_0}$. Then U_{i_0} is open, so by definition there's an $r > 0$ with $D_r(x) \subset U_{i_0} \subset \bigcup_{i \in I} U_i$.

Part (iii). Given $x \in U \cap V$, since U is open and $x \in U$, there's an $r > 0$ with $D_r(x) \subset U$, and since V is open and $x \in V$, there's an $s > 0$ with $D_s(x) \subset V$. Then letting $t = \min\{r, s\}$, we have $t > 0$ and $D_t(x) = D_r(x) \cap D_s(x) \subset U \cap V$. $\square$

Definition 9.2.43 (Closed)

A subset A of a metric space M is **closed** in M if for every sequence $x_n \in A$ that is convergent in M , we have $\lim_{n \rightarrow \infty} x_n \in A$.

Lemma 9.2.44

Closed balls are closed.

Proof. Consider $B_r(x) = \{y \in M \mid d(y, x) \leq r\}$ in a metric space M , and a sequence $x_n \in B_r(x)$ such that $x_n \rightarrow z$. We need to show that $z \in B_r(x)$. We have

$$\begin{aligned} d(z, x) &\leq d(z, x_n) + d(x_n, x) \\ &\leq d(z, x_n) + r \rightarrow r \end{aligned}$$

as $n \rightarrow \infty$. Thus $d(z, x) \leq r$, and hence $z \in B_r(x)$. $\square$

Example 9.2.45 (Closed but Not Open, and Open but Not Closed Sets)

The set $[0, 1] = B_{\frac{1}{2}}(1/2)$ is closed in $\mathbb{R}$. $[0, 1]$ is not open, for example $D_r(0) \not\subset [0, 1]$ for any $r > 0$.

The set $(0, 1) = D_{\frac{1}{2}}(1/2)$ is open, but it is not closed. Take $1/(n+1) \in (0, 1)$ for all $n \in \mathbb{N}$. Then $1/(n+1) \rightarrow 0$ in $\mathbb{R}$ but $0 \notin (0, 1)$.

Example 9.2.46 (An Open and Closed Set)

$\mathbb{R}$ is open and closed in $\mathbb{R}$.

Example 9.2.47 (A Neither Open or Closed Set)

The set $(0, 1]$ in $\mathbb{R}$ is neither open nor closed.

Lemma 9.2.48 (Relating Closed and Open)

Let A be a subset of a metric space M . Then A is closed in M if and only if $M \setminus A$ is open in M .

Proof. Assume A is closed, and that $M \setminus A$ is not open. Then there exists $x \in M \setminus A$ such that for all $r > 0$ we have $D_r(x) \not\subset M \setminus A$. Hence for all n there exists $x_n \in D_{1/n}(x) \cap A$. Then $d(x_n, x) < 1/n \rightarrow 0$, so $x_n \rightarrow x$ in M and $x_n \in A$ for all n , which contradicts that A is closed.

Now suppose that $M \setminus A$ is open but A is not closed. Then there exists some sequence

x_n in A such that $x_n \rightarrow x$ in M but $x \notin A$. Since $x \in M \setminus A$ and $M \setminus A$ is open, there exists $\varepsilon > 0$ with $D_\varepsilon(x) \subset M \setminus A$. Then since $x_n \rightarrow x$, there is some $N \in \mathbb{N}$ such that for all $n \geq N$ we have $x_n \in D_\varepsilon(x)$, and hence $x_n \in M \setminus A$, which is a contradiction. $\square$

We previously met isometries, which were maps between metric spaces that preserved the distance function. Now that we are trying to look slightly away from metrics and more towards open sets and neighborhoods, it's natural to think of a new definition of a function between metric spaces that preserves open sets.

Definition 9.2.49 (Homeomorphism)

A map $f : M \rightarrow M'$ between metric spaces is a **homeomorphism** if f is a bijection, and f and f^{-1} are both continuous.

Equivalently, f is a homeomorphism if for all open sets V in M' , $f^{-1}(V)$ is open in M , and for all open sets U in M , $f(U)$ is open in M' .

If there is a homeomorphism between M and M' , we say that M and M' are **homeomorphic**.

Example 9.2.50

The metric spaces $(0, \infty)$ and $(0, 1)$ are homeomorphic, with the homeomorphism $x \mapsto 1/(x+1)$ and inverse $x \mapsto 1/x - 1$.

While it is true that every isometry is a homeomorphism, the converse is absolutely false.

We will say that two metrics on a set are equivalent if they induce the same topology.

Definition 9.2.51 (Equivalent Metrics)

Let d and d' be metrics on a set M . We say that d and d' are **equivalent**, denoted $d \sim d'$, if they define the same topology on M . That is, for $U \subset M$, U is open in (M, d) if and only if U is open in (M, d') .

So $d \sim d'$ if and only if $\text{id} : (M, d) \rightarrow (M, d')$ is a homeomorphism.

Note that if $d \sim d'$, then (M, d) and (M, d') have the same convergent sequences and the same continuous maps.

Definition 9.2.52 (Uniformly and Lipschitz Equivalent)

Let d and d' be metrics on a set M . We say that d and d' are **uniformly equivalent** if $\text{id} : (M, d) \rightarrow (M, d')$ and $\text{id} : (M, d') \rightarrow (M, d)$ are uniformly continuous, and write $d \sim_u d'$.

We will say d and d' are **Lipschitz equivalent** if these functions are Lipschitz, and write $d \sim_{Lip} d'$.

Note that $d \sim_{Lip} d'$ if and only if there exists $a > 0$ and $b > 0$ such that

$$ad(x, y) \leq d'(x, y) \leq bd(x, y),$$

and also note that $d \sim_{Lip} d'$ implies $d \sim_u d'$ implies $d \sim d'$.

Example 9.2.53

Given a metric space (M, d) , $d'(x, y) = \min\{1, d(x, y)\}$ defines a metric on M , and $d' \sim_u d$.

Example 9.2.54

On a product space $M \times M'$, the metrics d_1 , d_2 and d_∞ are pairwise Lipschitz equivalent.

Example 9.2.55

On $C[0, 1]$, the L_1 -metric and the uniform metric are *not* equivalent.

We will return to these topological ideas later on.

§9.3 Completeness and the Contraction Mapping Theorem

§9.3.1 Completeness

In $\mathbb{R}$ and $\mathbb{C}$, every Cauchy sequence is convergent. In what other spaces is this true?

Definition 9.3.1 (Cauchy Sequence)

A sequence x_n in a metric space M is **Cauchy** if given $\varepsilon > 0$, there's some positive integer N such that $n, m \geq N$ implies that $d(x_n, x_m) < \varepsilon$.

Definition 9.3.2 (Bounded)

A sequence x_n in a metric space M is **bounded** if there exists some $z \in M$ and $r > 0$ such that for all n we have $x_n \in B_r(z)$.

Lemma 9.3.3 (Convergent Implies Cauchy Implies Bounded)

Every convergent sequence is Cauchy, and every Cauchy sequence is bounded.

Proof. Let x_n be a sequence in metric space M .

Suppose x_n is convergent in M , and let $x = \lim_{n \rightarrow \infty} x_n$. Given $\varepsilon > 0$, there is some positive integer N such that $n \geq N$ implies $d(x_n, x) < \varepsilon/2$. Then for all $m, n \geq N$, $d(x_m, x_n) \leq d(x_m, x) + d(x, x_n) < \varepsilon$. Thus if a sequence converges, then it's Cauchy.

Now assume that x_n is Cauchy in M . Then there's a positive integer N such that for all $m, n \geq N$ we have $d(x_m, x_n) < 1$. In particular, $d(x_n, x_N) < 1$ for $n \geq N$, that is, $x_n \in B_1(x_N)$ for $n \geq N$. So let $r = \max\{d(x_1, x_N), \dots, d(x_{N-1}, x_N), 1\}$. Then $x_n \in B_r(x_N)$ for all $n \in \mathbb{N}$, and so x_n is bounded. $\square$

In general, being bounded does not imply that a sequence is Cauchy (for example, take the sequence $0, 1, 0, 1, \dots$).

Slightly more subtle is that being Cauchy doesn't imply convergence, and we can construct a somewhat silly example. For example, $x_n = 1/n$ is Cauchy but doesn't converge in the metric space $(0, \infty)$. It seems that this example works because there's something 'missing' from the metric space – the limit of a sequence. Indeed, in this section we will care about metric spaces where such an implication *does hold*, in 'complete' metric spaces.

Definition 9.3.4 (Completeness)

A metric space M is **complete** if every Cauchy sequence in M converges in M .

Example 9.3.5

$\mathbb{R}$ and $\mathbb{C}$ are complete.

Proposition 9.3.6

If M and M' are complete metric spaces, then so is $M \oplus_p M'$.

Proof. Let $z_n = (x_n, x'_n)$ be a Cauchy sequence in $M \oplus_p M'$. Since $d(x_m, x_n) \leq d_p(z_m, z_n)$ and $d'(x'_m, x'_n) \leq d_p(z_m, z_n)$, both x_n and x'_n are Cauchy in M and M' respectively. By completeness, $x_n \rightarrow x$ in M and $x'_n \rightarrow x'$ in M' , and then letting $z = (x, x')$ we have

$$d_p(z_n, z) \leq d_1(z_n, z) = d(x_n, x) + d'(x'_n, x') \rightarrow 0,$$

so $z_n \rightarrow z$ in $M \oplus_p M'$. □

Example 9.3.7

$\mathbb{R}^n$ and $\mathbb{C}^n$ are complete in the ℓ_p -metric.

Theorem 9.3.8 (Completeness of a Function Space)

Let S be any set. Then $\ell_\infty(S)$ is complete in the uniform metric D .

Proof. Let f_n be a Cauchy sequence in $\ell_\infty(S)$. Then given $\varepsilon > 0$, there is some positive integer N such that for all $n, m \geq N$ we have

$$D(f_m, f_n) = \sup_{x \in S} |f_m(x) - f_n(x)| < \varepsilon.$$

So f_n is uniformly Cauchy. By the general principle of uniform convergence, f_n converges uniformly to some function f on S . We also know that f is bounded, so $f \in \ell_\infty(S)$. Now given $\varepsilon > 0$, there's some $N \in \mathbb{N}$ such that for all $n \geq N$ and $x \in S$ we have

$$|f_n(x) - f(x)| < \varepsilon,$$

and thus for $n \geq N$ we have $\sup_{x \in S} |f_n(x) - f(x)| = D(f_n, f) \leq \varepsilon$, so $f_n \rightarrow f$ in $(\ell_\infty(S), D)$. □

Proposition 9.3.9 (Completeness of a Subspace)

Let N be a subspace of a metric space M .

- (i) If N is complete, then N is closed in M .
- (ii) If M is complete and N is closed in M , then N is complete.

Proof. Part (i). Let x_n be a sequence in N and assume that $x_n \rightarrow x$ in M . We then need $x \in N$. Since x_n is convergent in M , x_n must also be Cauchy in M , and thus it is Cauchy in N . Then since N is complete, we must have $x_n \rightarrow y \in N$. But then $x_n \rightarrow y \in M$, and by uniqueness of limits, $y = x$ and $x \in N$.

Part (ii). Let x_n be a Cauchy sequence in N . Then x_n is Cauchy in M . Since M is complete, $x_n \rightarrow x$ in M for some $x \in M$. Since N is closed in M , we have $x \in N$. So $x_n \rightarrow x$ in N . $\square$

Theorem 9.3.10

Let (M, d) be a metric space, and define

$$C_b(M) = \{f \in \ell_\infty(M) \mid f \text{ is continuous}\}.$$

This is a subspace of $\ell_\infty(M)$ in the uniform metric D .

Then $C_b(M)$ is complete in the uniform metric.

Proof. It suffices to show that $C_b(M)$ is closed in $\ell_\infty(M)$. Let f_n be a sequence in $C_b(M)$, and assume that $f_n \rightarrow f$ in $\ell_\infty(M)$. We need to show that f is continuous.

Given some $a \in M$ and $\varepsilon > 0$, since $f_n \rightarrow f$ in $\ell_\infty(M)$, we can fix an $n \in \mathbb{N}$ such that $D(f_n, f) < \varepsilon$. Since f_n is continuous at a , there's a $\delta > 0$ such that for all $x \in M$ we have $d(x, a) < \delta$ implying $|f_n(x) - f_n(a)| < \varepsilon$. Hence for all $x \in M$ if $d(x, a) < \delta$ then

$$\begin{aligned} |f(x) - f(a)| &\leq |f(x) - f_n(x)| + |f_n(x) - f_n(a)| + |f_n(a) - f(a)| \\ &\leq 2D(f_n, f) + |f_n(x) - f_n(a)| \\ &\leq 3\varepsilon. \end{aligned}$$

$\square$

Corollary 9.3.11

$C[a, b]$, the space of continuous functions on the closed bounded interval $[a, b]$ is complete in the uniform metric.

This last corollary is going to be surprisingly useful. Completeness of function spaces is what will let us *construct* functions as limits – and in particular, it is the key to proving the existence of solutions to differential equations, as we are about to see.

§9.3.2 The Contraction Mapping Theorem

We now come to the highlight of this section, which is a genuinely useful theorem about complete metric spaces. It concerns *fixed points* of certain well-behaved maps from a metric space to itself.

Definition 9.3.12 (Contraction)

Let (M, d) be a metric space. A map $f : M \rightarrow M$ is a **contraction** if there exists some λ with $0 \leq \lambda < 1$ such that

$$d(f(x), f(y)) \leq \lambda d(x, y),$$

for all $x, y \in M$.

That is, a contraction is a map which is Lipschitz with constant strictly less than 1 – it shrinks distances by a definite factor. In particular every contraction is (uniformly) continuous.

Theorem 9.3.13 (Contraction Mapping Theorem)

Let M be a non-empty complete metric space, and let $f : M \rightarrow M$ be a contraction. Then f has a unique fixed point, that is, there is a unique $z \in M$ such that $f(z) = z$.

Proof. Let $\lambda \in [0, 1)$ be such that $d(f(x), f(y)) \leq \lambda d(x, y)$ for all $x, y \in M$.

We first show uniqueness. If $f(z) = z$ and $f(w) = w$, then

$$d(z, w) = d(f(z), f(w)) \leq \lambda d(z, w),$$

and since $\lambda < 1$ this forces $d(z, w) = 0$, so $z = w$.

Now for existence, the idea is to just pick a point and repeatedly apply f , and show that the sequence we get is Cauchy. So fix any $x_0 \in M$ (using non-emptiness), and define the sequence $x_n = f(x_{n-1})$ for $n \geq 1$. Applying the contraction property repeatedly,

$$d(x_n, x_{n+1}) = d(f(x_{n-1}), f(x_n)) \leq \lambda d(x_{n-1}, x_n) \leq \cdots \leq \lambda^n d(x_0, x_1).$$

Then for $m \geq n$, the triangle inequality gives

$$d(x_n, x_m) \leq \sum_{k=n}^{m-1} d(x_k, x_{k+1}) \leq \sum_{k=n}^{m-1} \lambda^k d(x_0, x_1) \leq \frac{\lambda^n}{1-\lambda} d(x_0, x_1).$$

Since $\lambda^n/(1-\lambda) \rightarrow 0$ as $n \rightarrow \infty$, given $\varepsilon > 0$ we can find N such that $d(x_n, x_m) < \varepsilon$ for all $m \geq n \geq N$. So the sequence x_n is Cauchy, and since M is complete, $x_n \rightarrow z$ for some $z \in M$.

Finally, f is continuous, so $x_{n+1} = f(x_n) \rightarrow f(z)$, but also $x_{n+1} \rightarrow z$, so by uniqueness of limits $f(z) = z$. $\square$

There is a nice picture of what is going on here for a contraction on $\mathbb{R}$. Starting anywhere and ‘cobwebbing’ between the graph of f and the line $y = x$, the iterates spiral into the fixed point, which is where the graphs cross.

Remark. Letting $m \rightarrow \infty$ in the bound for $d(x_n, x_m)$ in the proof above shows that

$$d(x_n, z) \leq \frac{\lambda^n}{1 - \lambda} d(x_0, x_1),$$

so the iterates converge to the fixed point *exponentially fast*. This makes the contraction mapping theorem practical as a numerical method, not just a theoretical tool.

Both hypotheses in the theorem – completeness of the space, and the Lipschitz constant being strictly less than 1 – are genuinely needed, as the following examples show.

Example 9.3.14 (Completeness is Necessary)

Consider $f : \mathbb{R} \setminus \{0\} \rightarrow \mathbb{R} \setminus \{0\}$ given by $f(x) = x/2$. This is a contraction (with $\lambda = 1/2$), but it has no fixed point – the ‘missing’ fixed point is 0, and the problem is that $\mathbb{R} \setminus \{0\}$ is not complete.

Example 9.3.15 (Shrinking Distances is Not Enough)

Consider $f : [1, \infty) \rightarrow [1, \infty)$ given by $f(x) = x + 1/x$. The domain is closed in $\mathbb{R}$ and hence complete, and it’s easy to check that $|f(x) - f(y)| < |x - y|$ for all $x \neq y$. But f has no fixed point, since $f(x) - x = 1/x > 0$ everywhere.

The issue is that there is no single $\lambda < 1$ that works for *all* pairs of points – the map shrinks distances, but not uniformly so. Similarly, $f(x) = x + 1$ on $\mathbb{R}$ is an isometry ($\lambda = 1$) with no fixed point.

§9.3.3 Application: Solving Differential Equations

At first glance, the contraction mapping theorem might look like a curiosity. Its real power comes from applying it to *function spaces*: if we can express ‘being a solution to a problem’ as ‘being a fixed point of a map on a complete space of functions’, then we get existence and uniqueness of solutions in one stroke. The classic application is to differential equations.

Let’s warm up with a specific example before proving the general theorem.

Example 9.3.16 (An Unusual Differential Equation)

Fix $y_0 \in \mathbb{R}$. We will show that there is a unique differentiable function $f : [0, \frac{1}{2}] \rightarrow \mathbb{R}$

such that $f(0) = y_0$ and

$$f'(t) = f(t^2) \quad \text{for all } t \in [0, \tfrac{1}{2}].$$

First note that if f is such a solution, then f is differentiable and hence continuous, so $f'(t) = f(t^2)$ is also continuous. Then by the fundamental theorem of calculus,

$$f(t) = y_0 + \int_0^t f(s^2) ds.$$

Conversely, if $f \in C[0, \frac{1}{2}]$ satisfies this integral equation, then by the fundamental theorem of calculus (the integrand being continuous) f is differentiable with $f'(t) = f(t^2)$, and $f(0) = y_0$. So solving the differential equation is *equivalent* to solving the integral equation in $C[0, \frac{1}{2}]$.

Now let $M = C[0, \frac{1}{2}]$ with the uniform metric D , which we know is non-empty and complete, and define $T : M \rightarrow M$ by

$$(Tg)(t) = y_0 + \int_0^t g(s^2) ds.$$

By the reasoning above, f solves our problem if and only if $Tf = f$. But for $g, h \in M$ and $t \in [0, \frac{1}{2}]$,

$$|(Tg)(t) - (Th)(t)| = \left| \int_0^t [g(s^2) - h(s^2)] ds \right| \leq t \sup_s |g(s^2) - h(s^2)| \leq \frac{1}{2} D(g, h).$$

Taking the supremum over t , we get $D(Tg, Th) \leq \frac{1}{2} D(g, h)$, so T is a contraction. By the contraction mapping theorem, T has a unique fixed point, which is the unique solution to our differential equation.

Remark. The choice of the interval $[0, \frac{1}{2}]$ mattered only in making the map a contraction – the same argument gives a unique solution f_δ on $[0, \delta]$ for any $\delta < 1$. By uniqueness, these solutions agree on common domains, so they patch together into a unique solution on $[0, 1)$.

The same circle of ideas gives the fundamental existence and uniqueness theorem for ordinary differential equations. Before we state it, we need to make sense of integrating a vector-valued function: for continuous $f = (f_1, \dots, f_n) : [c, d] \rightarrow \mathbb{R}^n$, we integrate coordinate-wise,

$$\int_c^d f(t) dt = \left(\int_c^d f_1(t) dt, \dots, \int_c^d f_n(t) dt \right),$$

and differentiability of such an f also means differentiability of each coordinate, with $f' = (f'_1, \dots, f'_n)$. A useful fact, which follows from the Cauchy-Schwarz inequality⁴, is that

$$\left\| \int_c^d f(t) dt \right\| \leq \int_c^d \|f(t)\| dt \leq (d - c) \sup_{t \in [c, d]} \|f(t)\|.$$

⁴Write $v = \int_c^d f(t) dt$. Then $\|v\|^2 = \sum_k v_k \int f_k = \int \langle v, f(t) \rangle dt \leq \int \|v\| \|f(t)\| dt$, and divide by $\|v\|$.

Theorem 9.3.17 (Picard-Lindelöf)

Let $y_0 \in \mathbb{R}^n$, let $a < b$ be reals, $R > 0$, and let

$$\phi : [a, b] \times B_R(y_0) \rightarrow \mathbb{R}^n$$

be a continuous function. Suppose ϕ is Lipschitz in the second variable, that is, there is some $K > 0$ such that

$$\|\phi(t, x) - \phi(t, y)\| \leq K\|x - y\|$$

for all $t \in [a, b]$ and $x, y \in B_R(y_0)$. Then there exists $\varepsilon > 0$ such that for any $t_0 \in [a, b]$, the initial value problem

$$f'(t) = \phi(t, f(t)), \quad f(t_0) = y_0$$

has a unique solution on $[c, d] = [t_0 - \varepsilon, t_0 + \varepsilon] \cap [a, b]$.

Proof. Since closed balls are closed, $B_R(y_0)$ is closed and bounded in $\mathbb{R}^n$, and one can check (say, coordinate-wise using Bolzano-Weierstrass, as we did for uniform continuity) that a continuous function on a closed bounded subset of $\mathbb{R}^{n+1}$ is bounded^a. So we may set

$$C = \sup\{\|\phi(t, x)\| \mid t \in [a, b], x \in B_R(y_0)\} < \infty,$$

and define $\varepsilon = \min\{R/C, 1/(2K)\}$. Fix $t_0 \in [a, b]$ and let $[c, d] = [t_0 - \varepsilon, t_0 + \varepsilon] \cap [a, b]$.

As before, we convert the problem into an integral equation. By the fundamental theorem of calculus applied coordinate-wise, a function $f : [c, d] \rightarrow B_R(y_0)$ solves the initial value problem if and only if f is continuous and

$$f(t) = y_0 + \int_{t_0}^t \phi(s, f(s)) ds \quad \text{for all } t \in [c, d].$$

Now we set up our function space. Since $B_R(y_0)$ is closed in the complete space $\mathbb{R}^n$, it is complete, and hence the space $M = C([c, d], B_R(y_0))$ of continuous functions $[c, d] \rightarrow B_R(y_0)$ is complete in the uniform metric D (as before, being uniformly Cauchy implies uniform convergence, and the uniform limit of continuous functions into a closed set is continuous into that set). It's also non-empty, as it contains the constant function $t \mapsto y_0$.

Define $T : M \rightarrow M$ by

$$(Tg)(t) = y_0 + \int_{t_0}^t \phi(s, g(s)) ds.$$

We should check this is well defined. If $g \in M$ then $s \mapsto \phi(s, g(s))$ is continuous, so the integral makes sense and Tg is continuous (indeed differentiable). Moreover for $t \in [c, d]$,

$$\|(Tg)(t) - y_0\| = \left\| \int_{t_0}^t \phi(s, g(s)) ds \right\| \leq |t - t_0| \sup_{s \in [c, d]} \|\phi(s, g(s))\| \leq \varepsilon C \leq R,$$

so Tg does map into $B_R(y_0)$, and $Tg \in M$. By construction, f solves the initial value problem if and only if $Tf = f$.

Finally, we check that T is a contraction. For $g, h \in M$ and $t \in [c, d]$,

$$\begin{aligned} \|(Tg)(t) - (Th)(t)\| &= \left\| \int_{t_0}^t [\phi(s, g(s)) - \phi(s, h(s))] ds \right\| \\ &\leq |t - t_0| \sup_{s \in [c, d]} \|\phi(s, g(s)) - \phi(s, h(s))\| \\ &\leq \varepsilon K \sup_{s \in [c, d]} \|g(s) - h(s)\| \leq \frac{1}{2} D(g, h), \end{aligned}$$

using the Lipschitz hypothesis and $\varepsilon \leq 1/(2K)$. Taking the supremum over t gives $D(Tg, Th) \leq \frac{1}{2} D(g, h)$, so T is a contraction on the non-empty complete metric space M , and by the contraction mapping theorem it has a unique fixed point. This fixed point is the unique solution to the initial value problem. $\square$

^aWe will be able to see this much more cleanly once we have discussed *compactness*.

Remark. A few comments on this theorem.

- (i) The theorem is *local* – it only guarantees a solution close to t_0 . In general there really is no solution on all of $[a, b]$; consider $f' = f^2$, $f(0) = 1$, whose solution $f(t) = 1/(1 - t)$ blows up in finite time.
- (ii) Any n -th order ODE $y^{(n)} = \psi(t, y, y', \dots, y^{(n-1)})$ can be handled by this theorem, by the standard trick of introducing the vector $(y, y', \dots, y^{(n-1)}) \in \mathbb{R}^n$ and rewriting the equation as a first-order system.

§9.4 Topological Spaces

When we studied metric spaces, we found that many important concepts – convergence, continuity, open and closed sets – could be phrased entirely in terms of *open sets*, with no direct mention of the metric. This suggests a further abstraction: throw away the metric entirely, and take the open sets themselves as the fundamental structure. This is the starting point of *topology*.

§9.4.1 Topologies

Recall the basic properties satisfied by the open subsets of a metric space: the empty set and the whole space are open, arbitrary unions of open sets are open, and finite intersections of open sets are open. We take precisely these properties as our axioms.

Definition 9.4.1 (Topology)

Let X be a set. A **topology** on X is a family τ of subsets of X such that

- (i) $\emptyset \in \tau$ and $X \in \tau$;
- (ii) if $U_i \in \tau$ for all i in some index set I , then $\bigcup_{i \in I} U_i \in \tau$;
- (iii) if $U, V \in \tau$, then $U \cap V \in \tau$.

A **topological space** is a pair (X, τ) where X is a set and τ is a topology on X . The members of τ are called the **open sets** of X .

By induction, (iii) implies that any *finite* intersection of open sets is open. As with metric spaces, we usually just refer to ‘the topological space X ’, leaving the topology implicit.

Example 9.4.2 (Metric Topology)

Let (M, d) be a metric space. Then the family of all d -open subsets of M is a topology on M , called the **metric topology** induced by d – this is exactly what we proved at the end of our discussion of the topology of metric spaces.

Definition 9.4.3 (Metrizable)

A topological space (X, τ) is **metrizable** if there exists a metric d on X which induces the topology τ .

Note that equivalent metrics induce the same topology, so a metrizable space never remembers *which* metric it came from. Not every topological space is metrizable, as we shall see shortly. First, some examples of topologies that don’t obviously come from metrics.

Example 9.4.4 (Discrete Topology)

For any set X , the family $\tau = \mathcal{P}(X)$ of *all* subsets of X is a topology, called the **discrete topology**. It is metrizable – it is induced by the discrete metric, since in that metric $D_{1/2}(x) = \{x\}$, so every singleton (and hence every set) is open.

Example 9.4.5 (Indiscrete Topology)

For any set X , the family $\tau = \{\emptyset, X\}$ is a topology, called the **indiscrete topology**. If $|X| \geq 2$, this is *not* metrizable. Indeed, suppose d were a metric inducing it, and take distinct $x, y \in X$. Then with $r = d(x, y) > 0$, the ball $D_r(x)$ is d -open, contains x but not y , and so is neither $\emptyset$ nor X – contradiction.

Example 9.4.6 (Cofinite Topology)

For any set X , the family

$$\tau = \{\emptyset\} \cup \{U \subset X \mid X \setminus U \text{ is finite}\}$$

is a topology on X , called the **cofinite topology**. If X is finite this is just the discrete topology, but if X is infinite then any two non-empty open sets intersect (their complements are finite, and X is not).

Definition 9.4.7 (Coarser and Finer)

If $\tau_1 \subset \tau_2$ are topologies on the same set X , we say τ_1 is **coarser** than τ_2 , and τ_2 is

finer than τ_1 .

So the indiscrete topology is the coarsest topology on X , and the discrete topology is the finest.

Often it is convenient to specify a topology by giving only some of its open sets, and generating the rest by taking unions. This gives us the notion of a *basis*.

Definition 9.4.8 (Basis)

Let (X, τ) be a topological space. A family $\mathcal{B} \subset \tau$ is a **basis** for τ if every member of τ is a union of members of $\mathcal{B}$. Equivalently, $\mathcal{B}$ is a basis if for every open U and every $x \in U$, there is some $B \in \mathcal{B}$ with $x \in B \subset U$.

Example 9.4.9 (Open Balls Form a Basis)

In a metric space M , the open balls $\{D_r(x) \mid x \in M, r > 0\}$ form a basis for the metric topology: if U is open then by definition every $x \in U$ has some $D_{r_x}(x) \subset U$, and $U = \bigcup_{x \in U} D_{r_x}(x)$. In fact the balls of radius $1/n$ for $n \in \mathbb{N}$ already suffice.

The next definition captures the most important property that distinguishes ‘metric-like’ spaces from stranger topologies: the ability to separate points.

Definition 9.4.10 (Hausdorff)

A topological space X is **Hausdorff** if for all $x \neq y$ in X , there exist open sets U, V in X such that $x \in U$, $y \in V$ and $U \cap V = \emptyset$.

In other words, distinct points can be ‘housed off’ from each other by disjoint open sets.

Proposition 9.4.11 (Metric Spaces are Hausdorff)

Every metrizable topological space is Hausdorff.

Proof. Let d be a metric inducing the topology, and let $x \neq y$. Set $r = d(x, y)/2 > 0$. Then $U = D_r(x)$ and $V = D_r(y)$ are open sets containing x and y respectively, and they are disjoint: if $z \in U \cap V$ then $d(x, y) \leq d(x, z) + d(z, y) < 2r = d(x, y)$, a contradiction. $\square$

Example 9.4.12 (Non-Metrizable Topologies)

The indiscrete topology on a set with at least two points is not Hausdorff (there aren’t enough open sets), which gives another proof that it isn’t metrizable. Sim-

ilarly, the cofinite topology on an infinite set is not Hausdorff, since any two non-empty open sets intersect – so it is not metrizable either.

§9.4.2 Closed Sets, Neighborhoods and Convergence

In metric spaces we could define closed sets via convergent sequences, and we then proved that a set is closed if and only if its complement is open. In a general topological space, sequences are no longer expressive enough to detect the topology, so we take the complement property as the *definition*.

Definition 9.4.13 (Closed Set)

A subset A of a topological space X is **closed** in X if $X \setminus A$ is open in X .

Taking complements in the axioms for a topology (using De Morgan's laws) immediately gives the following.

Proposition 9.4.14 (Properties of Closed Sets)

In a topological space X :

- (i) $\emptyset$ and X are closed;
- (ii) if A_i is closed for all i in a non-empty index set I , then $\bigcap_{i \in I} A_i$ is closed;
- (iii) if A, B are closed, then $A \cup B$ is closed.

Note that sets are not doors: a set can be open, closed, both (like $\emptyset$), or neither. For example, in a discrete space every set is both open and closed, while in the cofinite topology on an infinite set, the closed sets are exactly the finite sets and the whole space.

Definition 9.4.15 (Neighborhood)

Let X be a topological space, $x \in X$ and $U \subset X$. We say U is a **neighborhood** of x in X if there is an open set V with $x \in V \subset U$.

This matches our characterisation of neighborhoods in metric spaces. Just as before, open sets are precisely the sets that are neighborhoods of all of their points.

Proposition 9.4.16

A subset U of a topological space X is open if and only if U is a neighborhood of every $x \in U$.

Proof. If U is open and $x \in U$, then $V = U$ witnesses that U is a neighborhood of x . Conversely, if for each $x \in U$ there's an open V_x with $x \in V_x \subset U$, then $U = \bigcup_{x \in U} V_x$ is a union of open sets, hence open. $\square$

We can also define convergence, mimicking the neighborhood description of convergence that we proved for metric spaces.

Definition 9.4.17 (Convergence)

A sequence x_n in a topological space X **converges** to $x \in X$ if for every neighborhood U of x , there is some $N \in \mathbb{N}$ such that $x_n \in U$ for all $n \geq N$. We write $x_n \rightarrow x$.

It is equivalent to only require this for every *open* U containing x (any neighborhood contains such an open set). In metric spaces, this recovers exactly our old definition. In general topological spaces, however, convergence can behave very oddly.

Example 9.4.18 (Convergence Can Be Strange)

In an indiscrete topological space X , the only neighborhood of any point is X itself, so *every* sequence converges to *every* point.

In the cofinite topology on an infinite set X , a sequence x_n converges to x if and only if for each $y \neq x$, the set $\{n \mid x_n = y\}$ is finite. In particular, a sequence of *distinct* points converges to every point of X at once.

The property needed to rule out this behaviour and make limits unique is precisely the Hausdorff property.

Proposition 9.4.19 (Uniqueness of Limits in Hausdorff Spaces)

Let X be a Hausdorff topological space. If $x_n \rightarrow x$ and $x_n \rightarrow y$ in X , then $x = y$.

Proof. Suppose $x \neq y$. Then there are disjoint open sets $U \ni x$ and $V \ni y$. Since $x_n \rightarrow x$ there is N_1 with $x_n \in U$ for $n \geq N_1$, and since $x_n \rightarrow y$ there is N_2 with $x_n \in V$ for $n \geq N_2$. But then for $n \geq \max\{N_1, N_2\}$ we have $x_n \in U \cap V = \emptyset$, a contradiction. $\square$

Remark. In a metric space, we characterised closed sets as those closed under taking limits of sequences. In a general topological space only one direction survives: if A is closed, $x_n \in A$ and $x_n \rightarrow x$, then $x \in A$ (otherwise $X \setminus A$ would be an open neighborhood of x containing some x_n). But there are non-closed sets that are closed under limits – sequences are simply too short-sighted to see all of a general topology.

§9.4.3 Interiors, Closures and Density

Given an arbitrary subset A of a topological space, there is a canonical way to ‘round it down’ to an open set, and to ‘round it up’ to a closed one.

Definition 9.4.20 (Interior and Closure)

Let X be a topological space and $A \subset X$. The **interior** of A is

$$A^\circ = \bigcup \{U \subset X \mid U \text{ open in } X, U \subset A\},$$

and the **closure** of A is

$$\overline{A} = \bigcap \{F \subset X \mid F \text{ closed in } X, F \supset A\}.$$

Since unions of open sets are open, A° is open, and it is clearly the *largest* open subset of A . Similarly $\overline{A}$ is the smallest closed set containing A (the intersection is over a non-empty family, as X itself is closed). In particular, A is open if and only if $A = A^\circ$, and closed if and only if $A = \overline{A}$.

There is a more hands-on description of both.

Proposition 9.4.21 (Pointwise Descriptions)

Let X be a topological space and $A \subset X$. Then:

- (i) $A^\circ = \{x \in X \mid A \text{ is a neighborhood of } x\}$;
- (ii) $\overline{A} = \{x \in X \mid \text{every neighborhood of } x \text{ meets } A\}$.

Proof. Part (i). If A is a neighborhood of x , there is an open U with $x \in U \subset A$, so $x \in A^\circ$. Conversely if $x \in A^\circ$, then A° itself is an open set with $x \in A^\circ \subset A$.

Part (ii). Suppose $x \notin \overline{A}$. Then there is a closed $F \supset A$ with $x \notin F$, and $U = X \setminus F$ is a neighborhood of x with $U \cap A = \emptyset$. Conversely, suppose some neighborhood U of x misses A . Shrinking, we may take U open. Then $F = X \setminus U$ is closed and contains A , so $\overline{A} \subset F$, and since $x \notin F$ we get $x \notin \overline{A}$. $\square$

Example 9.4.22

In $\mathbb{R}$, take $A = [0, 1) \cup \{2\}$. Then $A^\circ = (0, 1)$ and $\overline{A} = [0, 1] \cup \{2\}$. For the rationals, $\mathbb{Q}^\circ = \emptyset$ (every interval contains irrationals) and $\overline{\mathbb{Q}} = \mathbb{R}$ (every interval contains rationals). For the integers, $\mathbb{Z}^\circ = \emptyset$ and $\overline{\mathbb{Z}} = \mathbb{Z}$.

Remark. In a *metric* space, $x \in \overline{A}$ if and only if there is a sequence in A converging to x (take $x_n \in D_{1/n}(x) \cap A$). In a general topological space, having such a sequence still implies $x \in \overline{A}$, but the converse can fail.

Definition 9.4.23 (Dense and Separable)

A subset A of a topological space X is **dense** in X if $\overline{A} = X$. We say X is **separable** if it has a countable dense subset.

Example 9.4.24

$\mathbb{R}^n$ is separable, since $\mathbb{Q}^n$ is countable and dense. An uncountable set with the discrete topology is *not* separable, since every subset is closed and so the only dense subset is the whole space.

§9.4.4 Subspaces

If Y is a subset of a topological space X , then Y inherits a topology from X in a natural way.

Definition 9.4.25 (Subspace Topology)

Let (X, τ) be a topological space and $Y \subset X$. The **subspace topology** on Y is

$$\tau|_Y = \{V \cap Y \mid V \in \tau\}.$$

It's easy to check that this is a topology (intersecting with Y commutes with unions and intersections). Note that a set open in Y need not be open in X .

Example 9.4.26

Let $X = \mathbb{R}$, $Y = [0, 2]$ and $U = (1, 2]$. Then $U = (1, 3) \cap Y$ is open in Y , but U is certainly not open in $\mathbb{R}$ – no interval around 2 fits inside U .

Remark. Reassuringly, the constructions we already have are all consistent with each other:

- (i) If $Z \subset Y \subset X$, the subspace topology that Z inherits from Y (with its subspace topology) is the same as the one it inherits directly from X .
- (ii) If (M, d) is a metric space and $N \subset M$, then the metric topology of the metric subspace (N, d) coincides with the subspace topology induced by the metric topology of M . This is because balls in N are exactly balls of M intersected with N .

Closed sets in a subspace have exactly the description you'd hope for.

Proposition 9.4.27 (Closed Sets and Closures in Subspaces)

Let X be a topological space, $A \subset Y \subset X$. Then A is closed in Y if and only if $A = B \cap Y$ for some closed B in X . Moreover, writing cl_Y for closure inside the space Y ,

$$\text{cl}_Y(A) = \overline{A} \cap Y,$$

where $\overline{A}$ denotes closure in X .

Proof. For the first claim, A is closed in Y if and only if $Y \setminus A$ is open in Y , that is, $Y \setminus A = V \cap Y$ for some open V in X . Taking $B = X \setminus V$, this says exactly $A = B \cap Y$ with B closed in X .

For the second, $\overline{A} \cap Y$ is closed in Y by the first part and contains A , so $\text{cl}_Y(A) \subset \overline{A} \cap Y$. Conversely, write $\text{cl}_Y(A) = B \cap Y$ with B closed in X . Then $A \subset B$, so $\overline{A} \subset B$, and hence $\overline{A} \cap Y \subset B \cap Y = \text{cl}_Y(A)$. $\square$

The corresponding statement for interiors is *false* in general – for example, with $A = Y = \{0\}$ inside $X = \mathbb{R}$, we have $\text{int}_Y(A) = \{0\}$ but $A^\circ = \emptyset$ in $\mathbb{R}$.

§9.4.5 Continuity and Homeomorphisms

Our characterisation of global continuity in metric spaces – preimages of open sets are open – becomes the *definition* of continuity for topological spaces.

Definition 9.4.28 (Continuity)

A function $f : X \rightarrow Y$ between topological spaces is **continuous** if for every open set V in Y , the preimage $f^{-1}(V)$ is open in X .

For metric spaces this agrees with the ε - δ definition, by our earlier work. Let's collect the basic properties.

Proposition 9.4.29 (Basic Properties of Continuity)

Let $f : X \rightarrow Y$ and $g : Y \rightarrow Z$ be functions between topological spaces.

- (i) Constant functions are continuous, and the identity $\text{id} : X \rightarrow X$ is continuous.
- (ii) f is continuous if and only if $f^{-1}(B)$ is closed in X for every closed B in Y .
- (iii) If f and g are continuous, then so is $g \circ f$.
- (iv) If $Y \subset X$ has the subspace topology, the inclusion $i : Y \rightarrow X$ is continuous, and hence if $f : X \rightarrow Z$ is continuous, so is the restriction $f|_Y = f \circ i$.

Proof. Part (i). If $f(x) = y_0$ for all x , then $f^{-1}(V)$ is X or $\emptyset$ depending on whether $y_0 \in V$, and both are open. For the identity, $\text{id}^{-1}(V) = V$.

Part (ii). This follows from $f^{-1}(Y \setminus B) = X \setminus f^{-1}(B)$, together with the fact that a set is open if and only if its complement is closed.

Part (iii). For open $W \subset Z$, we have $(g \circ f)^{-1}(W) = f^{-1}(g^{-1}(W))$, which is open since $g^{-1}(W)$ is open by the continuity of g , and preimages of open sets under f are open.

Part (iv). For open V in X , $i^{-1}(V) = V \cap Y$, which is open in Y by the definition of the subspace topology. $\square$

Definition 9.4.30 (Homeomorphism)

A function $f : X \rightarrow Y$ between topological spaces is a **homeomorphism** if f is a bijection and both f and f^{-1} are continuous. If such an f exists we say X and Y are **homeomorphic**, written $X \cong Y$.

A homeomorphism induces a bijection between the topologies of X and Y , so homeomorphic spaces are indistinguishable as topological spaces. This makes the following notion the central ‘sameness’ concept of the subject.

Definition 9.4.31 (Topological Property)

A property $\mathcal{P}$ of topological spaces is a **topological property** (or **topological invariant**) if whenever $X \cong Y$, the space X has property $\mathcal{P}$ if and only if Y does.

Example 9.4.32

Being Hausdorff, being metrizable and being separable are all topological properties. On the other hand, being *complete* with respect to a specific metric is not: $\mathbb{R} \cong (0, 1)$ as topological spaces, but the usual metric on $\mathbb{R}$ is complete while the usual metric on $(0, 1)$ is not. Completeness is a property of a metric, not of a topology.

Much of the power of topological invariants is in proving that spaces are *not* homeomorphic – if we can find a topological property that one space has and another lacks,

no homeomorphism can exist. We'll see genuinely useful invariants (connectedness and compactness) in the coming sections.

Definition 9.4.33 (Open Map)

A function $f : X \rightarrow Y$ is an **open map** if $f(U)$ is open in Y for every open U in X .

If f is a bijection, then f^{-1} is continuous exactly when f is an open map (since $(f^{-1})^{-1}(U) = f(U)$). So the homeomorphisms are exactly the continuous open bijections.

§9.4.6 Products

Given topological spaces X and Y , we want a sensible topology on the product $X \times Y$. Certainly if U is open in X and V is open in Y , we would like the 'open box' $U \times V$ to be open in $X \times Y$. Boxes are closed under finite intersections, since

$$(U \times V) \cap (U' \times V') = (U \cap U') \times (V \cap V'),$$

but a union of boxes need not be a box, so we must throw the unions in too. That is, we take the boxes as a *basis*.

Definition 9.4.34 (Product Topology)

Let X and Y be topological spaces. The **product topology** on $X \times Y$ is the topology whose open sets are the sets of the form

$$W = \bigcup_{i \in I} U_i \times V_i,$$

where each U_i is open in X and each V_i is open in Y .

Equivalently, $W \subset X \times Y$ is open if and only if for every $(x, y) \in W$ there are open sets $U \ni x$ in X and $V \ni y$ in Y with $U \times V \subset W$.

We should immediately check this is consistent with what we already do for metric spaces.

Example 9.4.35 (Products of Metric Spaces)

Let (M, d) and (M', d') be metric spaces, and consider the product metric d_∞ on $M \times M'$ (recall all the product metrics d_1, d_2, d_∞ are Lipschitz equivalent, so induce the same topology). For $z = (x, x')$ and $r > 0$,

$$D_r(z) = \{(y, y') \mid d(x, y) < r \text{ and } d'(x', y') < r\} = D_r(x) \times D_r(x'),$$

so open balls in d_∞ are precisely 'square' boxes. It follows easily that a subset of $M \times M'$ is d_∞ -open if and only if it is open in the product topology – the two constructions agree. In particular, the product topology on $\mathbb{R} \times \mathbb{R}$ is the usual Euclidean topology on $\mathbb{R}^2$.

The product topology is 'designed' to make the coordinate projections behave well, in the following precise sense.

Proposition 9.4.36 (Continuity and Products)

Let X, Y be topological spaces and give $X \times Y$ the product topology. Write $q_X : X \times Y \rightarrow X$ and $q_Y : X \times Y \rightarrow Y$ for the coordinate projections. Then:

- (i) q_X and q_Y are continuous;
- (ii) for any topological space Z , a function $g : Z \rightarrow X \times Y$ is continuous if and only if both $q_X \circ g$ and $q_Y \circ g$ are continuous.

Proof. Part (i). For open U in X , we have $q_X^{-1}(U) = U \times Y$, a box, hence open. Similarly for q_Y .

Part (ii). If g is continuous then $q_X \circ g$ and $q_Y \circ g$ are compositions of continuous maps. Conversely, suppose $h = q_X \circ g$ and $k = q_Y \circ g$ are continuous, so that $g(z) = (h(z), k(z))$. For open sets U in X and V in Y ,

$$g^{-1}(U \times V) = h^{-1}(U) \cap k^{-1}(V),$$

which is open in Z . A general open set W in $X \times Y$ is a union of boxes $\bigcup_i U_i \times V_i$, so $g^{-1}(W) = \bigcup_i g^{-1}(U_i \times V_i)$ is a union of open sets, hence open. $\square$

In other words, a map *into* a product is continuous exactly when its components are. This all extends to finite products $X_1 \times \cdots \times X_n$ in the obvious way, with basis the boxes $U_1 \times \cdots \times U_n$. If each X_i is metrizable, so is the product, using for example the d_∞ metric.

§9.4.7 Quotients

Products let us build bigger spaces from smaller ones; *quotients* let us build new spaces by *gluing*. The setup is a topological space X together with an equivalence relation R on X (we write $x \sim y$ for $(x, y) \in R$). We write X/R for the set of equivalence classes, and $q : X \rightarrow X/R$ for the **quotient map** sending each point to its equivalence class. The idea is that in X/R , equivalent points of X have been glued into a single point.

Definition 9.4.37 (Quotient Topology)

Let X be a topological space and R an equivalence relation on X . The **quotient topology** on X/R is

$$\tau = \{V \subset X/R \mid q^{-1}(V) \text{ is open in } X\}.$$

This is a topology because taking preimages commutes with unions and intersections: $q^{-1}(\emptyset) = \emptyset$, $q^{-1}(X/R) = X$, $q^{-1}(\bigcup V_i) = \bigcup q^{-1}(V_i)$ and $q^{-1}(U \cap V) = q^{-1}(U) \cap q^{-1}(V)$. Note that q is continuous by construction – indeed the quotient topology is the *finest* topology on X/R making q continuous.

Example 9.4.38 (The Circle as a Quotient)

Consider $\mathbb{R}$ with the equivalence relation $x \sim y$ if and only if $x - y \in \mathbb{Z}$, giving the quotient $\mathbb{R}/\mathbb{Z}$. Every real number is equivalent to one in $[0, 1]$, and the only identification within $[0, 1]$ is that $0 \sim 1$. So $\mathbb{R}/\mathbb{Z}$ is the interval $[0, 1]$ with its two

endpoints glued together – which should be a circle! We will prove that $\mathbb{R}/\mathbb{Z} \cong S^1$ once we have compactness available, which makes the proof essentially effortless.

Example 9.4.39 (Quotients Can Be Horrible)

Let $x \sim y$ if and only if $x - y \in \mathbb{Q}$, and consider $\mathbb{R}/\mathbb{Q}$. If $V \subset \mathbb{R}/\mathbb{Q}$ is open and non-empty, then $q^{-1}(V)$ is open and non-empty, so contains an interval (a, b) . But then given *any* $x \in \mathbb{R}$, we can pick a rational $r \in (a - x, b - x)$, and then $x + r \in (a, b)$, so $q(x) = q(x + r) \in V$. Hence $V = \mathbb{R}/\mathbb{Q}$, and the quotient topology on $\mathbb{R}/\mathbb{Q}$ is indiscrete!

In particular, quotients of metrizable spaces (indeed, of $\mathbb{R}$ itself) can fail to be Hausdorff or metrizable. Quotients require some care.

Example 9.4.40 (Gluing a Square)

Let $Q = [0, 1] \times [0, 1] \subset \mathbb{R}^2$. Identifying the left and right edges of Q via $(0, y) \sim (1, y)$ rolls the square up into a *cylinder*. If we additionally identify the top and bottom edges via $(x, 0) \sim (x, 1)$ (and consequently all four corners become one point), we get the **torus** – the surface of a doughnut. The picture to have in mind is:

Formally, the resulting quotient Q/R is homeomorphic to $\mathbb{R}^2/\mathbb{Z}^2$ (quotienting by the relation $x \sim y \iff x - y \in \mathbb{Z}^2$), and also to the familiar torus surface embedded in $\mathbb{R}^3$.

To actually *work* with quotients, the key tool is the way that maps out of X descend to maps out of X/R .

Proposition 9.4.41 (Factoring Maps Through Quotients)

Let X be a set, R an equivalence relation on X , and $q : X \rightarrow X/R$ the quotient map. Let $f : X \rightarrow Y$ be a function which **respects** R , meaning $x \sim y$ implies $f(x) = f(y)$. Then there is a unique map $\tilde{f} : X/R \rightarrow Y$ such that $f = \tilde{f} \circ q$.

Moreover $\tilde{f}$ has the same image as f , and if f **fully respects** R , meaning $x \sim y \iff f(x) = f(y)$, then $\tilde{f}$ is injective.

Proof. Any class $z \in X/R$ is $q(x)$ for some x , and the requirement $\tilde{f}(q(x)) = f(x)$ pins down $\tilde{f}(z)$ – this is well defined precisely because f respects R . Uniqueness and the image claim follow since q is surjective. If f fully respects R and $\tilde{f}(q(x)) = \tilde{f}(q(y))$, then $f(x) = f(y)$, so $x \sim y$ and $q(x) = q(y)$, giving injectivity. $\square$

Proposition 9.4.42 (Continuity of Factored Maps)

In the setting above, suppose additionally that X and Y are topological spaces and that X/R carries the quotient topology. Then:

- (i) if f is continuous, then so is $\tilde{f}$;
- (ii) if f is an open map, then so is $\tilde{f}$.

In particular, if f is a continuous surjection that fully respects R , then $\tilde{f}$ is a continuous bijection, and if f is additionally an open map, then $\tilde{f}$ is a homeomorphism $X/R \cong Y$.

Proof. Part (i). For open V in Y ,

$$q^{-1}(\tilde{f}^{-1}(V)) = (\tilde{f} \circ q)^{-1}(V) = f^{-1}(V),$$

which is open in X , so by the definition of the quotient topology, $\tilde{f}^{-1}(V)$ is open in X/R .

Part (ii). Let V be open in X/R , and set $U = q^{-1}(V)$, which is open in X . Since q is surjective, $q(U) = V$, so

$$\tilde{f}(V) = \tilde{f}(q(U)) = f(U),$$

which is open in Y since f is an open map. □

Finally, let us record when a quotient has a chance of being Hausdorff. Thinking of R as a subset of $X \times X$ (with the product topology), we have the following.

Proposition 9.4.43 (Hausdorff Quotients)

Let X be a topological space and R an equivalence relation on X .

- (i) If X/R is Hausdorff, then R is closed in $X \times X$.
- (ii) If R is closed in $X \times X$ and q is an open map, then X/R is Hausdorff.

Proof. Part (i). Let $W = (X \times X) \setminus R$; we show W is open. Given $(x, y) \in W$ we have $q(x) \neq q(y)$, so there are disjoint open sets $S \ni q(x)$ and $T \ni q(y)$ in X/R . Then $U = q^{-1}(S)$ and $V = q^{-1}(T)$ are open in X with $x \in U$, $y \in V$, and for any $(a, b) \in U \times V$ we have $q(a) \in S$ and $q(b) \in T$, so $q(a) \neq q(b)$, that is, $a \not\sim b$. Hence $(x, y) \in U \times V \subset W$, and W is open.

Part (ii). Let $z \neq w$ in X/R , and pick $x, y \in X$ with $q(x) = z$, $q(y) = w$. Then $x \not\sim y$, so (x, y) lies in the open set $W = (X \times X) \setminus R$, and there are open sets $U \ni x$, $V \ni y$ with $U \times V \subset W$. Since q is an open map, $q(U)$ and $q(V)$ are open, and they contain z and w respectively. They are disjoint: if $q(a) = q(b)$ with $a \in U$, $b \in V$, then $(a, b) \in R \cap (U \times V)$, contradicting $U \times V \subset W$. So X/R is Hausdorff. □

§9.5 Connectedness

We now come to our first substantial topological property. Recall the intermediate value theorem from Analysis I: a continuous function on an interval takes all values between any two of its values. Which feature of intervals makes this work? Intuitively, an interval is ‘all in one piece’ – and this is the idea we now make precise, for arbitrary topological spaces.

§9.5.1 Connected Spaces

Definition 9.5.1 (Connected)

A topological space X is **disconnected** if there exist open sets U, V in X such that

$$U \cap V = \emptyset, \quad U \cup V = X, \quad U, V \neq \emptyset.$$

In this case we say U and V **disconnect** X . We say X is **connected** if it is not disconnected.

Equivalently (taking complements), X is disconnected if and only if it has a subset which is open, closed, non-empty and not the whole space.

There is a slick reformulation of connectedness in terms of continuous functions, which is frequently the easiest version to use in proofs. Here $\mathbb{Z}$ carries the subspace topology from $\mathbb{R}$, which is its discrete topology.

Theorem 9.5.2 (Characterisations of Connectedness)

Let X be a topological space. The following are equivalent:

- (i) X is connected;
- (ii) if $f : X \rightarrow \mathbb{R}$ is continuous, then $f(X)$ is an interval;
- (iii) every continuous function $f : X \rightarrow \mathbb{Z}$ is constant.

Proof. (i) implies (ii). Suppose $f : X \rightarrow \mathbb{R}$ is continuous but $f(X)$ is not an interval. Then there are $a < b < c$ with $a, c \in f(X)$ but $b \notin f(X)$. Let $U = f^{-1}((-\infty, b))$ and $V = f^{-1}((b, \infty))$. These are open (preimages of open sets), disjoint, non-empty (they contain points mapping to a and c), and since b is not a value of f their union is all of X . So U, V disconnect X , a contradiction.

(ii) implies (iii). If $f : X \rightarrow \mathbb{Z}$ is continuous, then viewed as a map into $\mathbb{R}$ it is continuous, so $f(X)$ is an interval consisting of integers – which must be a single point.

(iii) implies (i). Suppose U, V disconnect X . Define $f : X \rightarrow \mathbb{Z}$ by $f = 0$ on U and $f = 1$ on V . For any $W \subset \mathbb{Z}$, the preimage $f^{-1}(W)$ is one of $\emptyset, U, V, X$, all of which are open, so f is continuous. But f is not constant, contradicting (iii). $\square$

We can now identify the connected subsets of the real line. Here, and always, a subset of a topological space is called connected if it is connected in its subspace topology. Recall that $I \subset \mathbb{R}$ is an **interval** if whenever $x < y < z$ with $x, z \in I$, we have $y \in I$.

Theorem 9.5.3 (Connected Subsets of $\mathbb{R}$)

A subset $X \subset \mathbb{R}$ is connected if and only if X is an interval.

Proof. If X is connected, then the inclusion $i : X \rightarrow \mathbb{R}$ is continuous, so $X = i(X)$ is an interval by the theorem above.

Conversely, suppose X is an interval and $f : X \rightarrow \mathbb{R}$ is continuous. If $x < y$ are points of X then $[x, y] \subset X$, and by the intermediate value theorem from Analysis I, f takes every value between $f(x)$ and $f(y)$ on $[x, y]$. Hence $f(X)$ is an interval, and by the theorem above, X is connected. $\square$

Note the pleasing exchange that has taken place here: the intermediate value theorem told us that intervals are connected, and conversely, once we know a space is connected, part (ii) of Theorem 9.5.2 is the intermediate value theorem for that space.

Example 9.5.4

Any indiscrete space is connected (there aren't enough open sets to disconnect it). The cofinite topology on an infinite set is connected (any two non-empty open sets meet). A discrete space with at least two points is disconnected.

When working with subspaces, it's convenient to phrase disconnection using open sets of the ambient space.

Lemma 9.5.5 (Disconnecting Subspaces)

Let Y be a subspace of a topological space X . Then Y is disconnected if and only if there are open sets U, V in X such that

$$U \cap V \cap Y = \emptyset, \quad Y \subset U \cup V, \quad U \cap Y \neq \emptyset, \quad V \cap Y \neq \emptyset.$$

In this situation we say that U and V disconnect Y in X .

Proof. Open subsets of Y are exactly the sets $U \cap Y$ for U open in X , so this is just unwinding the definition of the subspace topology. $\square$

Proposition 9.5.6 (Closures of Connected Sets)

Let Y be a connected subspace of a topological space X . Then $\overline{Y}$ is connected. More generally, any Z with $Y \subset Z \subset \overline{Y}$ is connected.

Proof. Suppose U, V are open in X and disconnect Z . Since $Y \subset Z$, we have $U \cap V \cap Y = \emptyset$ and $Y \subset U \cup V$. If both $U \cap Y$ and $V \cap Y$ were non-empty, then U, V would disconnect Y , which is connected – so without loss of generality $V \cap Y = \emptyset$. Then $Y \subset X \setminus V$, which is closed, so $\overline{Y} \subset X \setminus V$, and hence $V \cap Z \subset V \cap \overline{Y} = \emptyset$. This contradicts U, V disconnecting Z . $\square$

Theorem 9.5.7 (Continuous Images of Connected Spaces)

Let $f : X \rightarrow Y$ be a continuous function between topological spaces. If X is connected, then $f(X)$ is connected.

Proof. Suppose U, V are open in Y and disconnect $f(X)$. Then $f^{-1}(U)$ and $f^{-1}(V)$ are open in X , they are non-empty (as U and V meet $f(X)$), their union is X (as $f(X) \subset U \cup V$), and they are disjoint (if x was in both, $f(x) \in U \cap V \cap f(X) = \emptyset$). So they disconnect X , a contradiction. $\square$

In particular, connectedness is a topological property, and any quotient of a connected space is connected (the quotient map is a continuous surjection).

Lemma 9.5.8 (Unions of Overlapping Connected Sets)

Let $\mathcal{A}$ be a family of connected subsets of a topological space X such that $A \cap B \neq \emptyset$ for all $A, B \in \mathcal{A}$. Then $\bigcup_{A \in \mathcal{A}} A$ is connected.

Proof. Let $Y = \bigcup_{A \in \mathcal{A}} A$ and let $f : Y \rightarrow \mathbb{Z}$ be continuous; by Theorem 9.5.2 it's enough to show f is constant. For each $A \in \mathcal{A}$, the restriction $f|_A$ is continuous, so it is constant since A is connected. For any $A, B \in \mathcal{A}$, picking a point of $A \cap B$ shows these constants agree. Hence f is constant on Y . $\square$

Theorem 9.5.9 (Products of Connected Spaces)

If X and Y are connected topological spaces, then $X \times Y$ is connected.

Proof. We may assume both are non-empty. Fix $x_0 \in X$. The map $y \mapsto (x_0, y)$ is continuous (its components are constant and the identity), so its image $\{x_0\} \times Y$ is connected; similarly each $X \times \{y\}$ is connected. Now for $y \in Y$, let

$$A_y = (\{x_0\} \times Y) \cup (X \times \{y\}).$$

The two pieces meet in the point (x_0, y) , so each A_y is connected by Lemma 9.5.8. Furthermore, any two A_y, A_z contain $\{x_0\} \times Y$, so they pairwise intersect, and hence

$$\bigcup_{y \in Y} A_y = X \times Y$$

is connected, again by Lemma 9.5.8. $\square$

Example 9.5.10

$\mathbb{R}^n$ is connected for every n , being a product of copies of the interval $\mathbb{R}$.

§9.5.2 Path-Connectedness

There is a second, more intuitive notion of being ‘all in one piece’: you can walk from any point to any other without leaving the space.

Definition 9.5.11 (Path)

Let X be a topological space and $x, y \in X$. A **path** from x to y in X is a continuous function $\gamma : [0, 1] \rightarrow X$ with $\gamma(0) = x$ and $\gamma(1) = y$. We say X is **path-connected** if for all $x, y \in X$ there is a path from x to y in X .

Example 9.5.12 (Convex Sets are Path-Connected)

Any convex subset $C \subset \mathbb{R}^n$ (one containing the straight line segment between any two of its points) is path-connected: for $y, z \in C$ take the straight-line path $\gamma(t) = (1-t)y + tz$, which is continuous with image in C . In particular open balls $D_r(x)$ are path-connected, since for $y, z \in D_r(x)$,

$$\|\gamma(t) - x\| = \|(1-t)(y-x) + t(z-x)\| \leq (1-t)\|y-x\| + t\|z-x\| < r.$$

Theorem 9.5.13 (Path-Connected Implies Connected)

If a topological space X is path-connected, then X is connected.

Proof. Suppose U, V disconnect X , and take $x \in U, y \in V$. Let γ be a path from x to y . Then $\gamma^{-1}(U)$ and $\gamma^{-1}(V)$ are open, non-empty (they contain 0 and 1), disjoint, and cover $[0, 1]$ – so they disconnect $[0, 1]$. But $[0, 1]$ is an interval, hence connected, a contradiction. $\square$

The converse is false, and the standard counterexample is important enough to have a name: the *topologist’s sine curve*.

Example 9.5.14 (The Topologist’s Sine Curve)

Consider the set

$$X = \underbrace{\left\{ \left(x, \sin \frac{1}{x} \right) \mid x > 0 \right\}}_Y \cup \underbrace{\left\{ (0, y) \mid -1 \leq y \leq 1 \right\}}_Z \subset \mathbb{R}^2.$$

We claim that X is connected but not path-connected.

X is connected. The curve Y is the image of the connected set $(0, \infty)$ under the continuous map $x \mapsto (x, \sin \frac{1}{x})$, so Y is connected. We claim $X = \bar{Y}$; then X is connected by Proposition 9.5.6. To see $X \subset \bar{Y}$, fix $y \in [-1, 1]$. For each n , the map $x \mapsto 1/x$ sends $(0, \frac{1}{n})$ onto (n, ∞) , and $\sin$ takes the value y somewhere in any interval of length 2π , so there is $x_n \in (0, \frac{1}{n})$ with $\sin \frac{1}{x_n} = y$. Then $(x_n, y) \in Y$ and $(x_n, y) \rightarrow (0, y)$, so $(0, y) \in \bar{Y}$. Conversely X is closed: if $(x_n, y_n) \in X$ converges to (x, y) , then $y \in [-1, 1]$, and either $x = 0$, in which case $(x, y) \in Z \subset X$, or $x > 0$, in which case $x_n > 0$ eventually, so $y_n = \sin \frac{1}{x_n} \rightarrow \sin \frac{1}{x}$ by continuity and $(x, y) \in Y$. Hence $\bar{Y} \subset X$, so $X = \bar{Y}$.

X is not path-connected. Suppose $\gamma = (\gamma_1, \gamma_2) : [0, 1] \rightarrow X$ were a path from $(0, 0)$ to $(1, \sin 1)$. The idea is that any path leaving the vertical segment must traverse infinitely many oscillations in finite time. Suppose $\gamma_1(t) > 0$ for some t . By the intermediate value theorem, $\gamma_1([0, t]) \supset [0, \gamma_1(t)]$, so for any large n we can find $s < t$ with $\gamma_1(s) = \frac{1}{2\pi n}$, whence $\gamma_2(s) = \sin(2\pi n) = 0$; and similarly some $s' < t$ with $\gamma_1(s') = \frac{1}{2\pi n + \pi/2}$, whence $\gamma_2(s') = 1$. Iterating this (each time applying the argument on the interval up to the previously found time, with larger n), we obtain a decreasing sequence of times $1 \geq t_1 > t_2 > \cdots > 0$ with $\gamma_2(t_k)$ alternating between 0 and 1. The sequence t_k is decreasing and bounded below, so it converges to some $t^* \in [0, 1]$; but then $\gamma_2(t_k) \rightarrow \gamma_2(t^*)$ by continuity, which is impossible for a sequence alternating between 0 and 1. So no such path exists.

Despite this counterexample, for *open* subsets of Euclidean space the two notions do coincide. First, a lemma that is endlessly useful for building paths (and other functions) piece by piece.

Lemma 9.5.15 (Gluing Lemma)

Let $X = A \cup B$ be a topological space with A, B closed in X , and let $g : A \rightarrow Y$ and $h : B \rightarrow Y$ be continuous functions which agree on $A \cap B$. Then the function $f : X \rightarrow Y$ defined by

$$f(x) = \begin{cases} g(x) & \text{if } x \in A, \\ h(x) & \text{if } x \in B \end{cases}$$

is well defined and continuous.

Proof. Well-definedness is exactly the agreement on $A \cap B$. Now let V be closed in Y . Then

$$f^{-1}(V) = g^{-1}(V) \cup h^{-1}(V),$$

where $g^{-1}(V)$ is closed in A , and hence closed in X (it equals $A \cap G$ for some closed G in X , and an intersection of closed sets is closed); similarly $h^{-1}(V)$ is closed in X . So $f^{-1}(V)$ is closed in X for every closed V , and f is continuous. $\square$

With this, being joined by a path is an equivalence relation on any topological space: constant paths give reflexivity, reversing a path ($t \mapsto \gamma(1 - t)$) gives symmetry, and for transitivity we concatenate paths, defining

$$\eta(t) = \begin{cases} \gamma(2t) & \text{if } 0 \leq t \leq \frac{1}{2}, \\ \delta(2t - 1) & \text{if } \frac{1}{2} \leq t \leq 1, \end{cases}$$

which is continuous by the gluing lemma applied to $[0, \frac{1}{2}]$ and $[\frac{1}{2}, 1]$. The equivalence classes are called the **path-connected components** of X .

Theorem 9.5.16 (Open Subsets of $\mathbb{R}^n$)

Let U be an open subset of $\mathbb{R}^n$. Then U is connected if and only if U is path-connected.

Proof. Path-connected implies connected always, so suppose U is connected and non-empty, and fix $x_0 \in U$. Let

$$P = \{x \in U \mid \text{there is a path from } x_0 \text{ to } x \text{ in } U\}.$$

We will show P is both open and closed in U . Since U is connected and $x_0 \in P \neq \emptyset$, it will follow that $P = U$, which is what we want.

P is open. Let $x \in P$. Since U is open there is $r > 0$ with $D_r(x) \subset U$. Any $y \in D_r(x)$ is joined to x by a straight-line path in $D_r(x)$, and concatenating with a path from x_0 to x shows $y \in P$. So $D_r(x) \subset P$.

$U \setminus P$ is open. Let $x \in U \setminus P$, and again take $D_r(x) \subset U$. If some $y \in D_r(x)$ had a path from x_0 , then concatenating with the segment from y to x would put x in P – contradiction. So $D_r(x) \subset U \setminus P$.

Hence P is open and closed in U , and $P = U$ as claimed. $\square$

§9.5.3 Connected Components

A disconnected space breaks up into natural maximal connected pieces.

Definition 9.5.17 (Connected Component)

Let X be a topological space. Define a relation on X by $x \sim y$ if and only if there is some connected $A \subset X$ with $x, y \in A$. This is an equivalence relation^a, and its equivalence classes are called the **connected components** of X .

^aReflexivity: $\{x\}$ is connected. Symmetry is clear. Transitivity: if $x, y \in A$ and $y, z \in B$ with A, B connected, then $A \cup B$ is connected by Lemma 9.5.8 since $y \in A \cap B$, and it contains x and z .

Proposition 9.5.18 (Properties of Components)

The connected components of a topological space X are precisely the maximal connected subsets of X ; they are closed, and they partition X .

Proof. That they partition X is immediate as they are equivalence classes. Let $C = C_x$ be the component of x .

C is connected. For each $y \in C$ there is a connected $A_y \ni x, y$. Note $A_y \subset C$, since every point of A_y is related to x . Then $C = \bigcup_{y \in C} A_y$, the sets A_y pairwise intersect (all contain x), so C is connected by Lemma 9.5.8.

C is maximal. If $C \subset A$ with A connected, then every $y \in A$ satisfies $y \sim x$, so

$A \subset C$.

C is closed. $\overline{C}$ is connected by Proposition 9.5.6, so by maximality $\overline{C} = C$. $\square$

Example 9.5.19

The components of $\mathbb{R} \setminus \{0\}$ are $(-\infty, 0)$ and $(0, \infty)$. The components of $\mathbb{Q}$ (as a subspace of $\mathbb{R}$) are the singletons: any subset of $\mathbb{Q}$ with two points $p < q$ is disconnected by cutting at an irrational between them. Note this shows components need *not* be open in general.

Since connectedness is a topological invariant, so is the number of connected components, and this gives a genuinely useful way of telling spaces apart. Here is the classic application.

Theorem 9.5.20 ($\mathbb{R} \not\cong \mathbb{R}^n$ for $n \geq 2$)

For $n \geq 2$, the spaces $\mathbb{R}$ and $\mathbb{R}^n$ are not homeomorphic.

Proof. Suppose $f : \mathbb{R} \rightarrow \mathbb{R}^n$ were a homeomorphism. Removing a point, f restricts to a homeomorphism from $\mathbb{R} \setminus \{0\}$ to $\mathbb{R}^n \setminus \{f(0)\}$. But $\mathbb{R} \setminus \{0\}$ is disconnected, while $\mathbb{R}^n \setminus \{\text{point}\}$ for $n \geq 2$ is path-connected (any two points can be joined by a path of at most two straight segments avoiding the removed point) and hence connected. This contradicts connectedness being a topological property. $\square$

Remark. It is true in general that $\mathbb{R}^m \not\cong \mathbb{R}^n$ for $m \neq n$, but this is substantially harder – the standard proofs need tools from algebraic topology.

§9.6 Compactness

Our second major topological property is *compactness*. It is best thought of as the topological version of being finite: compact spaces are the ones on which ‘local’ information can always be patched into ‘global’ information using only finitely many patches.

§9.6.1 Open Covers and Compactness

To motivate the definition, recall from Analysis I that a continuous function on a closed bounded interval is bounded. Let’s think about what makes this work for a continuous $f : X \rightarrow \mathbb{R}$ on a general space. Continuity gives us *local* boundedness for free: every $x \in X$ lies in the open set

$$U_x = f^{-1}((f(x) - 1, f(x) + 1)),$$

and f is bounded on U_x . The sets U_x cover X . If we could always pass to *finitely many* of them, say $U_{x_1}, \dots, U_{x_k}$, still covering X , then f would be bounded on all of X by $\max_j |f(x_j)| + 1$. This finite-subcover property is exactly compactness.

Definition 9.6.1 (Open Cover and Compactness)

Let X be a topological space. An **open cover** of X is a family $\mathcal{U}$ of open subsets

of X with $\bigcup_{U \in \mathcal{U}} U = X$. A **subcover** of $\mathcal{U}$ is a subfamily $\mathcal{V} \subset \mathcal{U}$ which still covers X , and it is a **finite subcover** if $\mathcal{V}$ is finite.

We say X is **compact** if every open cover of X has a finite subcover.

For a subspace $Y \subset X$, it is easy to check (using the definition of the subspace topology) that Y is compact if and only if every family $\mathcal{U}$ of open sets of X whose union contains Y admits a finite subfamily whose union still contains Y . We use both formulations interchangeably.

The picture: out of a possibly enormous open cover (dashed), we can always select finitely many sets (solid) which still cover a compact space.

The motivating discussion above proves most of the following theorem.

Theorem 9.6.2 (Boundedness and the Extreme Value Theorem)

Let X be a compact topological space and $f : X \rightarrow \mathbb{R}$ continuous. Then f is bounded, and if $X \neq \emptyset$ then f attains its bounds.

Proof. For boundedness, cover X by the open sets $U_n = \{x \mid |f(x)| < n\}$ for $n \in \mathbb{N}$ (open as preimages of open intervals). By compactness finitely many suffice, and since the U_n are nested, $X = U_N$ for some N , so $|f| < N$ on X .

Now suppose $X \neq \emptyset$, and let $\alpha = \inf_X f$, which exists as f is bounded. Suppose for contradiction that $f(x) > \alpha$ for all $x \in X$. Then the open sets

$$V_n = f^{-1}\left(\left(\alpha + \frac{1}{n}, \infty\right)\right), \quad n \in \mathbb{N}$$

cover X , so again by compactness and nestedness, $X = V_N$ for some N . But then $f(x) > \alpha + \frac{1}{N}$ for all x , so $\inf_X f \geq \alpha + \frac{1}{N} > \alpha$, a contradiction. The supremum is attained by applying this to $-f$. $\square$

Of course, all this is only useful if we have a good supply of compact spaces. The fundamental example is the closed bounded interval.

Theorem 9.6.3 ($[0, 1]$ is Compact)

The closed interval $[0, 1]$ is compact.

Proof. Let $\mathcal{U}$ be a family of open sets in $\mathbb{R}$ covering $[0, 1]$. Say that $\mathcal{U}$ *finitely covers* a set $A \subset [0, 1]$ if finitely many members of $\mathcal{U}$ cover A ; note that if $A = B \cup C$ and

$\mathcal{U}$ finitely covers B and C , then it finitely covers A .

Suppose $\mathcal{U}$ does not finitely cover $[0, 1]$. Bisecting, at least one of $[0, \frac{1}{2}]$ and $[\frac{1}{2}, 1]$ is not finitely covered; call it $[a_1, b_1]$. Bisecting again and repeating, we get nested intervals

$$[0, 1] \supset [a_1, b_1] \supset [a_2, b_2] \supset \cdots, \quad b_n - a_n = 2^{-n},$$

none of which is finitely covered by $\mathcal{U}$. The sequence a_n is increasing and bounded, so $a_n \rightarrow x$ for some $x \in [0, 1]$, and $b_n = a_n + 2^{-n} \rightarrow x$ too.

Since $\mathcal{U}$ covers $[0, 1]$, there's some $U \in \mathcal{U}$ with $x \in U$, and since U is open, $(x - \varepsilon, x + \varepsilon) \subset U$ for some $\varepsilon > 0$. But for large enough n , both a_n and b_n lie in $(x - \varepsilon, x + \varepsilon)$, so $[a_n, b_n] \subset U$ is covered by the single set U – contradicting that $[a_n, b_n]$ is not finitely covered. $\square$

Example 9.6.4 (Compact and Non-Compact Spaces) (i) Any finite topological space is compact, as is any set with the indiscrete or cofinite topology^a.

(ii) If $x_n \rightarrow x$ in a topological space, then $\{x_n \mid n \in \mathbb{N}\} \cup \{x\}$ is compact: any cover contains some $U \ni x$, which contains all but finitely many of the x_n , and finitely many more sets mop up the rest.

(iii) An infinite discrete space is not compact: the cover by singletons has no finite subcover.

(iv) $\mathbb{R}$ is not compact: the cover by the intervals $(-n, n)$ for $n \in \mathbb{N}$ has no finite subcover. Similarly $(0, 1]$ is not compact, using the cover $(1/n, 2)$ for $n \in \mathbb{N}$ – note how this cover exploits the ‘missing’ endpoint 0.

^aFor the cofinite topology: pick any non-empty U in the cover; its complement is finite, and each missing point needs only one more set.

§9.6.2 Building New Compact Spaces

The next two results tell us how compactness interacts with subspaces, and they display a pleasing duality between ‘compact’ and ‘closed’.

Theorem 9.6.5 (Compactness and Closed Subspaces)

Let Y be a subspace of a topological space X .

- (i) If X is compact and Y is closed in X , then Y is compact.
- (ii) If X is Hausdorff and Y is compact, then Y is closed in X .

Proof. Part (i). Let $\mathcal{U}$ be a family of open sets of X covering Y . Since Y is closed, $\mathcal{U} \cup \{X \setminus Y\}$ is an open cover of X , which by compactness has a finite subcover. Discarding $X \setminus Y$ from it if present, we are left with finitely many members of $\mathcal{U}$ covering Y .

Part (ii). We show $X \setminus Y$ is open. Let $x \in X \setminus Y$. For each $y \in Y$, using the Hausdorff property pick disjoint open sets $U_y \ni x$ and $V_y \ni y$. The V_y cover Y , so

by compactness there is a finite $F \subset Y$ with $Y \subset \bigcup_{y \in F} V_y$. Then

$$U = \bigcap_{y \in F} U_y$$

is a finite intersection of open sets, so open, contains x , and misses every V_y for $y \in F$, hence misses Y . So $X \setminus Y$ is a neighborhood of each of its points, and Y is closed. $\square$

Note that part (ii) genuinely needs the Hausdorff hypothesis: in an infinite indiscrete space, every subset is compact, but only $\emptyset$ and the whole space are closed.

Theorem 9.6.6 (Continuous Images of Compact Spaces)

Let $f : X \rightarrow Y$ be a continuous function between topological spaces. If X is compact, then $f(X)$ is compact.

Proof. Let $\mathcal{U}$ be a family of open sets in Y covering $f(X)$. Then $\{f^{-1}(U) \mid U \in \mathcal{U}\}$ is an open cover of X , so finitely many $f^{-1}(U_1), \dots, f^{-1}(U_k)$ cover X , and then $U_1, \dots, U_k$ cover $f(X)$. $\square$

So compactness is a topological property, and any quotient of a compact space is compact. Also, combining with Theorem 9.6.3: any closed interval $[a, b] \cong [0, 1]$ is compact, and Theorem 9.6.2 recovers the familiar extreme value theorem of Analysis I.

Here is a first genuinely topological payoff. Recall that a continuous bijection need not have a continuous inverse – but compactness fixes this.

Theorem 9.6.7 (Topological Inverse Function Theorem)

Let $f : X \rightarrow Y$ be a continuous bijection from a compact space X to a Hausdorff space Y . Then f^{-1} is continuous, and hence f is a homeomorphism.

Proof. It's enough to show f is an open map, or equivalently (taking complements, f being a bijection) that f maps closed sets to closed sets. So let $K \subset X$ be closed. Since X is compact, K is compact; hence $f(K)$ is compact as a continuous image; hence $f(K)$ is closed in Y , since Y is Hausdorff. Done – notice how the previous two theorems slotted together perfectly. $\square$

Example 9.6.8 ($\mathbb{R}/\mathbb{Z} \cong S^1$)

We can now deliver on our promise from the section on quotients: $\mathbb{R}/\mathbb{Z}$ is homeomorphic to the circle

$$S^1 = \{v \in \mathbb{R}^2 \mid \|v\| = 1\}.$$

Define $f : \mathbb{R} \rightarrow S^1$ by $f(t) = (\cos 2\pi t, \sin 2\pi t)$. Then f is continuous (its components are), surjective, and $f(s) = f(t)$ if and only if $s - t \in \mathbb{Z}$, so f fully respects the relation defining $\mathbb{R}/\mathbb{Z}$. By our results on quotients, f descends to a continuous bijection $\tilde{f} : \mathbb{R}/\mathbb{Z} \rightarrow S^1$.

Now, $\mathbb{R}/\mathbb{Z} = q([0, 1])$ is the image of a compact space under the (continuous) quo-

tion map, so it is compact. Also S^1 is a metric space, hence Hausdorff. So $\tilde{f}$ is a continuous bijection from a compact space to a Hausdorff space, and by the topological inverse function theorem, it is a homeomorphism.

Next, products. The general form of this theorem – for infinite products – is a famous and much deeper result of Tychonov, but for finite products the proof is a pleasant exercise in cover manipulation.

Theorem 9.6.9 (Tychonov's Theorem, Finite Case)

If X and Y are compact topological spaces, then $X \times Y$ is compact.

Proof. Let $\mathcal{U}$ be an open cover of $X \times Y$. We first reduce to covers by boxes: each $z \in X \times Y$ lies in some $W_z \in \mathcal{U}$, and by the definition of the product topology there are open U_z, V_z with $z \in U_z \times V_z \subset W_z$. If finitely many of the boxes $U_z \times V_z$ cover $X \times Y$, then the corresponding W_z form a finite subcover of $\mathcal{U}$. So we may assume every member of $\mathcal{U}$ is a box $U \times V$.

Fix $x \in X$. The slice $\{x\} \times Y$ is the continuous image of Y (under $y \mapsto (x, y)$), so it is compact, and it is covered by $\mathcal{U}$. Hence there are finitely many boxes

$$U_{x,1} \times V_{x,1}, \dots, U_{x,n_x} \times V_{x,n_x} \in \mathcal{U}$$

covering $\{x\} \times Y$, and we may discard any that don't actually meet the slice, so that $x \in U_{x,j}$ for each j . Now let

$$U_x = \bigcap_{j=1}^{n_x} U_{x,j},$$

an open set containing x . The key point is that the same finite family covers the whole 'tube' over U_x :

$$U_x \times Y \subset \bigcup_{j=1}^{n_x} U_{x,j} \times V_{x,j},$$

since for $(u, y) \in U_x \times Y$, the point (x, y) lies in some $U_{x,j} \times V_{x,j}$, and then (u, y) does too as $u \in U_x \subset U_{x,j}$.

Finally, $\{U_x \mid x \in X\}$ is an open cover of the compact space X , so $X = \bigcup_{x \in F} U_x$ for some finite $F \subset X$. Then

$$X \times Y = \bigcup_{x \in F} U_x \times Y \subset \bigcup_{x \in F} \bigcup_{j=1}^{n_x} U_{x,j} \times V_{x,j},$$

a finite subcover. □

By induction, any finite product of compact spaces is compact. Combining everything, we arrive at the definitive description of the compact subsets of Euclidean space.

Theorem 9.6.10 (Heine-Borel)

A subset $K \subset \mathbb{R}^n$ is compact if and only if K is closed and bounded.

Proof. Suppose K is compact. $\mathbb{R}^n$ is a metric space, hence Hausdorff, so K is closed by Theorem 9.6.5. And $x \mapsto \|x\|$ is continuous, so it is bounded on K by Theorem 9.6.2, which says exactly that K is bounded.

Conversely, suppose K is closed and bounded, say $\|x\| \leq M$ for all $x \in K$. Then $K \subset [-M, M]^n$. Each $[-M, M]$ is compact (being homeomorphic to $[0, 1]$), so $[-M, M]^n$ is compact by Tychonov, and K is a closed subset of it, hence compact. $\square$

Example 9.6.11

Closed balls $B_r(x)$ in $\mathbb{R}^n$ are compact, as are spheres. And we can finally tie up a loose end from the proof of the Picard-Lindelöf theorem: a continuous function on $[a, b] \times B_R(y_0) \subset \mathbb{R}^{n+1}$ is bounded, since its domain is closed and bounded, hence compact.

§9.6.3 Sequential Compactness

In metric spaces we made heavy use of the Bolzano-Weierstrass property – every bounded sequence has a convergent subsequence. There is a corresponding abstract notion.

Definition 9.6.12 (Sequentially Compact)

A topological space X is **sequentially compact** if every sequence in X has a subsequence converging to a point of X .

It will be convenient to have some notation: given a sequence x_n and an infinite subset $M = \{m_1 < m_2 < \dots\} \subset \mathbb{N}$, we write $(x_m)_{m \in M}$ for the subsequence $x_{m_1}, x_{m_2}, \dots$. Note that if $L \subset M$ are infinite, then $(x_m)_{m \in L}$ is a subsequence of $(x_m)_{m \in M}$.

Example 9.6.13 (Bolzano-Weierstrass in $\mathbb{R}^n$)

Any closed bounded subset $K \subset \mathbb{R}^n$ is sequentially compact. Indeed, let $x_m = (x_{m,1}, \dots, x_{m,n})$ be a sequence in K ; each coordinate sequence is bounded. By Bolzano-Weierstrass applied to the first coordinate, there's an infinite $M_1 \subset \mathbb{N}$ such that $(x_{m,1})_{m \in M_1}$ converges. The second coordinate restricted to M_1 is still bounded, so there's an infinite $M_2 \subset M_1$ with $(x_{m,2})_{m \in M_2}$ convergent – and note the first coordinate still converges along M_2 . Continuing, we get $M_n \subset \dots \subset M_1$ such that all coordinates converge along M_n , so $(x_m)_{m \in M_n}$ converges in $\mathbb{R}^n$, with limit in K since K is closed.

So for subsets of $\mathbb{R}^n$, sequential compactness and compactness agree (both are ‘closed and bounded’). This is no accident: we will now show that they agree in *every* metric space. (For general topological spaces the two notions genuinely diverge – there are compact spaces that are not sequentially compact and vice versa – but the examples are exotic and beyond this course.)

We will actually prove a three-way equivalence, bringing in completeness as well. The third notion we need is a strengthening of boundedness.

Definition 9.6.14 (Totally Bounded)

Let (M, d) be a metric space. For $\varepsilon > 0$, a subset $F \subset M$ is an **ε -net** for M if

$$M = \bigcup_{y \in F} B_\varepsilon(y),$$

that is, every point of M is within ε of some point of F . We say M is **totally bounded** if for every $\varepsilon > 0$ there is a *finite* ε -net for M .

Totally bounded implies bounded, but not conversely: an infinite set with the discrete metric is bounded but has no finite $\frac{1}{2}$ -net. Similarly the closed unit ball of $\ell_\infty(\mathbb{N})$ is bounded but not totally bounded.

Definition 9.6.15 (Diameter)

For a non-empty subset A of a metric space, the **diameter** of A is $\text{diam } A = \sup\{d(x, y) \mid x, y \in A\}$.

Lemma 9.6.16 (Chopping Up a Totally Bounded Space)

Let M be a totally bounded metric space, let $A \subset M$ be non-empty and closed, and let $\varepsilon > 0$. Then we can write $A = B_1 \cup \cdots \cup B_K$ where each B_k is non-empty and closed with $\text{diam } B_k \leq \varepsilon$.

Proof. Let F be a finite $\frac{\varepsilon}{2}$ -net for M , so that $A = \bigcup_{x \in F} (A \cap B_{\varepsilon/2}(x))$. Throw away the x for which the intersection is empty, and for the rest let $B_x = A \cap B_{\varepsilon/2}(x)$. Each B_x is non-empty, closed (an intersection of closed sets), has $\text{diam } B_x \leq \text{diam } B_{\varepsilon/2}(x) \leq \varepsilon$, and together they cover A . $\square$

Theorem 9.6.17 (The Big Equivalence)

For a metric space (M, d) , the following are equivalent:

- (i) M is compact;
- (ii) M is sequentially compact;
- (iii) M is complete and totally bounded.

Proof. (i) implies (ii). Let x_n be a sequence in M , and for each n let $T_n = \{x_k \mid k > n\}$ be its n -th tail. We first claim $\bigcap_n \overline{T_n} \neq \emptyset$. If not, then the open sets $M \setminus \overline{T_n}$ cover M , so by compactness finitely many do; since the T_n are decreasing, this means $M = M \setminus \overline{T_N}$ for some N , that is, $\overline{T_N} = \emptyset$ – absurd, since $T_N \neq \emptyset$.

So pick $x \in \bigcap_n \overline{T_n}$. Since $x \in \overline{T_1}$, the ball $D_1(x)$ meets T_1 , so there is $k_1 > 1$ with $d(x_{k_1}, x) < 1$. Since $x \in \overline{T_{k_1}}$, the ball $D_{1/2}(x)$ meets T_{k_1} , giving $k_2 > k_1$ with $d(x_{k_2}, x) < \frac{1}{2}$. Continuing inductively, we get $k_1 < k_2 < \cdots$ with $d(x_{k_n}, x) < \frac{1}{n}$, so $x_{k_n} \rightarrow x$.

(ii) implies (iii). For completeness, let x_n be Cauchy, and use sequential compactness to extract a subsequence $x_{k_n} \rightarrow x$. Given $\varepsilon > 0$, take N so that $d(x_m, x_n) < \varepsilon$

for $m, n \geq N$. For fixed $n \geq N$, since $k_m \geq m$,

$$d(x_n, x) \leq d(x_n, x_{k_m}) + d(x_{k_m}, x) \leq \varepsilon + d(x_{k_m}, x) \rightarrow \varepsilon$$

as $m \rightarrow \infty$. So $d(x_n, x) \leq \varepsilon$ for all $n \geq N$, and $x_n \rightarrow x$.

For total boundedness, suppose it fails for some $\varepsilon > 0$: no finite set is an ε -net. Then we can inductively pick $x_1 \in M$ and

$$x_n \in M \setminus \bigcup_{j=1}^{n-1} B_\varepsilon(x_j),$$

since the union on the right never covers M . The resulting sequence has $d(x_m, x_n) > \varepsilon$ for all $m \neq n$, so it has no Cauchy subsequence, and hence no convergent subsequence – contradicting sequential compactness.

(iii) implies (i). Let $\mathcal{U}$ be an open cover of M , and suppose for contradiction that no finite subfamily covers M . We construct a nested sequence of ‘bad’ sets: let $A_0 = M$, and suppose we have found a non-empty closed A_{n-1} which is not finitely covered by $\mathcal{U}$. By Lemma 9.6.16 we can write A_{n-1} as a finite union of non-empty closed sets of diameter at most $\frac{1}{n}$; if each piece were finitely covered, so would A_{n-1} be, so some piece is not finitely covered – call it A_n . This gives non-empty closed sets

$$M = A_0 \supset A_1 \supset A_2 \supset \cdots, \quad \text{diam } A_n \leq \frac{1}{n},$$

with no A_n finitely covered by $\mathcal{U}$.

Now pick $x_n \in A_n$ for each n . For $m, n \geq N$ both x_m, x_n lie in A_N , so $d(x_m, x_n) \leq \frac{1}{N}$, and the sequence is Cauchy. By completeness $x_n \rightarrow x$ for some $x \in M$; since each A_N is closed and contains the tail of the sequence, $x \in A_N$ for every N . Take $U \in \mathcal{U}$ with $x \in U$ and $r > 0$ with $D_r(x) \subset U$. Choosing n with $d(x_n, x) < \frac{r}{2}$ and $\text{diam } A_n < \frac{r}{2}$, every $y \in A_n$ satisfies

$$d(y, x) \leq d(y, x_n) + d(x_n, x) < \frac{r}{2} + \frac{r}{2} = r,$$

so $A_n \subset D_r(x) \subset U$. But then A_n is covered by the single set $U \in \mathcal{U}$, contradicting that it is not finitely covered. $\square$

Remark. Note that (iii) makes the slogan ‘compact = complete + totally bounded’ precise: compactness is completeness plus an approximate finiteness. It also explains why compactness is such a strong hypothesis in analysis. As sanity checks: combining Example 9.6.13 with the theorem re-proves the hard direction of Heine-Borel from Bolzano-Weierstrass, and one can also check directly that a finite product of sequentially compact spaces is sequentially compact, giving an alternative proof of Tychonov’s theorem for metric spaces.

As a final application, we can deliver on a promise made back in our study of uniform continuity: the Bolzano-Weierstrass argument we used there works verbatim on any compact metric space.

Theorem 9.6.18 (Heine-Cantor)

Let $f : M \rightarrow M'$ be a continuous map between metric spaces, with M compact.

Then f is uniformly continuous.

Proof. If not, there is some $\varepsilon > 0$ such that for every n we can find $x_n, y_n \in M$ with $d(x_n, y_n) < \frac{1}{n}$ but $d'(f(x_n), f(y_n)) \geq \varepsilon$. By sequential compactness, passing to a subsequence we may assume $x_n \rightarrow x \in M$, and then $y_n \rightarrow x$ too since $d(x_n, y_n) \rightarrow 0$. By continuity, $f(x_n) \rightarrow f(x)$ and $f(y_n) \rightarrow f(x)$, so

$$d'(f(x_n), f(y_n)) \leq d'(f(x_n), f(x)) + d'(f(x), f(y_n)) \rightarrow 0,$$

contradicting $d'(f(x_n), f(y_n)) \geq \varepsilon$. □

§9.7 Differentiation from $\mathbb{R}^m$ to $\mathbb{R}^n$

For the final part of the course, we return from the abstract world of topological spaces to concrete multivariable analysis, and develop the theory of differentiation for functions $f : \mathbb{R}^m \rightarrow \mathbb{R}^n$. The metric and topological machinery we've built – open sets, completeness, connectedness, the contraction mapping theorem – will all earn its keep here.

§9.7.1 The Derivative as a Linear Map

What should it mean for $f : \mathbb{R}^m \rightarrow \mathbb{R}^n$ to be differentiable at a point? The one-dimensional definition,

$$f'(a) = \lim_{h \rightarrow 0} \frac{f(a+h) - f(a)}{h},$$

doesn't directly generalize – we can't divide by a vector $h \in \mathbb{R}^m$. The right move is to reformulate. In one dimension, f is differentiable at a with derivative λ if and only if

$$f(a+h) = f(a) + \lambda h + h\varepsilon(h),$$

where $\varepsilon(h) \rightarrow 0$ as $h \rightarrow 0$. Read this way, the derivative is not really a number – it's the *linear map* $h \mapsto \lambda h$ which best approximates the change in f near a . Linear maps make perfect sense between $\mathbb{R}^m$ and $\mathbb{R}^n$, and this is the definition that generalizes.

Before making this precise, we need a tiny bit of setup about the space of linear maps itself. Write $L(\mathbb{R}^m, \mathbb{R}^n)$ for the vector space of linear maps $T : \mathbb{R}^m \rightarrow \mathbb{R}^n$. Fixing standard bases $e_1, \dots, e_m$ of $\mathbb{R}^m$ and $e'_1, \dots, e'_n$ of $\mathbb{R}^n$, each T is represented by the $n \times m$ matrix with entries $T_{ji} = \langle Te_i, e'_j \rangle$, so $L(\mathbb{R}^m, \mathbb{R}^n)$ can be identified with $\mathbb{R}^{nm}$, and we give it the Euclidean norm

$$\|T\| = \left(\sum_{i=1}^m \sum_{j=1}^n T_{ji}^2 \right)^{1/2} = \left(\sum_{i=1}^m \|Te_i\|^2 \right)^{1/2}.$$

In particular $L(\mathbb{R}^m, \mathbb{R}^n)$ is a metric space with $d(S, T) = \|S - T\|$, and everything we know about $\mathbb{R}^{nm}$ (completeness, Heine-Borel, and so on) applies to it.

Lemma 9.7.1 (Linear Maps are Lipschitz)

For $T \in L(\mathbb{R}^m, \mathbb{R}^n)$ and $x \in \mathbb{R}^m$ we have $\|Tx\| \leq \|T\|\|x\|$. Consequently every linear map is Lipschitz, hence continuous. Moreover, for $S \in L(\mathbb{R}^n, \mathbb{R}^p)$ we have

$$\|ST\| \leq \|S\|\|T\|.$$

Proof. Writing $x = \sum_i x_i e_i$, we have $Tx = \sum_i x_i Te_i$, so by the triangle inequality and Cauchy-Schwarz,

$$\|Tx\| \leq \sum_{i=1}^m |x_i| \|Te_i\| \leq \left(\sum_{i=1}^m x_i^2 \right)^{1/2} \left(\sum_{i=1}^m \|Te_i\|^2 \right)^{1/2} = \|x\| \|T\|.$$

Then $\|Tx - Ty\| = \|T(x - y)\| \leq \|T\| \|x - y\|$, so T is Lipschitz. Finally,

$$\|ST\| = \left(\sum_{i=1}^m \|S(Te_i)\|^2 \right)^{1/2} \leq \left(\sum_{i=1}^m \|S\|^2 \|Te_i\|^2 \right)^{1/2} = \|S\| \|T\|. \quad \square$$

Now we can make our main definition. We work on open subsets, since differentiability at a should only depend on the behaviour of f near a .

Definition 9.7.2 (Differentiability)

Let $U \subset \mathbb{R}^m$ be open, $f : U \rightarrow \mathbb{R}^n$ and $a \in U$. We say f is **differentiable at a** if there exists a linear map $T \in L(\mathbb{R}^m, \mathbb{R}^n)$ such that

$$\frac{f(a+h) - f(a) - T(h)}{\|h\|} \rightarrow 0 \quad \text{as } h \rightarrow 0.$$

Equivalently, $f(a+h) = f(a) + T(h) + \|h\| \varepsilon(h)$, where $\varepsilon(h) \rightarrow 0 = \varepsilon(0)$ as $h \rightarrow 0$.

If f is differentiable at every point of U , we say f is **differentiable on U** .

Proposition 9.7.3 (Uniqueness of the Derivative)

The linear map T in the definition above is unique.

Proof. Suppose S and T both work. Subtracting the two conditions gives

$$\frac{S(h) - T(h)}{\|h\|} \rightarrow 0 \quad \text{as } h \rightarrow 0.$$

Fix $x \neq 0$ and take $h = x/k$ for $k \in \mathbb{N}$, so $h \rightarrow 0$ as $k \rightarrow \infty$. By linearity, $(S(h) - T(h))/\|h\|$ doesn't depend on k at all – it always equals $(S(x) - T(x))/\|x\|$. So this quantity is 0, and $S(x) = T(x)$ for all x . $\square$

We call this unique T the **derivative** of f at a , and write $f'(a) = Df(a) = T$. So $f'(a)$ is a *linear map* $\mathbb{R}^m \rightarrow \mathbb{R}^n$, and the defining property is

$$f(a+h) = f(a) + f'(a)(h) + o(\|h\|),$$

where as usual $o(\|h\|)$ denotes a quantity which, divided by $\|h\|$, tends to 0 as $h \rightarrow 0$. The right picture is that the affine function $x \mapsto f(a) + f'(a)(x - a)$ is the *best linear approximation* to f near a – its graph is the tangent line (or plane) to the graph of f , and the error dies off faster than linearly.

Remark (Recovering the One-Dimensional Derivative). When $m = 1$, a linear map $\mathbb{R} \rightarrow \mathbb{R}^n$ is just multiplication by a fixed vector $v \in \mathbb{R}^n$, and the condition becomes $(f(a+h) - f(a))/h \rightarrow v$: the familiar limit definition, now taking vector values. So for curves, the derivative-as-linear-map and the derivative-as-vector are the same information.

Let's compute some derivatives from the definition.

Example 9.7.4 (Constant and Linear Maps)

If $f(x) = b$ is constant, then $f(a+h) = f(a) + 0(h) + 0$, so f is differentiable with $f'(a) = 0$ for all a .

If $f(x) = Tx$ for a fixed $T \in L(\mathbb{R}^m, \mathbb{R}^n)$, then $f(a+h) = f(a) + T(h) + 0$, so $f'(a) = T$ for every a – a linear map is its own best linear approximation, everywhere.

Example 9.7.5 (The Norm-Squared Function)

Let $f : \mathbb{R}^m \rightarrow \mathbb{R}$ be $f(x) = \|x\|^2$. Then

$$f(a+h) = \|a\|^2 + 2\langle a, h \rangle + \|h\|^2 = f(a) + 2\langle a, h \rangle + o(\|h\|),$$

since $\|h\|^2/\|h\| = \|h\| \rightarrow 0$. The map $h \mapsto 2\langle a, h \rangle$ is linear, so f is differentiable with $f'(a)(h) = 2\langle a, h \rangle$.

Example 9.7.6 (Squaring a Matrix)

Let M_n denote the space of $n \times n$ real matrices, identified with $\mathbb{R}^{n^2}$, and let $f : M_n \rightarrow M_n$ be $f(A) = A^2$. Then

$$f(A+H) = A^2 + AH + HA + H^2,$$

and $H \mapsto AH + HA$ is linear, while $\|H^2\| \leq \|H\|^2 = o(\|H\|)$ using Lemma 9.7.1. So $f'(A)(H) = AH + HA$. (For $n = 1$ this is the statement that the derivative of x^2 is multiplication by $2x$ – but note that for $n > 1$ we cannot collapse $AH + HA$ to $2AH$, as matrices don't commute.)

As in one dimension, differentiability is stronger than continuity.

Proposition 9.7.7 (Differentiable Implies Continuous)

If $f : U \rightarrow \mathbb{R}^n$ is differentiable at $a \in U$, then f is continuous at a .

Proof. Write $f(x) = f(a) + f'(a)(x - a) + \|x - a\| \varepsilon(x - a)$. As $x \rightarrow a$: the middle term tends to 0 since linear maps are continuous, and the error term tends to 0. So $f(x) \rightarrow f(a)$. $\square$

The chain rule survives intact, and in fact its statement becomes cleaner than in one dimension: the derivative of a composition is the *composition* of the derivatives.

Theorem 9.7.8 (Chain Rule)

Let $U \subset \mathbb{R}^m$ and $V \subset \mathbb{R}^n$ be open, and let $f : U \rightarrow \mathbb{R}^n$ and $g : V \rightarrow \mathbb{R}^p$ with $f(U) \subset V$. If f is differentiable at a and g is differentiable at $b = f(a)$, then $g \circ f$ is differentiable at a , with

$$(g \circ f)'(a) = g'(b) \circ f'(a).$$

Proof. Write $S = f'(a)$ and $T = g'(b)$, so that

$$f(a + h) = f(a) + S(h) + \|h\| \varepsilon(h), \quad g(b + k) = g(b) + T(k) + \|k\| \zeta(k),$$

with $\varepsilon(h) \rightarrow 0$ and $\zeta(k) \rightarrow 0$. Substituting $k = k(h) = S(h) + \|h\| \varepsilon(h)$,

$$\begin{aligned} (g \circ f)(a + h) &= g(b + k) = g(b) + T(S(h) + \|h\| \varepsilon(h)) + \|k\| \zeta(k) \\ &= (g \circ f)(a) + (T \circ S)(h) + \underbrace{\|h\| T(\varepsilon(h)) + \|k\| \zeta(k)}_{\eta(h)}. \end{aligned}$$

It remains to show $\eta(h) = o(\|h\|)$. For the first piece, $\|T(\varepsilon(h))\| \leq \|T\| \|\varepsilon(h)\| \rightarrow 0$. For the second, note

$$\frac{\|k\|}{\|h\|} \leq \frac{\|S(h)\| + \|h\| \|\varepsilon(h)\|}{\|h\|} \leq \|S\| + \|\varepsilon(h)\|,$$

which is bounded for small h ; and $k \rightarrow 0$ as $h \rightarrow 0$, so $\zeta(k) \rightarrow 0$. Hence

$$\frac{\|\eta(h)\|}{\|h\|} \leq \|T(\varepsilon(h))\| + \frac{\|k\|}{\|h\|} \|\zeta(k)\| \rightarrow 0,$$

as required. $\square$

Just as for continuity, differentiability can be checked component by component.

Proposition 9.7.9 (Components)

Let $U \subset \mathbb{R}^m$ be open, $f : U \rightarrow \mathbb{R}^n$, and write $f_j = \pi_j \circ f$ for the components of f , where $\pi_j : \mathbb{R}^n \rightarrow \mathbb{R}$ is the j -th coordinate projection. Then f is differentiable at a if and only if every f_j is, and in that case

$$f'(a)(h) = \sum_{j=1}^n f'_j(a)(h) e'_j.$$

Proof. If f is differentiable at a , then since π_j is linear (so differentiable, and equal to its own derivative), the chain rule gives $f'_j(a) = \pi_j \circ f'(a)$, which is the claim. Conversely, if each f_j is differentiable at a , write $f_j(a+h) = f_j(a) + f'_j(a)(h) + \|h\|\varepsilon_j(h)$; summing against e'_j ,

$$f(a+h) = f(a) + \sum_{j=1}^n f'_j(a)(h)e'_j + \|h\| \sum_{j=1}^n \varepsilon_j(h)e'_j,$$

and the final error term is $o(\|h\|)$ since each $\varepsilon_j(h) \rightarrow 0$. $\square$

This is a very useful reduction – it means that in many proofs we may assume $n = 1$ without loss of generality. Finally, the usual algebraic rules.

Proposition 9.7.10 (Sums and Products)

Let $U \subset \mathbb{R}^m$ be open and let $f, g : U \rightarrow \mathbb{R}^n$ and $\phi : U \rightarrow \mathbb{R}$ all be differentiable at $a \in U$. Then $f + g$ and ϕf are differentiable at a , with

$$(f + g)'(a) = f'(a) + g'(a), \quad (\phi f)'(a)(h) = \phi(a)f'(a)(h) + [\phi'(a)(h)]f(a).$$

Proof. The sum rule follows immediately by adding the two defining expansions. For the product, expanding $\phi(a+h)f(a+h)$ using both expansions gives

$$(\phi f)(a) + \phi(a)f'(a)(h) + \phi'(a)(h)f(a) + \rho(h),$$

where $\rho(h)$ collects the remaining terms: $\phi'(a)(h) \cdot f'(a)(h)$, and various products involving an error term. The first satisfies $\|\phi'(a)(h)f'(a)(h)\| \leq \|\phi'(a)\|\|f'(a)\|\|h\|^2 = o(\|h\|)$, and the rest are also $o(\|h\|)$ since each contains a factor $\|h\|$ (or a bounded multiple of it) alongside a factor tending to zero. The map $h \mapsto \phi(a)f'(a)(h) + \phi'(a)(h)f(a)$ is linear, so the result follows. Taking $m = n = 1$ recovers the familiar product rule. $\square$

§9.7.2 Partial Derivatives

The definition of the derivative is clean, but to *compute* with it we want to reduce to one-dimensional derivatives. This is what directional and partial derivatives do.

Definition 9.7.11 (Directional and Partial Derivatives)

Let $U \subset \mathbb{R}^m$ be open, $f : U \rightarrow \mathbb{R}^n$, $a \in U$, and let $u \in \mathbb{R}^m$ be non-zero. If the limit

$$D_u f(a) = \lim_{t \rightarrow 0} \frac{f(a + tu) - f(a)}{t}$$

exists (in $\mathbb{R}^n$), we call it the **directional derivative** of f at a in the direction u .

When $u = e_i$ is a standard basis vector, we write $D_i f(a) = D_{e_i} f(a)$ and call it the **i -th partial derivative** of f at a . For scalar components we use the familiar notation $D_i f_j(a) = \frac{\partial f_j}{\partial x_i}(a)$.

Note that $D_u f(a)$ is exactly the derivative at 0 of the one-variable function $t \mapsto f(a + tu)$

– we restrict f to a line through a and differentiate along it.

Proposition 9.7.12 (The Derivative Determines All Directional Derivatives)

If f is differentiable at a , then $D_u f(a)$ exists for every direction $u \neq 0$, and

$$D_u f(a) = f'(a)(u).$$

In particular, writing $h = \sum_i h_i e_i$,

$$f'(a)(h) = \sum_{i=1}^m h_i D_i f(a),$$

so the derivative is determined by the m partial derivatives.

Proof. Setting $h = tu$ in the definition of differentiability,

$$\frac{f(a + tu) - f(a)}{t} = f'(a)(u) + \frac{|t|}{t} \|u\| \varepsilon(tu),$$

and the error term tends to 0 as $t \rightarrow 0$ (the factor $|t|/t$ is bounded). The second claim follows from linearity of $f'(a)$. $\square$

Definition 9.7.13 (Jacobian Matrix)

If f is differentiable at a , the matrix of $f'(a)$ with respect to the standard bases is called the **Jacobian matrix** $J_f(a)$. By the proposition, its i -th column is $D_i f(a)$, so its entries are

$$(J_f(a))_{ji} = D_i f_j(a) = \frac{\partial f_j}{\partial x_i}(a).$$

It is important that the converse of Proposition 9.7.12 fails: a function can have all directional derivatives at a point without being differentiable there.

Example 9.7.14 (Directional Derivatives Are Not Enough)

Define $f : \mathbb{R}^2 \rightarrow \mathbb{R}$ by

$$f(x, y) = \frac{x^3}{x^2 + y^2} \text{ for } (x, y) \neq (0, 0), \quad f(0, 0) = 0.$$

For any direction $u = (u_1, u_2)$, we have

$$\frac{f(tu) - f(0)}{t} = \frac{1}{t} \cdot \frac{t^3 u_1^3}{t^2 u_1^2 + t^2 u_2^2} = \frac{u_1^3}{\|u\|^2},$$

so all directional derivatives at the origin exist (and equal this value). But $u \mapsto u_1^3/\|u\|^2$ is *not linear* in u , so by Proposition 9.7.12, f cannot be differentiable at the origin.

However, if the partial derivatives exist *near* a and are continuous *at* a , then we do get differentiability. This is the workhorse criterion for checking differentiability in practice.

Theorem 9.7.15 (Continuous Partial Derivatives Imply Differentiability)

Let $U \subset \mathbb{R}^m$ be open, $f : U \rightarrow \mathbb{R}^n$, and $a \in U$. Suppose there is an open neighborhood $V \subset U$ of a on which all partial derivatives $D_i f$ exist, and that each $D_i f : V \rightarrow \mathbb{R}^n$ is continuous at a . Then f is differentiable at a .

Proof. By Proposition 9.7.9 we may assume $n = 1$. We also present the proof for $m = 2$ – the general case works in exactly the same way, one coordinate at a time, at the cost of heavier notation. Write $a = (p, q)$, and let

$$\psi(h, k) = f(p + h, q + k) - f(p, q) - hD_1f(p, q) - kD_2f(p, q).$$

We must show $\psi(h, k) = o(\|(h, k)\|)$; then f is differentiable at a with derivative $(h, k) \mapsto hD_1f(a) + kD_2f(a)$. The trick is to move from (p, q) to $(p + h, q + k)$ one coordinate at a time:

$$\psi(h, k) = \underbrace{[f(p + h, q + k) - f(p + h, q) - kD_2f(p, q)]}_{(1)} + \underbrace{[f(p + h, q) - f(p, q) - hD_1f(p, q)]}_{(2)}.$$

Term (2) is $o(|h|)$, hence $o(\|(h, k)\|)$, directly by the definition of $D_1f(p, q)$.

For term (1), fix h, k small and consider $\phi(t) = f(p + h, q + tk)$ for $t \in [0, 1]$. Then ϕ is differentiable with $\phi'(t) = kD_2f(p + h, q + tk)$, so by the one-dimensional mean value theorem there's some $\theta = \theta(h, k) \in (0, 1)$ with

$$f(p + h, q + k) - f(p + h, q) = \phi(1) - \phi(0) = kD_2f(p + h, q + \theta k).$$

Hence term (1) equals $k[D_2f(p + h, q + \theta k) - D_2f(p, q)]$. As $(h, k) \rightarrow 0$, the point $(p + h, q + \theta k) \rightarrow (p, q)$, so by continuity of D_2f at a , the bracket tends to 0, and term (1) is $o(|k|) = o(\|(h, k)\|)$. $\square$

Definition 9.7.16 (C^1 Function)

Let $U \subset \mathbb{R}^m$ be open. A function $f : U \rightarrow \mathbb{R}^n$ is **C^1 on U** (or **continuously differentiable**) if f is differentiable on U and the derivative map $f' : U \rightarrow L(\mathbb{R}^m, \mathbb{R}^n)$ is continuous.

Since the entries of the Jacobian are the partial derivatives, and convergence in $L(\mathbb{R}^m, \mathbb{R}^n) \cong \mathbb{R}^{nm}$ is entry-wise, f is C^1 on U if and only if all partial derivatives $D_i f_j$ exist and are continuous on U – combining Theorem 9.7.15 with Proposition 9.7.12.

§9.7.3 The Mean Value Inequality

The mean value *theorem* – that $f(b) - f(a) = f'(c)(b - a)$ for some intermediate c – fails for vector-valued functions; different components want different intermediate points⁵. But in analysis we almost always used the mean value theorem to *bound* increments, and the bound survives beautifully.

⁵Consider $f(t) = (\cos t, \sin t)$: we have $f(2\pi) - f(0) = 0$, but f' never vanishes.

Theorem 9.7.17 (Mean Value Inequality)

Let $U \subset \mathbb{R}^m$ be open and $f : U \rightarrow \mathbb{R}^n$ differentiable on U . Suppose $a, b \in U$ are such that the segment $[a, b] = \{(1-t)a + tb \mid t \in [0, 1]\}$ lies in U , and that $\|f'(z)\| \leq M$ for all $z \in [a, b]$. Then

$$\|f(b) - f(a)\| \leq M\|b - a\|.$$

Proof. Let $u = b - a$ (we may assume $u \neq 0$) and let $v = f(b) - f(a)$. The trick is to convert to a scalar problem by projecting onto v : define

$$\phi(t) = \langle f(a + tu), v \rangle, \quad t \in [0, 1].$$

By the chain rule (composing $t \mapsto a + tu$ with f , then with the linear map $\langle \cdot, v \rangle$), ϕ is differentiable with

$$\phi'(t) = \langle f'(a + tu)(u), v \rangle.$$

By the one-dimensional mean value theorem, there's some $\theta \in (0, 1)$ with $\phi(1) - \phi(0) = \phi'(\theta)$. But $\phi(1) - \phi(0) = \langle f(b) - f(a), v \rangle = \|v\|^2$, so by Cauchy-Schwarz and Lemma 9.7.1,

$$\|v\|^2 = \langle f'(a + \theta u)(u), v \rangle \leq \|f'(a + \theta u)\| \|u\| \|v\| \leq M\|b - a\| \|v\|.$$

If $v = 0$ there is nothing to prove; otherwise divide by $\|v\|$. □

Here is the promised payoff from connectedness.

Corollary 9.7.18 (Zero Derivative Implies Constant)

Let $U \subset \mathbb{R}^m$ be open and *connected*, and let $f : U \rightarrow \mathbb{R}^n$ be differentiable with $f'(a) = 0$ for all $a \in U$. Then f is constant.

Proof. For any $x \in U$, take $r > 0$ with $D_r(x) \subset U$. The ball is convex, so for $y \in D_r(x)$ the segment $[x, y]$ lies in U , and the mean value inequality with $M = 0$ gives $f(y) = f(x)$. So f is *locally constant*.

Now fix $x_0 \in U$ and let $P = \{x \in U \mid f(x) = f(x_0)\}$. By local constancy, both P and $U \setminus P$ are open. Since U is connected and $P \ni x_0$ is non-empty, we must have $P = U$. □

Note that connectedness is genuinely needed – on a disconnected open set, a function can be constant on each piece with different values.

§9.7.4 Second Derivatives

If $f : U \rightarrow \mathbb{R}^n$ is differentiable on U , its derivative is itself a function $f' : U \rightarrow L(\mathbb{R}^m, \mathbb{R}^n)$ into the (finite dimensional, normed) space of linear maps, and we can ask for *its* derivative.

Definition 9.7.19 (Second Derivative)

Let $U \subset \mathbb{R}^m$ be open, $f : U \rightarrow \mathbb{R}^n$, and $a \in U$. Suppose f is differentiable on some open neighborhood $V \subset U$ of a . We say f is **twice differentiable at a** if

$f' : V \rightarrow L(\mathbb{R}^m, \mathbb{R}^n)$ is differentiable at a , and write $f''(a)$ for its derivative, so

$$f''(a) \in L(\mathbb{R}^m, L(\mathbb{R}^m, \mathbb{R}^n)).$$

An element of $L(\mathbb{R}^m, L(\mathbb{R}^m, \mathbb{R}^n))$ is awkward to think about directly, but there is a standard way out: such a gadget is the same thing as a *bilinear map* $\mathbb{R}^m \times \mathbb{R}^m \rightarrow \mathbb{R}^n$. Explicitly, if $T \in L(\mathbb{R}^m, L(\mathbb{R}^m, \mathbb{R}^n))$, we identify it with the bilinear map $(h, k) \mapsto T(h)(k)$, and we will freely write $f''(a)(h, k)$ for $(f''(a)(h))(k)$.

Proposition 9.7.20 (Second Derivative as a Bilinear Approximation)

In the setting above, f is twice differentiable at a if and only if there is a bilinear map $T : \mathbb{R}^m \times \mathbb{R}^m \rightarrow \mathbb{R}^n$ such that for every fixed $k \in \mathbb{R}^m$,

$$f'(a+h)(k) = f'(a)(k) + T(h, k) + o(\|h\|) \quad \text{as } h \rightarrow 0,$$

and in that case $T = f''(a)$.

Proof. If f is twice differentiable at a , then $f'(a+h) = f'(a) + f''(a)(h) + \|h\|\varepsilon(h)$ where $\varepsilon(h) \rightarrow 0$ in $L(\mathbb{R}^m, \mathbb{R}^n)$. Evaluating at k and using $\|\varepsilon(h)(k)\| \leq \|\varepsilon(h)\|\|k\| \rightarrow 0$ gives the displayed formula.

Conversely, suppose the formula holds for each fixed k , and let

$$\varepsilon(h) = \frac{f'(a+h) - f'(a) - T(h)}{\|h\|} \in L(\mathbb{R}^m, \mathbb{R}^n).$$

By hypothesis $\varepsilon(h)(k) \rightarrow 0$ for each fixed k ; taking $k = e_1, \dots, e_m$ and using

$$\|\varepsilon(h)\| = \left(\sum_{i=1}^m \|\varepsilon(h)(e_i)\|^2 \right)^{1/2} \rightarrow 0,$$

we get $\varepsilon(h) \rightarrow 0$ in $L(\mathbb{R}^m, \mathbb{R}^n)$, which is twice differentiability with $f''(a) = T$. $\square$

Example 9.7.21

If f is linear then f' is the constant function $a \mapsto f$, so $f''(a) = 0$ everywhere. If $f : \mathbb{R}^m \times \mathbb{R}^n \rightarrow \mathbb{R}^p$ is *bilinear*, then a similar computation to the matrix-squaring example shows $f'(a, b)(h, k) = f(a, k) + f(h, b)$, which is *linear* as a function of (a, b) – so f'' is constant, equal to the bilinear map $((h, k), (h', k')) \mapsto f(h, k') + f(h', k)$.

Example 9.7.22 (Cubing a Matrix)

Let $f : M_n \rightarrow M_n$ be $f(A) = A^3$. Expanding $(A+H)^3$ and collecting terms of degree 1 in H ,

$$f'(A)(H) = A^2H + AHA + HA^2,$$

with the degree- ≥ 2 terms being $o(\|H\|)$. Then expanding $f'(A+H)(K) - f'(A)(K)$ and collecting the terms linear in H ,

$$f''(A)(H, K) = AHK + HAK + AKH + HKA + KAH + KHA,$$

which is indeed bilinear in (H, K) , and symmetric under swapping H and K . In one dimension these formulas collapse to the familiar $f'(a) = 3a^2$ and $f''(a) = 6a$.

The symmetry visible in that example is no coincidence. To see what it means concretely, evaluate the second derivative on directions: if f is twice differentiable at a , then for fixed v , the map $x \mapsto D_v f(x) = f'(x)(v)$ is differentiable at a , and by the proposition above,

$$D_u D_v f(a) = (D_v f)'(a)(u) = f''(a)(u, v).$$

In particular $D_i D_j f(a) = f''(a)(e_i, e_j)$: second partial derivatives are the entries of the second derivative.

Theorem 9.7.23 (Symmetry of Second Derivatives)

Let $U \subset \mathbb{R}^m$ be open, $f : U \rightarrow \mathbb{R}^n$, and $a \in U$. Suppose f is twice differentiable on an open V with $a \in V \subset U$, and that $f'' : V \rightarrow \text{Bil}(\mathbb{R}^m \times \mathbb{R}^m, \mathbb{R}^n)$ is continuous at a . Then for all u, v ,

$$f''(a)(u, v) = f''(a)(v, u),$$

that is, $f''(a)$ is a symmetric bilinear map. Equivalently, $D_u D_v f(a) = D_v D_u f(a)$.

Proof. Considering components (which commute with everything in sight), we may assume $n = 1$. The key object is the *second difference*

$$\phi(s, t) = f(a + su + tv) - f(a + tv) - f(a + su) + f(a),$$

for small $s, t > 0$ – the alternating sum of f over the vertices of the parallelogram spanned by su and tv . It is manifestly symmetric between the roles of (s, u) and (t, v) , and we will compute its size in two ways.

Fix s, t and let $\psi(y) = f(a + yu + tv) - f(a + yu)$, so that $\phi(s, t) = \psi(s) - \psi(0)$. By the mean value theorem, there's some $\alpha \in (0, 1)$ with

$$\phi(s, t) = s\psi'(\alpha s) = s[D_u f(a + \alpha su + tv) - D_u f(a + \alpha su)].$$

Applying the mean value theorem again, to $y \mapsto D_u f(a + \alpha su + yv)$, gives $\beta \in (0, 1)$ with

$$\phi(s, t) = st D_v D_u f(a + \alpha su + \beta tv) = st f''(a + \alpha su + \beta tv)(v, u).$$

Since f'' is continuous at a , letting $s, t \rightarrow 0$ gives

$$\frac{\phi(s, t)}{st} \rightarrow f''(a)(v, u).$$

But by symmetry of ϕ , running the same argument with $\psi(y) = f(a + su + yv) - f(a + yv)$ instead gives

$$\frac{\phi(s, t)}{st} \rightarrow f''(a)(u, v).$$

Limits are unique, so $f''(a)(u, v) = f''(a)(v, u)$. □

Remark. Taking $u = e_i$, $v = e_j$, this is the familiar statement that mixed partial derivatives commute,

$$\frac{\partial^2 f}{\partial x_i \partial x_j}(a) = \frac{\partial^2 f}{\partial x_j \partial x_i}(a),$$

for (say) twice continuously differentiable f – so for scalar f , the *Hessian matrix* $(D_i D_j f(a))_{ij}$ is symmetric. Some continuity hypothesis is genuinely needed; without it there are standard counterexamples where the two mixed partials at a point disagree.

§9.7.5 The Inverse Function Theorem

We finish the course with a genuine highlight – a theorem that combines nearly everything we have done: completeness and the contraction mapping theorem, open sets and continuity, the mean value inequality, and the derivative as a linear map.

The question is: when does a function f have a differentiable inverse? There is an obvious necessary condition. If $f : V \rightarrow W$ is a bijection between open sets, differentiable at a with differentiable inverse g at $f(a)$, then differentiating $g \circ f = \text{id}$ and $f \circ g = \text{id}$ with the chain rule shows that $g'(f(a)) \circ f'(a)$ and $f'(a) \circ g'(f(a))$ are both identity maps – so $f'(a)$ must be an *invertible* linear map⁶.

The inverse function theorem says that, for C^1 functions, this necessary condition is *locally sufficient*: wherever the derivative is invertible, the function itself is invertible near that point, with C^1 inverse.

Theorem 9.7.24 (Inverse Function Theorem)

Let $U \subset \mathbb{R}^n$ be open and $f : U \rightarrow \mathbb{R}^n$ a C^1 function. Let $a \in U$ and suppose $f'(a)$ is invertible. Then there exist open sets $V \ni a$ and $W \ni f(a)$, with $V \subset U$, such that $f|_V : V \rightarrow W$ is a bijection, and its inverse $g : W \rightarrow V$ is C^1 with

$$g'(y) = [f'(g(y))]^{-1} \quad \text{for all } y \in W.$$

Proof. We proceed in several steps.

Step 0: normalisation. We first argue that we may assume $a = 0$, $f(a) = 0$ and $f'(a) = I$, the identity map. Indeed, let $T = f'(a)$ and set

$$h(x) = T^{-1}(f(x+a) - f(a)),$$

defined on the open set $U - a \ni 0$. By the chain rule (linear maps being their own derivatives), h is differentiable with $h'(x) = T^{-1} \circ f'(x+a)$, so $h(0) = 0$ and $h'(0) = I$; moreover

$$\|h'(x) - h'(y)\| \leq \|T^{-1}\| \|f'(x+a) - f'(y+a)\|,$$

⁶Taking traces of the two identities also shows $m = n$: differentially-invertible maps only exist between spaces of equal dimension.

so h is also C^1 . If the theorem holds for h , then it holds for f , since $f(x) = T(h(x - a)) + f(a)$ and composing with the fixed homeomorphisms $x \mapsto x - a$, $y \mapsto T(y) + f(a)$ (whose derivatives are invertible) transports all the conclusions back. So assume $f(0) = 0$ and $f'(0) = I$.

Step 1: f doesn't collapse distances near 0. Since f' is continuous, there is $r > 0$ such that $B_r(0) \subset U$ and

$$\|f'(x) - I\| \leq \frac{1}{2} \quad \text{for all } x \in B_r(0).$$

Consider $p(x) = f(x) - x$, so $p'(x) = f'(x) - I$ has $\|p'(x)\| \leq \frac{1}{2}$ on $B_r(0)$. The ball is convex, so the mean value inequality gives, for $x, y \in B_r(0)$,

$$\|p(x) - p(y)\| \leq \frac{1}{2}\|x - y\|,$$

and hence

$$\|f(x) - f(y)\| \geq \|x - y\| - \|p(x) - p(y)\| \geq \frac{1}{2}\|x - y\|.$$

In particular f is injective on $B_r(0)$.

Step 2: f hits everything near 0. Let $s = r/2$. We claim that for every $w \in D_s(0)$ there is a unique $x \in D_r(0)$ with $f(x) = w$. Fix such a w and define

$$q(x) = w - p(x) = w - f(x) + x,$$

so that $f(x) = w$ if and only if $q(x) = x$: solving our equation means finding a fixed point of q . Now for $x \in B_r(0)$, using $p(0) = 0$,

$$\|q(x)\| \leq \|w\| + \|p(x) - p(0)\| < s + \frac{1}{2}\|x\| \leq \frac{r}{2} + \frac{r}{2} = r,$$

so q maps $B_r(0)$ into $D_r(0) \subset B_r(0)$. Moreover, for $x, y \in B_r(0)$,

$$\|q(x) - q(y)\| = \|p(x) - p(y)\| \leq \frac{1}{2}\|x - y\|,$$

so q is a contraction of the non-empty *complete* metric space $B_r(0)$ (closed and bounded in $\mathbb{R}^n$, hence complete). By the contraction mapping theorem, q has a unique fixed point $x \in B_r(0)$, and since q maps into the open ball, in fact $x \in D_r(0)$. This proves the claim.

Step 3: the local inverse, and its continuity. Let

$$W = D_s(0), \quad V = D_r(0) \cap f^{-1}(W).$$

Then W is open, and V is open as an intersection of open sets (f being continuous), with $0 \in V$. By Step 2, $f|_V : V \rightarrow W$ is a bijection; call its inverse $g : W \rightarrow V$. For $u, v \in W$, writing $x = g(u)$, $y = g(v)$, Step 1 gives

$$\|g(u) - g(v)\| = \|x - y\| \leq 2\|f(x) - f(y)\| = 2\|u - v\|,$$

so g is 2-Lipschitz, and in particular continuous.

Step 4: differentiability of the inverse. First note that for $x \in B_r(0)$, the linear map $f'(x)$ is invertible: if $f'(x)v = 0$ then

$$\|v\| = \|(I - f'(x))v\| \leq \|I - f'(x)\|\|v\| \leq \frac{1}{2}\|v\|,$$

so $v = 0$, and an injective linear map $\mathbb{R}^n \rightarrow \mathbb{R}^n$ is invertible.

Now fix $y \in W$ and let $x = g(y) \in V$, $S = f'(x)$. Let k be small enough that $y + k \in W$, and set $h = g(y + k) - g(y)$, so that $f(x + h) = y + k$ and, by the Lipschitz bound on g , $\|h\| \leq 2\|k\|$. Differentiability of f at x gives

$$k = f(x + h) - f(x) = S(h) + \|h\|\varepsilon(h), \quad \varepsilon(h) \rightarrow 0 \text{ as } h \rightarrow 0.$$

Applying S^{-1} ,

$$g(y + k) - g(y) - S^{-1}(k) = h - S^{-1}(S(h) + \|h\|\varepsilon(h)) = -\|h\|S^{-1}(\varepsilon(h)),$$

and hence

$$\frac{\|g(y + k) - g(y) - S^{-1}(k)\|}{\|k\|} \leq \frac{\|h\|}{\|k\|} \|S^{-1}\| \|\varepsilon(h)\| \leq 2\|S^{-1}\| \|\varepsilon(h)\|.$$

As $k \rightarrow 0$ we have $h \rightarrow 0$ (continuity of g), so the right hand side tends to 0. This shows g is differentiable at y with

$$g'(y) = S^{-1} = [f'(g(y))]^{-1}.$$

Finally, g' is continuous: it is the composition of the continuous maps g (Step 3), f' (as f is C^1), and matrix inversion, which is continuous on the set of invertible matrices since the entries of A^{-1} are rational functions (with non-vanishing denominator $\det A$) of the entries of A . So g is C^1 , completing the proof. $\square$

Remark. A couple of closing remarks on this theorem.

- (i) The conclusion is genuinely *local*. The map $f : \mathbb{R}^2 \rightarrow \mathbb{R}^2$ given in complex notation by $z \mapsto e^z$ has everywhere-invertible derivative, and is locally invertible near every point, but it is not injective globally (as $e^{z+2\pi i} = e^z$).
- (ii) The inverse function theorem is the gateway to the *implicit function theorem* and to the theory of manifolds and submanifolds – it is the tool that lets us straighten out nonlinear maps locally, and it will reappear throughout courses in differential geometry and analysis.

10 Complex Analysis

Complex analysis is the study of differentiable functions of a complex variable. Asking for a function $\mathbb{C} \rightarrow \mathbb{C}$ to be differentiable turns out to be a shockingly strong requirement – such functions are automatically infinitely differentiable, are determined on huge regions by their values on tiny ones, and their integrals along closed curves detect delicate information about singularities. The theory that develops from this single definition is remarkably rigid, remarkably beautiful, and (as we will see towards the end of these notes) genuinely useful for down-to-earth tasks like computing real integrals.

This article constitutes my notes for the ‘Complex Analysis’ course, held in Lent 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§10.1 Basic Notions

§10.1.1 Complex Differentiation

This course is about complex valued functions of a (single) complex variable, that is, functions

$$f : A \rightarrow \mathbb{C}, \quad \text{where } A \subseteq \mathbb{C}.$$

In this course we will focus on differentiable functions f (the definition of which we will give soon), but let’s start by recalling the notion of continuity.

Definition 10.1.1 (Continuity)

A function $f : A \rightarrow \mathbb{C}$ is **continuous** at a point $w \in A$ if for all $\varepsilon > 0$ there exists some $\delta > 0$ such that if $z \in A$ with $|z - w| < \delta$ then $|f(z) - f(w)| < \varepsilon$.

Note that by identifying $\mathbb{C}$ with $\mathbb{R}^2$ in the usual way, we can write $f(z) = u(x, y) + iv(x, y)$ for $z = x + iy \in A$ with $u, v : A \rightarrow \mathbb{R}$. With this, the triangle inequality implies that f is continuous at $w = c + id$ if and only if u, v are continuous at (c, d) .

We can now define the notion of differentiation for complex functions.

Definition 10.1.2 (Complex Differentiation)

Let $f : U \rightarrow \mathbb{C}$ where $U \subseteq \mathbb{C}$ is open. We say that f is **differentiable** at $w \in U$ if the limit

$$f'(w) = \lim_{z \rightarrow w} \frac{f(z) - f(w)}{z - w}$$

exists as a complex number.

Definition 10.1.3 (Holomorphic)

We say that f is **holomorphic at** $w \in U$ if there is $\varepsilon > 0$ such that $D(w, \varepsilon) \subset U$ where f is differentiable at every point in $D(w, \varepsilon)$. We say that f is **holomorphic**

if it is holomorphic at every point in U .

Remark. Sometime authors use the word ‘analytic’ instead of the word ‘holomorphic’.

Definition 10.1.4 (Entire)

If $f : \mathbb{C} \rightarrow \mathbb{C}$ is holomorphic on all of $\mathbb{C}$, we say f is **entire**.

It’s straightforward to check that the same rules of differentiation for real variables hold for complex functions (product rule, quotient rule, chain rule, etc), which makes computing complex derivatives relatively straightforward.

Example 10.1.5 (Complex Differentiable Functions)

- (i) Polynomials $p(z) = \sum_{k=0}^n a_k z^k$, $a_0, \dots, a_n \in \mathbb{C}$ are holomorphic on all of $\mathbb{C}$.
- (ii) If p and q are polynomials, then p/q is holomorphic on $\mathbb{C} \setminus \{z \mid q(z) = 0\}$.

We saw above that the notion of continuity is basically the same for both real and complex variables. A natural question is then if the same is true for complex differentiability. Indeed, the answer is no! Complex differentiability is a much stronger condition than asserting real differentiability on the real and imaginary components of a function.

We do however have a criterion for establishing complex differentiability from the real and imaginary parts.

Theorem 10.1.6 (Cauchy-Riemann Equations)

A function $f = u + iv : U \rightarrow \mathbb{C}$ is differentiable at $w = c + id \in U$ if and only if $u, v : U \rightarrow \mathbb{R}$ are differentiable at $(c, d) \in U$ and u, v satisfy the **Cauchy-Riemann** equations at (c, d) :

$$\begin{aligned} \frac{\partial u}{\partial x} &= \frac{\partial v}{\partial y} \\ \frac{\partial u}{\partial y} &= -\frac{\partial v}{\partial x} \quad \text{at } (c, d). \end{aligned}$$

If f is differentiable at $w = c + id$, then $f'(w) = \frac{\partial u}{\partial x}(c, d) + i \frac{\partial v}{\partial x}(c, d)$.

Proof. The function f is differentiable at w with derivative $f'(w) = p + iq$ if and only if

$$\lim_{z \rightarrow w} \frac{f(z) - f(w)}{z - w} = p + iq \iff \lim_{z \rightarrow w} \frac{f(z) - f(w) - (z - w)(p + iq)}{|z - w|} = 0.$$

Separating real and imaginary parts and writing $f = u + iv$, the above holds if and only if

$$\lim_{(x,y) \rightarrow (c,d)} \frac{u(x, y) - u(c, d) - p(x - c) + q(y - d)}{\sqrt{(x - c)^2 + (y - d)^2}} = 0$$

and

$$\lim_{(x,y) \rightarrow (c,d)} \frac{v(x, y) - v(c, d) - q(x - c) - p(y - d)}{\sqrt{(x - c)^2 + (y - d)^2}} = 0.$$

That is, if and only if u is differentiable at (c, d) with $Du(c, d)(x, y) = px - qy$, and v is differentiable at (c, d) with $Dv(c, d)(x, y) = qx + py$.

Taking partial derivatives, this is true if and only if u, v are differentiable at (c, d) and $u_x(c, d) = p = v_y(c, d)$ and $u_y(c, d) = -q = -v_x(c, d)$, that is, the Cauchy-Riemann equations hold at (c, d) .

We also get from the above that if f is differentiable at w , then $f'(w) = p + iq = u_x(c, d) + iv_x(c, d)$. $\square$

Remark (Warning). The real and imaginary parts u, v satisfying the Cauchy-Riemann equations at a point does *not* guarantee the differentiability of f , and a counterexample is given on the first example sheet.

We can easily use this criterion to show that many functions are not complex differentiable.

Example 10.1.7 (Conjugation isn't Differentiable)

Consider the function $f(z) = \bar{z} = x - iy$. For this, $u(x, y) = x$ and $v(x, y) = -y$, so $u_x = 1$ and $u_y = 0$, $v_x = 0$ and $v_y = -1$. So the Cauchy-Riemann equations do not hold anywhere, and f is not differentiable at any point.

Now, if we just wanted to show that the differentiability of $f = u + iv$ at $w = c + id$ implies that the partial derivatives u_x, u_y, v_x and v_y exist at (c, d) and satisfy the Cauchy-Riemann equations, then we can proceed more simply as follows.

Begin with the definition of differentiability

$$f'(w) = \lim_{h \rightarrow 0} \frac{f(w+h) - f(w)}{h}.$$

Then taking $h = t \in \mathbb{R}$, we get

$$f'(w) = \lim_{t \rightarrow 0} \left(\frac{u(c+t, d) - u(c, d)}{t} + i \frac{v(c+t, d) - v(c, d)}{t} \right),$$

from which the real and imaginary parts imply that the limits

$$\lim_{t \rightarrow 0} \frac{u(c+t, d) - u(c, d)}{t} \quad \text{and} \quad \lim_{t \rightarrow 0} \frac{v(c+t, d) - v(c, d)}{t}$$

both exist, that is, $u_x(c, d)$ and $v_x(c, d)$ exists, and $f'(w) = u_x(c, d) + iv_x(c, d)$. Similarly, taking $h = it$ with $t \in \mathbb{R}$ gives $f'(w) = v_y(c, d) - iu_y(c, d)$, so $u_x = v_y$ and $u_y = -v_x$ at (c, d) .

Because partial derivatives are a little easier to work with than the standard derivative of a function on $\mathbb{R}^2$, we can use a straightforward corollary of the Cauchy-Riemann equations for checking complex differentiability¹.

Corollary 10.1.8 (Cauchy-Riemann and Continuous Partial derivatives implies Holomorphic)

Let $f = u + iv : U \rightarrow \mathbb{C}$. If u, v have continuous partial derivatives at a point $(c, d) \in U$ and satisfy the Cauchy-Riemann equations at (c, d) , then f is differentiable

¹Remarkably, the *Looman-Menchoff* theorem says that it suffices for u and v to be continuous and satisfy the Cauchy-Riemann equations to achieve complex differentiability, but this is quite non-trivial to prove.

at $w = c + id$.

Proof. Continuity of partial derivatives of u implies that u is differentiable, and similarly for v . So this follows from our original theorem. $\square$

Complex differentiability is a *much* stronger notion than the differentiability of real and imaginary parts. This leads to some surprising theorems compared to the real case. For example:

- (a) *Liouville's Theorem.* If $f : \mathbb{C} \rightarrow \mathbb{C}$ is holomorphic and bounded then f is constant.
- (b) If $f : U \rightarrow \mathbb{C}$ is holomorphic, then f is automatically infinitely differentiable on U .

We will prove these and much more later on.

Remark (Harmonic Functions). Note that the second theorem implies that the partial derivatives of u, v exist to all orders, so we can differentiate the Cauchy-Riemann equations to get

$$u_{xx} = v_{yx}, \quad \text{and} \quad u_{yy} = -v_{xy},$$

and since $v_{yx} = v_{xy}$, we get

$$\nabla^2 u = u_{xx} + u_{yy} = 0 \quad \text{in } U,$$

and similarly $\nabla^2 v = 0$ in U . So *real and imaginary parts of a holomorphic function are harmonic*.

We will now consider curves in the complex plane.

Definition 10.1.9 (Curve)

A **curve** is a continuous map $\gamma : [a, b] \rightarrow \mathbb{C}$, where $[a, b] \subset \mathbb{R}$ is a closed interval. We say γ is a **C^1 curve** if γ' exists and is continuous on $[a, b]$.

Definition 10.1.10 (Path Connected)

An open set $U \subset \mathbb{C}$ is **path connected** if for any two points $z, w \in U$ there is a curve $\gamma : [0, 1] \rightarrow U$ such that $\gamma(0) = z$ and $\gamma(1) = w$.

Definition 10.1.11 (Domain)

A **domain** is a non-empty, open, path connected subset of $\mathbb{C}$.

Corollary 10.1.12 (Zero Derivative implies Constant)

If $U \subset \mathbb{C}$ is a domain and $f : U \rightarrow \mathbb{C}$ is holomorphic with $f'(z) = 0$ for every $z \in U$, then f is constant.

Proof. Write $f = u + iv$. By the Cauchy-Riemann equations, $f' = 0$ implies that $Du = 0$ and $Dv = 0$ in U . Then since U is a domain, we get that u and v are constant. $\square$

§10.1.2 Power Series

So far we've only seen very few explicit holomorphic functions (namely polynomials on $\mathbb{C}$ and rational functions on their domains). We'd like to generate more, which we can do by looking at *power series*.

Recall the notion of *radius of convergence*.

Theorem 10.1.13 (Radius of Convergence)

If $c_n \in \mathbb{C}$ is a sequence of complex numbers, then there is a unique $R \in [0, \infty]$, the **radius of convergence**, such that the power series

$$\sum_{n=0}^{\infty} c_n (z - a)^n, \quad z, a \in \mathbb{C}$$

converges absolutely if $|z - a| < R$ and diverges if $|z - a| > R$. If $0 < r < R$, then the series converges uniformly (with respect to z) on the compact disk $\overline{D}(a, r) = \{z \in \mathbb{C} : |z - a| \leq r\}$.

Note that there are no claims about convergence when $|z - a| = R$ for $R > 0$. There are also various expressions for R , for example

$$R = \sup\{r \geq 0 \mid |c_n| r^n \rightarrow 0 \text{ as } n \rightarrow \infty\}$$

and

$$\frac{1}{R} = \limsup_{n \rightarrow \infty} |c_n|^{1/n}.$$

We get quite natural behavior of power series with respect to complex differentiability.

Theorem 10.1.14 (Derivatives of Power Series)

Let $\sum_{n=0}^{\infty} c_n (z - a)^n$ be a power series with radius of convergence $R > 0$. Fix some $a \in \mathbb{C}$, and define $f : D(a, R) \rightarrow \mathbb{C}$ by $f(z) = \sum_{n=0}^{\infty} c_n (z - a)^n$. Then

- (i) f is holomorphic on $D(a, R)$;
- (ii) the derived series $\sum_{n=1}^{\infty} n c_n (z - a)^{n-1}$ also has radius convergence R , and is equal to $f'(z)$ for $z \in D(a, R)$.
- (iii) f has derivatives of all orders on $D(a, R)$, and $c_n = \frac{f^{(n)}(a)}{n!}$.
- (iv) if f vanishes on $D(a, \varepsilon)$ for some $\varepsilon > 0$, then $f \equiv 0$ on $D(a, R)$.

Proof. Parts (i) and (ii). Without loss of generality, take $a = 0$. Now we have $f(z) = \sum_{n=0}^{\infty} c_n z^n$ for $z \in D(0, R)$, where R is the radius of convergence.

The derived series $\sum_{n=1}^{\infty} n c_n z^{n-1}$ will have some radius of convergence $R_1 \in [0, \infty]$. To see that $R_1 \geq R$, let $z \in D(0, R)$, and choose ρ such that $|z| < \rho < R$. Then

$$n |c_n| |z|^{n-1} = \left(n \left| \frac{z}{\rho} \right|^{n-1} \right) |c_n| \rho^{n-1} \leq |c_n| \rho^{n-1}$$

for sufficiently large n (as $n |z/\rho|^{n-1} \rightarrow 0$ as $n \rightarrow \infty$). Since $\sum |c_n| \rho^n$ converges, it

follows that $\sum_{n=1}^{\infty} n|c_n||z|^{n-1}$ converges. Thus $D(0, R) \subset D(0, R_1)$ that is, $R_1 \geq R$.

Also, since $|c_n||z|^n \leq n|c_n||z|^{n-1} = |z|(n|c_n||z|^{n-1})$, if $\sum n|c_n||z|^{n-1}$ converges then so does $\sum |c_n||z|^n$, so $R_1 \leq R$. This implies that we must have $R_1 = R$.

To prove that f is differentiable with $f'(z) = \sum_{n=1}^{\infty} nc_n z^{n-1}$, fix some $z \in D(0, R)$. Then our key idea is that this assertion is equivalent to the continuity at z of the function $g : D(0, R) \rightarrow \mathbb{C}$ with

$$g(w) = \begin{cases} \frac{f(w)-f(z)}{w-z} & \text{if } w \neq z, \\ \sum_{n=1}^{\infty} nc_n z^{n-1} & \text{if } w = z. \end{cases}$$

By substituting for f , we get that $g(w) = \sum_{n=1}^{\infty} h_n(w)$ for $w \in D(0, R)$ where h_n is a sequence of functions given by

$$h_n(w) = \begin{cases} \frac{c_n(w^n - z^n)}{w - z} & \text{if } w \neq z, \\ nc_n z^{n-1} & \text{if } w = z. \end{cases}$$

Now h_n is continuous on $D(0, R)$ for all n , then using that $\frac{w^n - z^n}{w - z} = \sum_{j=0}^{n-1} z^j w^{n-1-j}$, we get that for any r with $|z| < r < R$ and any $w \in D(0, r)$ we have $|h_n(w)| \leq n|c_n|r^{n-1}$. Defining $M_n = n|c_n|r^{n-1}$, we can note that $\sum M_n < \infty$, so by the Weierstrass M-test, $\sum h_n$ converges uniformly on $D(0, r)$. But a uniform limit of continuous functions is continuous, so $g = \sum h_n$ is continuous in $D(0, r)$ and in particular at z , as required.

Part (iii). Repeatedly apply (ii), and the formula $c_n = f^{(n)}(a)/n!$ follows by differentiating the series n times and setting $z = a$.

Part (iv). If $f = 0$ on $D(a, \varepsilon)$, then $f^{(n)}(a) = 0$ for all n , so $c_n = 0$ for all n . Hence $f = 0$ on $D(a, R)$. $\square$

Remark. This theorem provides a way to generate a large class of holomorphic functions on a disk. Later we will show that every holomorphic function is *locally* given by a power series. Once we have that, (iii) above gives that holomorphic functions are automatically infinitely differentiable in their domain.

§10.1.3 The Exponential and the Logarithm

Let's now consider a specific example of a power series, the *complex exponential* function, which you are likely familiar with.

Definition 10.1.15 (Complex Exponential)

The **complex exponential** function is defined by the power series

$$e^z = \exp(z) = \sum_{n=0}^{\infty} \frac{z^n}{n!}.$$

Some basic properties of this function will also be familiar.

Proposition 10.1.16 (Properties of the Exponential)

- (i) e^z is entire, with $(e^z)' = e^z$.
- (ii) $e^z \neq 0$ and $e^{z+w} = e^z \cdot e^w$ for all $z, w \in \mathbb{C}$.
- (iii) $e^{x+iy} = e^x(\cos y + i \sin y)$ for $x, y \in \mathbb{R}$.
- (iv) $e^z = 1$ if and only if $z = 2\pi ni$ for some integer n .
- (v) Let $z \in \mathbb{C}$. Then there exists $w \in \mathbb{C}$ such that $e^w = z$ if and only if $z \neq 0$.

Proof. Part (i). The radius of convergence of the series is ∞ , and to see that $(e^z)' = e^z$, differentiate the series term-by-term.

Part (ii). Fix any $w \in \mathbb{C}$ and set $F(z) = e^{z+w} \cdot e^{-z}$. Then $F'(z) = -e^{z+w} \cdot e^{-z} + e^{z+w} \cdot e^{-z} = 0$, so $F(z)$ is constant, and equal to e^w . Thus $e^{z+w} \cdot e^{-z} = e^w$ for all $z, w \in \mathbb{C}$, and the result follows noting that $e^0 = 1$.

Part (iii). By the previous part, $e^{x+iy} = e^x \cdot e^{iy}$. Now use the definition of e^{iy} and the series for $\sin y$ and $\cos y$ with $y \in \mathbb{R}$.

Part (iv) and (v). Both follow directly from (iii). □

We can now consider the ‘inverse’ of this function, the *logarithm*.

Definition 10.1.17 (Logarithm)

Given $z \in \mathbb{C}$, we say that $w \in \mathbb{C}$ is a **logarithm** of z if $e^w = z$.

By our above theorem, we note that z has a logarithm if and only if $z \neq 0$, and also if z *does* have a logarithm then there are infinitely many such logarithms, each differing from each other by $2\pi ni$ for some integer n .

If w is a logarithm of z , then $e^{\operatorname{Re}(w)} = |z|$, so $\operatorname{Re}(w) = \ln |z|$ (the real logarithm of the positive number $|z|$). In particular, $\operatorname{Re}(w)$ is uniquely determined by z .

Definition 10.1.18 (Branches of the Logarithm)

Let $U \subset \mathbb{C} \setminus \{0\}$ be open. Then a **branch** of the logarithm on U is a continuous function $\lambda : U \rightarrow \mathbb{C}$ such that $e^{\lambda(z)} = z$ for each $z \in U$.

Remark. If λ is a branch of $\log$ on U , then λ is automatically holomorphic in U , with $\lambda'(z) = 1/z$, with the proof following by direct computation of limits.

Definition 10.1.19 (Principal Branch of the Logarithm)

The **principal branch** of the logarithm is the function

$$\operatorname{Log} : U_1 = \mathbb{C} \setminus \{x \in \mathbb{R} : x \leq 0\} \rightarrow \mathbb{C}$$

defined by

$$\operatorname{Log}(z) = \ln |z| + i \arg(z),$$

where $\arg(z)$ is the unique argument of $z \in U_1$ in $(-\pi, \pi)$.

Remark. Log does not have a continuous extension to $\mathbb{C} \setminus \{0\}$, since $\arg(z) \rightarrow \pi$ as $z \rightarrow -1$ with $\operatorname{Im}(z) > 0$, and $\arg(z) \rightarrow -\pi$ as $z \rightarrow -1$ with $\operatorname{Im}(z) < 0$. We will later see

that it is impossible to define a branch of $\log$ on $\mathbb{C} \setminus \{0\}$.

The negative real axis, which we removed from the domain of Log , is called a **branch cut**. The picture to have in mind is the following: as z crosses the cut, the argument (and hence the imaginary part of any would-be logarithm) jumps by 2π .

There was nothing special about our choice to cut along the negative real axis – removing any ray from the origin (indeed, any reasonable curve joining 0 to infinity) leaves a domain on which a branch of the logarithm can be defined. The principal branch is merely the standard convention.

Proposition 10.1.20 (Power Series for Log)

For $|z| < 1$, we have

$$\text{Log}(1+z) = \sum_{n=1}^{\infty} \frac{(-1)^{n-1} z^n}{n}.$$

Proof. Note that the radius of convergence of the series is 1 and $|z| < 1$ implies that $1+z \in U_1$, so both sides are defined on $|z| < 1$. Then let $F(z) = \text{Log}(1+z) - \sum_{n=1}^{\infty} \frac{(-1)^{n-1} z^n}{n}$, for $|z| < 1$. Then $F'(z) = \frac{1}{1+z} - \sum_{n=1}^{\infty} (-z)^{n-1} = 0$. So $F(z)$ is constant, and $F(z) = F(0) = 0$. $\square$

Using $\exp$ and Log we can define further useful functions.

- (i) For any constant $\alpha \in \mathbb{C}$, define

$$z^\alpha = e^{\alpha \text{Log}(z)}, \quad z \in U_1.$$

This is the principal branch of z^α . We have that z^α is holomorphic on U_1 with $(z^\alpha)' = \alpha z^{\alpha-1}$.

- (ii) We can define

$$\begin{aligned} \cos(z) &= \frac{e^{iz} + e^{-iz}}{2} \\ \sin(z) &= \frac{e^{iz} - e^{-iz}}{2i} \\ \cosh(z) &= \frac{e^z + e^{-z}}{2} \\ \sinh(z) &= \frac{e^z - e^{-z}}{2}. \end{aligned}$$

All of these functions are entire and their derivatives are given by the familiar expressions from real variables.

§10.1.4 Conformal Maps

We now look at a geometric property of holomorphic functions called *conformality*. Let $f : U \rightarrow \mathbb{C}$ be holomorphic, where $U \subset \mathbb{C}$ is open, as usual. Let $w \in U$, and suppose that $f'(w) \neq 0$.

Take two C^1 curves $\gamma_1, \gamma_2 : [-1, 1] \rightarrow U$, such that $\gamma_i(0) = w$ and $\gamma'_i(0) \neq 0$. Then $f \circ \gamma_i$ are C^1 curves passing through $f(w)$. Moreover, $(f \circ \gamma_i)'(0) = f'(w)\gamma'_i(0) \neq 0$.

This implies that

$$\frac{(f \circ \gamma_1)'(0)}{(f \circ \gamma_2)'(0)} = \frac{\gamma'_1(0)}{\gamma'_2(0)},$$

and hence

$$\arg(f \circ \gamma_1)'(0) - \arg(f \circ \gamma_2)'(0) = \arg \gamma'_1(0) - \arg \gamma'_2(0).$$

This means that the angle that the curves γ_1, γ_2 make at w is the same as the angle their images $f \circ \gamma_1$ and $f \circ \gamma_2$ make at $f(w)$, in size as well as in orientation. That is, f is ‘angle-preserving at w ’ whenever $f'(w) \neq 0$.

Geometrically, this is because multiplication by the complex number $f'(w) = re^{i\theta} \neq 0$ is a rotation by θ composed with a scaling by r . To first order, f acts near w by exactly this rotation and scaling: a small grid of curves through w is carried to a rotated and scaled grid through $f(w)$, with all angles intact.

Remark. If f is a C^1 map on U , the converse of the above also holds. That is, if $w \in U$ is such that $(f \circ \gamma)'(0) \neq 0$ for every C^1 curve γ with $\gamma(0) = w$ and $\gamma'(0) \neq 0$, and if f is angle preserving at w in the above sense, then $f'(w)$ exists and $f'(w) \neq 0$.

Definition 10.1.21 (Conformal)

A holomorphic function $f : U \rightarrow \mathbb{C}$ on an open set U is said to be **conformal** at the point $w \in U$ if $f'(w) \neq 0$.

Definition 10.1.22 (Conformal Equivalence)

Let $U, \tilde{U}$ be domains in $\mathbb{C}$. A map $f : U \rightarrow \tilde{U}$ is said to be a **conformal equivalence** between U and $\tilde{U}$ if f is a bijective holomorphic map with $f'(z) \neq 0$ for every $z \in U$.

Remark (Redundancy). If f is holomorphic and injective, then $f'(z) \neq 0$ for each z (we will see this later in the course). So, in the above definition, the requirement $f'(z) \neq 0$ is redundant.

Remark (Inverse Functions). It is automatic that the inverse $f^{-1} : \tilde{U} \rightarrow U$ is holomorphic. This follows from the **holomorphic inverse function theorem**, which can be proved using the real inverse function theorem.

We will now consider some examples of conformal equivalences.

Example 10.1.23 (Möbius Maps Give a Conformal Equivalence)

Consider the Möbius maps

$$f(z) = \frac{az + b}{cz + d}$$

where $a, b, c, d \in \mathbb{C}$ with $ad - bc \neq 0$. This function f is conformal on $\mathbb{C} \setminus \{-d/c\}$ if $c \neq 0$, and conformal on $\mathbb{C}$ if $c = 0$.

Möbius maps sometimes serve as explicit conformal equivalences between subdomains of $\mathbb{C}$.

For example, let $\mathbb{H}$ be the open upper-half plane, $\mathbb{H} = \{z \in \mathbb{C} \mid \text{Im}(z) > 0\}$. Then

$$\begin{aligned} z \in \mathbb{H} &\iff z \text{ is closer to } i \text{ than to } -i \\ &\iff |z - i| < |z + i| \\ &\iff \left| \frac{z - i}{z + i} \right| < 1. \end{aligned}$$

Thus $g = \frac{z-i}{z+i}$ maps $\mathbb{H}$ onto $D(0, 1)$, so $g : \mathbb{H} \rightarrow D(0, 1)$ is a conformal equivalence. The inverse is also a Möbius map, namely $w \mapsto i\frac{1+w}{1-w}$, so the disc and the half-plane are two interchangeable models of the ‘same’ domain.

Example 10.1.24 (Powers Give a Conformal Equivalence)

Let $f(z) = z^n$ where $n \in \mathbb{N}$, with

$$f : \{z \in \mathbb{C} \setminus \{0\} \mid 0 < \arg(z) < \pi/n\} \rightarrow \mathbb{H}.$$

This is a conformal equivalence, with inverse $f^{-1}(z) = z^{1/n}$.

It is worth pausing to actually *look* at what a map like $z \mapsto z^2$ does. Away from the origin (where the derivative vanishes) it is conformal, so a grid of horizontal and vertical lines is carried to two families of curves (in fact parabolas) which still meet each other at right angles.

Example 10.1.25 (Exponentials Give a Conformal Equivalence)

The restricted exponential function given by

$$\exp : \{z \in \mathbb{C} \mid -\pi < \text{Im}(z) < \pi\} \rightarrow \mathbb{C} \setminus \{x \in \mathbb{R} \mid x \leq 0\}$$

is a conformal equivalence, whose inverse is $\text{Log}(z)$.

Aside: The Riemann Mapping Theorem

There is an interesting result about many domains being conformally equivalent.

Theorem 10.1.26 (Riemann Mapping Theorem)

Any simply connected domain $U \subset \mathbb{C}$ with $U \neq \mathbb{C}$ is conformally equivalent to $D(0, 1)$.

Here, $U \subset \mathbb{C}$ is simply connected if every continuous map $\gamma : S^1 = \partial D(0, 1) \rightarrow U$ extends to a continuous map $\Gamma : \overline{D(0, 1)} \rightarrow U$ with $\Gamma|_{\partial D(0, 1)} = \gamma$. We will discuss simply connected domains in detail later on, but intuitively one should think of simply connected domains as the ones ‘without holes’.

A proof of this result can be found in many textbooks on complex analysis.

§10.2 Complex Integration

§10.2.1 Extending Riemann Integration

As we did with differentiation, we now want to extend our real (Riemann) notion of integration to the integration of complex functions $f : U \rightarrow \mathbb{C}$ with $U \subset \mathbb{C}$ along curves in U .

First we will look at complex functions of a single real variable.

Definition 10.2.1 (Integral on a Real Interval)

If $f : [a, b] \subset \mathbb{R} \rightarrow \mathbb{C}$ is a complex function and if f is continuous^a then we define the **integral** of f over $[a, b]$ to be

$$\int_a^b f(t) \, dt = \int_a^b \operatorname{Re}(f(t)) \, dt + i \int_a^b \operatorname{Im}(f(t)) \, dt.$$

^aOr, more generally, f is Riemann integrable in its real and imaginary parts.

In particular,

$$\int_a^b i g(t) \, dt = i \int_a^b g(t) \, dt$$

for a real function $g : [a, b] \rightarrow \mathbb{R}$. Hence, by direct calculation,

$$\int_a^b w f(t) \, dt = w \int_a^b f(t) \, dt$$

for any $w \in \mathbb{C}$.

Proposition 10.2.2 (Basic Estimate)

If $f : [a, b] \rightarrow \mathbb{C}$ is continuous then

$$\left| \int_a^b f(t) dt \right| \leq \int_a^b |f(t)| dt \leq (b-a) \sup_{t \in [a, b]} |f(t)|$$

with equality if and only if f is constant.

Proof. If $\int_a^b f(t) dt = 0$ then we are done. Otherwise, write $\int_a^b f(t) dt = re^{i\theta}$, with $\theta \in [0, 2\pi)$. Let $M = \sup_{t \in [a, b]} |f(t)|$. Then

$$\begin{aligned} \left| \int_a^b f(t) dt \right| &= r = e^{-i\theta} \int_a^b f(t) dt = \int_a^b e^{-i\theta} f(t) dt \\ &= \int_a^b \operatorname{Re}(e^{-i\theta} f(t)) dt + i \int_a^b \operatorname{Im}(e^{-i\theta} f(t)) dt. \end{aligned}$$

Since the left-hand-side is real,

$$\begin{aligned} \left| \int_a^b f(t) dt \right| &= \int_a^b \operatorname{Re}(e^{-i\theta} f(t)) dt \\ &\leq \int_a^b |e^{-i\theta} f(t)| dt \\ &= \int_a^b |f(t)| dt \\ &\leq (b-a)M. \end{aligned}$$

Equality holds if and only if $|f(t)| = M$ and $\operatorname{Re}(e^{-i\theta} f(t)) = M$ for all $t \in [a, b]$, that is, if and only if $|f(t)| = M$ and $\arg(f(t)) = \theta$ for all $t \in [a, b]$, that is, f is constant. $\square$

We can now define a more general notion of an integral along a curve in the complex plane (not just somewhere on the real line).

Definition 10.2.3 (Integral on a Complex Curve)

Let $U \subset \mathbb{C}$ be open and $f : U \rightarrow \mathbb{C}$ be continuous. Let $\gamma : [a, b] \rightarrow U$ be a C^1 curve. Then the **integral of f along γ** is

$$\int_{\gamma} f(z) dz = \int_a^b f(\gamma(t)) \gamma'(t) dt.$$

This integral has lots of nice basic properties that one might expect.

Proposition 10.2.4 (Invariance under Reparameterisation)

Let $\varphi : [a_1, b_1] \rightarrow [a, b]$ be C^1 and injective with $\varphi(a_1) = a$ and $\varphi(b_1) = b$. Let $\delta = \gamma \circ \varphi : [a_1, b_1] \rightarrow U$. Then we have

$$\int_{\delta} f(z) dz = \int_{\gamma} f(z) dz$$

Proof. Letting $s = \varphi(t)$, we have

$$\begin{aligned} \int_{\delta} f(z) \, dz &= \int_{a_1}^{b_1} f(\gamma \circ \varphi(t)) \gamma'(\varphi(t)) \varphi'(t) \, dt \\ &= \int_a^b f(\gamma(s)) \gamma'(s) \, ds \\ &= \int_{\gamma} f(z) \, dz. \end{aligned}$$

The second equality follows from the definition of the integral of a function of a real variable and the change of variables formula for integrals of real functions of a real variable. $\square$

Proposition 10.2.5 (Linearity)

We have

$$\int_{\gamma} (c_1 f_1(z) + c_2 f_2(z)) \, dz = c_1 \int_{\gamma} f_1(z) \, dz + c_2 \int_{\gamma} f_2(z) \, dz,$$

for constants $c_1, c_2 \in \mathbb{C}$.

Proof Sketch. Check definitions. $\square$

Proposition 10.2.6 (Additivity)

If $\gamma : [a, b] \rightarrow U$ is a C^1 curve and $a < c < b$, then

$$\int_{\gamma} f(z) \, dz = \int_{\gamma|_{[a, c]}} f(z) \, dz + \int_{\gamma|_{[c, b]}} f(z) \, dz.$$

Proof Sketch. Check definitions. $\square$

Proposition 10.2.7 (Inverse Path)

Define the inverse path $(-\gamma) : [-b, -a] \rightarrow U$ by $(-\gamma)(t) = \gamma(-t)$ for $-b \leq t \leq -a$. Then

$$\int_{(-\gamma)} f(z) \, dz = - \int_{\gamma} f(z) \, dz.$$

Proof Sketch. Check definitions. $\square$

We can get the euclidean length of a curve in the complex plane by the following (which we take as a definition).

Definition 10.2.8 (Length of a Curve)

Let $\gamma : [a, b] \rightarrow \mathbb{C}$ be a C^1 curve. The **length** of γ is defined by

$$\text{length}(\gamma) = \int_a^b |\gamma'(t)| \, dt$$

Definition 10.2.9 (Piecewise C^1 Curve)

A **piecewise C^1 curve** is a continuous map $\gamma : [a, b] \rightarrow \mathbb{C}$ such that there exists a finite subdivision $a = a_0 < a_1 < \cdots < a_n = b$ with the property that $\gamma_j = \gamma|_{[a_{j-1}, a_j]} : [a_{j-1}, a_j] \rightarrow \mathbb{C}$ is C^1 for $1 \leq j \leq n$.

If γ is a piecewise C^1 curve as above, we *define*

$$\int_{\gamma} f(z) \, dz = \sum_{j=1}^n \int_{\gamma_j} f(z) \, dz$$

and

$$\text{length}(\gamma) = \sum_{j=1}^n \text{length}(\gamma_j) = \sum_{j=1}^n \int_{a_{j-1}}^{a_j} |\gamma'(t)| \, dt.$$

Remark. Note that both definitions are independent of the subdivisions by the additivity property above.

With this, from now on a ‘curve’ will mean a piecewise C^1 curve.

Definition 10.2.10 (Sum of Curves)

If $\gamma_1 : [a, b] \rightarrow \mathbb{C}$ and $\gamma_2 : [c, d] \rightarrow \mathbb{C}$ are curves with $\gamma_1(b) = \gamma_2(c)$, we define the **sum** of γ_1 and γ_2 to be the curve $(\gamma_1 + \gamma_2) : [a, b + d - c] \rightarrow \mathbb{C}$, with

$$(\gamma_1 + \gamma_2)(t) = \begin{cases} \gamma_1(t) & \text{if } a \leq t \leq b, \\ \gamma_2(t - b + c) & \text{if } b \leq t \leq b + d - c. \end{cases}$$

We can then give another basic estimate for integrals over curves in the complex plane.

Proposition 10.2.11 (Another Basic Estimate)

For any continuous function $f : U \rightarrow \mathbb{C}$ and any curve $\gamma : [a, b] \rightarrow \mathbb{C}$, we have that

$$\left| \int_{\gamma} f(z) \, dz \right| \leq \text{length}(\gamma) \sup_{\gamma} |f|$$

where $\sup_{\gamma} |f| = \sup_{t \in [a, b]} |f(\gamma(t))|$.

Proof. If γ is C^1 , then

$$\left| \int_{\gamma} f(z) \, dz \right| = \left| \int_a^b f(\gamma(t)) \gamma'(t) \, dt \right|$$

$$\begin{aligned} &\leq \int_a^b |f(\gamma(t))| |\gamma'(t)| \, dt \\ &\leq \sup_{t \in [a,b]} |f(\gamma(t))| \text{length}(\gamma). \end{aligned}$$

If γ is piecewise C^1 then the result follows from the definition

$$\int_{\gamma} f(z) \, dz = \sum_{j=1}^n \int_{\gamma_j} f(z) \, dz$$

where γ_j is C^1 , and the triangle inequality. $\square$

§10.2.2 The Fundamental Theorem of Calculus

In real analysis, the fundamental theorem of calculus links differentiation and integration. The same is true for integrals along curves in the complex plane, and (as in the real case) it is the main computational tool we have for evaluating integrals directly.

Definition 10.2.12 (Antiderivative)

Let $U \subseteq \mathbb{C}$ be open and $f : U \rightarrow \mathbb{C}$ be continuous. An **antiderivative** of f is a holomorphic function $F : U \rightarrow \mathbb{C}$ such that $F'(z) = f(z)$ for all $z \in U$.

Theorem 10.2.13 (Fundamental Theorem of Calculus)

Let $U \subseteq \mathbb{C}$ be open and let $f : U \rightarrow \mathbb{C}$ be continuous with antiderivative F . Then for any curve $\gamma : [a, b] \rightarrow U$ we have

$$\int_{\gamma} f(z) \, dz = F(\gamma(b)) - F(\gamma(a)).$$

In particular, if γ is a *closed* curve (that is, $\gamma(a) = \gamma(b)$), then $\int_{\gamma} f(z) \, dz = 0$.

Proof. Suppose first that γ is C^1 . Then by the chain rule,

$$\int_{\gamma} f(z) \, dz = \int_a^b f(\gamma(t)) \gamma'(t) \, dt = \int_a^b \frac{d}{dt} [F(\gamma(t))] \, dt = F(\gamma(b)) - F(\gamma(a)),$$

where the last equality is the real fundamental theorem of calculus applied to the real and imaginary parts. If γ is only piecewise C^1 , apply the above on each piece and note that the sum telescopes. $\square$

Note that the theorem *assumes* that an antiderivative F exists – it says nothing about when this happens. Whether or not every holomorphic function on U has an antiderivative turns out to depend delicately on the geometry of U , and this question is really the engine behind the next few sections. Let's do the fundamental example.

Example 10.2.14 (Integrating z^n around a Circle)

Fix $R > 0$ and an integer n , and let $\gamma(t) = Re^{2\pi it}$ for $t \in [0, 1]$, the circle of radius R traversed once anticlockwise. We compute $\int_{\gamma} z^n dz$.

If $n \neq -1$, then $z^{n+1}/(n+1)$ is an antiderivative of z^n on $\mathbb{C} \setminus \{0\}$ (or on $\mathbb{C}$ if $n \geq 0$), so since γ is closed,

$$\int_{\gamma} z^n dz = 0.$$

If $n = -1$, we instead compute directly from the definition:

$$\int_{\gamma} \frac{dz}{z} = \int_0^1 \frac{2\pi i R e^{2\pi it}}{R e^{2\pi it}} dt = 2\pi i.$$

This example is small but its consequences are large. Since $2\pi i \neq 0$, the function $1/z$ has *no* antiderivative on any open set containing the circle $\{|z| = R\}$, for any $R > 0$. But if λ were a branch of the logarithm on $\mathbb{C} \setminus \{0\}$, then λ would be exactly such an antiderivative. So, as promised earlier, *there is no branch of the logarithm on $\mathbb{C} \setminus \{0\}$.*

Now, the fundamental theorem of calculus has a converse: if all integrals of f around closed curves vanish, then an antiderivative can be built.

Theorem 10.2.15 (Converse to the Fundamental Theorem of Calculus)

Let $U \subseteq \mathbb{C}$ be a domain and $f : U \rightarrow \mathbb{C}$ be continuous. If

$$\int_{\gamma} f(z) dz = 0$$

for every closed curve γ in U , then f has an antiderivative on U .

Proof. Fix a base point $a_0 \in U$. Since U is path connected, for each $w \in U$ we can choose^a a curve $\gamma_w : [0, 1] \rightarrow U$ from a_0 to w , and we define

$$F(w) = \int_{\gamma_w} f(z) dz.$$

This is well defined, i.e. independent of the choice of curve: if γ_w and $\tilde{\gamma}_w$ are two such curves, then $\gamma_w + (-\tilde{\gamma}_w)$ is a closed curve in U , so by hypothesis

$$0 = \int_{\gamma_w + (-\tilde{\gamma}_w)} f(z) dz = \int_{\gamma_w} f(z) dz - \int_{\tilde{\gamma}_w} f(z) dz.$$

We now check that F is differentiable with $F' = f$. Fix $w \in U$ and take $r > 0$ with $D(w, r) \subset U$. For $h \in \mathbb{C}$ with $0 < |h| < r$, let $\delta_h(t) = w + th$, $t \in [0, 1]$, be the radial segment from w to $w + h$. Then $\gamma_w + \delta_h + (-\gamma_{w+h})$ is a closed curve in U , so its integral vanishes, giving

$$F(w + h) = F(w) + \int_{\delta_h} f(z) dz = F(w) + hf(w) + \int_{\delta_h} (f(z) - f(w)) dz,$$

where we used $\int_{\delta_h} dz = h$. Hence by our basic estimate,

$$\left| \frac{F(w+h) - F(w)}{h} - f(w) \right| \leq \frac{1}{|h|} \cdot \text{length}(\delta_h) \sup_{z \in \delta_h} |f(z) - f(w)| = \sup_{z \in \delta_h} |f(z) - f(w)|,$$

and this tends to 0 as $h \rightarrow 0$ by the continuity of f at w . So $F'(w) = f(w)$. $\square$

^aStrictly, path connectedness gives a continuous curve, but for open sets one can always upgrade this to a piecewise C^1 curve, say by covering the curve with finitely many disks and taking line segments within them.

§10.2.3 Cauchy's Theorem for Star-Shaped Domains

We have just seen that ‘all closed curve integrals vanish’ is equivalent to having an antiderivative. The central theorem of this course, *Cauchy's theorem*, says that for a *holomorphic* function on a domain with reasonable geometry, all closed curve integrals really do vanish. In this section we prove this for *star-shaped* domains, which covers a surprising number of applications.

Definition 10.2.16 (Star-Shaped Domain)

A domain $U \subseteq \mathbb{C}$ is **star-shaped** if there is a point $a_0 \in U$ (a **centre**) such that for every $w \in U$, the straight line segment $[a_0, w]$ from a_0 to w lies entirely in U .

A star-shaped domain need not be convex (the domain above is not!), but every point can ‘see’ the centre along a straight line. Some quick observations, each of which is straightforward to check:

- (i) every disk $D(a, r)$ is convex;
- (ii) every convex domain is star-shaped (any point works as a centre);
- (iii) every star-shaped domain is path connected.

None of the reverse implications hold in general. For instance, $\mathbb{C} \setminus \{x \in \mathbb{R} : x \leq 0\}$ is star-shaped (take $a_0 = 1$, say) but certainly not convex, and an annulus $\{1 < |z| < 2\}$ is path connected but not star-shaped.

The strategy for proving Cauchy's theorem on a star-shaped domain is to first establish it for the simplest possible closed curves – boundaries of triangles – and then to leverage the converse of the fundamental theorem of calculus.

Definition 10.2.17 (Triangle)

A **triangle** T in $\mathbb{C}$ is the convex hull of three points $z_1, z_2, z_3 \in \mathbb{C}$, that is

$$T = \{az_1 + bz_2 + cz_3 \mid a, b, c \geq 0, a + b + c = 1\}.$$

We write ∂T for the boundary of T , viewed as the closed curve which traverses the three sides of T once.

Corollary 10.2.18 (Antiderivatives on Star-Shaped Domains)

Let U be a star-shaped domain and $f : U \rightarrow \mathbb{C}$ be continuous with

$$\int_{\partial T} f(z) \, dz = 0$$

for every triangle $T \subseteq U$. Then f has an antiderivative on U .

Proof. We repeat the proof of the converse to the fundamental theorem of calculus, being economical about which curves we use. Let a_0 be a centre of U , and for $w \in U$ define

$$F(w) = \int_{[a_0, w]} f(z) \, dz,$$

integrating along the straight segment, which lies in U as U is star-shaped. Given $w \in U$, choose $r > 0$ with $D(w, r) \subset U$, and let $h \in \mathbb{C}$ with $0 < |h| < r$. The key point is that the closed curve $[a_0, w] + [w, w+h] + [w+h, a_0]$ is precisely the boundary of the triangle T with vertices $a_0, w, w+h$, and this triangle lies in U : its sides do, and every point of the segment $[w, w+h]$ lies in $D(w, r) \subseteq U$, so every segment from a_0 to a point of T lies in U by the star-shape property^a. Hence by hypothesis

$$F(w+h) - F(w) = \int_{[w, w+h]} f(z) \, dz,$$

and exactly as before, continuity of f gives $F'(w) = f(w)$. □

^aTo see $T \subset U$ carefully: every point of T lies on a segment from a_0 to a point of $[w, w+h]$, and $[w, w+h] \subset D(w, r) \subset U$.

So everything now rests on showing that integrals of holomorphic functions around triangles vanish. This is the technical heart of Cauchy's theorem, and the proof – due to Goursat – is a beautiful ‘divide and conquer’ argument.

Theorem 10.2.19 (Cauchy's Theorem for Triangles)

Let $U \subseteq \mathbb{C}$ be open and $f : U \rightarrow \mathbb{C}$ be holomorphic. Then

$$\int_{\partial T} f(z) \, dz = 0$$

for every triangle $T \subseteq U$.

Proof. For a triangle T , write $\eta(T) = \int_{\partial T} f(z) \, dz$; our goal is $\eta(T) = 0$.

Subdivide T into four smaller triangles $T^{(1)}, \dots, T^{(4)}$ by joining the midpoints of its

sides, as in the picture below.

Traversing each $\partial T^{(j)}$ anticlockwise, the integrals over the three interior sides cancel in pairs (each is traversed once in each direction), so

$$\eta(T) = \sum_{j=1}^4 \eta(T^{(j)}).$$

By the triangle inequality, there is some j with $|\eta(T^{(j)})| \geq |\eta(T)|/4$. Set $T_0 = T$ and $T_1 = T^{(j)}$, and repeat this construction inductively to obtain nested triangles $T_0 \supset T_1 \supset T_2 \supset \dots$ with

$$|\eta(T_n)| \geq \frac{|\eta(T_0)|}{4^n}, \quad \text{and} \quad \text{length}(\partial T_n) = \frac{\text{length}(\partial T_0)}{2^n},$$

the latter since each subdivision halves all side lengths.

The T_n are nested non-empty compact sets with diameters tending to zero, so their intersection is a single point: $\bigcap_{n \geq 0} T_n = \{z_0\}$, with $z_0 \in T \subseteq U$.

Now we finally use that f is differentiable at z_0 . Given $\varepsilon > 0$, there is $\delta > 0$ such that $D(z_0, \delta) \subseteq U$ and

$$|f(z) - f(z_0) - f'(z_0)(z - z_0)| \leq \varepsilon |z - z_0| \quad \text{for all } z \in D(z_0, \delta).$$

Also, since the affine function $z \mapsto f(z_0) + f'(z_0)(z - z_0)$ has an antiderivative, its integral around any closed curve vanishes, so for every n ,

$$\eta(T_n) = \int_{\partial T_n} (f(z) - f(z_0) - f'(z_0)(z - z_0)) \, dz.$$

Choose n large enough that $T_n \subseteq D(z_0, \delta)$. Then for $z \in \partial T_n$ we have $|z - z_0| \leq \text{length}(\partial T_n)$, so estimating the integral,

$$\frac{|\eta(T_0)|}{4^n} \leq |\eta(T_n)| \leq \varepsilon \text{length}(\partial T_n)^2 = \frac{\varepsilon \text{length}(\partial T_0)^2}{4^n}.$$

Hence $|\eta(T_0)| \leq \varepsilon \text{length}(\partial T_0)^2$ for every $\varepsilon > 0$, forcing $\eta(T_0) = 0$. $\square$

For later applications (in particular when we prove the Cauchy integral formula) it is extremely useful to relax the hypothesis slightly, allowing f to fail to be differentiable at finitely many points, so long as it remains continuous there.

Theorem 10.2.20 (Cauchy's Theorem for Triangles, with Exceptional Points)

Let $U \subseteq \mathbb{C}$ be open, $S \subset U$ be finite, and let $f : U \rightarrow \mathbb{C}$ be continuous on U and

holomorphic on $U \setminus S$. Then $\int_{\partial T} f(z) dz = 0$ for every triangle $T \subseteq U$.

Proof. Subdivide T as before, but n times over, keeping *all* of the 4^n small triangles $T_1, \dots, T_N$ ($N = 4^n$). Again the interior sides cancel, so

$$\int_{\partial T} f(z) dz = \sum_{j=1}^N \int_{\partial T_j} f(z) dz.$$

By the previous theorem, $\int_{\partial T_j} f(z) dz = 0$ for every T_j that avoids S . Now, each point of S can lie in at most 6 of the small triangles (a point can be a vertex of at most 6 of them), and each small triangle has $\text{length}(\partial T_j) = 2^{-n} \text{length}(\partial T)$. Also f , being continuous on the compact set T , is bounded there, say $|f| \leq M$ on T . Hence

$$\left| \int_{\partial T} f(z) dz \right| \leq 6|S|M \cdot \frac{\text{length}(\partial T)}{2^n},$$

and letting $n \rightarrow \infty$ gives the result. $\square$

Combining our work, we obtain the form of Cauchy's theorem that we will use constantly.

Theorem 10.2.21 (Cauchy's Theorem for Star-Shaped Domains)

Let U be a star-shaped domain, and let $f : U \rightarrow \mathbb{C}$ be continuous on U and holomorphic on $U \setminus S$ for some finite set S . Then

$$\int_{\gamma} f(z) dz = 0$$

for every closed curve γ in U . In particular this holds when U is convex, and when f is holomorphic on all of U .

Proof. By the previous theorem, $\int_{\partial T} f(z) dz = 0$ for every triangle $T \subseteq U$. Since U is star-shaped, our corollary gives that f has an antiderivative on U , and then the fundamental theorem of calculus gives $\int_{\gamma} f(z) dz = 0$ for every closed γ . $\square$

Remark (Deforming Curves). The reader should think of Cauchy's theorem as a statement about the *geometry* of U as much as about f . The correct general statement, which we will prove later in the course, is that $\int_{\gamma} f dz = 0$ whenever the closed curve γ can be continuously shrunk to a point within U (that is, γ is *null-homotopic*), and more generally that $\int_{\gamma} f dz$ is unchanged when γ is continuously deformed within U . Star-shaped domains are exactly domains where every closed curve can be shrunk to the centre, sliding along straight lines. What can go wrong in general is visible already for $f(z) = 1/z$ on $\mathbb{C} \setminus \{0\}$: a circle around the origin cannot be shrunk to a point without crossing 0, and correspondingly its integral is $2\pi i \neq 0$.

§10.3 Cauchy's Integral Formula and its Applications

§10.3.1 The Cauchy Integral Formula

We now come to a truly remarkable result: the value of a holomorphic function at a point is completely determined by its values on a circle around that point, via an explicit integral formula. Almost all of the ‘magic’ properties of holomorphic functions flow from this.

Throughout, for a disk $D(a, \rho)$ we write $\int_{\partial D(a, \rho)} f(z) \, dz$ for $\int_{\gamma} f(z) \, dz$ where $\gamma(t) = a + \rho e^{2\pi i t}$, $t \in [0, 1]$, the boundary circle traversed once anticlockwise.

We will need a simple lemma about swapping limits and integrals.

Lemma 10.3.1 (Uniform Convergence and Integrals)

Let $\gamma : [a, b] \rightarrow \mathbb{C}$ be a curve and let f_n be a sequence of continuous functions on the image of γ , converging uniformly on the image of γ to f . Then

$$\int_{\gamma} f_n(z) \, dz \rightarrow \int_{\gamma} f(z) \, dz.$$

Proof. By our basic estimate,

$$\left| \int_{\gamma} f_n(z) \, dz - \int_{\gamma} f(z) \, dz \right| \leq \text{length}(\gamma) \sup_{\gamma} |f_n - f| \rightarrow 0.$$

□

Theorem 10.3.2 (Cauchy Integral Formula for a Disk)

Let $D = D(a, r)$ and let $f : D \rightarrow \mathbb{C}$ be holomorphic. Then for any $0 < \rho < r$ and any $w \in D(a, \rho)$,

$$f(w) = \frac{1}{2\pi i} \int_{\partial D(a, \rho)} \frac{f(z)}{z - w} \, dz.$$

Proof. Fix $w \in D(a, \rho)$ and define $h : D \rightarrow \mathbb{C}$ by

$$h(z) = \begin{cases} \frac{f(z) - f(w)}{z - w} & \text{if } z \neq w, \\ f'(w) & \text{if } z = w. \end{cases}$$

Then h is continuous on D and holomorphic on $D \setminus \{w\}$. Since D is convex, Cauchy's theorem (with one exceptional point) gives

$$0 = \int_{\partial D(a, \rho)} h(z) \, dz = \int_{\partial D(a, \rho)} \frac{f(z)}{z - w} \, dz - f(w) \int_{\partial D(a, \rho)} \frac{dz}{z - w}.$$

So it suffices to prove that

$$\int_{\partial D(a, \rho)} \frac{dz}{z - w} = 2\pi i.$$

For $z \in \partial D(a, \rho)$ we have $|w - a| < \rho = |z - a|$, so expanding as a geometric series,

$$\frac{1}{z - w} = \frac{1}{(z - a) \left(1 - \frac{w - a}{z - a}\right)} = \sum_{j=0}^{\infty} \frac{(w - a)^j}{(z - a)^{j+1}},$$

with the convergence uniform in $z \in \partial D(a, \rho)$ by the Weierstrass M-test (the terms are bounded by $(|w - a|/\rho)^j/\rho$). Hence by our lemma we may integrate term by term:

$$\int_{\partial D(a, \rho)} \frac{dz}{z - w} = \sum_{j=0}^{\infty} (w - a)^j \int_{\partial D(a, \rho)} \frac{dz}{(z - a)^{j+1}}.$$

For $j \geq 1$ the integrand $(z - a)^{-j-1}$ has an antiderivative near the circle, so those terms vanish; and for $j = 0$ we computed the integral directly before, obtaining $2\pi i$. This completes the proof. $\square$

Taking $w = a$ and parameterising the circle explicitly, we obtain a particularly pleasant special case.

Corollary 10.3.3 (Mean Value Property)

If $f : D(a, r) \rightarrow \mathbb{C}$ is holomorphic and $0 < \rho < r$, then

$$f(a) = \int_0^1 f(a + \rho e^{2\pi i t}) dt.$$

In other words – the value of a holomorphic function at a point is the *average* of its values on any circle centred at that point.

§10.3.2 Liouville's Theorem and the Fundamental Theorem of Algebra

Here is the first of the surprising rigidity theorems that we promised back in the first section.

Theorem 10.3.4 (Liouville's Theorem)

Let $f : \mathbb{C} \rightarrow \mathbb{C}$ be entire and bounded. Then f is constant.

Proof. Say $|f| \leq M$ on $\mathbb{C}$. Fix $w \in \mathbb{C}$, and let $\rho > 2|w|$. By the Cauchy integral formula applied on a large disk $D(0, \rho')$ with $\rho < \rho'$,

$$f(w) - f(0) = \frac{1}{2\pi i} \int_{\partial D(0, \rho)} f(z) \left(\frac{1}{z - w} - \frac{1}{z} \right) dz = \frac{1}{2\pi i} \int_{\partial D(0, \rho)} \frac{wf(z)}{z(z - w)} dz.$$

For z on the circle $|z| = \rho$ we have $|z - w| \geq \rho - |w| \geq \rho/2$, so estimating,

$$|f(w) - f(0)| \leq \frac{1}{2\pi} \cdot 2\pi\rho \cdot \frac{|w|M}{\rho \cdot \rho/2} = \frac{2|w|M}{\rho}.$$

Letting $\rho \rightarrow \infty$ gives $f(w) = f(0)$. Since w was arbitrary, f is constant. $\square$

Notice how strong this is: there is no entire analogue of $\sin$ on $\mathbb{R}$, bounded and wiggling forever – indeed $\sin$ itself is wildly unbounded on $\mathbb{C}$ (consider $\sin(iy)$). One spectacular

application is a genuinely short proof of the fundamental theorem of algebra.

Theorem 10.3.5 (Fundamental Theorem of Algebra)

Every non-constant polynomial with complex coefficients has a root in $\mathbb{C}$.

Proof. Let $p(z) = a_n z^n + \cdots + a_1 z + a_0$ with $n \geq 1$ and $a_n \neq 0$. For $z \neq 0$,

$$|p(z)| \geq |z|^n \left(|a_n| - \frac{|a_{n-1}|}{|z|} - \cdots - \frac{|a_0|}{|z|^n} \right),$$

and the bracket tends to $|a_n| > 0$ as $|z| \rightarrow \infty$. So there is $R > 0$ such that $|p(z)| \geq 1$ for all $|z| > R$.

Now suppose for contradiction that p has no root. Then $g = 1/p$ is entire. By the above, $|g| \leq 1$ outside $D(0, R)$; and $|g|$ is continuous on the compact set $\overline{D(0, R)}$, hence bounded there too. So g is a bounded entire function, and by Liouville's theorem g is constant – but then p is constant, a contradiction. $\square$

Remark. It follows by induction (dividing out roots) that every polynomial of degree $n \geq 1$ factors completely as $p(z) = a_n(z - z_1) \cdots (z - z_n)$. So $\mathbb{C}$ is algebraically closed – the analytic input of Liouville's theorem proves a purely algebraic statement.

§10.3.3 Taylor Expansions

We now show that holomorphic functions are *analytic*: locally, they are given by convergent power series. Together with our earlier work on power series, this instantly upgrades ‘differentiable once’ to ‘differentiable infinitely often’.

Theorem 10.3.6 (Taylor Expansion)

Let $f : D(a, R) \rightarrow \mathbb{C}$ be holomorphic. Then f has a convergent power series representation on $D(a, R)$:

$$f(w) = \sum_{n=0}^{\infty} c_n (w - a)^n, \quad \text{where} \quad c_n = \frac{1}{2\pi i} \int_{\partial D(a, \rho)} \frac{f(z)}{(z - a)^{n+1}} dz$$

for any $0 < \rho < R$.

Proof. Let $0 < \rho < R$ and $w \in D(a, \rho)$. By the Cauchy integral formula and the geometric series expansion from its proof (which converges uniformly for $z \in \partial D(a, \rho)$),

$$\begin{aligned} f(w) &= \frac{1}{2\pi i} \int_{\partial D(a, \rho)} \frac{f(z)}{z - w} dz = \frac{1}{2\pi i} \int_{\partial D(a, \rho)} f(z) \sum_{n=0}^{\infty} \frac{(w - a)^n}{(z - a)^{n+1}} dz \\ &= \sum_{n=0}^{\infty} \left(\frac{1}{2\pi i} \int_{\partial D(a, \rho)} \frac{f(z)}{(z - a)^{n+1}} dz \right) (w - a)^n, \end{aligned}$$

where the interchange of sum and integral is justified by our uniform convergence lemma (f is bounded on the circle, so the partial sums converge uniformly there).

Write $c_n(\rho)$ for the coefficient above. We have shown $f(w) = \sum c_n(\rho)(w-a)^n$ on $D(a, \rho)$, so by our theorem on derivatives of power series, $c_n(\rho) = f^{(n)}(a)/n!$. In particular $c_n(\rho)$ does not depend on ρ , so we may write c_n unambiguously. $\square$

Corollary 10.3.7 (Holomorphic Functions are Infinitely Differentiable)

If f is holomorphic on an open set $U \subseteq \mathbb{C}$, then f has derivatives of all orders on U , and they are all holomorphic on U .

Proof. Around any point of U there is a disk on which f is a convergent power series, and power series have derivatives of all orders inside their disk of convergence. $\square$

This settles the promise made at the start of the course, and it also completes the picture for the Cauchy-Riemann equations: if $f = u + iv$ is holomorphic then u, v are automatically C^∞ , and in particular the harmonic function remark from Section 1 applies in earnest.

Remark (Holomorphic = Analytic). We say f is **analytic** at a if it is given by a convergent power series in some neighbourhood of a . Combining the Taylor expansion theorem with our theorem on differentiating power series, the following are equivalent for a function on an open set U : f is holomorphic on U ; f is analytic at every point of U ; f has complex derivatives of all orders on U . Nothing like this is true on $\mathbb{R}$: the function $x \mapsto e^{-1/x^2}$ (extended by 0) is C^∞ but is not given by its Taylor series at 0.

From the Taylor coefficients we can also read off integral formulas for all derivatives, along with very useful bounds.

Theorem 10.3.8 (Cauchy Integral Formula for Derivatives & Cauchy Estimates)

Let $f : D(a, R) \rightarrow \mathbb{C}$ be holomorphic. Then for any $0 < \rho < R$ and $w \in D(a, \rho)$,

$$f^{(k)}(w) = \frac{k!}{2\pi i} \int_{\partial D(a, \rho)} \frac{f(z)}{(z-w)^{k+1}} dz.$$

Moreover, we have the estimate

$$\sup_{w \in D(a, R/2)} |f^{(k)}(w)| \leq \frac{k! 2^{k+1}}{R^k} \sup_{z \in D(a, R)} |f(z)|.$$

Proof. The case $k = 0$ is the Cauchy integral formula. For $k = 1$, consider $g(z) = f(z)/(z-w)$, holomorphic on $D(a, R) \setminus \{w\}$, with

$$g'(z) = \frac{f'(z)}{z-w} - \frac{f(z)}{(z-w)^2}.$$

Now g is an antiderivative of g' on $D(a, R) \setminus \{w\}$, which contains the circle $\partial D(a, \rho)$, so $\int_{\partial D(a, \rho)} g'(z) dz = 0$ by the fundamental theorem of calculus. Hence

$$\int_{\partial D(a, \rho)} \frac{f'(z)}{z-w} dz = \int_{\partial D(a, \rho)} \frac{f(z)}{(z-w)^2} dz,$$

and applying the Cauchy integral formula to the holomorphic function f' gives the $k = 1$ case. For general k we induct: assuming the formula for k (for all holomorphic functions on $D(a, R)$), the same trick with $g(z) = f(z)/(z - w)^{k+1}$ gives

$$\int_{\partial D(a, \rho)} \frac{f'(z)}{(z - w)^{k+1}} dz = (k + 1) \int_{\partial D(a, \rho)} \frac{f(z)}{(z - w)^{k+2}} dz,$$

and applying the inductive hypothesis to f' we get

$$f^{(k+1)}(w) = \frac{k!}{2\pi i} \int_{\partial D(a, \rho)} \frac{f'(z)}{(z - w)^{k+1}} dz = \frac{(k + 1)!}{2\pi i} \int_{\partial D(a, \rho)} \frac{f(z)}{(z - w)^{k+2}} dz.$$

For the estimate, we may assume $M = \sup_{D(a, R)} |f| < \infty$. Let $\rho \in (R/2, R)$ and $w \in D(a, R/2)$. Then $|z - w| \geq \rho - R/2$ for $z \in \partial D(a, \rho)$, so

$$|f^{(k)}(w)| \leq \frac{k!}{2\pi} \cdot 2\pi\rho \cdot \frac{M}{(\rho - R/2)^{k+1}} = \frac{k!\rho M}{(\rho - R/2)^{k+1}},$$

and letting $\rho \rightarrow R$ gives $|f^{(k)}(w)| \leq k!RM/(R/2)^{k+1} = k!2^{k+1}M/R^k$. $\square$

We can also now prove a converse to Cauchy's theorem, which gives a criterion for holomorphy requiring no differentiability assumptions whatsoever.

Theorem 10.3.9 (Morera's Theorem)

Let $U \subseteq \mathbb{C}$ be open and $f : U \rightarrow \mathbb{C}$ be continuous such that

$$\int_{\gamma} f(z) dz = 0$$

for every closed curve γ in U . Then f is holomorphic on U .

Proof. The statement is local, so we may assume U is a disk (restricting to a disk around each point, where the hypothesis still holds). Then by the converse to the fundamental theorem of calculus, f has an antiderivative F on U , i.e. $F' = f$. But F is holomorphic, so it is infinitely differentiable, and in particular $f = F'$ is holomorphic. $\square$

Corollary 10.3.10 (Removing Exceptional Points)

Let $U \subseteq \mathbb{C}$ be open, $S \subset U$ finite, and let $f : U \rightarrow \mathbb{C}$ be continuous on U and holomorphic on $U \setminus S$. Then f is holomorphic on U .

Proof. Around each point $a \in U$ take a disk $D(a, r) \subseteq U$. By Cauchy's theorem for star-shaped domains (with exceptional points), every closed curve integral of f in $D(a, r)$ vanishes, so by Morera's theorem f is holomorphic on $D(a, r)$. $\square$

§10.3.4 Zeros and the Identity Theorem

Power series give us very tight control over the zeros of holomorphic functions. Suppose $f : D(a, R) \rightarrow \mathbb{C}$ is holomorphic and not identically zero, and write its Taylor expansion

$f(z) = \sum_{n \geq 0} c_n(z-a)^n$. Since $f \not\equiv 0$, some coefficient is non-zero (by our power series theorem, if all $c_n = 0$ then $f \equiv 0$ on the disk), so we may let

$$m = \min\{n \geq 0 \mid c_n \neq 0\}.$$

Then we can factor

$$f(z) = (z-a)^m g(z), \quad \text{where} \quad g(z) = \sum_{n=m}^{\infty} c_n(z-a)^{n-m}$$

is holomorphic on $D(a, R)$ with $g(a) = c_m \neq 0$.

Definition 10.3.11 (Order of a Zero)

In the above setting, if $f(a) = 0$ (that is, $m \geq 1$), we say f has a **zero of order m** at a . Equivalently, m is the least n with $f^{(n)}(a) \neq 0$. A zero of order 1 is called a **simple zero**.

Theorem 10.3.12 (Principle of Isolated Zeros)

Let $f : D(a, R) \rightarrow \mathbb{C}$ be holomorphic and not identically zero. Then there is some $0 < r \leq R$ such that $f(z) \neq 0$ for all z with $0 < |z-a| < r$.

Proof. If $f(a) \neq 0$, this is immediate from continuity. If $f(a) = 0$, write $f(z) = (z-a)^m g(z)$ as above with $g(a) \neq 0$. By continuity of g there is $r > 0$ with $g \neq 0$ on $D(a, r)$, and then $f(z) \neq 0$ for $0 < |z-a| < r$. $\square$

In other words – the zeros of a non-trivial holomorphic function are *isolated*: each zero has a punctured neighbourhood free of other zeros. There is no holomorphic function vanishing on a little segment, or on a little disk, other than the zero function. This has a striking global consequence.

Theorem 10.3.13 (Identity Theorem)

Let $U \subseteq \mathbb{C}$ be a domain and $f, g : U \rightarrow \mathbb{C}$ be holomorphic. If the set $S = \{z \in U \mid f(z) = g(z)\}$ contains a non-isolated point^a, then $f = g$ on all of U .

^aA point $w \in S$ is *non-isolated* if every punctured disk $D(w, r) \setminus \{w\}$ meets S .

Proof. Let $h = f - g$, so $S = \{z \in U \mid h(z) = 0\}$, and suppose $w \in S$ is a non-isolated point of S . Define

$$\begin{aligned} U_0 &= \{z \in U \mid h \equiv 0 \text{ on some } D(z, r)\}, \\ U_1 &= \{z \in U \mid h^{(n)}(z) \neq 0 \text{ for some } n \geq 0\}. \end{aligned}$$

These are disjoint: if h vanishes identically near z then so do all its derivatives at z . They also cover U : if $z \notin U_1$ then every Taylor coefficient of h at z vanishes, and so $h \equiv 0$ on any disk $D(z, r) \subseteq U$, meaning $z \in U_0$.

Moreover both sets are open: U_0 is open essentially by definition, and U_1 is open since each $h^{(n)}$ is continuous. Since U is a domain (hence connected), one of U_0, U_1 is empty.

Finally, the non-isolated point w lies in U_0 : if it did not, then $h \not\equiv 0$ near w , so by the principle of isolated zeros h would be non-vanishing on some punctured disk around w , contradicting non-isolation. So $U_0 \neq \emptyset$, hence $U_1 = \emptyset$ and $U = U_0$, that is, $h \equiv 0$ on U . $\square$

Remark (Analytic Continuation). The identity theorem says that a holomorphic function on a domain is completely determined by its values on any set with a limit point – say, a tiny disk, or a convergent sequence. If $U \subseteq V$ are domains and $f : U \rightarrow \mathbb{C}$ is holomorphic, then there is *at most one* holomorphic $g : V \rightarrow \mathbb{C}$ with $g|_U = f$; such a g is called the **analytic continuation** of f to V . It may or may not exist! For instance $f(z) = \sum_{n \geq 0} z^n$ is holomorphic on $D(0, 1)$, and admits the analytic continuation $1/(1 - z)$ to $\mathbb{C} \setminus \{1\}$, far beyond the disk of convergence. In contrast, one can show that $f(z) = \sum_{n \geq 0} z^{n!}$ (also holomorphic on $D(0, 1)$) admits no analytic continuation past the unit disk whatsoever.

Example 10.3.14 (Real Identities Propagate)

Since $\sin^2 x + \cos^2 x = 1$ holds for all real x , the holomorphic function $\sin^2 z + \cos^2 z - 1$ vanishes on $\mathbb{R}$, a set with (many!) non-isolated points. By the identity theorem it vanishes identically, so $\sin^2 z + \cos^2 z = 1$ for *all* $z \in \mathbb{C}$. The same argument transfers essentially any polynomial identity from $\mathbb{R}$ to $\mathbb{C}$.

§10.3.5 The Maximum Modulus Principle

Another consequence of the mean value property is that a holomorphic function can never have an interior maximum of modulus, unless it is constant.

Theorem 10.3.15 (Local Maximum Modulus Principle)

Let $f : D(a, R) \rightarrow \mathbb{C}$ be holomorphic. If $|f(z)| \leq |f(a)|$ for all $z \in D(a, R)$, then f is constant.

Proof. Let $0 < \rho < R$. By the mean value property and the basic estimate,

$$|f(a)| = \left| \int_0^1 f(a + \rho e^{2\pi i t}) dt \right| \leq \sup_{t \in [0, 1]} |f(a + \rho e^{2\pi i t})| \leq |f(a)|,$$

using the hypothesis for the final inequality. So both inequalities are equalities. Equality in the basic estimate forces $t \mapsto f(a + \rho e^{2\pi i t})$ to be constant, with modulus $|f(a)|$ (by the first equality). Since $\rho \in (0, R)$ was arbitrary, $|f| \equiv |f(a)|$ is constant on $D(a, R)$.

Finally, a holomorphic function of constant modulus is constant. If $|f|^2 = u^2 + v^2$ is a non-zero constant, differentiating gives $uu_x + vv_x = 0$ and $uu_y + vv_y = 0$; using the Cauchy-Riemann equations to eliminate the y -derivatives, $uu_x - vv_x = 0$ and $uu_y + vv_x = 0$, and solving this linear system (whose determinant is $u^2 + v^2 \neq 0$) gives $u_x = u_y = 0$, and similarly for v . So $f' = 0$ and f is constant on the (connected) disk. If instead $|f| \equiv 0$ then $f \equiv 0$. $\square$

Corollary 10.3.16 (Maximum Modulus Principle)

Let U be a bounded open set and let $f : \overline{U} \rightarrow \mathbb{C}$ be continuous on $\overline{U}$ and holomorphic on U . Then $|f|$ attains its maximum over $\overline{U}$ on the boundary ∂U .

Proof. Since $\overline{U}$ is compact and $|f|$ continuous, the maximum is attained at some $w \in \overline{U}$. If $w \in \partial U$ we are done, so suppose $w \in U$, and take $D(w, r) \subseteq U$. By the local maximum modulus principle, f is constant on $D(w, r)$, and hence by the identity theorem f is constant on the connected component U' of U containing w . By continuity f is constant on $\overline{U'}$, so the value $|f(w)|$ is also attained at points of $\partial U' \subseteq \partial U$.^a $\square$

^aTo see $\partial U' \subseteq \partial U$: a boundary point z of U' cannot lie in U , for otherwise a small disk around z in U would be connected to points of U' , forcing $z \in U'$, which is impossible as U' is open. So $z \in \overline{U} \setminus U = \partial U$.

§10.4 Uniform Limits of Holomorphic Functions

We now look at sequences of holomorphic functions that converge uniformly – or rather, uniformly on the parts of the domain that matter.

Definition 10.4.1 (Locally Uniform Convergence)

Let $U \subset \mathbb{C}$ be open, and let $f_n : U \rightarrow \mathbb{C}$ be a sequence of functions. We say that f_n converges **locally uniformly** on U if for each $a \in U$ there is some $r > 0$ such that f_n converges uniformly on $D(a, r)$.

Example 10.4.2 (Sequence of Functions Converging Locally Uniformly)

Consider the sequence of functions $f_n(z) = z^n$. Then $f_n \rightarrow 0$ locally uniformly on $D(0, 1)$, but not uniformly on $D(0, 1)$. This is because $f_n \rightarrow 0$ uniformly on any disk $D(0, r)$ if $r < 1$, but $\sup_{z \in D(0, 1)} |f_n(z)| = 1$ for each n .

Proposition 10.4.3

The sequence of functions f_n converges locally uniformly on U if and only if f_n converges uniformly on each compact subset $K \subset U$.

Proof. For the forward direction, suppose f_n converges locally uniformly, and let $K \subset U$ be compact. Each $a \in K$ has a disk $D(a, r_a)$ on which f_n converges uniformly, and these disks cover K , so by compactness finitely many of them, say $D(a_1, r_{a_1}), \dots, D(a_m, r_{a_m})$, cover K . Given $\varepsilon > 0$, for each i there is N_i such that $|f_n(z) - f(z)| < \varepsilon$ for all $n \geq N_i$ and $z \in D(a_i, r_{a_i})$; taking $N = \max_i N_i$ handles all $z \in K$ at once. So f_n converges uniformly on K .

Conversely, for each $a \in U$ there is $r > 0$ with the compact disk $\overline{D(a, r)} \subset U$, and uniform convergence on $\overline{D(a, r)}$ implies uniform convergence on $D(a, r)$. $\square$

Theorem 10.4.4 (Uniform Limits of Holomorphic Functions)

Let $U \subset \mathbb{C}$ be open, and $f_n : U \rightarrow \mathbb{C}$ be a sequence of holomorphic functions. If f_n converges locally uniformly on U to some function $f : U \rightarrow \mathbb{C}$, then f is holomorphic. Moreover, $f'_n \rightarrow f'$ locally uniformly on U ^a.

^aBy applying this result iteratively, we also get $f_n^{(k)} \rightarrow f^{(k)}$ locally uniformly on U , for every k .

Proof. Let $a \in U$, and choose $r > 0$ such that $\overline{D(a, r)} \subset U$ and $f_n \rightarrow f$ uniformly on $\overline{D(a, r)}$. A uniform limit of continuous functions is continuous, so f is continuous on $\overline{D(a, r)}$.

Now let γ be any closed curve in $D(a, r)$. The disk $D(a, r)$ is convex, so Cauchy's theorem gives $\int_{\gamma} f_n(z) dz = 0$ for every n . By uniform convergence on the image of γ (a subset of $\overline{D(a, r)}$), our lemma on swapping limits and integrals gives

$$\int_{\gamma} f(z) dz = \lim_{n \rightarrow \infty} \int_{\gamma} f_n(z) dz = 0.$$

Then Morera's theorem shows that f is holomorphic on $D(a, r)$, and since $a \in U$ was arbitrary, f is holomorphic on U .

For the convergence of derivatives, again take $a \in U$ and r as above. Applying the Cauchy estimate (with $k = 1$, $R = r$) to the holomorphic function $f_n - f$,

$$\sup_{z \in D(a, r/2)} |f'_n(z) - f'(z)| \leq \frac{4}{r} \sup_{z \in D(a, r)} |f_n(z) - f(z)| \rightarrow 0$$

as $n \rightarrow \infty$. So $f'_n \rightarrow f'$ uniformly on $D(a, r/2)$, giving locally uniform convergence. $\square$

This result spectacularly fails for real functions, as seen by the following theorem (which we will not prove).

Theorem 10.4.5 (Weierstrass Approximation Theorem)

Let $f : [a, b] \rightarrow \mathbb{R}$ be a continuous function on a compact interval $[a, b] \subset \mathbb{R}$. Then there is a sequence of polynomials converging to f uniformly on $[a, b]$.

Since there are continuous nowhere-differentiable functions on $[a, b]$, a uniform limit of real polynomials – the nicest functions imaginable – need not be differentiable at even a single point. For holomorphic functions, by contrast, local uniform limits preserve *everything*.

§10.5 Winding Numbers and the General Cauchy Theorem

So far, Cauchy's theorem needs the domain to be star-shaped. To go further we need a way of measuring how a closed curve sits inside a general domain – in particular, how many times it wraps around any given point. This is the *winding number*, and with it we can state and prove Cauchy's theorem in essentially complete generality.

§10.5.1 Winding Numbers

Let $\gamma : [a, b] \rightarrow \mathbb{C}$ be a closed curve and let w be a point not on the curve. For each t we can certainly write

$$\gamma(t) = w + r(t)e^{i\theta(t)},$$

where $r(t) = |\gamma(t) - w| > 0$ is uniquely determined and continuous. The angle $\theta(t)$ is only determined up to adding multiples of 2π – but as we will show below, it is possible to make a *continuous* choice of θ , and this is what makes the following definition sensible.

Definition 10.5.1 (Winding Number)

Let $\gamma : [a, b] \rightarrow \mathbb{C}$ be a closed curve, $w \notin \text{image}(\gamma)$, and let $\theta : [a, b] \rightarrow \mathbb{R}$ be a continuous function with $\gamma(t) = w + r(t)e^{i\theta(t)}$. The **winding number** (or **index**) of γ about w is

$$I(\gamma; w) = \frac{\theta(b) - \theta(a)}{2\pi}.$$

Two things need checking. First, since $\gamma(a) = \gamma(b)$, we have $e^{i(\theta(b) - \theta(a))} = 1$, so $I(\gamma; w)$ is an *integer*. Second, it is well defined: if θ_1 is another continuous choice, then $(\theta_1 - \theta)/2\pi$ is a continuous integer-valued function on an interval, hence constant, so both choices give the same value of $I(\gamma; w)$.

The picture shows a closed curve along with the winding number of the curve about points of the various regions of the complement – points it wraps around once, twice, and not at all.

For the curves we care about (piecewise C^1), a continuous angle function always exists, and better still, the winding number is computed by an integral.

Lemma 10.5.2 (Existence of Continuous Argument)

Let $\gamma : [a, b] \rightarrow \mathbb{C} \setminus \{w\}$ be a (piecewise C^1) curve. Then there is a piecewise C^1 function $\theta : [a, b] \rightarrow \mathbb{R}$ with $\gamma(t) = w + r(t)e^{i\theta(t)}$, where $r(t) = |\gamma(t) - w|$. Moreover, if γ is closed, then

$$I(\gamma; w) = \frac{1}{2\pi i} \int_{\gamma} \frac{dz}{z - w}.$$

Proof. Define

$$h(t) = \int_a^t \frac{\gamma'(s)}{\gamma(s) - w} ds.$$

The integrand is bounded and continuous away from the finitely many points where γ' jumps, so h is continuous and piecewise C^1 , with $h'(t) = \gamma'(t)/(\gamma(t) - w)$ away

from those points. Then

$$\frac{d}{dt} [(\gamma(t) - w)e^{-h(t)}] = \gamma'(t)e^{-h(t)} - (\gamma(t) - w)h'(t)e^{-h(t)} = 0$$

except at finitely many points, so by continuity $(\gamma(t) - w)e^{-h(t)}$ is constant, equal to $\gamma(a) - w$. Writing $\gamma(a) - w = r(a)e^{i\alpha}$, we get

$$\gamma(t) - w = r(a)e^{\operatorname{Re} h(t)}e^{i(\alpha + \operatorname{Im} h(t))},$$

so $\theta(t) = \alpha + \operatorname{Im} h(t)$ is a continuous (piecewise C^1) argument function, and comparing moduli, $r(t) = r(a)e^{\operatorname{Re} h(t)}$.

Now suppose γ is closed. Then $r(b) = r(a)$, so $\operatorname{Re} h(b) = 0$, and

$$I(\gamma; w) = \frac{\theta(b) - \theta(a)}{2\pi} = \frac{\operatorname{Im} h(b)}{2\pi} = \frac{h(b)}{2\pi i} = \frac{1}{2\pi i} \int_a^b \frac{\gamma'(s)}{\gamma(s) - w} ds = \frac{1}{2\pi i} \int_\gamma \frac{dz}{z - w}.$$

□

Proposition 10.5.3 (Winding Numbers are Locally Constant)

Let $\gamma : [a, b] \rightarrow \mathbb{C}$ be a closed curve. Then $w \mapsto I(\gamma; w)$ is locally constant on $\mathbb{C} \setminus \operatorname{image}(\gamma)$; in particular, it is constant on each connected component of this set.

Proof. The function $w \mapsto \frac{1}{2\pi i} \int_\gamma \frac{dz}{z - w}$ is continuous on the open set $\mathbb{C} \setminus \operatorname{image}(\gamma)$ (the integrand depends continuously on w , uniformly for z on the curve, since $|z - w|$ is bounded below near any fixed w_0). A continuous integer-valued function is locally constant, and a locally constant function is constant on connected components. □

Proposition 10.5.4 (Winding Number Far Away)

Let $\gamma : [a, b] \rightarrow \mathbb{C}$ be a closed curve. Then $\mathbb{C} \setminus \operatorname{image}(\gamma)$ has exactly one unbounded connected component Ω , and $I(\gamma; w) = 0$ for all $w \in \Omega$.

Proof. The image of γ is compact, so it lies in some disk $D(0, R)$. The connected set $\mathbb{C} \setminus D(0, R)$ lies in a single component Ω of the complement of the curve, which is then unbounded; every other component avoids $\mathbb{C} \setminus D(0, R)$ and hence is contained in $D(0, R)$, i.e. is bounded. Finally, if $w \in \mathbb{C} \setminus D(0, R)$, then $z \mapsto 1/(z - w)$ is holomorphic on the convex set $D(0, R)$ which contains γ , so $I(\gamma; w) = 0$ by Cauchy's theorem for convex domains. By local constancy, $I(\gamma; \cdot) = 0$ on all of Ω . □

§10.5.2 The General Cauchy Theorem

We can now state the theorem. The correct condition on the curve turns out to be the following.

Definition 10.5.5 (Homologous to Zero)

Let $U \subseteq \mathbb{C}$ be open. A closed curve γ in U is **homologous to zero** in U if

$I(\gamma; w) = 0$ for every $w \in \mathbb{C} \setminus U$.

Intuitively $-\gamma$ does not wind around any of the ‘holes’ of U (points outside U). Note this is automatic if $U = \mathbb{C}$.

Before the main theorem, we need a somewhat technical lemma on difference quotients.

Lemma 10.5.6 (Difference Quotients are Jointly Continuous)

Let $U \subseteq \mathbb{C}$ be open and $f : U \rightarrow \mathbb{C}$ be holomorphic. Define $g : U \times U \rightarrow \mathbb{C}$ by

$$g(z, w) = \begin{cases} \frac{f(z) - f(w)}{z - w} & \text{if } z \neq w, \\ f'(w) & \text{if } z = w. \end{cases}$$

Then g is continuous. Moreover, for any closed curve γ in U , the function $h(w) = \int_{\gamma} g(z, w) dz$ is holomorphic on U .

Proof. Continuity of g is clear at points (z, w) with $z \neq w$. For a point (a, a) , let $\varepsilon > 0$, and use continuity of f' (recall f' is holomorphic, in particular continuous) to pick $\delta > 0$ with $D(a, \delta) \subseteq U$ and $|f'(\zeta) - f'(a)| < \varepsilon$ for $\zeta \in D(a, \delta)$. For $z, w \in D(a, \delta)$ with $z \neq w$, the segment from w to z lies in $D(a, \delta)$, and

$$f(z) - f(w) = \int_0^1 \frac{d}{dt} f(tz + (1-t)w) dt = (z - w) \int_0^1 f'(tz + (1-t)w) dt,$$

so that

$$\begin{aligned} |g(z, w) - g(a, a)| &= \left| \int_0^1 [f'(tz + (1-t)w) - f'(a)] dt \right| \\ &\leq \sup_{t \in [0,1]} |f'(tz + (1-t)w) - f'(a)| < \varepsilon. \end{aligned}$$

The case $z = w$ is simply $|f'(z) - f'(a)| < \varepsilon$. Hence g is continuous at (a, a) .

Now let γ be a closed curve in U and $h(w) = \int_{\gamma} g(z, w) dz$. First, h is continuous: if $w_n \rightarrow w_0$ in U , choose $\delta > 0$ with $\overline{D(w_0, \delta)} \subset U$; then g is uniformly continuous on the compact set $\text{image}(\gamma) \times \overline{D(w_0, \delta)}$, so $g(\cdot, w_n) \rightarrow g(\cdot, w_0)$ uniformly on $\text{image}(\gamma)$, and hence $h(w_n) \rightarrow h(w_0)$ by our uniform convergence lemma.

To see h is holomorphic, we use Morera. Fix $w_0 \in U$ and a disk $D(w_0, \delta) \subseteq U$, and let β be any closed curve in $D(w_0, \delta)$. Writing out both integrals as integrals over parameter intervals, Fubini’s theorem^a lets us swap the order of integration:

$$\int_{\beta} h(w) dw = \int_{\beta} \left(\int_{\gamma} g(z, w) dz \right) dw = \int_{\gamma} \left(\int_{\beta} g(z, w) dw \right) dz.$$

But for each fixed z , the function $w \mapsto g(z, w)$ is continuous on U and holomorphic on $U \setminus \{z\}$, hence holomorphic on U by our corollary on removing exceptional points. Since $D(w_0, \delta)$ is convex, $\int_{\beta} g(z, w) dw = 0$ by Cauchy’s theorem. Hence

$\int_{\beta} h(w) dw = 0$ for all closed β in $D(w_0, \delta)$, so h is holomorphic on $D(w_0, \delta)$ by Morera's theorem, and w_0 was arbitrary. $\square$

^aFor continuous integrands on products of compact intervals, Fubini's theorem – that the two iterated integrals agree – follows by uniform continuity: approximate the integrand uniformly by step functions, for which the interchange is immediate.

Theorem 10.5.7 (General Cauchy Theorem & Integral Formula)

Let $U \subseteq \mathbb{C}$ be a non-empty open set and γ a closed curve in U , homologous to zero in U . Then for every holomorphic $f : U \rightarrow \mathbb{C}$:

- (i) $I(\gamma; w)f(w) = \frac{1}{2\pi i} \int_{\gamma} \frac{f(z)}{z - w} dz$ for every $w \in U \setminus \text{image}(\gamma)$;
- (ii) $\int_{\gamma} f(z) dz = 0$.

Proof. Let us first note that (i) implies (ii): apply (i) to the holomorphic function $F(z) = (z - w)f(z)$ for any fixed $w \in U \setminus \text{image}(\gamma)$; since $F(w) = 0$, we get $\int_{\gamma} f(z) dz = 0$.

So we prove (i), which (multiplying up) is precisely the statement that $h(w) = \int_{\gamma} g(z, w) dz = 0$ for all $w \in U \setminus \text{image}(\gamma)$, where g is the difference quotient function of the previous lemma. By that lemma, h is holomorphic on U . The plan is to extend h to an entire function which vanishes at infinity, and then invoke Liouville.

Let

$$V = \{w \in \mathbb{C} \setminus \text{image}(\gamma) \mid I(\gamma; w) = 0\}.$$

Since γ is homologous to zero in U , we have $\mathbb{C} \setminus U \subseteq V$, i.e. $U \cup V = \mathbb{C}$. Also V is open, since $I(\gamma; \cdot)$ is locally constant. On the overlap $U \cap V$, for $w \in U \cap V$,

$$h(w) = \int_{\gamma} \frac{f(z) - f(w)}{z - w} dz = \int_{\gamma} \frac{f(z)}{z - w} dz - 2\pi i I(\gamma; w)f(w) = \int_{\gamma} \frac{f(z)}{z - w} dz,$$

as $I(\gamma; w) = 0$ there. So h agrees on $U \cap V$ with the function

$$h_1(w) = \int_{\gamma} \frac{f(z)}{z - w} dz, \quad w \in V,$$

which is holomorphic on V (by the standard argument: it is continuous, and holomorphic under the integral sign – or simply repeat the Morera argument of the lemma). Hence

$$H(w) = \begin{cases} h(w) & \text{if } w \in U, \\ h_1(w) & \text{if } w \in V \end{cases}$$

is a well-defined entire function.

Now pick R with $\text{image}(\gamma) \subset D(0, R)$. Then $\mathbb{C} \setminus D(0, R)$ lies in the unbounded component of the complement of γ , where the winding number vanishes, so $\mathbb{C} \setminus D(0, R) \subseteq$

V. For $|w| > R$,

$$|H(w)| = |h_1(w)| \leq \frac{\text{length}(\gamma)}{|w| - R} \sup_{z \in \text{image}(\gamma)} |f(z)| \rightarrow 0 \quad \text{as } |w| \rightarrow \infty.$$

In particular H is bounded (continuous on a compact disk, small outside it), so by Liouville's theorem H is constant – and since $H(w) \rightarrow 0$, that constant is 0. Hence $h \equiv 0$ on U , as required. $\square$

This machine has some immediate and very useful corollaries about systems of curves.

Corollary 10.5.8 (Cauchy's Theorem for Several Curves)

Let $U \subseteq \mathbb{C}$ be open and let $\gamma_1, \dots, \gamma_n$ be closed curves in U such that

$$\sum_{j=1}^n I(\gamma_j; w) = 0 \quad \text{for all } w \in \mathbb{C} \setminus U.$$

Then for every holomorphic $f : U \rightarrow \mathbb{C}$,

$$\sum_{j=1}^n \int_{\gamma_j} f(z) \, dz = 0, \quad \text{and} \quad f(w) \sum_{j=1}^n I(\gamma_j; w) = \sum_{j=1}^n \frac{1}{2\pi i} \int_{\gamma_j} \frac{f(z)}{z - w} \, dz$$

for every $w \in U$ not on any of the curves.

Proof. Run the proof of the theorem again, defining $h(w) = \sum_j \int_{\gamma_j} g(z, w) \, dz$ and $V = \{w \mid \sum_j I(\gamma_j; w) = 0\}$; every step goes through verbatim. $\square$

Corollary 10.5.9 (Curves with Equal Winding Numbers)

Let $U \subseteq \mathbb{C}$ be open and β_1, β_2 be closed curves in U with $I(\beta_1; w) = I(\beta_2; w)$ for every $w \in \mathbb{C} \setminus U$. Then

$$\int_{\beta_1} f(z) \, dz = \int_{\beta_2} f(z) \, dz$$

for every holomorphic $f : U \rightarrow \mathbb{C}$.

Proof. Apply the previous corollary to the curves $\gamma_1 = \beta_1$ and $\gamma_2 = -\beta_2$, noting $I(-\beta_2; w) = -I(\beta_2; w)$. $\square$

§10.5.3 Homotopy and Simply Connected Domains

The condition ‘homologous to zero’ is exactly the right one, but it can be awkward to verify directly. A more intuitive (and slightly stronger) condition comes from the notion of *continuously deforming* curves.

Definition 10.5.10 (Homotopy)

Let $U \subseteq \mathbb{C}$ be a domain and $\gamma_0, \gamma_1 : [a, b] \rightarrow U$ be closed curves. We say γ_0 and γ_1

are **homotopic** in U if there is a continuous map $H : [0, 1] \times [a, b] \rightarrow U$ such that

$$H(0, t) = \gamma_0(t), \quad H(1, t) = \gamma_1(t), \quad H(s, a) = H(s, b)$$

for all $s \in [0, 1]$ and $t \in [a, b]$.

Writing $\gamma_s(t) = H(s, t)$, the definition says exactly that $\{\gamma_s\}_{s \in [0, 1]}$ is a family of closed curves in U deforming γ_0 continuously into γ_1 , without ever leaving U .

Definition 10.5.11 (Null-Homotopic)

A closed curve in a domain U is **null-homotopic** if it is homotopic in U to a constant curve.

The key fact is that deforming a curve cannot change any of the winding numbers that matter.

Theorem 10.5.12 (Homotopic Curves have Equal Winding Numbers)

If $\gamma_0, \gamma_1 : [a, b] \rightarrow U$ are homotopic closed curves in a domain U , then $I(\gamma_0; w) = I(\gamma_1; w)$ for every $w \in \mathbb{C} \setminus U$. In particular, a null-homotopic closed curve is homologous to zero in U .

Proof. We will use the following fact, which is an exercise on the example sheets: if $\gamma, \tilde{\gamma}$ are closed curves with

$$|\gamma(t) - \tilde{\gamma}(t)| < |w - \gamma(t)| \quad \text{for all } t,$$

then $I(\gamma; w) = I(\tilde{\gamma}; w)$. (Intuitively – if $\tilde{\gamma}$ stays closer to γ than γ is to w , then in walking along $\tilde{\gamma}$ instead of γ we can never gain or lose a loop around w .)

Let H be a homotopy from γ_0 to γ_1 , and fix $w \in \mathbb{C} \setminus U$. The image $K = H([0, 1] \times [a, b])$ is compact and contained in U , so there is $\varepsilon > 0$ with $|w - H(s, t)| > 2\varepsilon$ for all (s, t) . By uniform continuity of H , there is $n \in \mathbb{N}$ such that

$$|s - s'| + |t - t'| \leq \frac{\max\{1, b - a\}}{n} \implies |H(s, t) - H(s', t')| < \varepsilon.$$

For $k = 0, 1, \dots, n$ let $\Gamma_k(t) = H(k/n, t)$, closed curves interpolating from γ_0 to γ_1 with $|\Gamma_{k-1}(t) - \Gamma_k(t)| < \varepsilon < |w - \Gamma_{k-1}(t)|$ for all t .

If each Γ_k were piecewise C^1 we would be done by the example sheet fact. In general they are merely continuous, so we approximate: let $a_j = a + j(b - a)/n$ for $0 \leq j \leq n$,

and let $\tilde{\Gamma}_k$ be the closed polygonal curve agreeing with Γ_k at each a_j and affine on each $[a_{j-1}, a_j]$. On $[a_{j-1}, a_j]$, the value $\tilde{\Gamma}_k(t)$ is a convex combination of $\Gamma_k(a_{j-1})$ and $\Gamma_k(a_j)$, both within ε of $\Gamma_k(t)$ by uniform continuity; so $|\tilde{\Gamma}_k(t) - \Gamma_k(t)| < \varepsilon$ for all t . Next we estimate the distance between consecutive polygonal curves: $\tilde{\Gamma}_{k-1}(t) - \tilde{\Gamma}_k(t)$ is a convex combination of $\Gamma_{k-1}(a_{j-1}) - \Gamma_k(a_{j-1})$ and $\Gamma_{k-1}(a_j) - \Gamma_k(a_j)$, each of modulus less than ε , so $|\tilde{\Gamma}_{k-1}(t) - \tilde{\Gamma}_k(t)| < \varepsilon$. Also

$$|w - \tilde{\Gamma}_{k-1}(t)| \geq |w - \Gamma_{k-1}(t)| - |\Gamma_{k-1}(t) - \tilde{\Gamma}_{k-1}(t)| > 2\varepsilon - \varepsilon = \varepsilon.$$

So the example sheet fact applies to each consecutive pair, giving $I(\tilde{\Gamma}_0; w) = I(\tilde{\Gamma}_1; w) = \cdots = I(\tilde{\Gamma}_n; w)$. Finally, $|\tilde{\Gamma}_0(t) - \gamma_0(t)| < \varepsilon < |w - \gamma_0(t)|$ gives $I(\tilde{\Gamma}_0; w) = I(\gamma_0; w)$, and similarly at the other end, $I(\tilde{\Gamma}_n; w) = I(\gamma_1; w)$. Hence $I(\gamma_0; w) = I(\gamma_1; w)$.

For the last statement: a constant curve has all winding numbers zero, so a null-homotopic curve has $I(\gamma; w) = 0$ for every $w \notin U$. $\square$

Corollary 10.5.13 (Deformation Invariance of Integrals)

If γ_0, γ_1 are homotopic closed curves in a domain U , then

$$\int_{\gamma_0} f(z) \, dz = \int_{\gamma_1} f(z) \, dz$$

for every holomorphic $f : U \rightarrow \mathbb{C}$.

Proof. Combine the theorem with our corollary on curves with equal winding numbers. $\square$

Definition 10.5.14 (Simply Connected)

A domain U is **simply connected** if every closed curve in U is null-homotopic.

Intuitively, simply connected domains are the domains ‘without holes’. For example, every star-shaped domain U with centre a_0 is simply connected: given a closed curve γ , the map $H(s, t) = (1 - s)\gamma(t) + sa_0$ is a homotopy in U (each point $H(s, t)$ lies on the segment from $\gamma(t)$ to the centre) from γ to the constant curve at a_0 .

Theorem 10.5.15 (Cauchy's Theorem for Simply Connected Domains)

Let U be a simply connected domain and $f : U \rightarrow \mathbb{C}$ be holomorphic. Then

$$\int_{\gamma} f(z) \, dz = 0$$

for every closed curve γ in U .

Proof. Every closed curve in U is null-homotopic, hence homologous to zero, so the general Cauchy theorem applies. $\square$

Remark. The converse is also true (though harder to prove): if $\int_{\gamma} f \, dz = 0$ for all

holomorphic f and closed curves γ in U , then U is simply connected. However, at the level of individual curves the two notions genuinely differ: in $U = \mathbb{C} \setminus \{w_1, w_2\}$ (two punctures), there are closed curves that are homologous to zero but *not* null-homotopic – the classic example traces around both punctures in a clever ‘figure-of-eight-like’ pattern so that both winding numbers cancel to zero, yet the curve cannot be shrunk to a point. Homology counts winding; homotopy remembers more.

§10.6 Isolated Singularities and Laurent Series

The Cauchy integral formula lets us integrate functions of the form $f(z)/(z - a)$ where f is holomorphic at a . But many natural functions – say $e^{1/z}$ near $z = 0$ – fail to be holomorphic at a point in a more serious way, and we would still like to integrate them around that point. This leads us to classify how a holomorphic function can behave near an isolated ‘bad point’, and to a generalisation of Taylor series adapted to such points.

§10.6.1 Removable Singularities and Poles

Definition 10.6.1 (Isolated Singularity)

Let $U \subseteq \mathbb{C}$ be open and $a \in U$. If $f : U \setminus \{a\} \rightarrow \mathbb{C}$ is holomorphic, we say f has an **isolated singularity** at a .

The mildest possibility is that the singularity is illusory.

Definition 10.6.2 (Removable Singularity)

An isolated singularity a of f is a **removable singularity** if f can be defined at a in such a way that the extended function is holomorphic on U .

Proposition 10.6.3 (Characterising Removable Singularities)

Let U be open, $a \in U$, and $f : U \setminus \{a\} \rightarrow \mathbb{C}$ be holomorphic. The following are equivalent:

- (i) f has a removable singularity at a ;
- (ii) $\lim_{z \rightarrow a} f(z)$ exists in $\mathbb{C}$;
- (iii) $|f|$ is bounded on $D(a, \varepsilon) \setminus \{a\}$ for some $\varepsilon > 0$;
- (iv) $\lim_{z \rightarrow a} (z - a)f(z) = 0$.

Proof. The implications (i) $\Rightarrow$ (ii) $\Rightarrow$ (iii) $\Rightarrow$ (iv) are each immediate. The content is (iv) $\Rightarrow$ (i). Define $h : U \rightarrow \mathbb{C}$ by

$$h(z) = \begin{cases} (z - a)^2 f(z) & \text{if } z \neq a, \\ 0 & \text{if } z = a. \end{cases}$$

Then h is holomorphic on $U \setminus \{a\}$, and at a ,

$$\lim_{z \rightarrow a} \frac{h(z) - h(a)}{z - a} = \lim_{z \rightarrow a} (z - a)f(z) = 0,$$

using (iv). So h is differentiable at a too, with $h(a) = h'(a) = 0$, i.e. h is holomorphic on U . Its Taylor expansion at a therefore starts at the quadratic term: on some $D(a, r)$ we have $h(z) = (z - a)^2 g(z)$ with g holomorphic on $D(a, r)$. Comparing with the definition of h , we get $f = g$ on $D(a, r) \setminus \{a\}$, so defining $f(a) = g(a)$ extends f holomorphically. $\square$

Example 10.6.4

The function $f(z) = \frac{e^z - 1}{z}$ is holomorphic on $\mathbb{C} \setminus \{0\}$, and $zf(z) = e^z - 1 \rightarrow 0$ as $z \rightarrow 0$, so the singularity at 0 is removable. Indeed, dividing the Taylor series of $e^z - 1$ by z exhibits the extension $\sum_{k \geq 1} z^{k-1}/k!$ directly, an entire function.

If a singularity is not removable, then by (iii) above f is unbounded near a . The tame way this can happen is if f blows up cleanly.

Definition 10.6.5 (Pole)

An isolated singularity a of f is a **pole** if $|f(z)| \rightarrow \infty$ as $z \rightarrow a$.

Definition 10.6.6 (Essential Singularity)

An isolated singularity which is neither removable nor a pole is called an **essential singularity**.

Example 10.6.7

- (i) $f(z) = (z - a)^{-k}$ for $k \in \mathbb{N}$ has a pole at a .
- (ii) $f(z) = e^{1/z}$ has an essential singularity at 0. Indeed, $|f(iy)| = 1$ for real $y \neq 0$, while $f(x) \rightarrow \infty$ as $x \rightarrow 0^+$ along the reals – so $|f|$ neither stays bounded nor tends to infinity.

Poles are completely understood in terms of zeros of holomorphic functions.

Proposition 10.6.8 (Characterising Poles)

Let $f : U \setminus \{a\} \rightarrow \mathbb{C}$ be holomorphic. The following are equivalent:

- (i) f has a pole at a ;
- (ii) there is $\varepsilon > 0$ and a holomorphic $h : D(a, \varepsilon) \rightarrow \mathbb{C}$ with $h(a) = 0$, $h \neq 0$ on $D(a, \varepsilon) \setminus \{a\}$, and $f = 1/h$ on $D(a, \varepsilon) \setminus \{a\}$;
- (iii) there is a unique integer $k \geq 1$ and a unique holomorphic $g : U \rightarrow \mathbb{C}$ with $g(a) \neq 0$ such that

$$f(z) = (z - a)^{-k} g(z) \quad \text{on } U \setminus \{a\}.$$

Proof. (i) $\Rightarrow$ (ii). Since $|f(z)| \rightarrow \infty$, there is $\varepsilon > 0$ with $|f| \geq 1$ on $D(a, \varepsilon) \setminus \{a\}$, so $1/f$ is holomorphic and bounded (by 1) there. By the removable singularity criterion, $1/f$ extends to a holomorphic h on $D(a, \varepsilon)$, and since $|f| \rightarrow \infty$ we must have $h(a) = 0$; clearly $h \neq 0$ away from a and $f = 1/h$.

(ii) $\Rightarrow$ (iii). By our factorisation of zeros, $h(z) = (z - a)^k h_1(z)$ for some $k \geq 1$ and holomorphic h_1 with $h_1 \neq 0$ on $D(a, \varepsilon)$ (shrinking ε if needed). Then $g_1 = 1/h_1$ is holomorphic on $D(a, \varepsilon)$ and $f(z) = (z - a)^{-k} g_1(z)$ there. Now define $g : U \rightarrow \mathbb{C}$ by $g = g_1$ on $D(a, \varepsilon)$ and $g(z) = (z - a)^k f(z)$ on $U \setminus \{a\}$; the two definitions agree on the overlap, so g is well-defined, holomorphic, and $g(a) = g_1(a) \neq 0$.

For uniqueness, if $(z - a)^{-k} g(z) = (z - a)^{-\tilde{k}} \tilde{g}(z)$ with $g(a), \tilde{g}(a) \neq 0$, then $g(z) = (z - a)^{k-\tilde{k}} \tilde{g}(z)$ away from a ; if $k \neq \tilde{k}$ this forces one of $g(a), \tilde{g}(a)$ to vanish (letting $z \rightarrow a$), a contradiction. So $k = \tilde{k}$, and then $g = \tilde{g}$ off a , hence everywhere by continuity.

(iii) $\Rightarrow$ (i). Immediate: $|f(z)| = |z - a|^{-k} |g(z)| \rightarrow \infty$ as $z \rightarrow a$ since $g(a) \neq 0$. $\square$

Definition 10.6.9 (Order of a Pole)

If f has a pole at a , the unique integer $k \geq 1$ above is the **order** of the pole. A pole of order 1 is called a **simple pole**.

Definition 10.6.10 (Meromorphic)

Let U be open and $S \subset U$ be a discrete subset (all of its points are isolated). If $f : U \setminus S \rightarrow \mathbb{C}$ is holomorphic and every point of S is a removable singularity or a pole of f , we say f is **meromorphic** on U .

Remark (The Riemann Sphere). A pole is not really a ‘bad point’ at all, if one is willing to enlarge the target. Adding a point at infinity to $\mathbb{C}$ yields the *Riemann sphere* $\mathbb{C} \cup \{\infty\}$, and a meromorphic function on U becomes a genuinely continuous (indeed holomorphic, suitably interpreted) map $U \rightarrow \mathbb{C} \cup \{\infty\}$ by sending poles to ∞ . From this point of view the only true singularities are essential ones. This perspective is developed properly in the Part II course *Riemann Surfaces*.

Near an essential singularity, on the other hand, the behaviour is truly wild.

Theorem 10.6.11 (Casorati-Weierstrass)

Let $f : U \setminus \{a\} \rightarrow \mathbb{C}$ be holomorphic with an essential singularity at a . Then for every $\varepsilon > 0$, the image $f(D(a, \varepsilon) \setminus \{a\})$ is *dense* in $\mathbb{C}$: for any $b \in \mathbb{C}$ and any $\delta > 0$, there are points z arbitrarily close to a with $|f(z) - b| < \delta$.

Proof. Suppose not: there are $b \in \mathbb{C}$, $\delta > 0$ and $\varepsilon > 0$ such that $|f(z) - b| \geq \delta$ for all $z \in D(a, \varepsilon) \setminus \{a\}$. Then

$$g(z) = \frac{1}{f(z) - b}$$

is holomorphic and bounded (by $1/\delta$) on $D(a, \varepsilon) \setminus \{a\}$, so g extends holomorphically over a . If $g(a) \neq 0$ then $f = b + 1/g$ is bounded near a , so a is removable; if $g(a) = 0$

then $|f(z)| = |b + 1/g(z)| \rightarrow \infty$ as $z \rightarrow a$, so a is a pole. Either way we contradict the singularity being essential. $\square$

Remark (Picard's Theorem). Much more is true: *Picard's theorem* states that near an essential singularity, f attains every complex value, with at most a single exception, infinitely often. (For $e^{1/z}$ the exceptional value is 0.) The proof is well beyond this course.

§10.6.2 Laurent Series

We can now generalise Taylor series to functions holomorphic on an *annulus* – in particular on a punctured disk, the natural home of an isolated singularity. The price is that negative powers of $(z - a)$ appear; the reward is that they tell us everything about the singularity.

Theorem 10.6.12 (Laurent Expansion)

Let $0 \leq r < R \leq \infty$ and let f be holomorphic on the annulus

$$A = \{z \in \mathbb{C} \mid r < |z - a| < R\}.$$

Then:

- (i) f has a unique convergent series expansion on A ,

$$f(z) = \sum_{n=-\infty}^{\infty} c_n (z - a)^n = \sum_{n=1}^{\infty} c_{-n} (z - a)^{-n} + \sum_{n=0}^{\infty} c_n (z - a)^n;$$

- (ii) for any $\rho \in (r, R)$, the coefficients are given by

$$c_n = \frac{1}{2\pi i} \int_{\partial D(a, \rho)} \frac{f(z)}{(z - a)^{n+1}} dz;$$

- (iii) if $r < \rho' \leq \rho < R$, the two series in (i) converge uniformly on $\{\rho' \leq |z - a| \leq \rho\}$.

Proof. Fix $w \in A$, and choose ρ_1, ρ_2 with $r < \rho_1 < |w - a| < \rho_2 < R$. As in the proof of the Cauchy integral formula, the function

$$g(z) = \begin{cases} \frac{f(z) - f(w)}{z - w} & \text{if } z \neq w, \\ f'(w) & \text{if } z = w \end{cases}$$

is continuous on A and holomorphic on $A \setminus \{w\}$, hence holomorphic on A (removable singularity). The circles $\partial D(a, \rho_1)$ and $\partial D(a, \rho_2)$ are homotopic in A (deform the radius continuously), so

$$\int_{\partial D(a, \rho_1)} g(z) \, dz = \int_{\partial D(a, \rho_2)} g(z) \, dz.$$

Substituting the definition of g and using $I(\partial D(a, \rho_1); w) = 0$ (as $|w - a| > \rho_1$) and $I(\partial D(a, \rho_2); w) = 1$, we obtain the annular Cauchy integral formula

$$f(w) = \frac{1}{2\pi i} \int_{\partial D(a, \rho_2)} \frac{f(z)}{z - w} \, dz - \frac{1}{2\pi i} \int_{\partial D(a, \rho_1)} \frac{f(z)}{z - w} \, dz.$$

Now expand each integrand in a geometric series, exactly as for Taylor series. On $\partial D(a, \rho_2)$ we have $|w - a| < |z - a|$, so

$$\frac{1}{z - w} = \sum_{n=0}^{\infty} \frac{(w - a)^n}{(z - a)^{n+1}},$$

uniformly in z ; while on $\partial D(a, \rho_1)$ we have $|z - a| < |w - a|$, so

$$\frac{1}{z - w} = - \sum_{n=0}^{\infty} \frac{(z - a)^n}{(w - a)^{n+1}},$$

again uniformly. Integrating term by term (using our uniform convergence lemma) gives

$$f(w) = \sum_{n=0}^{\infty} c_n (w - a)^n + \sum_{n=1}^{\infty} c_{-n} (w - a)^{-n},$$

where c_n (for $n \geq 0$) is given by the integral over $\partial D(a, \rho_2)$ as in (ii), and c_{-n} (for $n \geq 1$) by the integral over $\partial D(a, \rho_1)$. Since any two circles $\partial D(a, \rho)$, $\rho \in (r, R)$, are homotopic in A and the integrands are holomorphic on A , the integrals do not depend on the radius used, giving (ii) as stated.

For (iii) and uniqueness, suppose $f(z) = \sum_{n=-\infty}^{\infty} c_n (z - a)^n$ on A for some coefficients c_n . The non-negative part $\sum_{n \geq 0} c_n (z - a)^n$ converges on A , so its radius of convergence is at least R , giving uniform convergence on $|z - a| \leq \rho < R$. For the negative part, substitute $\zeta = (z - a)^{-1}$: the series $\sum_{n \geq 1} c_{-n} \zeta^n$ converges for $1/R < |\zeta| < 1/r$, so has radius of convergence at least $1/r$, and converges uniformly on $|\zeta| \leq 1/\rho'$, i.e. on $|z - a| \geq \rho'$. This proves (iii). Then for any $m \in \mathbb{Z}$ we may integrate the uniformly convergent series term by term against $(z - a)^{-m-1}$:

$$\int_{\partial D(a, \rho)} \frac{f(z)}{(z - a)^{m+1}} \, dz = \sum_{n=-\infty}^{\infty} c_n \int_{\partial D(a, \rho)} (z - a)^{n-m-1} \, dz = 2\pi i c_m,$$

since $\int_{\partial D(a, \rho)} (z - a)^j \, dz = 0$ for $j \neq -1$ (antiderivative!) and $= 2\pi i$ for $j = -1$. So the coefficients are forced to be those of (ii), giving uniqueness. $\square$

Remark. If f happens to extend holomorphically to the full disk $D(a, R)$, then each coefficient c_{-m} with $m \geq 1$ vanishes by Cauchy's theorem (the integrand is then holomorphic on the disk), and the Laurent series is just the Taylor series. The new content

is precisely for functions with no such extension.

Applying this on a punctured disk ($r = 0$), the shape of the Laurent series reads off the type of singularity.

Proposition 10.6.13 (Classification of Singularities via Laurent Series)

Let f be holomorphic on the punctured disk $D(a, R) \setminus \{a\}$, with Laurent expansion $f(z) = \sum_{n \in \mathbb{Z}} c_n(z - a)^n$. Then:

- (i) a is a removable singularity if and only if $c_n = 0$ for all $n < 0$;
- (ii) a is a pole of order k if and only if $c_{-k} \neq 0$ and $c_n = 0$ for all $n < -k$;
- (iii) a is an essential singularity if and only if $c_n \neq 0$ for infinitely many $n < 0$.

Proof. If $c_n = 0$ for $n < 0$, the series defines a holomorphic function on $D(a, R)$ agreeing with f away from a , so the singularity is removable; conversely if the singularity is removable the Laurent series is the Taylor series of the extension.

If $c_{-k} \neq 0$ and lower coefficients vanish, then $f(z) = (z - a)^{-k}g(z)$ where $g(z) = \sum_{n \geq 0} c_{n-k}(z - a)^n$ is holomorphic on $D(a, R)$ with $g(a) = c_{-k} \neq 0$; by our characterisation, a is a pole of order k . Conversely a pole of order k has this form, and expanding g in a Taylor series produces such a Laurent series (unique!).

Finally (iii) holds since (i) and (ii) are equivalences and the three cases are exhaustive and mutually exclusive. $\square$

Example 10.6.14 (Laurent Series of $e^{1/z}$)

Substituting $1/z$ into the exponential series,

$$e^{1/z} = \sum_{n=0}^{\infty} \frac{z^{-n}}{n!} = 1 + \frac{1}{z} + \frac{1}{2!z^2} + \cdots, \quad z \neq 0.$$

Infinitely many negative coefficients are non-zero, confirming that 0 is an essential singularity.

Example 10.6.15 (Different Annuli, Different Series)

A function can have different Laurent expansions on different annuli. Take

$$f(z) = \frac{1}{z(1-z)} = \frac{1}{z} + \frac{1}{1-z}.$$

On the punctured disk $0 < |z| < 1$ we expand $\frac{1}{1-z}$ as a geometric series:

$$f(z) = \frac{1}{z} + 1 + z + z^2 + \cdots,$$

exhibiting a simple pole at 0. But on the annulus $1 < |z| < \infty$ we must instead

expand in powers of $1/z$:

$$\frac{1}{1-z} = -\frac{1}{z} \cdot \frac{1}{1-1/z} = -\frac{1}{z} - \frac{1}{z^2} - \dots,$$

so there $f(z) = -z^{-2} - z^{-3} - \dots$. The moral: a Laurent expansion is always relative to a choice of annulus.

§10.7 The Residue Theorem

We now assemble everything into the single most useful computational theorem of the course. It turns out that when integrating around an isolated singularity, only *one* Laurent coefficient survives.

§10.7.1 Residues

Definition 10.7.1 (Residue and Principal Part)

Let $f : D(a, R) \setminus \{a\} \rightarrow \mathbb{C}$ be holomorphic, with Laurent expansion $\sum_{n=-\infty}^{\infty} c_n(z-a)^n$. The **residue** of f at a is

$$\operatorname{Res}_{z=a} f = c_{-1},$$

and the **principal part** of f at a is the series

$$f_P(z) = \sum_{n=1}^{\infty} c_{-n}(z-a)^{-n}.$$

Why is c_{-1} singled out? Because $(z-a)^n$ has an antiderivative for every n *except* $n = -1$. So when we integrate the Laurent series term by term around a closed curve, only the c_{-1} term can contribute – and it contributes exactly $2\pi i c_{-1}$ times the winding number. Let us make this precise, in full generality.

Note first that the series defining f_P converges for all $z \neq a$ (its convergence in $0 < |z-a| < R$ forces, via the substitution $\zeta = (z-a)^{-1}$, a radius of convergence of at least $1/r$ for every $r > 0$), and the convergence is uniform on compact subsets of $\mathbb{C} \setminus \{a\}$. In particular f_P is holomorphic on $\mathbb{C} \setminus \{a\}$, and $f - f_P$ has a removable singularity at a .

Theorem 10.7.2 (Residue Theorem)

Let $U \subseteq \mathbb{C}$ be open, let $a_1, \dots, a_k \in U$ be distinct points, and let

$$f : U \setminus \{a_1, \dots, a_k\} \rightarrow \mathbb{C}$$

be holomorphic. If γ is a closed curve in U , homologous to zero in U , with no a_j on the curve, then

$$\frac{1}{2\pi i} \int_{\gamma} f(z) \, dz = \sum_{j=1}^k I(\gamma; a_j) \operatorname{Res}_{z=a_j} f.$$

Proof. Let $f_P^{(j)}$ be the principal part of f at a_j , a holomorphic function on $\mathbb{C} \setminus \{a_j\}$, and set

$$h = f - (f_P^{(1)} + \cdots + f_P^{(k)}),$$

holomorphic on $U \setminus \{a_1, \dots, a_k\}$. Fix j : near a_j , the difference $f - f_P^{(j)}$ has a removable singularity (its Laurent series has no negative terms), and each $f_P^{(\ell)}$ with $\ell \neq j$ is holomorphic at a_j . So h has a removable singularity at each a_j , and extends to a holomorphic function on all of U . By the general Cauchy theorem, $\int_\gamma h(z) dz = 0$, so

$$\frac{1}{2\pi i} \int_\gamma f(z) dz = \sum_{j=1}^k \frac{1}{2\pi i} \int_\gamma f_P^{(j)}(z) dz.$$

Finally, the series for $f_P^{(j)}$ converges uniformly on the (compact) image of γ , so we may integrate term by term; every term $(z - a_j)^{-n}$ with $n \geq 2$ has an antiderivative on $\mathbb{C} \setminus \{a_j\}$ and integrates to zero, leaving

$$\frac{1}{2\pi i} \int_\gamma f_P^{(j)}(z) dz = \frac{c_{-1}^{(j)}}{2\pi i} \int_\gamma \frac{dz}{z - a_j} = I(\gamma; a_j) \operatorname{Res}_{z=a_j} f.$$

□

In practice γ will wind once around each singularity we care about and zero times around everything else, and then the theorem reads: *the integral is $2\pi i$ times the sum of the residues inside.*

§10.7.2 Computing Residues

To use the residue theorem we need to actually compute residues. Thankfully, for poles this rarely requires finding the whole Laurent series.

Proposition 10.7.3 (Residue Computation Rules)

- (i) If f has a simple pole at a , then

$$\operatorname{Res}_{z=a} f = \lim_{z \rightarrow a} (z - a)f(z).$$

- (ii) If $f(z) = (z - a)^{-k}g(z)$ with g holomorphic at a and $g(a) \neq 0$ (a pole of order k), then

$$\operatorname{Res}_{z=a} f = \frac{g^{(k-1)}(a)}{(k-1)!}.$$

- (iii) If $f = g/h$ with g, h holomorphic at a , $g(a) \neq 0$, and h having a simple zero at a , then

$$\operatorname{Res}_{z=a} f = \frac{g(a)}{h'(a)}.$$

Proof. For (ii) (which contains (i) as the case $k = 1$): expanding g in its Taylor series at a , the coefficient of $(z - a)^{-1}$ in the Laurent series of $(z - a)^{-k}g(z)$ is the

coefficient of $(z - a)^{k-1}$ in the Taylor series of g , namely $g^{(k-1)}(a)/(k-1)!$.

For (iii): $h(z) = (z - a)h_1(z)$ with h_1 holomorphic, $h_1(a) = h'(a) \neq 0$, so f has a simple pole at a and by (i)

$$\operatorname{Res}_{z=a} f = \lim_{z \rightarrow a} \frac{(z - a)g(z)}{h(z)} = \lim_{z \rightarrow a} \frac{g(z)}{\left(\frac{h(z)-h(a)}{z-a}\right)} = \frac{g(a)}{h'(a)}.$$

□

Example 10.7.4

Let $f(z) = \frac{e^{iz}}{1+z^2}$. The denominator factors as $(z - i)(z + i)$, so f has simple poles at $\pm i$, and by rule (iii),

$$\operatorname{Res}_{z=i} f = \frac{e^{i \cdot i}}{2i} = \frac{e^{-1}}{2i}.$$

§10.7.3 Evaluating Real Integrals

We now come to the payoff: the residue theorem is a machine for computing real integrals that resist elementary methods. The general strategy is always the same:

- (1) pick a holomorphic (or meromorphic) function related to the real integrand;
- (2) pick a closed contour, part of which runs along (a piece of) the real axis;
- (3) compute the contour integral by residues;
- (4) show the contribution of the auxiliary parts of the contour vanishes (or converges to something known) in a limit.

Example 10.7.5 (A Semicircular Contour)

We compute

$$\int_{-\infty}^{\infty} \frac{dx}{1+x^2} \quad (= \pi, \text{ as we know from } \arctan).$$

Let $f(z) = \frac{1}{1+z^2}$, which has simple poles at $\pm i$. For $R > 1$, let γ be the closed contour consisting of the segment $[-R, R]$ along the real axis, followed by the semicircular arc $\gamma_R(t) = Re^{it}$, $t \in [0, \pi]$, in the upper half-plane.

The contour is a closed curve in the star-shaped domain $\mathbb{C}$ (so certainly homologous to zero), winding once around i and zero times around $-i$. By the residue theorem

and rule (iii),

$$\int_{\gamma} f(z) \, dz = 2\pi i \operatorname{Res}_{z=i} \frac{1}{1+z^2} = 2\pi i \cdot \frac{1}{2i} = \pi.$$

On the arc, $|1+z^2| \geq R^2 - 1$, so

$$\left| \int_{\gamma_R} f(z) \, dz \right| \leq \pi R \cdot \frac{1}{R^2 - 1} \rightarrow 0 \quad \text{as } R \rightarrow \infty.$$

Hence

$$\int_{-\infty}^{\infty} \frac{dx}{1+x^2} = \lim_{R \rightarrow \infty} \int_{-R}^R \frac{dx}{1+x^2} = \pi.$$

That example could have been done in first year – but the same contour computes many integrals that certainly could not. When the integrand involves oscillating factors like e^{ix} , the arc estimate needs more care, and the following lemma is the standard tool.

Lemma 10.7.6 (Jordan's Lemma)

Let f be a continuous complex-valued function on the semicircle $C_R^+ = \{Re^{it} \mid t \in [0, \pi]\}$, and let $\gamma_R^+(t) = Re^{it}$, $t \in [0, \pi]$. Then for $\alpha > 0$,

$$\left| \int_{\gamma_R^+} f(z) e^{i\alpha z} \, dz \right| \leq \frac{\pi}{\alpha} \sup_{z \in C_R^+} |f(z)|.$$

In particular, if $\sup_{z \in C_R^+} |f(z)| \rightarrow 0$ as $R \rightarrow \infty$, then $\int_{\gamma_R^+} f(z) e^{i\alpha z} \, dz \rightarrow 0$.

Proof. Let $M_R = \sup_{C_R^+} |f|$. On the arc, $|e^{i\alpha z}| = e^{-\alpha R \sin t}$, so

$$\left| \int_{\gamma_R^+} f(z) e^{i\alpha z} \, dz \right| \leq \int_0^\pi M_R e^{-\alpha R \sin t} R \, dt = 2RM_R \int_0^{\pi/2} e^{-\alpha R \sin t} \, dt,$$

using the symmetry $\sin(\pi - t) = \sin t$. Now on $(0, \pi/2]$ we have the classical bound $\sin t \geq 2t/\pi$ (the function $\sin t/t$ decreases on this interval, with value $2/\pi$ at $\pi/2$), so

$$2RM_R \int_0^{\pi/2} e^{-\alpha R \sin t} \, dt \leq 2RM_R \int_0^{\pi/2} e^{-2\alpha R t/\pi} \, dt = \frac{\pi M_R}{\alpha} (1 - e^{-\alpha R}) \leq \frac{\pi M_R}{\alpha}.$$

□

The point of Jordan's lemma is that decay of f alone (however slow) suffices – the oscillation of $e^{i\alpha z}$ does the rest. A companion lemma handles small arcs around simple poles that sit *on* our contour.

Lemma 10.7.7 (Small Arcs around Simple Poles)

Let f be holomorphic on $D(a, R) \setminus \{a\}$ with a simple pole at a , and for $0 < \varepsilon < R$

let $\gamma_\varepsilon : [\alpha, \beta] \rightarrow \mathbb{C}$ be the arc $\gamma_\varepsilon(t) = a + \varepsilon e^{it}$. Then

$$\lim_{\varepsilon \rightarrow 0^+} \int_{\gamma_\varepsilon} f(z) \, dz = (\beta - \alpha) i \operatorname{Res}_{z=a} f.$$

Proof. Write $f(z) = \frac{c}{z-a} + g(z)$ with $c = \operatorname{Res}_{z=a} f$ and g holomorphic on $D(a, R)$ (this is exactly the Laurent expansion of a simple pole). Then g is bounded near a , say $|g| \leq M$ on $D(a, R/2)$, so

$$\left| \int_{\gamma_\varepsilon} g(z) \, dz \right| \leq (\beta - \alpha) \varepsilon M \rightarrow 0,$$

while direct computation gives

$$\int_{\gamma_\varepsilon} \frac{c}{z-a} \, dz = c \int_\alpha^\beta \frac{i\varepsilon e^{it}}{\varepsilon e^{it}} \, dt = (\beta - \alpha) ic.$$

□

Example 10.7.8 (The Dirichlet Integral)

We compute the famous integral

$$\int_0^\infty \frac{\sin x}{x} \, dx = \frac{\pi}{2}.$$

The natural function to use is $f(z) = e^{iz}/z$, which has a simple pole at 0 – right on the contour we would like to use! So we *indent*: for $0 < \varepsilon < R$, consider the closed contour γ consisting of the segment $[\varepsilon, R]$, the large semicircular arc $\gamma_R(t) = Re^{it}$, $t \in [0, \pi]$, the segment $[-R, -\varepsilon]$, and the small *clockwise* arc γ_ε from $-\varepsilon$ to ε over the top of the origin.

Now f is holomorphic on $\mathbb{C} \setminus \{0\}$, and γ winds zero times around 0 – the indentation was designed exactly to avoid it – so γ is homologous to zero in $\mathbb{C} \setminus \{0\}$, and the general Cauchy theorem gives $\int_\gamma f(z) \, dz = 0$. That is,

$$\int_{[\varepsilon, R]} \frac{e^{ix}}{x} \, dx + \int_{\gamma_R} f \, dz + \int_{[-R, -\varepsilon]} \frac{e^{ix}}{x} \, dx + \int_{\gamma_\varepsilon} f \, dz = 0.$$

Substituting $x \mapsto -x$ in the third integral and combining with the first,

$$\int_\varepsilon^R \frac{e^{ix} - e^{-ix}}{x} \, dx = 2i \int_\varepsilon^R \frac{\sin x}{x} \, dx.$$

By Jordan's lemma (with $f(z) = 1/z$, $\sup_{C_R^+} |1/z| = 1/R \rightarrow 0$), the integral over γ_R tends to 0 as $R \rightarrow \infty$. The small arc γ_ε is traversed clockwise from angle π to 0, so by the small arcs lemma its integral tends to $-\pi i \operatorname{Res}_{z=0} f = -\pi i$ as $\varepsilon \rightarrow 0^+$. Putting everything together,

$$2i \int_0^\infty \frac{\sin x}{x} dx - \pi i = 0, \quad \text{that is} \quad \int_0^\infty \frac{\sin x}{x} dx = \frac{\pi}{2}.$$

Next, an integral involving a branch cut, where the multi-valuedness of z^α is not an obstacle but the very thing that makes the method work.

Example 10.7.9 (A Keyhole Contour)

For $0 < \alpha < 1$, we show

$$\int_0^\infty \frac{x^{-\alpha}}{1+x} dx = \frac{\pi}{\sin \pi \alpha}.$$

Work on the cut plane $U = \mathbb{C} \setminus \{x \in \mathbb{R} \mid x \geq 0\}$, on which we choose the branch $g(z) = z^{-\alpha} = e^{-\alpha \ell(z)}$, where $\ell(z) = \ln |z| + i \arg(z)$ with $\arg(z) \in (0, 2\pi)$. Let $f(z) = g(z)/(1+z)$, holomorphic on $U \setminus \{-1\}$ with a simple pole at -1 and

$$\operatorname{Res}_{z=-1} f = g(-1) = e^{-\alpha(\ln 1 + i\pi)} = e^{-i\pi\alpha}.$$

For $0 < \varepsilon < 1 < R$ and small $\theta > 0$, let γ be the 'keyhole contour' below: out along the ray $\arg z = \theta$ from radius ε to R , anticlockwise around the big circle to the ray $\arg z = 2\pi - \theta$, back along that ray, and clockwise around the small circle.

The domain U is not star-shaped, but the winding number of γ about every point of the positive real axis (and about 0) is zero, so γ is homologous to zero in U ; and $I(\gamma; -1) = 1$. By the residue theorem,

$$\int_\gamma f(z) dz = 2\pi i e^{-i\pi\alpha}.$$

Consider the pieces. On the outgoing ray $\gamma_1(t) = te^{i\theta}$, $t \in [\varepsilon, R]$,

$$\int_{\gamma_1} f(z) dz = \int_\varepsilon^R \frac{t^{-\alpha} e^{-i\alpha\theta} e^{i\theta}}{1 + te^{i\theta}} dt \xrightarrow{\theta \rightarrow 0^+} \int_\varepsilon^R \frac{t^{-\alpha}}{1+t} dt,$$

with uniform convergence of the integrands on $[\varepsilon, R]$. On the returning ray γ_2 ($\arg z = 2\pi - \theta$, traversed inwards from radius R down to radius ε), the branch of $z^{-\alpha}$ picks up an extra factor tending to $e^{-2\pi i\alpha}$ as $\theta \rightarrow 0^+$, so in that limit this piece contributes

$$-e^{-2\pi i\alpha} \int_{\varepsilon}^R \frac{t^{-\alpha}}{1+t} dt,$$

the minus sign coming from the direction of traversal. Meanwhile, on the circular arcs we estimate

$$\left| \int_{\gamma_R} f dz \right| \leq 2\pi R \cdot \frac{R^{-\alpha}}{R-1} = \frac{2\pi R^{1-\alpha}}{R-1}, \quad \left| \int_{\gamma_{\varepsilon}} f dz \right| \leq \frac{2\pi \varepsilon^{1-\alpha}}{1-\varepsilon},$$

both independent of θ . Since $0 < \alpha < 1$, both bounds vanish as $R \rightarrow \infty$, $\varepsilon \rightarrow 0^+$ respectively. Taking $\theta \rightarrow 0^+$, then $\varepsilon \rightarrow 0^+$ and $R \rightarrow \infty$,

$$(1 - e^{-2\pi i\alpha}) \int_0^{\infty} \frac{t^{-\alpha}}{1+t} dt = 2\pi i e^{-i\pi\alpha},$$

and dividing through,

$$\int_0^{\infty} \frac{t^{-\alpha}}{1+t} dt = \frac{2\pi i}{e^{i\pi\alpha} - e^{-i\pi\alpha}} = \frac{\pi}{\sin \pi\alpha}.$$

§10.7.4 Summing Series

The residue theorem can also sum infinite series. The trick is to find a meromorphic function with poles at all the integers with known residues – and $\pi \cot(\pi z)$, which has a simple pole of residue 1 at every integer, is precisely such a function.

Example 10.7.10 (The Basel Problem)

We prove

$$\sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{6}.$$

Consider

$$f(z) = \frac{\pi \cot(\pi z)}{z^2} = \frac{\pi \cos(\pi z)}{z^2 \sin(\pi z)}.$$

The zeros of $\sin(\pi z)$ are exactly the integers, and are simple. So f has simple poles at each $n \in \mathbb{Z} \setminus \{0\}$ with, by our rules,

$$\operatorname{Res}_{z=n} f = \frac{\pi \cos(\pi n)/n^2}{\pi \cos(\pi n)} = \frac{1}{n^2},$$

and a pole of order 3 at 0. There, from the Taylor expansions of $\cos$ and $\sin$,

$$\begin{aligned} \cot z &= \frac{1 - z^2/2 + O(z^4)}{z(1 - z^2/6 + O(z^4))} = \frac{1}{z} \left(1 - \frac{z^2}{2} + O(z^4) \right) \left(1 + \frac{z^2}{6} + O(z^4) \right) \\ &= \frac{1}{z} - \frac{z}{3} + O(z^3), \end{aligned}$$

so that

$$f(z) = \frac{\pi \cot(\pi z)}{z^2} = \frac{1}{z^3} - \frac{\pi^2}{3z} + O(z), \quad \text{giving} \quad \text{Res}_{z=0} f = -\frac{\pi^2}{3}.$$

Now, for $N \in \mathbb{N}$, let γ_N be the positively oriented boundary of the square with vertices $(\pm(N + \frac{1}{2}), \pm(N + \frac{1}{2}))$.

The square passes half-way between consecutive integers, so it encloses the poles $0, \pm 1, \dots, \pm N$, each with winding number 1. By the residue theorem,

$$\int_{\gamma_N} f(z) \, dz = 2\pi i \left(2 \sum_{n=1}^N \frac{1}{n^2} - \frac{\pi^2}{3} \right).$$

On the other hand, one can check that $|\cot(\pi z)|$ is bounded on γ_N by a constant C independent of N (on the vertical sides $\cot(\pi z)$ is purely imaginary with modulus at most 1; on the horizontal sides $|\cot(\pi z)| \leq \coth(\pi/2)$). Since $|z| \geq N + \frac{1}{2}$ on the square and $\text{length}(\gamma_N) = 4(2N + 1)$,

$$\left| \int_{\gamma_N} f(z) \, dz \right| \leq \frac{\pi C}{(N + \frac{1}{2})^2} \cdot 4(2N + 1) \rightarrow 0 \quad \text{as } N \rightarrow \infty.$$

Letting $N \rightarrow \infty$ in the previous display therefore gives

$$2 \sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{3}, \quad \text{that is} \quad \sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{6}.$$

The same method, with $\pi \cot(\pi z)$ replaced by $\pi \operatorname{cosec}(\pi z)$ and other kernels, evaluates a whole family of classical series.

§10.8 The Argument Principle and Rouché's Theorem

Our final circle of ideas uses the residue theorem to *count*. The quantity $\frac{f'}{f}$ – the ‘logarithmic derivative’ of f – turns out to have poles exactly at the zeros and poles of f , with residues recording their orders, and integrating it counts zeros and poles inside a contour.

§10.8.1 The Argument Principle

Proposition 10.8.1 (Logarithmic Derivatives)

If f has a zero (respectively, a pole) of order k at $z = a$, then f'/f has a simple pole at a with residue k (respectively $-k$).

Proof. If a is a zero of order k , write $f(z) = (z - a)^k g(z)$ on some disk $D(a, r)$, with g holomorphic and non-vanishing there. Then

$$\frac{f'(z)}{f(z)} = \frac{k(z - a)^{k-1}g(z) + (z - a)^k g'(z)}{(z - a)^k g(z)} = \frac{k}{z - a} + \frac{g'(z)}{g(z)},$$

and g'/g is holomorphic on $D(a, r)$, so f'/f has a simple pole at a with residue k . For a pole of order k , write $f(z) = (z - a)^{-k} g(z)$ and the same computation gives residue $-k$. $\square$

Definition 10.8.2

For a zero or pole a of f , we write $\text{ord}_f(a)$ for its order.

Theorem 10.8.3 (Argument Principle)

Let f be a meromorphic function on a domain U , with finitely many zeros $a_1, \dots, a_k$ and poles $b_1, \dots, b_\ell$. Let γ be a closed curve in U , homologous to zero in U , with no zero or pole of f on the curve. Then

$$\frac{1}{2\pi i} \int_{\gamma} \frac{f'(z)}{f(z)} dz = \sum_{i=1}^k I(\gamma; a_i) \text{ord}_f(a_i) - \sum_{j=1}^{\ell} I(\gamma; b_j) \text{ord}_f(b_j).$$

Proof. The function $g = f'/f$ is holomorphic away from the zeros and poles of f (at a removable singularity of f , take the holomorphic extension; if that extension is non-vanishing there, g is holomorphic there too, and if it vanishes we have simply found another zero). So the singularities of g in U are precisely $a_1, \dots, a_k, b_1, \dots, b_\ell$, all simple poles with residues $\text{ord}_f(a_i)$ and $-\text{ord}_f(b_j)$ by the proposition. Now apply the residue theorem to g . $\square$

Why is this called the *argument* principle? Let $\Gamma = f \circ \gamma$, a closed curve avoiding 0 (since f has no zeros or poles on γ). Then, writing $[a, b]$ for the parameter interval of γ ,

$$I(\Gamma; 0) = \frac{1}{2\pi i} \int_{\Gamma} \frac{dw}{w} = \frac{1}{2\pi i} \int_a^b \frac{f'(\gamma(t))\gamma'(t)}{f(\gamma(t))} dt = \frac{1}{2\pi i} \int_{\gamma} \frac{f'(z)}{f(z)} dz.$$

So the left-hand side of the argument principle is precisely *the number of times $f \circ \gamma$ winds around the origin* – the total change in $\arg f$ along γ , divided by 2π . Zeros inside make the image wind anticlockwise; poles, clockwise.

To turn the argument principle into clean counting statements, we want curves for which all the winding numbers are 0 or 1.

Definition 10.8.4 (Bounding a Domain)

Let Ω be a domain and γ a closed curve. We say γ **bounds** Ω if

$$I(\gamma; w) = \begin{cases} 1 & \text{for } w \in \Omega, \\ 0 & \text{for } w \notin \Omega \cup \text{image}(\gamma). \end{cases}$$

For example, $\partial D(0, 1)$ bounds $D(0, 1)$. If γ bounds Ω then Ω is bounded (all winding numbers vanish far away), and one can check $\partial\Omega \subseteq \text{image}(\gamma)$. The fundamental supply of such curves comes from the *Jordan curve theorem*: every simple closed curve γ (one with no self-intersections) splits the plane into exactly two components, one bounded and one unbounded, and γ or $-\gamma$ bounds the bounded component. This is intuitively obvious and surprisingly hard to prove; we will take it as known, and in any concrete example the winding numbers can be checked by hand anyway.

Corollary 10.8.5 (Counting Zeros and Poles)

Let γ be a closed curve bounding a domain Ω , and let f be meromorphic on an open set $U \supseteq \Omega \cup \text{image}(\gamma)$, with no zeros or poles on $\text{image}(\gamma)$. Then f has finitely many zeros and poles in Ω , and if N and P denote the number of zeros and poles respectively, counted with multiplicity,

$$N - P = \frac{1}{2\pi i} \int_{\gamma} \frac{f'(z)}{f(z)} dz = I(f \circ \gamma; 0).$$

Proof. First, finiteness. The closure $\overline{\Omega}$ is compact (as Ω is bounded) and contained in $\Omega \cup \text{image}(\gamma) \subseteq U$. If f had infinitely many poles in $\overline{\Omega}$, they would accumulate at some $w \in \overline{\Omega} \subseteq U$; but the singular set of a meromorphic function is discrete, and a non-singular point has a neighbourhood free of singularities – either way, a contradiction. If f had infinitely many zeros in $\overline{\Omega}$, they would accumulate at some $w \in \overline{\Omega}$, which is either a regular point or a removable singularity of f (it cannot be a pole, since $f \rightarrow \infty$ at a pole but $f = 0$ along the accumulating zeros); then by the identity theorem $f \equiv 0$ near w , and hence (applying the identity theorem on the domain Ω minus the singular set, which is still connected) f vanishes throughout Ω , contradicting $f \neq 0$ on the boundary curve.

Since γ bounds Ω , we have $I(\gamma; w) = 0$ for every $w \notin \Omega \cup \text{image}(\gamma)$; in particular γ is homologous to zero in U . Every zero or pole in Ω has winding number 1, and those outside contribute nothing, so the argument principle gives exactly $N - P$; and we identified the integral with $I(f \circ \gamma; 0)$ above. $\square$

§10.8.2 The Local Degree and the Open Mapping Theorem

The argument principle also tells us what a holomorphic map looks like *locally*.

Definition 10.8.6 (Local Degree)

Let f be holomorphic and non-constant on a disk $D(a, R)$. The **local degree** of f at a , written $\deg_f(a)$, is the order of the zero of $f(z) - f(a)$ at $z = a$.

Note this is a well-defined positive integer: $f(z) - f(a)$ is not identically zero (else f is constant), so has a zero of some finite order $d \geq 1$ at a . For instance, $f(z) = (z-1)^4 + 1$ has $\deg_f(1) = 4$.

Theorem 10.8.7 (Local Degree Theorem)

Let $f : D(a, R) \rightarrow \mathbb{C}$ be holomorphic and non-constant with $\deg_f(a) = d$. Then there is $r_0 > 0$ such that for every $r \in (0, r_0]$ there is $\varepsilon > 0$ with the property: for every w with $0 < |w - f(a)| < \varepsilon$, the equation $f(z) = w$ has exactly d distinct roots in $D(a, r) \setminus \{a\}$.

Proof. Let $g(z) = f(z) - f(a)$. Since g is non-constant, $g \not\equiv 0$ and $g' \not\equiv 0$ on $D(a, R)$, so by the principle of isolated zeros we may choose $r_0 \in (0, R)$ such that g and g' have no zeros on $D(a, r_0) \setminus \{a\}$.

Fix $r \in (0, r_0]$, let $\gamma(t) = a + re^{2\pi it}$, and let $\Gamma = g \circ \gamma$. The image of Γ is compact and misses 0 (as $g \not\equiv 0$ on the circle), so there is $\varepsilon > 0$ with $D(0, \varepsilon) \cap \text{image}(\Gamma) = \emptyset$.

Now let $0 < |w - f(a)| < \varepsilon$. Since winding numbers are constant on the connected set $D(0, \varepsilon)$,

$$I(\Gamma; w - f(a)) = I(\Gamma; 0).$$

By our counting corollary applied to g on the disk (the circle γ bounds $D(a, r)$), $I(\Gamma; 0)$ is the number of zeros of g in $D(a, r)$, which is d (the single zero at a , counted with multiplicity d). On the other hand, $I(\Gamma; w - f(a))$ counts the zeros of $g(z) - (w - f(a)) = f(z) - w$ in $D(a, r)$, with multiplicity. So $f(z) = w$ has d roots in $D(a, r)$ counted with multiplicity.

Finally, these roots are distinct and none equals a : since $w \neq f(a)$, $z = a$ is not a root; and at any root $z \neq a$ we have $f'(z) = g'(z) \neq 0$ by our choice of r_0 , so each root is simple. $\square$

So near a point of local degree d , a holomorphic map is d -to-one onto a neighbourhood of the image point (think of $z \mapsto z^d$ near 0, which is the model case). One consequence deserves to be a headline theorem.

Theorem 10.8.8 (Open Mapping Theorem)

A non-constant holomorphic function on a domain maps open sets to open sets.

Proof. Let $f : U \rightarrow \mathbb{C}$ be holomorphic and non-constant on the domain U , let $V \subseteq U$ be open, and let $b = f(a) \in f(V)$ with $a \in V$. Note f is non-constant on every disk in U (by the identity theorem, constancy on a disk forces constancy on U). Choose $r > 0$ small enough that $D(a, r) \subseteq V$ and the local degree theorem applies with some $\varepsilon > 0$; then every $w \in D(b, \varepsilon)$ with $w \neq b$ is attained by f on $D(a, r)$, and b itself is attained at a . Hence $D(b, \varepsilon) \subseteq f(D(a, r)) \subseteq f(V)$, so $f(V)$ is open. $\square$

Remark. Compare with the real situation: $x \mapsto x^2$ maps the open interval $(-1, 1)$ onto $[0, 1)$, which is not open. Once again holomorphic functions are far more rigid than smooth real ones.

The local degree theorem also settles a promise from Section 1: *if f is holomorphic and injective, then $f' \neq 0$ everywhere.* Indeed, if $f'(a) = 0$ then $f(z) - f(a)$ has a zero of

order $d \geq 2$ at a , and the local degree theorem produces points near a where f takes the same value $d \geq 2$ times – contradicting injectivity. So in our definition of conformal equivalence, the non-vanishing derivative condition was automatic.

§10.8.3 Rouché's Theorem

Our last theorem is a wonderfully practical tool for locating zeros. The idea is often called ‘walking the dog’. Suppose you walk a closed loop around a lamppost (the origin), holding a dog on a lead. If the lead always stays shorter than your distance to the lamppost, then the dog is dragged around the lamppost exactly as many times as you walk around it – the dog can never sneak an extra loop, nor miss one. Here you are $g \circ \gamma$, the dog is $f \circ \gamma$, and the lead has length $|f - g|$.

Theorem 10.8.9 (Rouché's Theorem)

Let γ be a closed curve bounding a domain Ω , and let f, g be holomorphic on an open set $U \supseteq \Omega \cup \text{image}(\gamma)$. If

$$|f(z) - g(z)| < |g(z)| \quad \text{for all } z \in \text{image}(\gamma),$$

then f and g have the same number of zeros in Ω , counted with multiplicity.

Proof. The strict inequality forces $g \neq 0$ on the curve (else $0 \leq |f - g| < 0$) and then also $f \neq 0$ on the curve ($|f| \geq |g| - |f - g| > 0$). Let $h = f/g$, which is meromorphic on U , holomorphic and non-vanishing on an open set containing $\text{image}(\gamma)$. Both f and g have finitely many zeros in Ω by our counting corollary (neither vanishes identically, as neither vanishes on the curve).

The hypothesis says exactly that

$$|h(z) - 1| < 1 \quad \text{on } \text{image}(\gamma),$$

so the closed curve $h \circ \gamma$ lies in the disk $D(1, 1)$, which does not contain 0. Since the winding number about 0 vanishes on the unbounded component of the complement of $h \circ \gamma$, and 0 can be joined to infinity without crossing $D(1, 1)$, we get $I(h \circ \gamma; 0) = 0$.

By the argument principle (counting corollary) applied to h ,

$$0 = I(h \circ \gamma; 0) = N_h - P_h,$$

where N_h, P_h are the numbers of zeros and poles of h in Ω with multiplicity. Now at any point $w \in \Omega$, writing ord_w for the order of vanishing at w (negative at a pole), we have $\text{ord}_w(h) = \text{ord}_w(f) - \text{ord}_w(g)$, and summing over all relevant points,

$$N_h - P_h = \sum_{w \in \Omega} \text{ord}_w(h) = \sum_{w \in \Omega} \text{ord}_w(f) - \sum_{w \in \Omega} \text{ord}_w(g) = N_f - N_g,$$

where N_f, N_g count the zeros of f and g in Ω with multiplicity (the sums are finite, over the zeros of f and g). Hence $N_f = N_g$. $\square$

Example 10.8.10 (Locating Roots of $z^4 + 6z + 3$)

Let $f(z) = z^4 + 6z + 3$. We claim f has exactly three roots (with multiplicity) in the annulus $\{1 < |z| < 2\}$.

On the circle $|z| = 2$: taking $g(z) = z^4$, we have

$$|f(z) - g(z)| = |6z + 3| \leq 15 < 16 = |z^4| = |g(z)|,$$

so by Rouché's theorem f has the same number of zeros in $D(0, 2)$ as z^4 , namely 4. So all four roots of f lie in $|z| < 2$ (and none on $|z| = 2$, by the strict inequality).

On the circle $|z| = 1$: taking $g(z) = 6z$ instead,

$$|f(z) - g(z)| = |z^4 + 3| \leq 4 < 6 = |6z| = |g(z)|,$$

so f has as many zeros in $D(0, 1)$ as $6z$, namely one (and none on $|z| = 1$).

Subtracting, exactly $4 - 1 = 3$ roots lie in $\{1 < |z| < 2\}$.

Example 10.8.11 (A Perturbation Result)

Rouché's theorem explains why roots of polynomials move continuously with the coefficients. For instance, suppose $p(z) = z^n + c_{n-1}z^{n-1} + \cdots + c_0$ and z_0 is a simple root. For any sufficiently small $\delta > 0$, we have $m = \min_{|z-z_0|=\delta} |p(z)| > 0$, and then any polynomial q with $|q(z) - p(z)| < m$ on the circle $|z - z_0| = \delta$ has, by Rouché's theorem (with $g = p$, $f = q$), exactly one root in $D(z_0, \delta)$. Sufficiently small changes of the coefficients therefore move the root only slightly.

And that – from a single innocuous-looking limit defining $f'(w)$, all the way to counting the roots of polynomials by walking dogs around lampposts – is the IB Complex Analysis course.

11 Complex Methods

Complex analysis has a strange quality to it – results that are hard-won over the reals (and often false there!) come almost for free once we work over $\mathbb{C}$. A function that is complex differentiable once is differentiable infinitely often, is given locally by its Taylor series, and is essentially determined everywhere by its behaviour on a tiny region. This course is about what you can *do* with all of that structure. We will use complex functions to map complicated regions onto simple ones (and solve Laplace’s equation while doing so), evaluate real integrals that resist every technique of real calculus, and invert Fourier and Laplace transforms to solve differential equations.

This article constitutes my notes for the ‘Complex Methods’ course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered. These notes are also designed to complement my notes for the ‘Complex Analysis’ course, which covers the same core theory but with an emphasis on rigour¹. In this article we take the applied point of view: proofs are given when they are short or genuinely illuminating, and are otherwise sketched or omitted with a reference.

§11.1 Analytic Functions

The star of this course is the *analytic function* – a complex function which is complex differentiable. This first section develops what that means, how to recognise such functions, and the surprisingly rigid structure that differentiability imposes. Already in this section we will meet the connection with Laplace’s equation, which drives many of the physical applications later on.

§11.1.1 The Extended Complex Plane

We will assume basic familiarity with the complex numbers themselves: every $z \in \mathbb{C}$ can be written as $z = x + iy$ with $x, y \in \mathbb{R}$, or in polar form as

$$z = re^{i\theta} = r(\cos \theta + i \sin \theta),$$

where $r = |z|$ and $\theta = \arg z$. The argument is only defined up to adding multiples of 2π , a seemingly innocent remark that will cause us a surprising amount of grief in Section 2.

An ‘open set’ will mean the same as it does in analysis: $D \subseteq \mathbb{C}$ is **open** if for every $z \in D$ there is some $\epsilon > 0$ such that the disc $\{w : |w - z| < \epsilon\}$ lies in D . A **domain** is a non-empty open set in which any two points can be joined by a path lying in the set. Domains are the natural habitat of the functions in this course.

It is frequently convenient to add a single ‘point at infinity’ to the complex plane.

¹The two courses share their central theorems – Cauchy’s theorem, Taylor and Laurent series, the residue theorem – and lead to the same examination questions on that material. Where a careful proof exists in my Complex Analysis notes I will generally cite it rather than repeat it, and spend the space here on computations and applications instead.

Definition 11.1.1 (Extended Complex Plane)

The **extended complex plane** is $\mathbb{C}^* = \mathbb{C} \cup \{\infty\}$, the complex plane together with a single extra point ∞ .

One can visualise $\mathbb{C}^*$ as a sphere (the *Riemann sphere*): place a sphere on the plane, and join each point $z \in \mathbb{C}$ to the north pole by a straight line. That line meets the sphere at one other point, and this gives a bijection between $\mathbb{C}$ and the sphere minus the north pole. The north pole itself then corresponds to ∞ . Points far from the origin in any direction are all close to the north pole, which is why a single point at infinity (rather than one for each direction, as one does with $\pm\infty$ in $\mathbb{R}$) is the natural choice.

To study the behaviour of a function f ‘at infinity’, we simply study $f(1/z)$ at $z = 0$. We will use this idea repeatedly, and it is worth internalising: *infinity is not a special place, it just looks far away from where we are standing.*

§11.1.2 Complex Differentiation and the Cauchy–Riemann Equations

We define differentiability exactly as we do over the reals.

Definition 11.1.2 (Differentiability)

A function $f : \mathbb{C} \rightarrow \mathbb{C}$ is **differentiable** at z if the limit

$$f'(z) = \lim_{\delta z \rightarrow 0} \frac{f(z + \delta z) - f(z)}{\delta z}$$

exists.

The definition looks identical to the real one, but it is far more demanding. The increment δz is a complex number, and may approach 0 from *any direction* in the plane – along the real axis, along the imaginary axis, along a spiral – and the limit must be the same however it does so. This is a strong constraint, and it is what gives complex differentiable functions their remarkable properties.

Definition 11.1.3 (Analytic Function)

A function f is **analytic**^a at a point z if it is differentiable throughout some open set containing z . A function analytic on all of $\mathbb{C}$ is called **entire**.

^aThe words *holomorphic* and *regular* are also used, particularly in the Complex Analysis course. In this course ‘analytic’ is traditional.

Note the subtlety: analyticity at z requires differentiability *near* z , not just at z . This makes analyticity a much more robust notion, and it is the one we care about.

Let’s extract something concrete from the definition. Write $z = x + iy$ and

$$f(z) = u(x, y) + iv(x, y),$$

where u and v are real-valued functions of two real variables. Suppose f is differentiable at z . Then we may compute $f'(z)$ by letting $\delta z \rightarrow 0$ along whichever direction we please, and comparing the answers.

Taking $\delta z = \delta x$ real, we get

$$f'(z) = \lim_{\delta x \rightarrow 0} \frac{f(z + \delta x) - f(z)}{\delta x} = \frac{\partial u}{\partial x} + i \frac{\partial v}{\partial x}.$$

Taking $\delta z = i \delta y$ purely imaginary instead,

$$f'(z) = \lim_{\delta y \rightarrow 0} \frac{f(z + i \delta y) - f(z)}{i \delta y} = \frac{1}{i} \left(\frac{\partial u}{\partial y} + i \frac{\partial v}{\partial y} \right) = \frac{\partial v}{\partial y} - i \frac{\partial u}{\partial y}.$$

These must be equal, and comparing real and imaginary parts gives the fundamental equations of the subject.

Theorem 11.1.4 (Cauchy–Riemann Equations)

If $f = u + iv$ is differentiable at $z = x + iy$, then at that point

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y}, \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}.$$

The converse is almost true: it can fail if the partial derivatives exist but are badly discontinuous.

Theorem 11.1.5 (Converse to Cauchy–Riemann)

If u and v have continuous first-order partial derivatives satisfying the Cauchy–Riemann equations throughout an open set D , then $f = u + iv$ is analytic on D .

Proof (Sketch). With continuous partials we can expand to first order:

$$\begin{aligned} \delta f &= u(x + \delta x, y + \delta y) - u(x, y) + i(v(x + \delta x, y + \delta y) - v(x, y)) \\ &= \left(\frac{\partial u}{\partial x} + i \frac{\partial v}{\partial x} \right) \delta x + \left(\frac{\partial u}{\partial y} + i \frac{\partial v}{\partial y} \right) \delta y + o(|\delta z|). \end{aligned}$$

Applying the Cauchy–Riemann equations to the second bracket turns the right hand side into $\left(\frac{\partial u}{\partial x} + i \frac{\partial v}{\partial x} \right) (\delta x + i \delta y) + o(|\delta z|)$, so $\delta f / \delta z$ tends to a limit independent of the direction of δz . $\square$

So, up to a regularity condition that never bites in practice, *analytic* = *Cauchy–Riemann*. This gives us a practical test, and it's worth seeing it in action both on functions that pass and functions that fail.

Example 11.1.6 (Analytic Functions) (i) Any polynomial in z is entire – sums, products and compositions of differentiable functions are differentiable, with the same proofs as in real analysis (the familiar product, quotient and chain rules all hold).

(ii) The exponential

$$e^z = e^x (\cos y + i \sin y)$$

is entire, as one can check directly from the Cauchy–Riemann equations: $u = e^x \cos y$ and $v = e^x \sin y$ give $u_x = e^x \cos y = v_y$ and $u_y = -e^x \sin y = -v_x$. Differentiating, $\frac{d}{dz} e^z = u_x + i v_x = e^z$, as we'd hope.

(iii) Any rational function $P(z)/Q(z)$ is analytic away from the zeros of Q . These

‘almost analytic’ functions will be of great interest when we come to residue calculus – the places where analyticity fails are exactly where the action is.

Example 11.1.7 (Non-Analytic Functions)

Consider $f(z) = \bar{z} = x - iy$, so $u = x$ and $v = -y$. Then $u_x = 1$ but $v_y = -1$, so the Cauchy–Riemann equations fail *everywhere*, and $\bar{z}$ is nowhere differentiable, despite being a perfectly smooth function of (x, y) . Similarly $f(z) = |z|^2 = x^2 + y^2$ has $u_x = 2x$, $v_y = 0$, $u_y = 2y$, $v_x = 0$, so the equations hold only at $z = 0$. Thus $|z|^2$ is differentiable at the origin only, and analytic *nowhere* – there is no open set of differentiability.

The moral of these examples: a function is analytic when it is genuinely a function ‘of z alone’, and not of $\bar{z}$. This slogan can be made precise – writing $x = (z + \bar{z})/2$ and $y = (z - \bar{z})/2i$, one can treat z and $\bar{z}$ as independent variables, and then the Cauchy–Riemann equations become the single equation

$$\frac{\partial f}{\partial \bar{z}} = 0.$$

Before moving on, let’s assemble the standard library of analytic functions, since we will compute with them constantly. Each is defined by the natural extension of its real Taylor series (or in terms of e^z), and each is entire:

$$\begin{aligned} \sin z &= \frac{e^{iz} - e^{-iz}}{2i}, & \cos z &= \frac{e^{iz} + e^{-iz}}{2}, \\ \sinh z &= \frac{e^z - e^{-z}}{2}, & \cosh z &= \frac{e^z + e^{-z}}{2}. \end{aligned}$$

Over $\mathbb{C}$, the trigonometric and hyperbolic families merge into one: from the definitions,

$$\sin(iz) = i \sinh z, \quad \cos(iz) = \cosh z,$$

and all the usual addition formulas hold verbatim (they are identities between analytic functions that agree on $\mathbb{R}$ – and, as is shown in Complex Analysis, analytic functions agreeing on a line agree everywhere). Some facts worth internalising now, as they shape all the contour arguments to come:

- (i) e^z is periodic with period $2\pi i$, and is *never zero*: $|e^z| = e^x > 0$.
- (ii) $\sin z$ and $\cos z$ are *unbounded* off the real axis – e.g. $\cos(iy) = \cosh y \rightarrow \infty$. Boundedness of $\sin$ and $\cos$ is a purely real-variable accident.
- (iii) The zeros of $\sin z$ and $\cos z$ are exactly the familiar real ones, $n\pi$ and $(n + \frac{1}{2})\pi$. Writing $\sin(x+iy) = \sin x \cosh y + i \cos x \sinh y$, both terms vanish only when $y = 0$ and $\sin x = 0$.
- (iv) Correspondingly $\sinh z$ has zeros exactly at $z = n\pi i$, and $\cosh z$ at $z = (n + \frac{1}{2})\pi i$ – on the *imaginary* axis. These lattices of zeros will reappear as lattices of poles of $1/\cosh$ and friends in Section 6.

For working in polar coordinates – which we will do constantly once branch cuts appear – it is useful to have the polar form of the Cauchy–Riemann equations.

Proposition 11.1.8 (Cauchy–Riemann in Polar Form)

Let $f(z) = u(r, \theta) + iv(r, \theta)$ where $z = re^{i\theta}$. Then the Cauchy–Riemann equations take the form

$$\frac{\partial u}{\partial r} = \frac{1}{r} \frac{\partial v}{\partial \theta}, \quad \frac{\partial v}{\partial r} = -\frac{1}{r} \frac{\partial u}{\partial \theta},$$

and then $f'(z) = e^{-i\theta}(u_r + iv_r)$.

Proof. This is a chain rule computation. From $x = r \cos \theta$, $y = r \sin \theta$ we get

$$\frac{\partial u}{\partial r} = u_x \cos \theta + u_y \sin \theta, \quad \frac{\partial u}{\partial \theta} = -u_x r \sin \theta + u_y r \cos \theta,$$

and similarly for v . Substituting the Cartesian Cauchy–Riemann equations $u_x = v_y$, $u_y = -v_x$ into these expressions gives

$$\frac{1}{r} \frac{\partial v}{\partial \theta} = -v_x \sin \theta + v_y \cos \theta = u_y \sin \theta + u_x \cos \theta = \frac{\partial u}{\partial r},$$

and the second equation follows in the same way. For the derivative, approach along a ray of constant θ , so $\delta z = e^{i\theta} \delta r$, giving $f'(z) = e^{-i\theta}(u_r + iv_r)$. $\square$

Example 11.1.9 (Powers and Logarithms)

Take $f(z) = z^c$ for a real constant c , defined (for now, for $r > 0$ and some range of θ) by $f = r^c e^{ic\theta}$, so $u = r^c \cos c\theta$ and $v = r^c \sin c\theta$. Then

$$u_r = cr^{c-1} \cos c\theta = \frac{1}{r} v_\theta, \quad v_r = cr^{c-1} \sin c\theta = -\frac{1}{r} u_\theta,$$

so z^c is analytic where defined, with

$$f'(z) = e^{-i\theta} \cdot cr^{c-1} e^{ic\theta} = cz^{c-1}.$$

An identical computation shows $\log z = \log r + i\theta$ satisfies the polar Cauchy–Riemann equations with $\frac{d}{dz} \log z = e^{-i\theta} \cdot \frac{1}{r} = \frac{1}{z}$. The phrase ‘where defined’ is hiding real content here – pinning down where these functions can be defined is the subject of Section 2.

§11.1.3 Harmonic Functions

We now come to the first connection with applied mathematics, and it is a spectacular one. Recall Laplace’s equation for a function $\phi(x, y)$:

$$\nabla^2 \phi = \frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0.$$

This is arguably the most important partial differential equation there is: it governs steady-state temperature distributions, electrostatic potentials, gravitational potentials, and the flow of ideal fluids.

Definition 11.1.10 (Harmonic Function)

A function $\phi : \mathbb{R}^2 \rightarrow \mathbb{R}$ satisfying $\nabla^2 \phi = 0$ is **harmonic**.

Here is the connection.

Proposition 11.1.11

If $f = u + iv$ is analytic on a domain D , then u and v are both harmonic on D .

Proof. We use the fact (immediate from results in Complex Analysis, where it is shown that analytic functions are infinitely differentiable) that u and v have continuous second derivatives. Then, using the Cauchy–Riemann equations twice,

$$\frac{\partial^2 u}{\partial x^2} = \frac{\partial}{\partial x} \frac{\partial v}{\partial y} = \frac{\partial}{\partial y} \frac{\partial v}{\partial x} = \frac{\partial}{\partial y} \left(-\frac{\partial u}{\partial y} \right) = -\frac{\partial^2 u}{\partial y^2},$$

so u is harmonic, and likewise for v . □

So the real and imaginary parts of *any* analytic function hand us solutions of Laplace’s equation, entirely for free. The functions u and v obtained in this way are not unrelated, and we give the relationship a name.

Definition 11.1.12 (Harmonic Conjugate)

Two harmonic functions u and v satisfying the Cauchy–Riemann equations are **harmonic conjugates**, and then $u + iv$ is analytic.

Given a harmonic function u , we can reconstruct its harmonic conjugate (up to a constant) directly from the Cauchy–Riemann equations, by integrating one equation and differentiating the result. This is best seen by example.

Example 11.1.13 (Finding a Harmonic Conjugate)

Let $u(x, y) = x^2 - y^2$, which is easily checked to be harmonic. We seek v with

$$\frac{\partial v}{\partial y} = \frac{\partial u}{\partial x} = 2x \quad \implies \quad v = 2xy + g(x)$$

for some function g of x alone. The other Cauchy–Riemann equation demands

$$\frac{\partial v}{\partial x} = 2y + g'(x) = -\frac{\partial u}{\partial y} = 2y,$$

so g is a constant, and $v = 2xy + c$. Sure enough,

$$u + iv = x^2 - y^2 + 2ixy + ic = z^2 + ic,$$

and we have recognised our harmonic function as the real part of an analytic one.

One caution about existence. The construction above is local – it works on any disc – but on domains with holes, a harmonic function need not have a *single-valued* conjugate globally. The standard example is $u = \log |z|$ on the punctured plane: its conjugate wants to be $\theta = \arg z$, which (as Section 2 will make much of) cannot be defined continuously all the way around the origin. On simply connected domains this problem never arises,

and every harmonic function is globally the real part of an analytic one.

Example 11.1.14 (A Conjugate in Polar Coordinates)

Let $u = r^2 \cos 2\theta$ (which is $\operatorname{Re} z^2$ in disguise, but let's pretend we don't know that). The polar Cauchy–Riemann equations give

$$\frac{\partial v}{\partial \theta} = r \frac{\partial u}{\partial r} = 2r^2 \cos 2\theta \quad \implies \quad v = r^2 \sin 2\theta + g(r),$$

and then $\frac{\partial v}{\partial r} = 2r \sin 2\theta + g'(r)$ must equal $-\frac{1}{r}u_\theta = 2r \sin 2\theta$, so g is constant. Thus $v = r^2 \sin 2\theta + c$ and $u + iv = r^2 e^{2i\theta} + ic = z^2 + ic$, as expected.

The level curves of u and v carry geometric information too. If $f = u + iv$ is analytic, then

$$\nabla u \cdot \nabla v = u_x v_x + u_y v_y = -u_x u_y + u_y u_x = 0,$$

using the Cauchy–Riemann equations. So *the level curves of u and v are orthogonal* wherever $f' \neq 0$. If u is an electrostatic potential, the curves $u = \text{const}$ are equipotentials and the curves $v = \text{const}$ are field lines; if v is the stream function of a fluid flow, the curves $v = \text{const}$ are streamlines and u is the velocity potential. One analytic function packages the whole picture. We will exploit this systematically in Section 3.

Let's record the fluid dynamics dictionary now, as we will want it later.

Remark (Complex Potentials for Fluid Flow). For steady, incompressible, irrotational flow in the plane with velocity (u_1, u_2) , there is a velocity potential ϕ (with $\nabla \phi = (u_1, u_2)$, existing since the flow is irrotational) and a stream function ψ (existing since the flow is incompressible), and both are harmonic. The **complex potential** is the analytic function

$$w(z) = \phi + i\psi,$$

and the velocity is recovered from $w'(z) = u_1 - iu_2$. The flow is along the level curves of ψ . For example, $w(z) = Uz$ is uniform flow with speed U in the x -direction, and $w(z) = U(z + a^2/z)$ will turn out to describe flow past a circular cylinder of radius a .

§11.2 Multivalued Functions and Branch Cuts

We have already brushed against the problem twice: both $\log z$ and z^c were only defined once we chose a range for $\theta = \arg z$. This section confronts the issue properly. It is a genuinely subtle business – more subtle than it first appears – and it matters a great deal in practice, since the placement of branch cuts is exactly what makes certain real integrals computable in Section 6.

§11.2.1 The Problem with the Logarithm

For $z = re^{i\theta} \neq 0$ we would like to define

$$\log z = \log r + i\theta.$$

But θ is only defined up to multiples of 2π , so this definition assigns infinitely many values to each point:

$$\log i = \frac{\pi i}{2} \quad \text{or} \quad \frac{5\pi i}{2} \quad \text{or} \quad -\frac{3\pi i}{2} \quad \text{or} \quad \dots$$

We say $\log$ is a **multivalued function**. One might hope to fix this by just picking a value at each point – say, always take $\theta \in (0, 2\pi]$. But an arbitrary choice like this creates discontinuities, and where those discontinuities can and cannot go is the heart of the matter.

Consider tracking a value of $\log z$ continuously along each of the following three curves.

On C_1 , which stays in the right half-plane, we can fix $\theta \in (-\frac{\pi}{2}, \frac{\pi}{2})$ throughout, and $\log z$ is continuous and single-valued all the way round. On C_2 we can similarly fix a range of θ and all is well. But on C_3 , which encircles the origin, there is no possible choice: following the curve anticlockwise once, θ must increase continuously by 2π , so when we return to our starting point the value of $\log z$ has increased by $2\pi i$. The function must either jump somewhere on C_3 , or fail to be single-valued. The origin is the source of the problem, and we give such points a name.

Definition 11.2.1 (Branch Point)

A **branch point** of a function is a point which it is impossible to encircle with a closed curve on which the function is both continuous and single-valued. The function is said to have a **branch point singularity** there.

Example 11.2.2 (Spotting Branch Points) (i) $\log(z - a)$ has a branch point at $z = a$.

(ii) $z^c = r^c e^{ic\theta}$ has a branch point at the origin whenever $c \notin \mathbb{Z}$: going once anticlockwise around a circle of radius r_0 , continuity forces the value to move from r_0^c to $r_0^c e^{2\pi ic}$, and these differ unless c is an integer.

(iii) $\log z$ also has a branch point *at infinity*: setting $\zeta = 1/z$, we get $\log z = -\log \zeta$, which has a branch point at $\zeta = 0$. Similarly z^c has a branch point at infinity for $c \notin \mathbb{Z}$.

(iv) $f(z) = \log\left(\frac{z-1}{z+1}\right) = \log(z-1) - \log(z+1)$ has branch points at ± 1 , but *not* at infinity: with $\zeta = 1/z$ we get $\log\left(\frac{1-\zeta}{1+\zeta}\right)$, and for ζ near 0 the quantity $\frac{1-\zeta}{1+\zeta}$ stays near 1, well away from the troublesome points of $\log$. So small circles about $\zeta = 0$ cause no jump. (Equivalently: a giant circle in the z -plane winds around *both* branch points, and the two jumps of $\pm 2\pi i$ cancel.)

§11.2.2 Branch Cuts

Since the trouble comes from curves that wind around branch points, the remedy is blunt but effective: forbid them.

Definition 11.2.3 (Branch Cut)

A **branch cut** is a curve in the plane, joining branch points (or running from a branch point to infinity), which curves are forbidden from crossing. On the cut plane we can then make a consistent choice of value of the function; such a choice is called a **branch**, and it is single-valued and continuous on any curve avoiding the cut.

For $\log z$, the standard choice is to cut along the negative real axis, and take $\theta \in (-\pi, \pi]$:

This is called the **principal branch** of the logarithm, and its value the **principal value**. The principal branch is analytic on the cut plane, with $\frac{d}{dz} \log z = \frac{1}{z}$, but on the cut itself it is not even continuous: just above the cut at $z = x + i0^+$ (with $x < 0$) we have $\log z = \log |x| + i\pi$, while just below at $z = x + i0^-$ we have $\log z = \log |x| - i\pi$. The function jumps by $2\pi i$ across the cut. This jump is not a defect – in Section 6 it will be precisely the tool that lets us evaluate integrals.

Some remarks on the choices being made here:

- (i) The cut itself is a choice. Any curve from 0 to ∞ works – the non-negative imaginary axis (with, say, $\theta \in (-\frac{3\pi}{2}, \frac{\pi}{2}]$), or even a wiggly curve. All that matters is that curves can no longer wind around the branch point.
- (ii) Even after fixing the cut, the branch is a further choice: with the cut on the negative real axis we could take $\theta \in (\pi, 3\pi]$ instead, which changes $\log z$ by $2\pi i$ everywhere.
- (iii) In any problem where a branch matters, you must specify it – either by giving the range of θ explicitly, or by giving the location of the cut together with the value of the branch at one point (the values everywhere else are then pinned down by continuity).

The same considerations apply verbatim to z^c for $c \notin \mathbb{Z}$, whose branches on the cut plane are $r^c e^{ic\theta}$ with θ in a chosen range of length 2π . Note the different branches of z^c differ by constant factors $e^{2\pi i ck}$, and for $z^{1/2}$ there are exactly two branches, differing by a sign – just as we would expect for a square root.

Remark (Riemann Surfaces). There is a more elegant point of view, due to Riemann: rather than forbidding curves from crossing the cut, imagine infinitely many copies of the cut plane stacked above one another, with the top edge of each cut glued to the bottom edge of the cut on the next sheet up. Crossing the cut moves you to the adjacent sheet, where $\log z$ takes its next branch's values. On this spiral staircase – the *Riemann surface*

of $\log$ – the logarithm is a perfectly ordinary single-valued analytic function. Riemann surfaces get an entire Part II course, and we say no more about them here.

§11.2.3 Multiple Branch Cuts

When a function has several branch points, we may need several cuts, and there is some genuine artistry in choosing them well.

Example 11.2.4 (Two Cuts to Infinity)

Consider $f(z) = (z(z-1))^{1/3}$, with branch points at 0 and 1 (and at ∞). One valid choice is to cut from 0 out to $-\infty$ along the real axis, and from 1 out to $+\infty$:

Writing $z = re^{i\theta}$ with $\theta \in (-\pi, \pi]$ and $z - 1 = r_1 e^{i\theta_1}$ with $\theta_1 \in [0, 2\pi)$, we define

$$f(z) = \sqrt[3]{rr_1} e^{i(\theta+\theta_1)/3}.$$

Crossing either cut makes one of the angles jump, so f jumps – but away from the cuts, f is continuous and single-valued, as no curve can now encircle either branch point alone.

However, sometimes we can get away with less. If a function has *no* branch point at infinity, then large curves winding around all the finite branch points are harmless – so we shouldn't waste a cut ruling them out.

Example 11.2.5 (A Finite Cut)

Take again

$$f(z) = \log \left(\frac{z-1}{z+1} \right),$$

with branch points at ± 1 but not at ∞ . Here we may take a single finite cut along the segment $[-1, 1]$:

Write $z + 1 = re^{i\theta}$ and $z - 1 = r_1 e^{i\theta_1}$, and – this is the part requiring thought – take

both $\theta, \theta_1 \in [0, 2\pi)$. Then define

$$f(z) = \log(r_1/r) + i(\theta_1 - \theta).$$

Let's check this is continuous away from the cut. Crossing the real axis to the *left* of the cut ($x < -1$): both θ and θ_1 pass smoothly through π , so nothing happens. Crossing to the *right* of the cut ($x > 1$): both θ and θ_1 jump by 2π – but f depends only on the difference $\theta_1 - \theta$, so it doesn't notice. Crossing the cut itself ($-1 < x < 1$): θ_1 jumps by 2π while θ varies smoothly, so f jumps by $2\pi i$, exactly as a branch cut should.

This example is worth understanding well – finite branch cuts of this type appear frequently on example sheets and in applications, and choosing the angle ranges correctly is the whole game. Let's do one more of the same flavour, since the square-root version is the one that appears most often.

Example 11.2.6 (Branches of $\sqrt{z^2 - 1}$)

The function $f(z) = (z^2 - 1)^{1/2} = ((z - 1)(z + 1))^{1/2}$ has branch points at ± 1 . Is there a branch point at infinity? With $\zeta = 1/z$,

$$f = \frac{1}{\zeta}(1 - \zeta^2)^{1/2},$$

and $(1 - \zeta^2)^{1/2}$ is single-valued near $\zeta = 0$ (the argument stays near 1) – so no: for large $|z|$, $f(z) \approx \pm z$ consistently. We may therefore use a single finite cut along $[-1, 1]$.

Write $z - 1 = r_1 e^{i\theta_1}$ and $z + 1 = r_2 e^{i\theta_2}$ with $\theta_1, \theta_2 \in [0, 2\pi)$, and set

$$f(z) = \sqrt{r_1 r_2} e^{i(\theta_1 + \theta_2)/2}.$$

Crossing the real axis to the right of the cut, both angles jump by 2π , so $(\theta_1 + \theta_2)/2$ jumps by 2π – invisible in the exponential. Crossing to the left of the cut, both angles pass smoothly through π . Crossing the cut itself, only θ_2 jumps, so f changes sign: a genuine discontinuity, as expected. On the top of the cut ($z = x$ with $-1 < x < 1$, approached from above) we have $\theta_1 = \pi$, $\theta_2 = 0$, so $f = i\sqrt{1 - x^2}$; on the bottom, $f = -i\sqrt{1 - x^2}$. For large real $z = x > 1$ we get $f = \sqrt{x^2 - 1} > 0$, so this branch behaves like $+z$ at infinity.

Functions of exactly this type appear when one inverts Joukowski-type maps ($w = \frac{1}{2}(z + \frac{1}{z})$ gives $z = w + \sqrt{w^2 - 1}$), and the cut along $[-1, 1]$ is the image of the unit circle – the two branches correspond to the inside and outside of the circle.

A final practical point: a branch is often specified not by angle ranges but by its *value at one point*, and one must then be able to evaluate it elsewhere by continuity. With the branch of $\sqrt{z^2 - 1}$ above (cut $[-1, 1]$, $f(2) = +\sqrt{3}$), what is $f(-2)$? Reading off the angles at $z = -2$: $\theta_1 = \theta_2 = \pi$, so $f(-2) = \sqrt{1 \cdot 3} e^{i(\pi + \pi)/2} = -\sqrt{3}$. Note this is *not* $+\sqrt{(-2)^2 - 1}$ – a single consistent branch of $\sqrt{z^2 - 1}$ must behave like $+z$ at one end of the real axis and hence like z (i.e. negatively) at the other. Blindly taking positive square roots on both ends describes *two different branches*, and is the single most common branch-cut error.

§11.3 Conformal Maps

Here is the plan for this section. Laplace's equation is easy to solve on nice domains (half-planes, discs, strips) and hard to solve on nasty ones. Analytic functions, viewed as maps from one region of the plane to another, turn out to preserve exactly the structure Laplace's equation cares about. So if we can map our nasty domain onto a nice one by an analytic bijection, we can solve our problem on the nice domain and pull the solution back. This section builds up a toolkit of such maps, and then puts them to work.

§11.3.1 Möbius Maps

We begin with a class of maps you have met before, in IA Groups.

Definition 11.3.1 (Möbius Map)

A **Möbius map** is a map of the form

$$z \mapsto w = \frac{az + b}{cz + d},$$

where $a, b, c, d \in \mathbb{C}$ and $ad - bc \neq 0$.

The condition $ad - bc \neq 0$ rules out the degenerate case where the map is constant. A Möbius map is analytic everywhere except at $z = -d/c$, where the denominator vanishes. The right way to think about this is as a map of the *extended* complex plane: setting

$$-\frac{d}{c} \mapsto \infty, \quad \infty \mapsto \frac{a}{c},$$

a Möbius map becomes a bijection $\mathbb{C}^* \rightarrow \mathbb{C}^*$, with inverse

$$w \mapsto \frac{-dw + b}{cw - a},$$

which is another Möbius map. Composites of Möbius maps are also Möbius maps – indeed they form a group under composition.

For our purposes their key property concerns circles and lines. It is convenient to treat these uniformly: a line is simply a circle through ∞ .

Definition 11.3.2 (Circline)

A **circline** is a circle or a straight line.

Proposition 11.3.3

Möbius maps send circlines to circlines.

Proof. Every circline can be written as a circle of Apollonius

$$|z - z_1| = \lambda |z - z_2|$$

for some $z_1, z_2 \in \mathbb{C}$ and $\lambda > 0$, with $\lambda = 1$ giving lines and $\lambda \neq 1$ circles (this was on the first IA Vectors and Matrices example sheet). Substituting $z = \frac{-dw+b}{cw-a}$ and

clearing denominators, this becomes

$$|(cz_1 + d)w - (az_1 + b)| = \lambda |(cz_2 + d)w - (az_2 + b)|.$$

If $cz_1 + d$ and $cz_2 + d$ are both non-zero, dividing through puts this in Apollonius form again, so the image is a circline; if one of them vanishes the equation directly describes a circle (or line). $\square$

Note carefully what is *not* claimed: circles may map to lines and vice versa. A circle passing through the point sent to ∞ must map to a line.

Proposition 11.3.4 (Three-Point Determination)

Given distinct points $\alpha, \beta, \gamma \in \mathbb{C}^*$ and distinct $\alpha', \beta', \gamma' \in \mathbb{C}^*$, there is a Möbius map sending $\alpha \mapsto \alpha', \beta \mapsto \beta', \gamma \mapsto \gamma'$.

Proof. The map

$$f_1(z) = \frac{\beta - \gamma}{\beta - \alpha} \cdot \frac{z - \alpha}{z - \gamma}$$

sends $\alpha \mapsto 0, \beta \mapsto 1, \gamma \mapsto \infty$. Building f_2 in the same way from the primed points, the composition $f_2^{-1} \circ f_1$ does the job (and is Möbius, since Möbius maps form a group). $\square$

Since three points determine a circline, this means we can find a Möbius map taking any circline to any other – and hence, with a little care about which side is which, taking any disc or half-plane to any other disc or half-plane. This is exactly the flexibility we will want.

§11.3.2 Conformal Maps

Definition 11.3.5 (Conformal Map)

A **conformal map** $f : U \rightarrow V$, where U, V are open subsets of $\mathbb{C}$, is an analytic map with $f'(z) \neq 0$ for all $z \in U$. If additionally f is a bijection $U \rightarrow V$, we call it a **conformal equivalence**.

The name comes from the following geometric property.

Proposition 11.3.6 (Conformal Maps Preserve Angles)

A conformal map preserves the angle – in both magnitude and orientation – between intersecting curves.

Proof. Let $z_1(t)$ be a curve passing through $z_0 = z_1(t_1)$ with non-zero tangent $z_1'(t_1)$, making angle $\phi = \arg z_1'(t_1)$ with the real axis. The image curve $Z_1(t) = f(z_1(t))$ has tangent

$$Z_1'(t_1) = f'(z_0) z_1'(t_1),$$

which makes angle $\arg f'(z_0) + \phi$ with the real axis (using $f'(z_0) \neq 0$ so its argument makes sense). So *every* curve through z_0 has its tangent direction rotated by the same angle $\arg f'(z_0)$, and hence angles between pairs of curves are preserved. $\square$

In fact the converse holds too (an angle-preserving map is conformal), though we won't prove it. Do note where the proof uses $f' \neq 0$: at a point where f' vanishes, angles are genuinely *not* preserved – we will see in a moment that $z \mapsto z^2$ doubles angles at the origin.

When computing with conformal maps, the following procedure for finding the image $f(U)$ is invaluable: *find the image of the boundary ∂U , which will be the boundary of V ; then take any single convenient point of U and see which side of that boundary its image lands on.*

§11.3.3 A Catalogue of Conformal Maps

In practice one builds complicated conformal maps by composing simple standard ones (compositions of conformal maps are conformal, by the chain rule). Here is the standard toolkit.

(i) Linear maps. $z \mapsto az + b$ with $a \neq 0$ rotates by $\arg a$, scales by $|a|$, and translates by b . Conformal everywhere.

(ii) Powers. $z \mapsto z^\alpha$ (with a suitable branch when $\alpha \notin \mathbb{Z}$) is conformal away from the origin, and maps the sector $0 < \arg z < \phi$ to the sector $0 < \arg w < \alpha\phi$: it *multiplies angles at the origin by α* . For instance, $z \mapsto z^2$ maps the quarter-disc to the half-disc:

$$U = \{z : |z| < 1, 0 < \arg z < \frac{\pi}{2}\} \longrightarrow V = \{w : |w| < 1, 0 < \arg w < \pi\}.$$

The right angles of ∂U at $z = 1$ and $z = i$ are preserved (as f is conformal there), but the right angle at the origin is doubled to a straight line – which is fine, because $0 \notin U$ (U is open, and $f'(0) = 0$ means f was never claimed to be conformal there).

It is illuminating to watch $w = z^2$ act on a coordinate grid. Writing $w = u + iv$, the vertical line $x = c$ maps to $u = c^2 - y^2$, $v = 2cy$ – a leftward-opening parabola – and the horizontal line $y = c$ to a rightward-opening one. The two families of parabolas intersect *at right angles*, as the images of an orthogonal grid under a conformal map must:

Note also how the first quadrant (the region shown) opens out to fill the whole upper half-plane, in accordance with the doubling of angles at the origin.

Going the other way, fractional powers *open out* sectors. To map the left half-plane $U = \{\operatorname{Re} z < 0\}$ to the wedge $\{-\frac{\pi}{4} < \arg w < \frac{\pi}{4}\}$, we want to halve angles, so we try $z^{1/2}$ – but we must place the branch cut *outside* U , since $z^{1/2}$ is not even continuous, let alone analytic, on its cut. Cutting along the negative imaginary axis and taking

$\theta \in (-\frac{\pi}{2}, \frac{3\pi}{2}]$, the map $re^{i\theta} \mapsto \sqrt{r}e^{i\theta/2}$ sends U to the wedge $\frac{\pi}{4} < \arg w < \frac{3\pi}{4}$, and following with a rotation we arrive at

$$f(z) = -iz^{1/2}.$$

(iii) The exponential. $w = e^z = e^x e^{iy}$ sends horizontal lines $y = c$ to rays $\arg w = c$, and vertical lines $x = c$ to circles $|w| = e^c$. Consequently it maps a rectangle $x_1 < x < x_2$, $y_1 < y < y_2$ conformally onto a sector of an annulus, and in the degenerate cases:

- the horizontal strip $0 < \operatorname{Im} z < \pi$ maps to the upper half-plane;
- the half-strip $\operatorname{Re} z < 0$, $0 < \operatorname{Im} z < \pi$ maps to the upper half-disc.

With an appropriate branch, $\log z$ performs the inverse operations, flattening sectors and annuli into strips and rectangles. This pair of maps is the standard tool for ‘unrolling’ angular regions.

(iv) Möbius maps. As discussed, these shuttle between discs and half-planes. The single most useful example is

$$f(z) = \frac{z-1}{z+1},$$

which maps the unit disc to the left half-plane. To see this, note the boundary circle passes through $-1 \mapsto \infty$, $i \mapsto i$ and $1 \mapsto 0$, so its image is the circline through ∞ , i , 0 – the imaginary axis. Checking an interior point, $f(0) = -1$, so the disc maps to the left half-plane.

A useful alternative derivation: $w = \frac{z-1}{z+1}$ rearranges to $z = -\frac{w+1}{w-1}$, and then

$$|z| < 1 \iff |w+1| < |w-1|,$$

which says exactly that w is closer to -1 than to 1 , i.e. $\operatorname{Re} w < 0$.

The map $z \mapsto 1/z$ is also just a Möbius map, and is particularly handy for dealing with regions bounded by lines and circles through the origin. For instance, the vertical line $\operatorname{Re} z = c$ (with $c > 0$) is a circline through ∞ avoiding 0 , so its image under $1/z$ is a circle through the origin; tracking the points $c \mapsto \frac{1}{c}$ and $c \pm i\infty \mapsto 0$, it is the circle of radius $\frac{1}{2c}$ centred at $\frac{1}{2c}$. Consequently $1/z$ maps the half-plane $\operatorname{Re} z > c$ to the open disc bounded by that circle – a useful trick for problems involving two nested or tangent circles.

Let's see the toolkit in action on a composite problem.

Example 11.3.7 (Half-Disc to Disc)

Let's find a conformal equivalence from the upper half-disc $U = \{|z| < 1, \operatorname{Im} z > 0\}$ to the unit disc.

A tempting first guess is $z \mapsto z^2$, since it maps the upper half-disc onto the disc minus the segment $[0, 1)$ – but that slit is missing, so this is not onto, and no good. Instead we go via half-planes:

1. $f_1(z) = \frac{z-1}{z+1}$ maps U to the second quadrant. (Check: the diameter $(-1, 1)$ maps to the negative real axis, the semicircular arc to the positive imaginary axis, and the interior point $i/2$ maps to $\frac{i/2-1}{i/2+1} = \frac{-3+4i}{5}$, indeed in the second quadrant.)
2. $f_2(z) = iz^2$: squaring maps the second quadrant to the lower half-plane, and multiplying by i rotates it to the right half-plane.
3. $f_3(z) = \frac{z-1}{z+1}$ maps the right half-plane to the unit disc: the imaginary axis maps to the unit circle (it is the set of points equidistant from 1 and -1 , which maps to $|w| = 1$ by the displayed equivalence above), and $f_3(1) = 0$.

The required map is $f_3 \circ f_2 \circ f_1$. One could expand this into a single formula, but there is rarely any reason to.

Example 11.3.8 (Strip to Disc)

Similarly, let's map the strip $S = \{0 < \operatorname{Im} z < 1\}$ conformally onto the unit disc. First scale to the standard strip: $z \mapsto \pi z$ gives $0 < \operatorname{Im} z < \pi$. Then exponentiate: e^z maps this strip to the upper half-plane (from the catalogue). Finally, a Möbius map takes the upper half-plane to the disc: $w \mapsto \frac{w-i}{w+i}$ sends the real axis to the unit circle (each real w is equidistant from i and $-i$) and the interior point i to 0. Composing,

$$f(z) = \frac{e^{\pi z} - i}{e^{\pi z} + i}.$$

Notice what happened to the boundary: the two edges of the strip, each a copy of $\mathbb{R}$, are wrapped onto complementary arcs of the circle, meeting at the images of the two 'ends' of the strip, $f(-\infty) = -1$ and $f(+\infty) = 1$. Keeping track of boundary correspondences like this is exactly what transported the boundary conditions in the Laplace problems below.

Remark (The Riemann Mapping Theorem). One might worry about how far this game can be pushed – which regions *can* be conformally mapped onto the disc? The answer is remarkably generous: *every* simply connected domain other than $\mathbb{C}$ itself is conformally equivalent to the unit disc (the *Riemann mapping theorem*). The proof is thoroughly non-constructive and belongs to a later course; for us its value is moral support. The map we need always exists – the examples in this section are about actually finding it.

§11.3.4 The Joukowski Map

One more map deserves special mention, both for its historical importance and because it shows conformal maps doing real engineering work.

Definition 11.3.9 (Joukowski Map)

The **Joukowski map** is

$$w = J(z) = \frac{1}{2} \left(z + \frac{1}{z} \right).$$

This is conformal except at $z = \pm 1$, where $J'(z) = \frac{1}{2}(1 - 1/z^2)$ vanishes. Since $J(z) = J(1/z)$, the map is two-to-one on $\mathbb{C} \setminus \{0\}$; it is a conformal equivalence from the *exterior* of the unit circle to the complement of the segment $[-1, 1]$. Indeed, on the unit circle itself $z = e^{i\theta}$ we get $w = \cos \theta$: the circle is flattened onto the segment $[-1, 1]$, traversed twice.

Circles of radius $r > 1$ map to ellipses with semi-axes $\frac{1}{2}(r + \frac{1}{r})$ and $\frac{1}{2}(r - \frac{1}{r})$. The magic happens when we apply J to a circle which passes through $z = 1$ but encloses $z = -1$ slightly off-centre: because J fails to be conformal at $z = 1$, the smooth circle acquires a sharp cusp there, and the image is an *aerofoil* – a wing cross-section with a rounded leading edge and sharp trailing edge.

The point of this construction: we understand ideal fluid flow past a circular cylinder completely (we are about to write it down), and the Joukowski map transports that flow conformally to flow past the aerofoil. This was how early aerodynamicists first computed the lift on a wing.

§11.3.5 Solving Laplace's Equation with Conformal Maps

Now we put the machinery to work. The key fact is the one from Section 1: harmonic functions are (locally) real parts of analytic functions, and compositions of analytic functions are analytic. This gives:

Proposition 11.3.10

Let $f : U \rightarrow V$ be conformal and let Φ be harmonic on V . Then

$$\phi(x, y) = \Phi(\operatorname{Re} f(x + iy), \operatorname{Im} f(x + iy))$$

is harmonic on U .

Proof. Since Φ is harmonic, we can write $\Phi = \operatorname{Re} F$ for some analytic F on V (its analytic completion, $F = \Phi + i\Psi$ with Ψ the harmonic conjugate^a). Then $F \circ f$ is analytic on U , being a composition of analytic functions, and $\phi = \operatorname{Re}(F \circ f)$ is harmonic. $\square$

^aOn a simply connected domain this always exists; the nice target domains we choose will always be simply connected.

In other words: *harmonicity survives conformal changes of variable*. This justifies the following algorithm for solving $\nabla^2\phi = 0$ on a difficult domain U with given (Dirichlet, say) boundary conditions:

1. Find a conformal equivalence $f : U \rightarrow V$ with V nice (a half-plane, strip or disc).
2. Transport the boundary conditions: each boundary point $z \in \partial U$ carries its boundary value over to $f(z) \in \partial V$.
3. Solve $\nabla^2\Phi = 0$ on V with the transported boundary conditions – ideally by inspection.
4. Then $\phi = \Phi \circ f$ (in the sense of the proposition) solves the original problem.

Example 11.3.11 (Laplace's Equation on a Quadrant)

Let's find a bounded solution of $\nabla^2\phi = 0$ on the first quadrant $x, y > 0$, with $\phi(x, 0) = 0$ and $\phi(0, y) = 1$.

The quadrant is a sector of angle $\frac{\pi}{2}$, so we unroll it with a logarithm: $f(z) = \log z$ (principal branch) maps it to the strip

$$V = \left\{ w : 0 < \operatorname{Im} w < \frac{\pi}{2} \right\},$$

with the positive real axis (where $\phi = 0$) going to the boundary line $\operatorname{Im} w = 0$, and the positive imaginary axis (where $\phi = 1$) to the line $\operatorname{Im} w = \frac{\pi}{2}$.

On the strip, the boundary conditions do not depend on $\operatorname{Re} w$, so we look for a solution depending only on $\operatorname{Im} w = v$, and $\nabla^2\Phi = 0$ forces Φ to be linear in v :

$$\Phi(u, v) = \frac{2}{\pi}v.$$

Pulling back,

$$\phi(x, y) = \frac{2}{\pi} \operatorname{Im} \log z = \frac{2}{\pi} \arg z = \frac{2}{\pi} \tan^{-1} \left(\frac{y}{x} \right).$$

In hindsight the answer is obvious – the level sets are rays from the origin, interpolating linearly in angle between the two boundary rays – but the method required no cleverness, and works just as well when the answer is not guessable.

Example 11.3.12 (Temperature in a Half-Disc)

Let's solve $\nabla^2 T = 0$ in the upper half-disc $|z| < 1$, $\operatorname{Im} z > 0$, with $T = 1$ on the curved boundary and $T = 0$ on the diameter.

From our catalogue, $f_1(z) = \frac{z-1}{z+1}$ maps the half-disc to the second quadrant, sending the diameter to the negative real axis and the arc to the positive imaginary axis. Then $w = \log \left(\frac{z-1}{z+1} \right)$, taking the branch with $\arg \in [\frac{\pi}{2}, \pi]$ on the closed quadrant, maps the region to the strip $\frac{\pi}{2} < \operatorname{Im} w < \pi$, with the arc's image at $\operatorname{Im} w = \frac{\pi}{2}$ and the diameter's at $\operatorname{Im} w = \pi$. The solution linear in $\operatorname{Im} w$ with the right boundary values is $\Phi = 2 - \frac{2}{\pi} \operatorname{Im} w$, so

$$T(x, y) = 2 - \frac{2}{\pi} \arg \left(\frac{z-1}{z+1} \right).$$

(As always, one should pause and sanity-check: on the arc, $\arg \frac{z-1}{z+1} = \frac{\pi}{2}$ – the two boundary points ± 1 subtend a right angle from any point of the semicircle – giving $T = 1$, and on the diameter the argument is π , giving $T = 0$.)

Example 11.3.13 (Uniform Flow Past a Cylinder)

As a final showpiece, consider ideal fluid flow, uniform at infinity with speed U parallel to the x -axis, past a solid cylinder $|z| \leq a$. We claim the complex potential is

$$w(z) = U \left(z + \frac{a^2}{z} \right).$$

Why: this is analytic in the flow region $|z| > a$; as $z \rightarrow \infty$, $w'(z) = U(1 - a^2/z^2) \rightarrow U$, giving the right behaviour at infinity; and on the boundary circle $z = ae^{i\theta}$,

$$w = U(ae^{i\theta} + ae^{-i\theta}) = 2Ua \cos \theta,$$

which is real – so the stream function $\psi = \text{Im } w$ vanishes on the cylinder, making it a streamline, as a solid boundary must be. (Notice this is just a scaled Joukowski map!) The stream function is

$$\psi(x, y) = Uy \left(1 - \frac{a^2}{x^2 + y^2} \right),$$

and the streamlines $\psi = \text{const}$ look as follows.

The velocity on the boundary is $|w'(ae^{i\theta})| = 2U|\sin \theta|$: the flow is stationary at the front and rear *stagnation points* $\theta = 0, \pi$, and fastest at the top and bottom. Composing with a Joukowski-type map now transports this entire flow field to the flow past an aerofoil, streamline by streamline – conformality guarantees the boundary remains a streamline.

Example 11.3.14 (Flow in a Corner)

Conformal maps also generate flows directly: if $w(z)$ is a complex potential for a flow in a region V , and $g : U \rightarrow V$ is conformal, then $w \circ g$ is a complex potential in U (it is analytic, and boundary streamlines pull back to boundary streamlines).

Uniform flow in the upper half-plane has potential $w(z) = Uz$. The map $g(z) = z^2$ takes the quarter-plane $x, y > 0$ to the upper half-plane. So

$$w(z) = Uz^2 = U(x^2 - y^2) + 2iUxy$$

is the potential for flow in a right-angled corner: the stream function is $\psi = 2Uxy$, whose level curves are the hyperbolas $xy = \text{const}$, sliding along the two walls (which

form the streamline $\psi = 0$). The velocity $w'(z) = 2Uz$ vanishes at the corner itself – a stagnation point, as the geometry demands. More generally $w = Uz^{\pi/\phi}$ describes flow in a corner of opening angle ϕ , and the exponent controls the (in)famous behaviour of the velocity at the vertex: for $\phi > \pi$ (flow around a protruding edge) the velocity is infinite there.

The same technique solves electrostatics problems: the potential between conductors held at fixed voltages is harmonic with Dirichlet boundary conditions, so we conformally map the gap between the conductors to a strip or annulus where the potential is obvious, and pull back. The half-disc example above, reread with ‘temperature’ replaced by ‘potential’ and the boundaries by conductors, is already such an example. Here is one more, with cylindrical rather than flat geometry.

Example 11.3.15 (A Coaxial Cable)

Two conducting cylinders, radii $r_1 < r_2$, are held at potentials 0 and V ; we want the potential ϕ in the annulus between them. The map $w = \log z$ (any branch, locally) sends the annulus to the vertical strip $\log r_1 < \operatorname{Re} w < \log r_2$, and the boundary circles to the strip’s edges. In the strip the solution linear in $\operatorname{Re} w$ is immediate, and pulling back,

$$\phi = V \frac{\log(r/r_1)}{\log(r_2/r_1)}, \quad r = |z|.$$

Strictly the annulus is not simply connected and $\log z$ is not single-valued on it – but its *real* part $\log |z|$ is, and that is all the solution uses. The field lines are the level curves of the conjugate $\operatorname{Im} \log z = \theta$: radial lines, orthogonal to the equipotential circles, as they must be.

§11.4 Contour Integration and Cauchy’s Theorem

We now change gears entirely, and spend the rest of the course on the theory of *integration* of complex functions. If differentiating complex functions felt like a modest generalisation of the real theory, integrating them will not: complex integration has a completely different character, dominated by one theorem (Cauchy’s), and it leads to computational techniques that look like magic the first few times you see them.

Throughout this part of the course, our treatment runs parallel to the Complex Analysis course. The definitions below are the same as the ones given there; the difference is that we will move quickly to computation, citing my Complex Analysis notes for the careful proofs.

§11.4.1 Contours and Integrals

Definition 11.4.1 (Contour)

A **curve** γ is a continuous map $\gamma : [a, b] \rightarrow \mathbb{C}$. A **contour** is a piecewise smooth curve; it is **closed** if $\gamma(a) = \gamma(b)$, and **simple** if it does not intersect itself (except that a closed contour returns to its start).

Definition 11.4.2 (Contour Integral)

The **contour integral** of f along a contour γ is

$$\int_{\gamma} f(z) \, dz = \int_a^b f(\gamma(t)) \gamma'(t) \, dt.$$

For a closed contour we sometimes write $\oint_{\gamma} f(z) \, dz$, and unless stated otherwise closed contours are traversed *anticlockwise*.

One can check (by the chain rule) that the integral is independent of the parametrisation chosen, so it really is an integral ‘along the curve’. Equivalently, the integral is a limit of Riemann sums $\sum f(z_k) \delta z_k$ over subdivisions of the contour, which is the picture to keep in mind: we sum up values of f weighted by *complex* displacements along the curve.

The elementary properties are what you would expect: the integral is linear in f , additive over concatenation of contours, and changes sign if the contour is traversed backwards. The workhorse inequality is the following, which we will use dozens of times.

Lemma 11.4.3 (Estimation Lemma)

If $|f(z)| \leq M$ on a contour γ of length L , then

$$\left| \int_{\gamma} f(z) \, dz \right| \leq ML.$$

Proof. Bounding the Riemann sums, $|\sum f(z_k) \delta z_k| \leq M \sum |\delta z_k| \leq ML$. (A careful proof is in my Complex Analysis notes.) $\square$

In practice this appears as ‘length times sup’, often in asymptotic form: a semicircle of radius R has length πR , so if $|f| = O(R^{-2})$ on it then the integral is $O(R^{-1}) \rightarrow 0$. Estimates of exactly this shape will kill off the ‘unwanted’ parts of our contours in Section 6.

An important question: does a contour integral depend on the contour, or only on its endpoints? For general functions, it certainly depends on the contour.

Example 11.4.4 (Path Dependence)

Let’s integrate $f(z) = \bar{z}$ from 0 to $1+i$ along two different contours: γ_1 , the straight line $\gamma_1(t) = (1+i)t$ for $t \in [0, 1]$; and γ_2 , going along the real axis to 1 and then vertically up to $1+i$.

Along γ_1 :

$$\int_{\gamma_1} \bar{z} \, dz = \int_0^1 \overline{(1+i)t} \cdot (1+i) \, dt = |1+i|^2 \int_0^1 t \, dt = 1.$$

Along γ_2 : on the horizontal leg $z = t$, $\bar{z} = t$, contributing $\int_0^1 t \, dt = \frac{1}{2}$; on the vertical leg $z = 1 + it$, $dz = i \, dt$, contributing $\int_0^1 (1 - it)i \, dt = i + \frac{1}{2}$. Total: $1 + i$.

So the two routes disagree – unsurprisingly, since $\bar{z}$ is not analytic. Repeating the

computation with the analytic function $f(z) = z$ gives $\frac{(1+i)^2}{2} = i$ along *both* routes (as the reader should check). Path-independence for analytic functions is not an accident; it is Cauchy's theorem, to which we are heading.

For functions with an antiderivative, the fundamental theorem of calculus works exactly as over $\mathbb{R}$:

Proposition 11.4.5 (Fundamental Theorem of Calculus)

If F is analytic on a domain containing the contour γ from a to b , and $F' = f$, then

$$\int_{\gamma} f(z) \, dz = F(b) - F(a).$$

In particular the integral depends only on the endpoints, and vanishes if γ is closed.

Proof. Parametrise γ over $[t_0, t_1]$ and apply the chain rule: $\int_{t_0}^{t_1} f(\gamma(t))\gamma'(t) \, dt = \int_{t_0}^{t_1} \frac{d}{dt} F(\gamma(t)) \, dt = F(b) - F(a)$. $\square$

Example 11.4.6 (A Fundamental Computation)

Let γ be the circle of radius r about the origin, traversed anticlockwise, and let $n \in \mathbb{Z}$. Parametrising $\gamma(\theta) = re^{i\theta}$,

$$\oint_{\gamma} z^n \, dz = \int_0^{2\pi} r^n e^{in\theta} \cdot ire^{i\theta} \, d\theta = ir^{n+1} \int_0^{2\pi} e^{i(n+1)\theta} \, d\theta = \begin{cases} 2\pi i & n = -1, \\ 0 & n \neq -1. \end{cases}$$

This tiny computation is secretly the entire subject. Every power of z integrates to zero around a closed loop – except $\frac{1}{z}$, which detects the loop and contributes $2\pi i$. The residue theorem in Section 6 is little more than this example dressed up.

Note why $n = -1$ is special: z^n has antiderivative $\frac{z^{n+1}}{n+1}$ for $n \neq -1$, and integrals of functions with (single-valued) antiderivatives around closed loops vanish, by the fundamental theorem of calculus. But the antiderivative of $\frac{1}{z}$ is $\log z$, which is multivalued – going once around the circle, $\log z$ climbs by $2\pi i$, and that is exactly the value of the integral. Branch cuts and contour integrals are two faces of the same phenomenon.

The same computation viewed through open contours is also instructive. Integrating $\frac{1}{z}$ from -1 to 1 along the semicircle $e^{i\theta}$, θ from π down to 0 , through the *upper* half-plane:

$$\int_{\pi}^0 \frac{1}{e^{i\theta}} ie^{i\theta} \, d\theta = -i\pi,$$

while through the *lower* half-plane (θ from $-\pi$ up to 0) the answer is $+i\pi$. The two routes differ by $2\pi i$ – the closed-loop value – and each individually is ‘ $\log 1 - \log(-1)$ ’ for a different branch of $\log$. Everything is consistent, provided one keeps track of which side of the singularity the contour passes.

§11.4.2 Cauchy's Theorem

We need one topological notion.

Definition 11.4.7 (Simply Connected)

A domain D is **simply connected** if every closed curve in D encloses only points of D – informally, D has no holes.

Theorem 11.4.8 (Cauchy's Theorem)

If f is analytic on a simply connected domain D , then for every closed contour γ in D ,

$$\oint_{\gamma} f(z) \, dz = 0.$$

Proof (Sketch). This is *the* theorem of the course, and it deserves a real proof – which is given in my Complex Analysis notes. The quick heuristic, assuming f' continuous, comes from Green's theorem: writing $f = u + iv$ and $dz = dx + i \, dy$,

$$\oint_{\gamma} f \, dz = \oint_{\gamma} (u \, dx - v \, dy) + i \oint_{\gamma} (v \, dx + u \, dy),$$

and applying Green's theorem to each part turns the integrands into $(-v_x - u_y)$ and $(u_x - v_y)$ respectively over the enclosed region – both of which vanish by the Cauchy–Riemann equations. The honest proof avoids assuming f' is continuous, and is genuinely harder. $\square$

The hypothesis of simple connectedness is doing real work: it guarantees that f is analytic *everywhere inside* γ , not just on it. Integrating $\frac{1}{z}$ around the unit circle – which gave $2\pi i$, not 0 – does not contradict the theorem, because no simply connected domain contains the circle while avoiding the singularity at 0.

Cauchy's theorem has two immediate consequences that we use constantly, usually without comment.

Proposition 11.4.9 (Deformation of Contours) (i) If γ_1 and γ_2 are two contours from a to b , and f is analytic on a region containing both and the area between them, then $\int_{\gamma_1} f \, dz = \int_{\gamma_2} f \, dz$.

(ii) If γ_1 and γ_2 are closed contours, one inside the other, and f is analytic on the region between them, then $\oint_{\gamma_1} f \, dz = \oint_{\gamma_2} f \, dz$.

Proof. For (i), the concatenation of γ_1 with γ_2 reversed is a closed contour to which Cauchy's theorem applies. For (ii), join the two contours by a thin 'cross-cut': the resulting single closed contour encloses only the region between γ_1 and γ_2 , where f is analytic, so the integral around it vanishes; the two passes along the cross-cut cancel in the limit as it narrows, leaving $\oint_{\gamma_1} f \, dz - \oint_{\gamma_2} f \, dz = 0$. $\square$

The slogan for (ii): *contours may be freely deformed, so long as they never cross a singularity*. This is the practical form in which Cauchy's theorem enters computations – we shrink complicated contours onto small circles around the singularities they enclose.

§11.4.3 Cauchy's Integral Formula

Theorem 11.4.10 (Cauchy's Integral Formula)

Let f be analytic on and inside a simple closed contour γ , and let z_0 lie inside γ . Then

$$f(z_0) = \frac{1}{2\pi i} \oint_{\gamma} \frac{f(z)}{z - z_0} dz.$$

Proof. The integrand is analytic except at z_0 , so by deformation we may replace γ by the circle $z = z_0 + \epsilon e^{i\theta}$ of small radius ϵ . On this circle,

$$\oint \frac{f(z)}{z - z_0} dz = \int_0^{2\pi} \frac{f(z_0 + \epsilon e^{i\theta})}{\epsilon e^{i\theta}} i\epsilon e^{i\theta} d\theta = i \int_0^{2\pi} f(z_0 + \epsilon e^{i\theta}) d\theta \rightarrow 2\pi i f(z_0)$$

as $\epsilon \rightarrow 0$, by continuity of f . Since the left hand side is independent of ϵ , it equals $2\pi i f(z_0)$. $\square$

Pause on how strange this is: the values of an analytic function *everywhere inside* a contour are completely determined by its values *on* the contour. Nothing remotely like this is true for real differentiable functions. It reflects the rigidity of analytic functions – being differentiable in the complex sense ties all the values together.

Differentiating under the integral sign (which can be justified) gives formulas for all derivatives:

$$f^{(n)}(z_0) = \frac{n!}{2\pi i} \oint_{\gamma} \frac{f(z)}{(z - z_0)^{n+1}} dz.$$

In particular *an analytic function is infinitely differentiable* – the fact we borrowed back in Section 1 to prove harmonicity. The same formulas power the theory of Taylor series, to which we now turn shortly; first, two quick consequences that show off how much information the integral formula packs.

Proposition 11.4.11 (Mean Value Property)

If f is analytic on a disc about z_0 , then $f(z_0)$ is the average of f over any circle $|z - z_0| = r$ in the disc:

$$f(z_0) = \frac{1}{2\pi} \int_0^{2\pi} f(z_0 + re^{i\theta}) d\theta.$$

Taking real parts, harmonic functions also have the mean value property.

Proof. Apply Cauchy's integral formula on the circle and parametrise, exactly as in its proof (this time with no limit needed). $\square$

Theorem 11.4.12 (Liouville's Theorem)

A bounded entire function is constant.

Proof. Say $|f| \leq M$ everywhere. For any z_0 , apply the derivative formula on a circle

of radius R about z_0 and estimate:

$$|f'(z_0)| = \left| \frac{1}{2\pi i} \oint \frac{f(z)}{(z - z_0)^2} dz \right| \leq \frac{1}{2\pi} \cdot 2\pi R \cdot \frac{M}{R^2} = \frac{M}{R} \rightarrow 0$$

as $R \rightarrow \infty$. So $f' \equiv 0$, and f is constant. $\square$

Liouville's theorem is the standard route to the fundamental theorem of algebra (if a polynomial P had no root, $1/P$ would be a bounded entire function), and for us it also explains a fact we keep using implicitly: interesting entire functions – e^z , $\sin z$ – *must* be unbounded somewhere. Both results, along with much more in this vein (Morera's theorem, the identity theorem, the maximum modulus principle), are treated properly in my Complex Analysis notes.

§11.5 Laurent Series and Singularities

Analytic functions are exactly the functions given locally by power series – and near their singularities, they are given by power series allowing negative powers. This section sets up that machinery and uses it to classify singularities, which is precisely what we need to compute residues efficiently.

§11.5.1 Taylor and Laurent Series

Theorem 11.5.1 (Taylor Series)

If f is analytic on the disc $|z - z_0| < R$, then on that disc

$$f(z) = \sum_{n=0}^{\infty} a_n (z - z_0)^n, \quad a_n = \frac{f^{(n)}(z_0)}{n!} = \frac{1}{2\pi i} \oint_{\gamma} \frac{f(z)}{(z - z_0)^{n+1}} dz,$$

where γ is any simple closed contour in the disc encircling z_0 . The series converges (uniformly on compact subsets) in the disc.

The proof (expand $\frac{1}{z-w}$ as a geometric series inside Cauchy's integral formula and integrate term by term) is in my Complex Analysis notes. Note the remarkable strength of the statement compared with the real case: mere differentiability guarantees an everywhere-convergent local power series. There is no complex analogue of the smooth-but-not-analytic function e^{-1/x^2} .

Example 11.5.2

The classics, valid for all $z \in \mathbb{C}$:

$$e^z = \sum_{n=0}^{\infty} \frac{z^n}{n!}, \quad \sin z = \sum_{n=0}^{\infty} \frac{(-1)^n z^{2n+1}}{(2n+1)!}, \quad \cos z = \sum_{n=0}^{\infty} \frac{(-1)^n z^{2n}}{(2n)!},$$

and for $|z| < 1$,

$$\frac{1}{1-z} = \sum_{n=0}^{\infty} z^n, \quad \log(1+z) = \sum_{n=1}^{\infty} \frac{(-1)^{n+1} z^n}{n}$$

(principal branch). The radius of convergence of a Taylor series is always the distance from z_0 to the nearest singularity – which finally explains a real-analysis mystery, namely why $\frac{1}{1+x^2}$, a perfectly smooth function on all of $\mathbb{R}$, has Taylor series with radius of convergence only 1: the function has (complex!) singularities at $\pm i$, at distance 1 from the origin.

What if f has a singularity at z_0 itself, or we are working in an annulus around a hole? We then allow negative powers.

Theorem 11.5.3 (Laurent Series)

If f is analytic in an annulus $R_1 < |z - z_0| < R_2$, then on that annulus

$$f(z) = \sum_{n=-\infty}^{\infty} a_n(z - z_0)^n, \quad a_n = \frac{1}{2\pi i} \oint_{\gamma} \frac{f(z)}{(z - z_0)^{n+1}} dz,$$

where γ is any simple closed contour in the annulus encircling z_0 . The expansion is unique, and converges uniformly on compact subsets of the annulus.

Uniqueness is worth emphasising for practical reasons: *any* valid method of producing such an expansion – long division, substituting into known series, partial fractions – must give *the* Laurent series. We never compute the coefficient integrals directly.

Example 11.5.4 (Computing Laurent Series) (i) Around $z_0 = 0$,

$$\frac{e^z}{z^3} = \frac{1}{z^3} \left(1 + z + \frac{z^2}{2} + \cdots \right) = \frac{1}{z^3} + \frac{1}{z^2} + \frac{1}{2z} + \frac{1}{6} + \frac{z}{24} + \cdots$$

(ii) $e^{1/z}$ has Laurent series $\sum_{n=0}^{\infty} \frac{z^{-n}}{n!}$ around 0, with *infinitely many* negative powers.

(iii) The function $\frac{1}{z(z-1)}$ has *different* Laurent expansions in the annuli $0 < |z| < 1$ and $|z| > 1$:

$$\frac{1}{z(z-1)} = -\frac{1}{z} \cdot \frac{1}{1-z} = -\frac{1}{z} - 1 - z - z^2 - \cdots \quad (0 < |z| < 1),$$

while for $|z| > 1$ we expand in powers of $\frac{1}{z}$ instead:

$$\frac{1}{z(z-1)} = \frac{1}{z^2} \cdot \frac{1}{1-1/z} = \frac{1}{z^2} + \frac{1}{z^3} + \frac{1}{z^4} + \cdots$$

Same function, same centre, different annuli, different series – uniqueness is per-annulus.

(iv) Expansions about points other than the singularity work the same way. For $\frac{1}{z(z-2)}$ about $z_0 = 1$: writing $\zeta = z - 1$,

$$\frac{1}{z(z-2)} = \frac{1}{(\zeta+1)(\zeta-1)} = \frac{1}{\zeta^2-1} = -(1 + \zeta^2 + \zeta^4 + \cdots) \quad (|\zeta| < 1)$$

– a Taylor series, no negative powers, since the function is analytic at $z = 1$; the nearest singularities (at 0 and 2) set the radius of convergence to 1. In the outer region $|\zeta| > 1$ we would instead expand in $\frac{1}{\zeta}$ and find only negative powers.

§11.5.2 Zeros and the Classification of Singularities

Definition 11.5.5 (Order of a Zero)

A **zero** of an analytic function f is a point with $f(z_0) = 0$. Its **order** is the index of the first non-vanishing Taylor coefficient at z_0 ; a zero of order 1 is called **simple**.

So $z^3 + iz = z(z^2 + i)$ has a simple zero at the origin (and at the two square roots of $-i$), and $\sinh^3 z$ has a zero of order 3 at $z = n\pi i$ for each $n \in \mathbb{Z}$. Zeros of order k look locally like $c(z - z_0)^k$.

Definition 11.5.6 (Isolated Singularity)

If f is analytic on a punctured neighbourhood $0 < |z - z_0| < r$ of z_0 but not at z_0 itself, then z_0 is an **isolated singularity** of f .

Branch points are the standard example of *non-isolated* singularities in this course – there is no punctured neighbourhood of a branch point on which the function is even single-valued, so no Laurent expansion exists there. At an isolated singularity, however, we have a Laurent series, and we classify the singularity by how badly the series fails to be a Taylor series. Suppose $f(z) = \sum_{n=-\infty}^{\infty} a_n(z - z_0)^n$ on $0 < |z - z_0| < r$.

- (i) If $a_n = 0$ for all $n < 0$, then z_0 is a **removable singularity**: defining $f(z_0) = a_0$ extends f analytically across z_0 . Example: $\frac{\sin z}{z}$ at 0.
- (ii) If $a_n = 0$ for $n < -N$ but $a_{-N} \neq 0$ (some $N \geq 1$), then z_0 is a **pole of order N** . Poles of order 1, 2, 3 are called *simple*, *double*, *triple*. Example: $\frac{e^z}{z^3}$ has a triple pole at 0, as we computed. Near a pole, $|f(z)| \rightarrow \infty$.
- (iii) Otherwise – infinitely many negative coefficients – z_0 is an **essential singularity**. Example: $e^{1/z}$ at 0.

Poles are the well-behaved singularities, and essentially all singularities met in this course are poles. Note f has a pole of order N at z_0 exactly when $\frac{1}{f}$ has a zero of order N there (poles of f are zeros of $1/f$ and vice versa), which is usually the fastest way to find the order of a pole: for instance $\frac{1}{\sinh^3 z}$ has a triple pole at each $z = n\pi i$.

Essential singularities are genuinely wild: in any neighbourhood of an essential singularity, f takes values arbitrarily close to *every* complex number (Casorati–Weierstrass; Picard proved the stronger statement that it takes every value with at most one exception, infinitely often). We will treat this as a good reason to stay away from them.

Let's practice the classification – this is the sort of thing one must be able to do at sight.

Example 11.5.7 (Classifying Singularities) (i) $\frac{z}{\sin z}$: at $z = 0$, both numerator and denominator have simple zeros, so the singularity is *removable* (with value 1). At $z = n\pi$ for $n \neq 0$, the denominator has a simple zero and the numerator

doesn't vanish: *simple poles*.

- (ii) $\tan z = \frac{\sin z}{\cos z}$: simple poles at the zeros $(n + \frac{1}{2})\pi$ of $\cos$, each with residue $\frac{\sin z}{-\sin z} = -1$ by the $\frac{g}{h'}$ rule (coming shortly).
- (iii) $\frac{\cos z - 1}{z^4}$: the numerator has a *double* zero at 0 (its series starts at $-\frac{z^2}{2}$), so this is a double pole, with Laurent series $-\frac{1}{2z^2} + \frac{1}{24} - \dots$. Note the residue is 0 – poles can have zero residue.
- (iv) $\sin \frac{1}{z}$: essential singularity at 0 (the Laurent series $\frac{1}{z} - \frac{1}{3!z^3} + \dots$ has infinitely many negative terms).
- (v) $\frac{1}{\sin(1/z)}$: this has simple poles at $z = \frac{1}{n\pi}$, which *accumulate* at 0. So $z = 0$ is a singularity but not an isolated one – there is no punctured disc around 0 free of other singularities – and it is therefore none of the three types. No Laurent series about 0 exists.

Remark (Behaviour at Infinity). As always, we classify the point at infinity by looking at $f(1/z)$ at 0. A polynomial of degree n has a pole of order n at ∞ ; a rational function is analytic at ∞ iff its denominator degree is at least its numerator degree; and e^z has an *essential* singularity at ∞ (as $e^{1/z}$ does at 0) – which is one way to understand why e^z attains every non-zero value in every half-plane $\operatorname{Re} z > R$.

§11.5.3 Residues

For the applications, one Laurent coefficient towers above the rest in importance.

Definition 11.5.8 (Residue)

The **residue** of f at an isolated singularity z_0 is the coefficient a_{-1} of its Laurent expansion about z_0 , written $\operatorname{Res}_{z=z_0} f(z)$.

Why single out a_{-1} ? Integrate the Laurent series term by term around a small circle about z_0 : by our fundamental computation, every term dies except the $\frac{1}{z-z_0}$ term, and

$$\oint f(z) \, dz = 2\pi i a_{-1}.$$

So the residue is exactly what survives integration. This observation *is* the residue theorem, up to bookkeeping; but before stating it, let's build the toolkit for computing residues without ever writing down a full Laurent expansion.

Proposition 11.5.9 (Computing Residues)

Let z_0 be a pole of f .

- (i) If the Laurent series is available or easy, read off a_{-1} .
- (ii) If z_0 is a simple pole,

$$\operatorname{Res}_{z=z_0} f(z) = \lim_{z \rightarrow z_0} (z - z_0) f(z).$$

(iii) If $f = \frac{g}{h}$ with $g(z_0) \neq 0$ and h having a simple zero at z_0 , then

$$\operatorname{Res}_{z=z_0} f(z) = \frac{g(z_0)}{h'(z_0)}.$$

(iv) If z_0 is a pole of order N ,

$$\operatorname{Res}_{z=z_0} f(z) = \lim_{z \rightarrow z_0} \frac{1}{(N-1)!} \frac{d^{N-1}}{dz^{N-1}} \left((z - z_0)^N f(z) \right).$$

Proof. For (ii) and (iv), write out the Laurent series: $(z - z_0)^N f(z) = a_{-N} + a_{-N+1}(z - z_0) + \dots$ is analytic at z_0 , and differentiating $N - 1$ times and evaluating at z_0 isolates $(N - 1)! a_{-1}$. For (iii), note

$$\lim_{z \rightarrow z_0} (z - z_0) \frac{g(z)}{h(z)} = g(z_0) \lim_{z \rightarrow z_0} \frac{z - z_0}{h(z) - h(z_0)} = \frac{g(z_0)}{h'(z_0)}. \quad \square$$

Method (iii) is used more than all the others combined. A quick gallery:

Example 11.5.10 (Computing Residues) (i) $\frac{e^z}{z^3}$ at $z = 0$: from the Laurent series above, the residue is $\frac{1}{2}$.

(ii) $\frac{1}{1+z^4}$ at $z_0 = e^{i\pi/4}$: by (iii), the residue is $\frac{1}{4z_0^3} = \frac{z_0}{4z_0^4} = -\frac{1}{4}e^{i\pi/4}$. (Multiplying top and bottom by z_0 to use $z_0^4 = -1$ is a trick worth remembering.)

(iii) $\frac{e^{iz}}{\sinh z}$ at $z = \pi i$: $\sinh$ has a simple zero there, so by (iii) the residue is $\frac{e^{i\pi i}}{\cosh \pi i} = \frac{e^{-\pi}}{\cos \pi} = -e^{-\pi}$.

(iv) $\frac{1}{(z^2 + a^2)^2}$ at $z = ia$ (a double pole, $a > 0$): by (iv),

$$\operatorname{Res} = \lim_{z \rightarrow ia} \frac{d}{dz} \frac{1}{(z + ia)^2} = \frac{-2}{(2ia)^3} = -\frac{i}{4a^3}.$$

(v) Essential singularities have residues too – the definition only needs the Laurent coefficient – but the pole formulas above do not apply, and one must go back to the series. For instance $e^{1/z}$ has residue 1 at the origin (the $n = 1$ term of $\sum \frac{z^{-n}}{n!}$), and $ze^{1/z}$, whose expansion $z + 1 + \frac{1}{2z} + \dots$ has residue $\frac{1}{2}$.

§11.6 The Calculus of Residues

This section contains the computational heart of the course. The residue theorem turns the evaluation of contour integrals into the algebra of computing residues – and with the right contours, an enormous variety of *real* integrals fall to it. The section is essentially a sequence of worked examples, each illustrating a standard contour or trick; between them they cover everything that appears on example sheets and exams.

§11.6.1 The Residue Theorem

Theorem 11.6.1 (Residue Theorem)

Let f be analytic on and inside a simple closed contour γ (traversed anticlockwise), except at finitely many isolated singularities $z_1, \dots, z_n$ inside γ . Then

$$\oint_{\gamma} f(z) \, dz = 2\pi i \sum_{k=1}^n \operatorname{Res}_{z=z_k} f(z).$$

Proof. Deform γ , without crossing any singularity, into small circles γ_k around each z_k joined by cross-cuts (the cross-cut contributions cancel in pairs as they narrow, exactly as in the proof of contour deformation). This gives

$$\oint_{\gamma} f(z) \, dz = \sum_{k=1}^n \oint_{\gamma_k} f(z) \, dz.$$

On each small circle, integrate the Laurent expansion of f about z_k term by term: every power of $(z - z_k)$ integrates to zero except the (-1) -th, which gives $2\pi i a_{-1} = 2\pi i \operatorname{Res}_{z=z_k} f$. $\square$

A fully rigorous version of this argument (with winding numbers, and without the appeal to pictures) is in my Complex Analysis notes. For this course, the picture *is* the point: the integral around γ only sees the singularities inside, each contributing $2\pi i$ times its residue.

Everything else in this section is technique for *choosing* γ .

§11.6.2 Integrals Along the Real Axis

The prototype problem: evaluate $\int_{-\infty}^{\infty} f(x) \, dx$ for a rational function f decaying at infinity. The strategy is to ‘close the contour’: integrate $f(z)$ around the contour consisting of the real segment $[-R, R]$ together with the semicircle γ_R of radius R in the upper half-plane, apply the residue theorem, and let $R \rightarrow \infty$, arguing that the semicircle’s contribution dies.

Example 11.6.2 (The Prototype)

Let's evaluate

$$I = \int_0^{\infty} \frac{dx}{1+x^2}.$$

Of course we know the answer is $\arctan \infty = \frac{\pi}{2}$; the point is to establish the method

on familiar ground. Consider

$$\oint_{\gamma} \frac{dz}{1+z^2}$$

around the contour above. The integrand factors as $\frac{1}{(z-i)(z+i)}$, so the only enclosed singularity is the simple pole at $z = i$, with residue $\frac{1}{2i}$. The residue theorem gives, for all $R > 1$,

$$\int_{\gamma_0} \frac{dz}{1+z^2} + \int_{\gamma_R} \frac{dz}{1+z^2} = 2\pi i \cdot \frac{1}{2i} = \pi.$$

As $R \rightarrow \infty$, the first integral tends to $\int_{-\infty}^{\infty} \frac{dx}{1+x^2} = 2I$ by evenness. For the second, on γ_R we have $|1+z^2| \geq R^2 - 1$, so by the estimation lemma

$$\left| \int_{\gamma_R} \frac{dz}{1+z^2} \right| \leq \frac{\pi R}{R^2 - 1} \rightarrow 0.$$

Hence $2I = \pi$, so $I = \frac{\pi}{2}$ as expected.

Some remarks before the next examples, all of them important for practice:

- (i) The informal version of the tail estimate, universally used: on γ_R , the integrand is $O(R^{-2})$ and the contour has length πR , so the integral is $O(R^{-1}) \rightarrow 0$. Any rational function with denominator degree exceeding numerator degree by at least 2 dies this way.
- (ii) We could equally have closed in the *lower* half-plane. The enclosed pole is then $-i$ with residue $-\frac{1}{2i}$, but the contour is traversed clockwise, contributing a compensating sign: same answer. Close wherever the estimate works; when both work, pick whichever contains nicer poles.
- (iii) The method's value is its generality – replace $1+x^2$ by $1+x^8$ and the trigonometric substitution collapses, but the contour argument goes through verbatim.

Example 11.6.3 (A Double Pole)

For $a > 0$,

$$\int_0^{\infty} \frac{dx}{(x^2 + a^2)^2}.$$

Same contour. The only enclosed singularity is the *double* pole at $z = ia$, whose residue we computed in Section 5: $-\frac{i}{4a^3}$. The semicircle integrand is $O(R^{-4})$, so its integral is $O(R^{-3}) \rightarrow 0$, and

$$2I = 2\pi i \left(-\frac{i}{4a^3} \right) = \frac{\pi}{2a^3}, \quad I = \frac{\pi}{4a^3}.$$

Example 11.6.4 (Choosing a Cleverer Contour)

Consider

$$I = \int_0^{\infty} \frac{dx}{1+x^4}.$$

The semicircular contour works: the enclosed poles are $e^{i\pi/4}$ and $e^{3i\pi/4}$, with residues

$-\frac{1}{4}e^{i\pi/4}$ and $-\frac{1}{4}e^{3i\pi/4}$ (using the $\frac{g}{h}$ formula and the $z_0^4 = -1$ trick), giving after a little algebra $I = \frac{\pi}{2\sqrt{2}}$.

But since the integrand has the symmetry $f(iz) = f(z)$, there is a slicker choice: the quarter-circle contour $0 \rightarrow R \rightarrow iR \rightarrow 0$ (out along the real axis, around the arc, back down the imaginary axis). The return leg contributes, substituting $z = iy$,

$$\int_R^0 \frac{i \, dy}{1 + y^4} \rightarrow -iI,$$

the arc dies as usual, and only the single pole $e^{i\pi/4}$ is enclosed. So

$$(1 - i)I = 2\pi i \left(-\frac{1}{4}e^{i\pi/4}\right), \quad I = \frac{-\frac{\pi i}{2}e^{i\pi/4}}{1 - i} = \frac{\pi}{2\sqrt{2}},$$

with less residue arithmetic. Matching the contour to the symmetry of the integrand is a recurring theme.

Example 11.6.5 (A Wedge Contour)

The quarter-circle idea generalises to any integrand with a rotational symmetry. Consider

$$I = \int_0^\infty \frac{dx}{1 + x^3}.$$

(Note we *cannot* close a semicircle here: the integrand is not even, so $\int_{-\infty}^\infty$ is not $2I$ – indeed the integrand has a pole at $x = -1$ on the negative real axis.) The symmetry is $z \mapsto e^{2\pi i/3}z$, which permutes the poles and fixes the integrand. So take the wedge contour: out along the real axis to R , around the arc of angle $\frac{2\pi}{3}$, and back along the ray $\arg z = \frac{2\pi}{3}$. On the returning ray, $z = e^{2\pi i/3}t$ gives $1 + z^3 = 1 + t^3$ and $dz = e^{2\pi i/3} dt$, so that leg contributes $-e^{2\pi i/3}I$; the arc dies as $O(R^{-2})$.

The wedge encloses exactly one pole, $z_0 = e^{i\pi/3}$, with residue $\frac{1}{3z_0^2} = \frac{z_0}{3z_0^3} = -\frac{z_0}{3}$. Hence

$$(1 - e^{2\pi i/3})I = -\frac{2\pi i}{3}e^{i\pi/3},$$

and factoring $1 - e^{2\pi i/3} = -e^{i\pi/3}(e^{i\pi/3} - e^{-i\pi/3}) = -2ie^{i\pi/3} \sin \frac{\pi}{3}$,

$$I = \frac{\pi/3}{\sin(\pi/3)} = \frac{2\pi}{3\sqrt{3}}.$$

The same wedge of angle $\frac{2\pi}{n}$ handles $\int_0^\infty \frac{dx}{1+x^n}$ for any $n \geq 2$, giving $\frac{\pi/n}{\sin(\pi/n)}$.

Example 11.6.6 (The Fresnel Integrals)

A wedge can rotate an integral onto an axis where it becomes elementary, even with *no poles at all*. The Fresnel integrals

$$\int_0^\infty \cos(x^2) \, dx \quad \text{and} \quad \int_0^\infty \sin(x^2) \, dx$$

(which converge, delicately, by the increasingly rapid oscillation) are the real and imaginary parts of $\int_0^\infty e^{ix^2} dx$. Integrate the *entire* function e^{iz^2} around the wedge of angle $\frac{\pi}{4}$: out to R , around the arc, and back along the ray $z = e^{i\pi/4}t$. Cauchy's theorem says the total is zero.

The point of the angle $\frac{\pi}{4}$: on the returning ray, $z^2 = it^2$, so

$$e^{iz^2} = e^{i \cdot it^2} = e^{-t^2},$$

and the wild oscillatory integrand becomes the Gaussian. The ray leg contributes $-e^{i\pi/4} \int_0^R e^{-t^2} dt$. On the arc, $|e^{iz^2}| = e^{-R^2 \sin 2\theta}$, and the Jordan-style bound $\sin 2\theta \geq \frac{4\theta}{\pi}$ on $[0, \frac{\pi}{4}]$ gives

$$\left| \int_{\text{arc}} \right| \leq R \int_0^{\pi/4} e^{-4R^2\theta/\pi} d\theta \leq \frac{\pi}{4R} \rightarrow 0.$$

Hence, letting $R \rightarrow \infty$ and using $\int_0^\infty e^{-t^2} dt = \frac{\sqrt{\pi}}{2}$,

$$\int_0^\infty e^{ix^2} dx = e^{i\pi/4} \cdot \frac{\sqrt{\pi}}{2},$$

and separating real and imaginary parts,

$$\int_0^\infty \cos(x^2) dx = \int_0^\infty \sin(x^2) dx = \frac{1}{2} \sqrt{\frac{\pi}{2}}.$$

No residues were harmed in this example – the entire content of the calculation was the freedom to rotate the contour.

§11.6.3 Trigonometric Integrals

For integrals of a rational function of $\sin \theta$ and $\cos \theta$ over a full period, no limiting process is needed at all: the unit circle *is* the contour.

Substitute $z = e^{i\theta}$, so that as θ runs from 0 to 2π , z traverses the unit circle γ anticlockwise, and

$$\cos \theta = \frac{1}{2} \left(z + \frac{1}{z} \right), \quad \sin \theta = \frac{1}{2i} \left(z - \frac{1}{z} \right), \quad d\theta = \frac{dz}{iz}.$$

Example 11.6.7

For $a > 1$, let's compute

$$I = \int_0^{2\pi} \frac{d\theta}{a + \cos \theta}.$$

Substituting,

$$I = \oint_\gamma \frac{1}{a + \frac{1}{2}(z + z^{-1})} \frac{dz}{iz} = \frac{2}{i} \oint_\gamma \frac{dz}{z^2 + 2az + 1}.$$

The denominator has roots $z_\pm = -a \pm \sqrt{a^2 - 1}$, real, with $z_+ z_- = 1$; since $a > 1$ we

have $|z_-| > 1 > |z_+|$, so only z_+ is enclosed. Its residue is $\frac{1}{z_+ - z_-} = \frac{1}{2\sqrt{a^2 - 1}}$, and

$$I = \frac{2}{i} \cdot 2\pi i \cdot \frac{1}{2\sqrt{a^2 - 1}} = \frac{2\pi}{\sqrt{a^2 - 1}}.$$

Example 11.6.8 (The Poisson Kernel Integral)

For $|a| < 1$, let's compute

$$I = \int_0^{2\pi} \frac{d\theta}{1 - 2a \cos \theta + a^2},$$

which the reader may recognise as the normalisation of the Poisson kernel from IB Methods. The denominator factors beautifully after the substitution: since $1 - 2a \cos \theta + a^2 = (1 - ae^{i\theta})(1 - ae^{-i\theta})$,

$$I = \oint_{\gamma} \frac{1}{(1 - az)(1 - a/z)} \frac{dz}{iz} = \frac{1}{i} \oint_{\gamma} \frac{dz}{(1 - az)(z - a)}.$$

The integrand has simple poles at $z = a$ (inside the unit circle) and $z = \frac{1}{a}$ (outside) – note how the two poles are inversions of each other, mirroring the symmetry of the original expression. Only $z = a$ contributes:

$$I = \frac{1}{i} \cdot 2\pi i \cdot \frac{1}{1 - a^2} = \frac{2\pi}{1 - a^2}.$$

§11.6.4 Jordan's Lemma

Integrals like $\int \frac{\cos x}{1+x^2} dx$ bring a new difficulty. To use contour methods we must extend the integrand off the real axis, and the natural-looking extension $\frac{\cos z}{1+z^2}$ is a trap: $\cos z = \frac{e^{iz} + e^{-iz}}{2}$ grows exponentially as $\text{Im } z \rightarrow \pm\infty$ (in *both* half-planes!), so no closing semicircle can die. The correct move is to integrate $\frac{e^{iz}}{1+z^2}$, which is bounded in the upper half-plane since $|e^{iz}| = e^{-\text{Im } z}$, and take real parts at the end.

For decay of the semicircle we then need a slightly finer estimate than ‘length times sup’, because $|e^{iz}|$ is only small on *most* of the semicircle – near the real axis it is of size 1. The right tool:

Lemma 11.6.9 (Jordan's Lemma)

Let f be analytic in the upper half-plane apart from finitely many singularities, with $f(z) \rightarrow 0$ as $|z| \rightarrow \infty$. Then for any constant $\lambda > 0$,

$$\int_{\gamma_R} f(z) e^{i\lambda z} dz \rightarrow 0 \quad \text{as } R \rightarrow \infty,$$

where γ_R is the semicircle of radius R in the upper half-plane. For $\lambda < 0$ the same holds with the semicircle in the lower half-plane.

Proof. Parametrise $z = Re^{i\theta}$. The whole point is the bound $|e^{i\lambda z}| = e^{-\lambda R \sin \theta}$,

together with the elementary inequality $\sin \theta \geq \frac{2\theta}{\pi}$ on $[0, \frac{\pi}{2}]$ (the sine curve lies above its chord). Splitting the semicircle symmetrically and using this:

$$\begin{aligned} \left| \int_{\gamma_R} f(z) e^{i\lambda z} dz \right| &\leq R \sup_{z \in \gamma_R} |f(z)| \int_0^\pi e^{-\lambda R \sin \theta} d\theta \leq 2R \sup_{z \in \gamma_R} |f(z)| \int_0^{\pi/2} e^{-2\lambda R \theta / \pi} d\theta \\ &= \frac{\pi}{\lambda} (1 - e^{-\lambda R}) \sup_{z \in \gamma_R} |f(z)| \rightarrow 0, \end{aligned}$$

since $\sup_{\gamma_R} |f| \rightarrow 0$ by hypothesis. $\square$

The lesson to remember alongside the lemma: *the factor $e^{i\lambda z}$ decides which half-plane to close in* – upper for $\lambda > 0$, lower for $\lambda < 0$. If f decays like R^{-2} we don't need the lemma (crude estimation suffices), but when $f \sim R^{-1}$ – as for Fourier transforms of rational functions with degree gap 1 – Jordan's lemma is essential.

Example 11.6.10

For $\alpha > 0$, let's find

$$I = \int_0^\infty \frac{\cos \alpha x}{1+x^2} dx.$$

Close $\frac{e^{i\alpha z}}{1+z^2}$ in the upper half-plane (as $\alpha > 0$). The enclosed pole is $z = i$ with residue $\frac{e^{i\alpha \cdot i}}{2i} = \frac{e^{-\alpha}}{2i}$, so

$$\int_{-\infty}^\infty \frac{e^{i\alpha x}}{1+x^2} dx = 2\pi i \cdot \frac{e^{-\alpha}}{2i} = \pi e^{-\alpha}.$$

Taking real parts and halving (the integrand $\frac{\cos \alpha x}{1+x^2}$ is even; its companion $\frac{\sin \alpha x}{1+x^2}$ is odd, so the answer was real all along),

$$I = \frac{\pi}{2} e^{-\alpha}.$$

It is worth noticing the answer is *not analytic in α* at 0 – it is $\frac{\pi}{2} e^{-|\alpha|}$ for real α – a hint that something interesting (closing in opposite half-planes) happens as α changes sign.

Example 11.6.11 (Where Jordan is Genuinely Needed)

For $a > 0$, let's compute

$$I = \int_0^\infty \frac{x \sin x}{x^2 + a^2} dx.$$

Close $f(z)e^{iz}$ with $f(z) = \frac{z}{z^2+a^2}$ in the upper half-plane. This time $f \sim \frac{1}{R}$ on the arc, so the crude bound gives $\pi R \cdot O(R^{-1}) = O(1)$ – useless – and Jordan's lemma is doing real work. The enclosed pole is $z = ia$:

$$\int_{-\infty}^\infty \frac{x e^{ix}}{x^2 + a^2} dx = 2\pi i \operatorname{Res}_{z=ia} \frac{z e^{iz}}{z^2 + a^2} = 2\pi i \cdot \frac{ia e^{-a}}{2ia} = \pi i e^{-a}.$$

Taking imaginary parts and halving (the integrand is even),

$$I = \frac{\pi}{2} e^{-a}.$$

(The real part of the identity reads $\text{PV} \int \frac{x \cos x}{x^2 + a^2} dx = 0$, correct by oddness.)

§11.6.5 Indented Contours and Principal Values

Next complication: a pole *on* the contour. The classic example is

$$I = \int_{-\infty}^{\infty} \frac{\sin x}{x} dx.$$

The real integrand is perfectly finite at $x = 0$ (removable singularity), but the function we want to close with, $\frac{e^{iz}}{z}$, has a genuine pole at the origin, sitting exactly on our contour. The fix is to *indent*: walk along the real axis from $-R$ to $-\epsilon$, hop over the pole via a small semicircle C_ϵ in the upper half-plane, continue from ϵ to R , and close with the big semicircle C_R .

The small detour contributes something computable in the limit:

Lemma 11.6.12 (Indentation Lemma)

If f has a *simple* pole at z_0 , and C_ϵ is an arc of angular width ϕ on the circle $|z - z_0| = \epsilon$, traversed anticlockwise, then

$$\int_{C_\epsilon} f(z) dz \rightarrow i\phi \operatorname{Res}_{z=z_0} f(z) \quad \text{as } \epsilon \rightarrow 0.$$

Proof. Write $f(z) = \frac{a_{-1}}{z-z_0} + g(z)$ with g analytic near z_0 . The g part is bounded, so its integral is $O(\epsilon)$. Parametrising the principal part over the arc gives $a_{-1} \int i d\theta = i\phi a_{-1}$. $\square$

So a *semicircular* indentation picks up exactly *half* a residue, $\pm i\pi \operatorname{Res} f$ (sign according to direction). Note this is special to simple poles – for higher-order poles the indentation integral diverges, matching the fact that the corresponding principal value integrals genuinely diverge.

Example 11.6.13 (The Dirichlet Integral)

Continuing with $\int_{-\infty}^{\infty} \frac{\sin x}{x} dx$: the indented contour encloses *no* singularities, so by

Cauchy's theorem

$$\left(\int_{-R}^{-\epsilon} + \int_{\epsilon}^R \right) \frac{e^{ix}}{x} dx + \int_{C_\epsilon} \frac{e^{iz}}{z} dz + \int_{C_R} \frac{e^{iz}}{z} dz = 0.$$

The big arc dies by Jordan's lemma ($f(z) = \frac{1}{z} \rightarrow 0$, and note we genuinely need Jordan here – crude estimation gives $\pi R \cdot \frac{1}{R} \not\rightarrow 0$). The indentation is traversed *clockwise* over angle π , contributing $-i\pi \operatorname{Res}_{z=0} \frac{e^{iz}}{z} = -i\pi$ in the limit. Hence

$$\operatorname{PV} \int_{-\infty}^{\infty} \frac{e^{ix}}{x} dx = i\pi,$$

and taking imaginary parts,

$$\int_{-\infty}^{\infty} \frac{\sin x}{x} dx = \pi.$$

(The real part says $\operatorname{PV} \int \frac{\cos x}{x} dx = 0$, which is true by oddness – but only as a principal value, the symmetric limit $\lim_{\epsilon \rightarrow 0} (\int_{-\infty}^{-\epsilon} + \int_{\epsilon}^{\infty})$. For $\frac{\sin x}{x}$ the singularity is removable, so the principal value is an honest integral and no caveat is needed.)

The general bookkeeping is worth extracting from the example. Closing an indented contour and sending $\epsilon \rightarrow 0$ always yields, for simple poles *on* the (say, real-axis) contour,

$$\operatorname{PV} \int_{-\infty}^{\infty} f(x) dx = 2\pi i \sum_{\text{inside}} \operatorname{Res} f + \pi i \sum_{\text{on the contour}} \operatorname{Res} f$$

(when closing in the upper half-plane, with the arc dying) – poles sitting on the contour count with weight $\frac{1}{2}$, because the indentation walks half-way around them.

Example 11.6.14 (A Double Pole on the Axis, Almost)

Let's compute

$$\int_{-\infty}^{\infty} \frac{\sin^2 x}{x^2} dx.$$

Writing $\sin^2 x = \frac{1 - \cos 2x}{2}$, the natural complex extension is

$$f(z) = \frac{1 - e^{2iz}}{2z^2},$$

whose *real-axis* real part is our integrand. Although $\frac{1}{2z^2}$ suggests a double pole, the numerator vanishes at 0 too: expanding, $1 - e^{2iz} = -2iz + 2z^2 + \dots$, so

$$f(z) = -\frac{i}{z} + 1 + O(z),$$

a *simple* pole with residue $-i$. Close the indented contour in the upper half-plane; it encloses nothing, and the two pieces of f both die on the big arc ($\frac{1}{2z^2}$ crudely, $\frac{e^{2iz}}{2z^2}$ by Jordan or crudely too). The half-residue rule then gives

$$\operatorname{PV} \int_{-\infty}^{\infty} \frac{1 - e^{2ix}}{2x^2} dx = \pi i \cdot (-i) = \pi,$$

and taking real parts (the principal value is again an honest integral, the singularity of $\frac{\sin^2 x}{x^2}$ being removable),

$$\int_{-\infty}^{\infty} \frac{\sin^2 x}{x^2} dx = \pi.$$

Amusingly, this is the same value as $\int \frac{\sin x}{x} dx$ – a coincidence the reader may enjoy explaining via integration by parts.

§11.6.6 Integrals with Branch Cuts: the Keyhole Contour

Now for the technique promised in Section 2, where the discontinuity across a branch cut is turned from nuisance into tool. The standard problem: integrals of the form $\int_0^\infty x^\alpha R(x) dx$ with $\alpha \notin \mathbb{Z}$ and R rational.

The trick: integrate $z^\alpha R(z)$ with the branch cut along the *positive real axis* – right where we want to integrate! – using the branch $z^\alpha = r^\alpha e^{i\alpha\theta}$ with $\theta \in [0, 2\pi)$. Just above the cut, $z^\alpha \approx x^\alpha$; just below, $z^\alpha \approx x^\alpha e^{2\pi i\alpha}$. Because $\alpha \notin \mathbb{Z}$ these differ, so the two sides of the cut do *not* cancel – they combine to a non-zero multiple of the integral we want. The contour is the **keyhole**: a large circle C_R , a small circle C_ϵ around the branch point, and two straight legs hugging the cut from above and below.

Example 11.6.15 (A Keyhole Integral)

For $-1 < \alpha < 1$ (so that the integral converges at both ends), let's evaluate

$$I = \int_0^\infty \frac{x^\alpha}{1 + \sqrt{2}x + x^2} dx.$$

Integrate $f(z) = \frac{z^\alpha}{1 + \sqrt{2}z + z^2}$, with the branch of z^α fixed above, around the keyhole. Four pieces:

- On C_R : the integrand is $O(R^{\alpha-2})$ and the length is $O(R)$, so the integral is $O(R^{\alpha-1}) \rightarrow 0$, using $\alpha < 1$.
- On C_ϵ : integrand $O(\epsilon^\alpha)$, length $O(\epsilon)$, total $O(\epsilon^{\alpha+1}) \rightarrow 0$ since $\alpha > -1$.
- Just above the cut ($\theta = 0$): $\int_\epsilon^R \frac{x^\alpha dx}{1 + \sqrt{2}x + x^2} \rightarrow I$.
- Just below the cut ($\theta = 2\pi$, traversed right to left): $\int_R^\epsilon \frac{x^\alpha e^{2\pi i\alpha} dx}{1 + \sqrt{2}x + x^2} \rightarrow$

$$-e^{2\pi i\alpha} I.$$

So the whole contour integral tends to $(1 - e^{2\pi i\alpha})I$. The poles are the roots of $z^2 + \sqrt{2}z + 1$, namely $e^{3\pi i/4}$ and $e^{5\pi i/4}$ – and here the branch choice matters: the lower pole must be labelled $e^{5\pi i/4}$, *not* $e^{-3\pi i/4}$, since our θ lives in $[0, 2\pi)$, and using the wrong label produces the wrong value of z^α . By the $\frac{g}{h'}$ formula, with $h' = 2z + \sqrt{2}$ giving $h'(e^{3\pi i/4}) = \sqrt{2}i$ and $h'(e^{5\pi i/4}) = -\sqrt{2}i$, the residues are

$$\frac{e^{3\pi i\alpha/4}}{\sqrt{2}i}, \quad \frac{e^{5\pi i\alpha/4}}{-\sqrt{2}i}.$$

The residue theorem then gives

$$(1 - e^{2\pi i\alpha})I = \frac{2\pi i}{\sqrt{2}i} (e^{3\pi i\alpha/4} - e^{5\pi i\alpha/4}) = \sqrt{2}\pi e^{\pi i\alpha} (e^{-\pi i\alpha/4} - e^{\pi i\alpha/4}).$$

Writing $1 - e^{2\pi i\alpha} = -e^{\pi i\alpha}(e^{\pi i\alpha} - e^{-\pi i\alpha}) = -2ie^{\pi i\alpha} \sin \pi\alpha$ and the bracket as $-2i \sin \frac{\pi\alpha}{4}$,

$$I = \frac{\sqrt{2}\pi \sin(\pi\alpha/4)}{\sin \pi\alpha}.$$

As a sanity check, $\alpha \rightarrow 0$ gives $I \rightarrow \frac{\sqrt{2}\pi}{4} = \frac{\pi}{2\sqrt{2}}$, agreeing with $\int_0^\infty \frac{dx}{1+\sqrt{2}x+x^2}$ computed by completing the square.

Not every branch-cut integral needs the full keyhole. If the integral is over the whole real line, it is often enough to place the cut in the half-plane we are *not* closing in (e.g. cut along the negative imaginary axis and close upwards), so the closed contour never meets the cut at all. And for integrals against $\log x$, a useful alternative to the keyhole is a semicircular contour with the branch cut pointing downwards, comparing the contributions of $\log$ on the two halves of the real axis. Let's see this in action.

Example 11.6.16 (A Logarithmic Integral)

Let's evaluate

$$I = \int_0^\infty \frac{\log x}{1+x^2} dx.$$

Integrate $f(z) = \frac{\log z}{1+z^2}$ around the *indented semicircular* contour of the Dirichlet-integral example – along the real axis from $-R$ to R , hopping over the origin by a small semicircle, closed by the big upper semicircle – with the branch cut of $\log$ along the negative *imaginary* axis, $\theta \in (-\frac{\pi}{2}, \frac{3\pi}{2})$, so the cut stays clear of the contour.

The small arc contributes $O(\epsilon \log \frac{1}{\epsilon}) \rightarrow 0$ (the logarithmic singularity is too weak to matter – note this is different from the simple-pole indentations of before), and the big arc contributes $O(\frac{\log R}{R}) \rightarrow 0$. On the positive real axis, $\log z = \log x$; on the negative real axis, $z = x = |x|e^{i\pi}$ with our branch, so $\log z = \log |x| + i\pi$. Hence in the limit the contour integral equals

$$\int_0^\infty \frac{\log x}{1+x^2} dx + \int_0^\infty \frac{\log x + i\pi}{1+x^2} dx = 2I + i\pi \cdot \frac{\pi}{2}.$$

The enclosed pole is at $z = i = e^{i\pi/2}$, with residue

$$\frac{\log i}{2i} = \frac{i\pi/2}{2i} = \frac{\pi}{4},$$

so the residue theorem gives $2I + \frac{i\pi^2}{2} = 2\pi i \cdot \frac{\pi}{4} = \frac{i\pi^2}{2}$. The imaginary parts balance identically – a free consistency check on the branch bookkeeping – and

$$I = 0.$$

A surprising answer, but a correct one: substituting $x \mapsto \frac{1}{x}$ maps the integral to its own negative. The same contour with $\frac{\log z}{(1+z^2)^2}$ or $\frac{(\log z)^2}{1+z^2}$ gives genuinely non-zero values (e.g. $-\frac{\pi}{4}$ for the first), and the method is identical.

§11.6.7 Rectangular Contours

Semicircular contours fail for integrands built from cosh, sinh and friends: these are periodic in the *imaginary* direction, so a growing semicircle swallows more and more poles, and the arc never dies. The remedy is to respect the periodicity: use a *rectangle* of fixed height, chosen so that the top edge reproduces the bottom edge up to a constant factor.

Example 11.6.17

For $-1 < \alpha < 1$, let's compute

$$I = \int_{-\infty}^{\infty} \frac{e^{\alpha x}}{\cosh x} dx.$$

The poles of $\frac{1}{\cosh}$ sit at $z = (n + \frac{1}{2})\pi i$, an infinite ladder up the imaginary axis. Since $\cosh(z + \pi i) = -\cosh z$, we take the rectangle with corners $\pm R$, $\pm R + \pi i$, which encloses exactly one pole, at $\frac{\pi i}{2}$.

The bottom edge tends to I . The top edge, parametrised as $z = x + \pi i$ with x from R to $-R$, gives

$$\int_R^{-R} \frac{e^{\alpha x} e^{\alpha \pi i}}{-\cosh x} dx \rightarrow e^{\alpha \pi i} I,$$

the two sign changes (reversed direction, cosh flipping sign) cancelling. On the right-hand edge $z = R + iy$ we have the pleasant identity $|\cosh z|^2 = \sinh^2 R + \cos^2 y \geq \sinh^2 R$, so the integrand is $O(e^{(\alpha-1)R}) \rightarrow 0$ (here $\alpha < 1$ matters), and its integral over the fixed height π dies; similarly the left edge dies using $\alpha > -1$.

The enclosed residue, by the $\frac{g}{h}$ rule, is

$$\operatorname{Res}_{z=\pi i/2} \frac{e^{\alpha z}}{\cosh z} = \frac{e^{\alpha \pi i/2}}{\sinh \frac{\pi i}{2}} = \frac{e^{\alpha \pi i/2}}{i \sin \frac{\pi}{2}} = -ie^{\alpha \pi i/2}.$$

Assembling with the residue theorem:

$$(1 + e^{\alpha \pi i})I = 2\pi i \left(-ie^{\alpha \pi i/2}\right) = 2\pi e^{\alpha \pi i/2},$$

and dividing through by $e^{\alpha \pi i/2}$,

$$I(e^{-\alpha \pi i/2} + e^{\alpha \pi i/2}) = 2\pi \implies I = \frac{\pi}{\cos(\alpha \pi/2)}.$$

(Check: at $\alpha = 0$ this says $\int \frac{dx}{\cosh x} = \pi$, which is the classic $[2 \tan^{-1}(\tanh \frac{x}{2}) \cdot 2]$ computation – or just believe the contour.)

Example 11.6.18 (Summing a Series by Residues)

Rectangular (here square) contours can even sum series. Consider

$$\oint_{\gamma_N} \frac{\cot \pi z}{z^2} dz$$

where γ_N is the square with corners $(N + \frac{1}{2})(\pm 1 \pm i)$ – positioned so the sides pass between the poles of $\cot \pi z$, which lie at the integers. One can show $|\cot \pi z|$ is bounded on these squares uniformly in N (by $\coth \frac{\pi}{2}$, say: on the vertical sides $\cot \pi z$ reduces to $\mp \tanh \pi y$, and on the horizontal sides it is within $\coth \pi(N + \frac{1}{2})$ of $\mp i$), so the integral is $O(N^{-1}) \rightarrow 0$.

Meanwhile the residue theorem counts the poles inside: at each non-zero integer n , $\cot \pi z$ has a simple pole with residue $\frac{1}{\pi}$, contributing $\frac{1}{\pi n^2}$; and at $z = 0$ there is a triple pole with residue $-\frac{\pi}{3}$ (from $\cot \pi z = \frac{1}{\pi z} - \frac{\pi z}{3} - \dots$). Letting $N \rightarrow \infty$,

$$0 = 2\pi i \left(2 \sum_{n=1}^{\infty} \frac{1}{\pi n^2} - \frac{\pi}{3} \right) \implies \sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{6}.$$

This is, admittedly, an extravagant derivation of Euler's sum – but unlike most derivations it generalises instantly: the same contour applied to $\frac{\cot \pi z}{z^{2k}}$ evaluates $\sum n^{-2k}$ for every k .

Let's close the section by collecting the decision procedure, since in an exam the choice of contour *is* the question:

Integral looks like	Contour to reach for
$\int_{-\infty}^{\infty}$ (rational, decay ≥ 2)	semicircle, crude estimate
$\int_{-\infty}^{\infty}$ (rational) $\times e^{i\lambda x}$, $\cos$, $\sin$	semicircle ($e^{i\lambda z}$ version!), Jordan
$\int_0^{2\pi}$ (rational in $\cos \theta, \sin \theta$)	unit circle, $z = e^{i\theta}$
pole on the contour / PV	indent by a small semicircle: half-residues
$\int_0^{\infty} x^{\alpha} \times$ (rational), $\alpha \notin \mathbb{Z}$	keyhole around the positive real axis
$\int_0^{\infty} \log x \times$ (rational)	indented semicircle, or keyhole with $(\log z)^2$
$\cosh$, $\sinh$, $e^{\alpha x}$ in the integrand	rectangle of height matching the period
series $\sum f(n)$	square through half-integers, with $\cot \pi z$

In every case the workflow is the same four steps: choose the complex extension of the integrand (and branch, if needed); choose the contour; kill the unwanted pieces by estimation, Jordan or indentation lemmas; and count residues.

§11.7 Fourier Transforms

The last two sections of the course concern *transform theory*: the Fourier transform, which you met in IB Methods, and its cousin the Laplace transform, which you did not (for reasons that will become clear – its inversion formula is a contour integral). The new weapon of residue calculus lets us actually *compute* transforms and inverse transforms that were previously out of reach.

§11.7.1 Definition and Basic Properties

Definition 11.7.1 (Fourier Transform)

The **Fourier transform** of a function $f : \mathbb{R} \rightarrow \mathbb{C}$ (decaying suitably at $\pm\infty$) is

$$\tilde{f}(k) = \int_{-\infty}^{\infty} f(x) e^{-ikx} dx,$$

and the function is recovered by the **inverse transform**

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{f}(k) e^{ikx} dk.$$

(Conventions differ – the signs in the exponent and the placement of the 2π get shuffled between authors. Any statement you prove should survive a change of convention.) We write $\tilde{f} = \mathcal{F}(f)$, and when f is a function of time t the transform variable is traditionally called ω .

From IB Methods we recall the key properties, all following from elementary manipulations of the integral: the transform is linear, and

$$\mathcal{F}(f(x-a)) = e^{-ika} \tilde{f}(k), \quad \mathcal{F}(f(ax)) = \frac{1}{|a|} \tilde{f}\left(\frac{k}{a}\right), \quad \mathcal{F}(f'(x)) = ik \tilde{f}(k),$$

together with the convolution theorem $\mathcal{F}(f * g) = \tilde{f} \tilde{g}$. The derivative rule is the engine of applications: differential equations become algebraic equations in transform space.

There is one refinement of the inversion formula worth knowing. The correct general statement is

$$\frac{1}{2} (f(x^+) + f(x^-)) = \frac{1}{2\pi} \text{PV} \int_{-\infty}^{\infty} \tilde{f}(k) e^{ikx} dk :$$

at a jump discontinuity the inverse transform returns the *average* of the two one-sided values, and the integral needs only exist as a principal value, $\lim_{R \rightarrow \infty} \int_{-R}^R$. This is excellent news for us, because principal values at infinity are exactly what closing contours computes.

§11.7.2 Transforms via Contour Integration

Example 11.7.2 (The Gaussian)

Let $f(x) = e^{-x^2/2}$. Completing the square,

$$\tilde{f}(k) = \int_{-\infty}^{\infty} e^{-x^2/2 - ikx} dx = e^{-k^2/2} \int_{-\infty}^{\infty} e^{-(x+ik)^2/2} dx,$$

and the remaining integral is $\int e^{-z^2/2} dz$ along the horizontal line $\text{Im } z = k$. Since $e^{-z^2/2}$ is entire, we may shift this line down to the real axis: integrate around the rectangle with corners $\pm R$, $\pm R + ik$, note the vertical ends have integrand bounded by $e^{-(R^2 - k^2)/2} \rightarrow 0$, and apply Cauchy's theorem. So the integral equals $\int_{-\infty}^{\infty} e^{-x^2/2} dx = \sqrt{2\pi}$, giving

$$\tilde{f}(k) = \sqrt{2\pi} e^{-k^2/2}.$$

The Gaussian is (up to scaling) its own Fourier transform.

Example 11.7.3 (Inversion by Jordan's Lemma)

Let

$$f(x) = \begin{cases} e^{-ax} & x > 0 \\ 0 & x < 0 \end{cases}$$

for a constant $a > 0$. A direct computation gives $\tilde{f}(k) = \frac{1}{a + ik}$. Let's now run the inversion integral through our contour machinery and check we recover f :

$$f(x) = \frac{1}{2\pi} \text{PV} \int_{-\infty}^{\infty} \frac{e^{ikx}}{a + ik} dk.$$

The integrand, as a function of complex k , has a single simple pole at $k = ia$ (in the upper half-plane), and decays like $|k|^{-1}$ – too slowly for crude estimates, so Jordan's lemma it is. The factor e^{ikx} tells us where to close: upwards for $x > 0$, downwards for $x < 0$.

For $x > 0$, closing upwards encircles the pole:

$$f(x) = \frac{1}{2\pi} \cdot 2\pi i \text{Res}_{k=ia} \frac{e^{ikx}}{i(k - ia)} = e^{-ax}.$$

For $x < 0$, closing downwards encircles nothing, so $f(x) = 0$. And at the jump $x = 0$: the principal value gives $\frac{1}{2\pi} \text{PV} \int \frac{dk}{a + ik} = \frac{1}{2}$ (the $\frac{a}{a^2 + k^2}$ part integrates to π ; the odd part cancels) – precisely the average $\frac{f(0^+) + f(0^-)}{2}$, as the refined inversion formula promised.

This half-plane dichotomy – close up for positive ‘time’, down for negative – is the

mechanism behind causality in physical applications, and we are about to see it again as the reason Laplace transforms describe systems that start at $t = 0$.

Example 11.7.4 (The Lorentzian Pair)

For $a > 0$ consider $f(x) = e^{-a|x|}$. Directly,

$$\tilde{f}(k) = \int_{-\infty}^0 e^{(a-ik)x} dx + \int_0^{\infty} e^{-(a+ik)x} dx = \frac{1}{a-ik} + \frac{1}{a+ik} = \frac{2a}{a^2 + k^2},$$

the *Lorentzian*. Inverting by residues confirms the round trip: the inversion integrand $2a e^{ikx}/(k-ia)(k+ia)$ has poles at $\pm ia$, and for $x > 0$ we close upwards around $k = ia$,

$$f(x) = \frac{1}{2\pi} \cdot 2\pi i \cdot \frac{2a e^{-ax}}{2ia} = e^{-ax},$$

and for $x < 0$ close downwards around $k = -ia$ (collecting a sign for the clockwise direction) to get e^{ax} . So $f(x) = e^{-a|x|}$, as it should be. This pair is worth remembering: exponential decay in one domain corresponds to algebraic decay with poles at $\pm ia$ in the other, and the distance a of the pole from the real axis sets the decay rate.

Remark (Parseval's Identity). We recall from IB Methods, without proof, that

$$\int_{-\infty}^{\infty} |f(x)|^2 dx = \frac{1}{2\pi} \int_{-\infty}^{\infty} |\tilde{f}(k)|^2 dk.$$

Combined with residue-computed transforms this evaluates yet more real integrals: applying it to the pair above, for instance, gives $\int \frac{4a^2 dk}{(a^2+k^2)^2} = 2\pi \int e^{-2a|x|} dx = \frac{2\pi}{a}$, recovering our earlier result $\int_{-\infty}^{\infty} \frac{dk}{(k^2+a^2)^2} = \frac{\pi}{2a^3}$ with no contour at all.

§11.7.3 Solving Differential Equations

A quick reminder of the standard workflow from IB Methods, which transfers wholesale to this course. To solve a linear constant-coefficient equation, transform it, solve algebraically, and invert – with the inversion now done by residues where a table fails.

Example 11.7.5 (An ODE on the Real Line)

Let's find the decaying solution of

$$y'' - y = -f(x)$$

for given decaying f . Transforming, $-k^2 \tilde{y} - \tilde{y} = -\tilde{f}$, so

$$\tilde{y} = \frac{\tilde{f}(k)}{1+k^2},$$

and by the convolution theorem $y = f * g$ where g has transform $\frac{1}{1+k^2}$. We can find g by the same inversion technique as above: for $x > 0$ close upwards around the pole $k = i$,

$$g(x) = \frac{1}{2\pi} \cdot 2\pi i \cdot \frac{e^{i(i)x}}{2i} = \frac{1}{2} e^{-x},$$

and by symmetry $g(x) = \frac{1}{2}e^{-|x|}$ in general. So

$$y(x) = \frac{1}{2} \int_{-\infty}^{\infty} e^{-|x-x'|} f(x') \, dx',$$

which the reader may recognise as the Green's function solution from IB Methods – with the Green's function now produced by a residue rather than by patching boundary conditions.

The same scheme solves PDEs, transforming in one variable to leave an ODE in the others.

Example 11.7.6 (The Heat Equation on the Line)

Let's solve the diffusion equation on the whole line,

$$\frac{\partial u}{\partial t} = \kappa \frac{\partial^2 u}{\partial x^2}, \quad u(x, 0) = u_0(x),$$

by transforming in x . Writing $\tilde{u}(k, t)$ for the transform, the PDE becomes an ODE in t for each mode:

$$\frac{\partial \tilde{u}}{\partial t} = -\kappa k^2 \tilde{u} \quad \implies \quad \tilde{u}(k, t) = \tilde{u}_0(k) e^{-\kappa k^2 t}.$$

Each Fourier mode simply decays, at a rate growing like k^2 – diffusion is a low-pass filter. To return to real space, recognise the product as a convolution: we need the function whose transform is $e^{-\kappa k^2 t}$, which by our Gaussian computation (run backwards, with the scaling property) is

$$\frac{1}{\sqrt{4\pi\kappa t}} e^{-x^2/4\kappa t}.$$

Hence

$$u(x, t) = \frac{1}{\sqrt{4\pi\kappa t}} \int_{-\infty}^{\infty} e^{-(x-x')^2/4\kappa t} u_0(x') \, dx' :$$

the initial data smeared by a spreading Gaussian (the *heat kernel*), recovering the IB Methods result with the Gaussian transform now honestly derived by contour shifting.

For *initial value* problems in time – where the equation starts at $t = 0$ with prescribed data, rather than living on the whole line – the Laplace transform of the next section is the natural tool, and we will return to PDEs at the end of it.

§11.8 Laplace Transforms

The Fourier transform has two blind spots as a tool for differential equations. First, it requires decay: functions like e^t , or even the constant function 1, have no Fourier transform, so growing solutions are out of reach. Second, it has no natural slot for *initial conditions* – transforming an ODE on the whole line yields a particular solution with no arbitrary constants. The Laplace transform fixes both, at the modest price of only handling functions defined on $t \geq 0$.

Throughout this section, every function is implicitly zero for negative time: when we write $f(t) = e^t$ we mean $e^t H(t)$, where H is the Heaviside step function.

§11.8.1 Definition and First Examples

Definition 11.8.1 (Laplace Transform)

The **Laplace transform** of $f(t)$ (with $f(t) = 0$ for $t < 0$) is

$$\hat{f}(p) = \mathcal{L}(f)(p) = \int_0^\infty f(t)e^{-pt} dt,$$

defined for those p for which the integral converges – which includes all $\operatorname{Re} p$ sufficiently large provided f grows no faster than exponentially.

(The transform variable is called s at least as often as p .) Note the close kinship with the Fourier transform: formally $\hat{f}(p) = \tilde{f}(-ip)$. The exponential weight e^{-pt} with $\operatorname{Re} p$ large is what tames growing functions.

Example 11.8.2 (Basic Transforms)

All of the following are direct computations with the definition:

$$(i) \quad \mathcal{L}(1) = \int_0^\infty e^{-pt} dt = \frac{1}{p}.$$

$$(ii) \quad \mathcal{L}(t) = \frac{1}{p^2}, \text{ integrating by parts; more generally } \mathcal{L}(t^n) = \frac{n!}{p^{n+1}}.$$

$$(iii) \quad \mathcal{L}(e^{\lambda t}) = \int_0^\infty e^{(\lambda-p)t} dt = \frac{1}{p-\lambda}, \text{ valid for } \operatorname{Re} p > \operatorname{Re} \lambda.$$

$$(iv) \quad \text{Writing } \sin t = \frac{1}{2i}(e^{it} - e^{-it}) \text{ and using (iii) twice,}$$

$$\mathcal{L}(\sin t) = \frac{1}{2i} \left(\frac{1}{p-i} - \frac{1}{p+i} \right) = \frac{1}{p^2 + 1},$$

$$\text{and similarly } \mathcal{L}(\cos t) = \frac{p}{p^2 + 1}.$$

For reference (and revision), here is the resulting table, which together with the properties of the next subsection covers nearly everything met in practice:

$f(t)$	1	t^n	$e^{\lambda t}$	$\sin \omega t$	$\cos \omega t$	$t^{-1/2}$
$\hat{f}(p)$	$\frac{1}{p}$	$\frac{n!}{p^{n+1}}$	$\frac{1}{p-\lambda}$	$\frac{\omega}{p^2 + \omega^2}$	$\frac{p}{p^2 + \omega^2}$	$\sqrt{\frac{\pi}{p}}$

(The last entry, whose derivation is a Gaussian integral, will make a curious appearance when we meet branch cuts in the inversion formula.)

Each computation is initially valid only in some half-plane $\operatorname{Re} p > c$, but the resulting formulas – $\frac{1}{p}$, $\frac{1}{p-\lambda}$ and so on – are analytic functions on the whole plane minus their singularities. We henceforth regard $\hat{f}$ as defined everywhere by **analytic continuation**: same function, bigger domain. This matters because the inversion formula will want to roam over the whole p -plane and take residues at the singularities.

§11.8.2 Properties of the Laplace Transform

Proposition 11.8.3 (Properties of the Laplace Transform)

Let f have transform $\hat{f}(p)$. Then:

- (i) (Linearity) $\mathcal{L}(\alpha f + \beta g) = \alpha \hat{f} + \beta \hat{g}$.
- (ii) (Translation) $\mathcal{L}(f(t - t_0)H(t - t_0)) = e^{-pt_0} \hat{f}(p)$ for $t_0 > 0$.
- (iii) (Scaling) $\mathcal{L}(f(\lambda t)) = \frac{1}{\lambda} \hat{f}(p/\lambda)$ for $\lambda > 0$.
- (iv) (Shifting) $\mathcal{L}(e^{p_0 t} f(t)) = \hat{f}(p - p_0)$.
- (v) (Derivative of function) $\mathcal{L}(f'(t)) = p\hat{f}(p) - f(0)$, and iterating,

$$\mathcal{L}(f''(t)) = p^2 \hat{f}(p) - pf(0) - f'(0).$$
- (vi) (Derivative of transform) $\hat{f}'(p) = \mathcal{L}(-tf(t))$, and more generally we have $\hat{f}^{(n)}(p) = \mathcal{L}((-t)^n f(t))$.
- (vii) (Asymptotic limits) $p\hat{f}(p) \rightarrow f(0)$ as $p \rightarrow \infty$, and $p\hat{f}(p) \rightarrow f(\infty)$ as $p \rightarrow 0$ (when the latter limit exists).

Proof. Properties (i)–(iv) are immediate substitutions in the integral. For (v), integrate by parts:

$$\int_0^\infty f'(t)e^{-pt} dt = [f(t)e^{-pt}]_0^\infty + p \int_0^\infty f(t)e^{-pt} dt = p\hat{f}(p) - f(0).$$

For (vi), differentiate under the integral sign. For (vii), take $p \rightarrow \infty$ and $p \rightarrow 0$ respectively in the identity $p\hat{f}(p) = f(0) + \int_0^\infty f'(t)e^{-pt} dt$ from (v). $\square$

Property (v) is the whole reason the Laplace transform exists as a tool: differentiation becomes multiplication by p , and the initial conditions enter automatically. Compare the Fourier rule $\mathcal{F}(f') = ik\hat{f}$, which has no memory of $f(0)$.

Property (vi) is also worth appreciating as a computational device, read from right to left:

$$\mathcal{L}(t \sin t) = -\frac{d}{dp} \frac{1}{p^2 + 1} = \frac{2p}{(p^2 + 1)^2}.$$

Example 11.8.4 (A Timely Warning)

Property (ii) inserts a Heaviside function, and forgetting it is the classic error. For example

$$\mathcal{L}^{-1}\left(\frac{e^{-p}}{p^2}\right) = (t - 1)H(t - 1),$$

the ramp that switches on at $t = 1$ – not $(t - 1)$, which would be negative before then.

§11.8.3 The Inverse Laplace Transform

Now for the part that belongs to this course rather than to Methods. Inverting a Laplace transform is a contour integral along a vertical line.

Theorem 11.8.5 (Bromwich Inversion Formula)

Let $\hat{f}$ be the Laplace transform of f . Then

$$f(t) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \hat{f}(p) e^{pt} dp,$$

where the **Bromwich contour** $\operatorname{Re} p = c$ is a vertical line lying to the *right* of all singularities of $\hat{f}$.

Proof. This is Fourier inversion in disguise. Since f grows at most exponentially, choose c so large that $g(t) = f(t)e^{-ct}$ decays; then g has a Fourier transform, and

$$\tilde{g}(\omega) = \int_{-\infty}^{\infty} f(t)e^{-ct}e^{-i\omega t} dt = \hat{f}(c + i\omega),$$

using $f = 0$ for $t < 0$. Fourier inversion gives

$$f(t)e^{-ct} = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{f}(c + i\omega) e^{i\omega t} d\omega,$$

and substituting $p = c + i\omega$ (so $dp = i d\omega$) and multiplying by e^{ct} yields the formula. The condition on c ensures the half-plane $\operatorname{Re} p \geq c$ is free of singularities, which is what makes g decay – and, as we now see, what forces $f(t) = 0$ for $t < 0$. $\square$

In practice we do not integrate along the line directly; we close the contour and use residues.

Proposition 11.8.6 (Inversion by Residues)

Suppose $\hat{f}(p)$ has finitely many isolated singularities $p_1, \dots, p_n$ and $\hat{f}(p) \rightarrow 0$ as $|p| \rightarrow \infty$. Then for $t > 0$,

$$f(t) = \sum_{k=1}^n \operatorname{Res}_{p=p_k} (\hat{f}(p) e^{pt}),$$

and $f(t) = 0$ for $t < 0$.

Proof. The factor e^{pt} plays the role of $e^{i\lambda z}$ in Jordan's lemma, rotated a quarter turn: $|e^{pt}| = e^{t \operatorname{Re} p}$ is small where $t \operatorname{Re} p$ is very negative.

For $t < 0$, close the Bromwich contour with a large semicircle to the *right*, where $\operatorname{Re} p \geq c$ and so $|e^{pt}| \leq e^{ct}$. The closed contour encloses no singularities – they all lie to the left of the line – so the integral vanishes by Cauchy's theorem, and (the arc dying by the Jordan-type estimate) $f(t) = 0$. This is the promised consistency check: functions with Laplace transforms vanish for negative t , and it is the placement of the Bromwich line to the right of all singularities that encodes it.

For $t > 0$, close to the *left* instead. For R large enough the semicircle engulfs every singularity:

The arc integral tends to zero (crudely if $\hat{f} = o(|p|^{-1})$; by the Jordan-type estimate in general, using only $\hat{f} \rightarrow 0$), so the residue theorem applied to the closed contour gives

$$f(t) = \frac{1}{2\pi i} \cdot 2\pi i \sum_{k=1}^n \operatorname{Res}_{p=p_k} (\hat{f}(p)e^{pt}),$$

as claimed. $\square$

Example 11.8.7 (Recovering Old Friends) (i) $\hat{f}(p) = \frac{1}{p-1}$: a single simple pole at $p = 1$ (so take $c > 1$). For $t > 0$,

$$f(t) = \operatorname{Res}_{p=1} \frac{e^{pt}}{p-1} = e^t. \quad \checkmark$$

(ii) $\hat{f}(p) = p^{-n}$: a pole of order n at the origin. For $t > 0$,

$$f(t) = \operatorname{Res}_{p=0} \frac{e^{pt}}{p^n} = \lim_{p \rightarrow 0} \frac{1}{(n-1)!} \frac{d^{n-1}}{dp^{n-1}} e^{pt} = \frac{t^{n-1}}{(n-1)!}. \quad \checkmark$$

(iii) $\hat{f}(p) = \frac{1}{p^2 + \omega^2}$: simple poles at $\pm i\omega$, on the imaginary axis (so any $c > 0$ works). For $t > 0$,

$$f(t) = \frac{e^{i\omega t}}{2i\omega} + \frac{e^{-i\omega t}}{-2i\omega} = \frac{\sin \omega t}{\omega}. \quad \checkmark$$

Poles on the imaginary axis give pure oscillation – no decay, no growth – consistent with the pole-diagram picture we will draw below.

(iv) $\hat{f}(p) = \frac{e^{-p}}{p}$: here $\hat{f} \not\rightarrow 0$ in the left half-plane (the numerator e^{-p} blows up), so we must not blindly close and take residues. Instead absorb the exponential into the time variable: the Bromwich integrand is $\frac{e^{p(t-1)}}{p}$, so writing $t' = t - 1$ we close right for $t' < 0$ (getting 0) and left for $t' > 0$ (getting $\operatorname{Res}_{p=0} \frac{e^{pt'}}{p} = 1$). Thus $f(t) = H(t - 1)$, in accordance with the translation property.

What if $\hat{f}$ has a *branch point*? Then there is no annulus of analyticity, no Laurent series, no residue – and the contour must be reshaped so that it never crosses the cut. The standard geometry, for a branch point at the origin with cut along the negative real axis, is the *Bromwich keyhole*: close to the left, but detour along both sides of the cut and

around the branch point.

Example 11.8.8 (Inversion Through a Branch Cut)

Let's invert $\hat{f}(p) = p^{-1/2}$ (principal branch, cut along the negative real axis). Around the Bromwich keyhole the integrand $e^{pt}p^{-1/2}$ is analytic, so the integral over the whole closed contour vanishes; the large arcs die as before, and the little circle around the branch point contributes $O(\epsilon^{1/2}) \rightarrow 0$. So the Bromwich integral equals minus the contribution of the two legs along the cut.

Above the cut, $p = xe^{i\pi}$ with x running from ∞ to 0: there $p^{-1/2} = x^{-1/2}e^{-i\pi/2} = -ix^{-1/2}$ and $dp = -dx$. Below the cut, $p = xe^{-i\pi}$ with x from 0 to ∞ : there $p^{-1/2} = ix^{-1/2}$ and $dp = -dx$. Adding,

$$\begin{aligned} f(t) &= -\frac{1}{2\pi i} \left(\int_{\infty}^0 e^{-xt}(-ix^{-1/2})(-dx) + \int_0^{\infty} e^{-xt}(ix^{-1/2})(-dx) \right) \\ &= \frac{1}{\pi} \int_0^{\infty} e^{-xt} x^{-1/2} dx. \end{aligned}$$

Substituting $u = xt$, the integral is $t^{-1/2}\Gamma(\frac{1}{2}) = \sqrt{\pi/t}$, and so

$$f(t) = \frac{1}{\sqrt{\pi t}}.$$

This matches the known transform $\mathcal{L}(t^{-1/2}) = \sqrt{\pi/p}$. Notice the qualitative moral: poles of $\hat{f}$ produce exponentials $e^{p_k t}$ in f , while a branch cut produces a *continuum* of decaying exponentials – here giving algebraic decay $t^{-1/2}$, a behaviour no finite collection of poles could create.

§11.8.4 Solving Differential Equations

The Laplace transform converts ODEs (in t) into algebraic equations, and initial value problems are its natural habitat: the data $y(0), y'(0)$ are built into the derivative rule. The workflow is: transform, solve for $\hat{y}$, invert by residues (or partial fractions and the table).

Example 11.8.9 (A Damped Oscillator)

Let's solve

$$\ddot{y} + 2\dot{y} + 5y = 0, \quad y(0) = 1, \quad \dot{y}(0) = 1.$$

Transforming, using $\mathcal{L}(\ddot{y}) = p^2\hat{y} - py(0) - \dot{y}(0)$ and $\mathcal{L}(\dot{y}) = p\hat{y} - y(0)$:

$$(p^2 + 2p + 5)\hat{y} - p - 1 - 2 = 0 \implies \hat{y} = \frac{p+3}{p^2 + 2p + 5}.$$

The poles sit at the roots of $p^2 + 2p + 5$, namely $p_{\pm} = -1 \pm 2i$, and it is worth drawing them, because the pole diagram of $\hat{y}$ is a portrait of the solution: the real part of the poles (-1) is the decay rate, the imaginary part (± 2) the oscillation frequency.

Inverting by residues, for $t > 0$:

$$y(t) = \sum_{p_{\pm}} \text{Res} \frac{(p+3)e^{pt}}{(p-p_+)(p-p_-)} = \frac{(2+2i)e^{(-1+2i)t}}{4i} + \frac{(2-2i)e^{(-1-2i)t}}{-4i},$$

and combining the conjugate terms,

$$y(t) = e^{-t} (\cos 2t + \sin 2t).$$

A quick check: $y(0) = 1$, and $\dot{y}(0) = -1 + 2 = 1$. The pole diagram told us the form $e^{-t}(\dots \cos 2t + \dots \sin 2t)$ before we computed anything.

Example 11.8.10 (Switched-On Forcing)

The translation property makes forcing that switches on at a later time completely painless – a situation where classical ‘particular integral’ methods get awkward. Let's solve

$$\ddot{y} + 3\dot{y} + 2y = H(t-1), \quad y(0) = \dot{y}(0) = 0:$$

a system at rest, kicked by a constant force starting at $t = 1$. Transforming (the zero initial conditions keep things clean, and $\mathcal{L}(H(t-1)) = \frac{e^{-p}}{p}$ by translation):

$$(p^2 + 3p + 2)\hat{y} = \frac{e^{-p}}{p} \implies \hat{y} = \frac{e^{-p}}{p(p+1)(p+2)}.$$

First invert the rational part by partial fractions (or equally by residues at $0, -1, -2$):

$$\frac{1}{p(p+1)(p+2)} = \frac{1/2}{p} - \frac{1}{p+1} + \frac{1/2}{p+2} \implies g(t) = \frac{1}{2} - e^{-t} + \frac{1}{2}e^{-2t}.$$

Then the factor e^{-p} translates in time:

$$y(t) = g(t-1)H(t-1) = \left(\frac{1}{2} - e^{-(t-1)} + \frac{1}{2}e^{-2(t-1)}\right)H(t-1).$$

The solution is identically zero until the forcing arrives (causality again, automatic), rises smoothly, and settles to the static value $\frac{1}{2}$ forced by the equation as $t \rightarrow \infty$ – which we could have predicted from the transform alone via the asymptotic property: $p\hat{y}(p) \rightarrow \frac{1}{1.2} = \frac{1}{2}$ as $p \rightarrow 0$.

Example 11.8.11 (A Variable-Coefficient Equation)

The transform can even help when coefficients are polynomial in t , via the derivative-of-transform rule – the price is that multiplication by t becomes $-\frac{d}{dp}$, so we trade our ODE in t for an ODE in p ; the trade is worthwhile when the new equation is first order. Consider Laguerre's equation (with parameter 1),

$$t\ddot{y} + (1-t)\dot{y} + y = 0, \quad y(0) = 1.$$

Using $\mathcal{L}(tg(t)) = -\frac{d}{dp}\hat{g}(p)$ with $g = \ddot{y}$ and $g = \dot{y}$:

$$\begin{aligned}\mathcal{L}(t\dot{y}) &= -\frac{d}{dp}(p\hat{y} - y(0)) = -p\hat{y}' - \hat{y}, \\ \mathcal{L}(t\ddot{y}) &= -\frac{d}{dp}(p^2\hat{y} - py(0) - \dot{y}(0)) = -p^2\hat{y}' - 2p\hat{y} + y(0).\end{aligned}$$

Substituting into the equation, the initial-condition terms cancel and everything tidies down to

$$p(p-1)\hat{y}' = (2-p)\hat{y} \quad \implies \quad \frac{\hat{y}'}{\hat{y}} = \frac{2-p}{p(p-1)} = -\frac{2}{p} + \frac{1}{p-1},$$

by partial fractions. Integrating, $\log \hat{y} = -2 \log p + \log(p-1) + \text{const}$, i.e.

$$\hat{y} = C \frac{p-1}{p^2} = C \left(\frac{1}{p} - \frac{1}{p^2} \right)$$

for a constant of integration C . We can fix C from the asymptotic property (vii): $p\hat{y} = C(1 - \frac{1}{p}) \rightarrow C$ as $p \rightarrow \infty$, and this must equal $y(0) = 1$, so $C = 1$. Inverting term by term,

$$y(t) = 1 - t,$$

which indeed satisfies the equation: $t \cdot 0 + (1-t)(-1) + (1-t) = 0$. (This is the Laguerre polynomial L_1 ; the second, non-polynomial solution of the ODE grows too fast in a non-smooth way at the origin to be captured with these initial data.)

Example 11.8.12 (Systems of ODEs)

A linear system $\dot{\mathbf{x}} = M\mathbf{x}$ with $\mathbf{x}(0) = \mathbf{x}_0$ transforms to $p\hat{\mathbf{x}} - \mathbf{x}_0 = M\hat{\mathbf{x}}$, so

$$\hat{\mathbf{x}}(p) = (pI - M)^{-1}\mathbf{x}_0.$$

The entries of $(pI - M)^{-1}$ are rational with denominator $\det(pI - M)$: the poles of the transform are the *eigenvalues* of M , and inverting by residues recovers the usual expansion in modes $e^{\lambda_i t}$. Once again the pole locations are the physics.

§11.8.5 The Convolution Theorem

Definition 11.8.13 (Convolution)

The **convolution** of f and g is

$$(f * g)(t) = \int_{-\infty}^{\infty} f(t - t')g(t') \, dt',$$

which for functions vanishing on $t < 0$ reduces to $(f * g)(t) = \int_0^t f(t - t')g(t') \, dt'$.

Theorem 11.8.14 (Convolution Theorem)

$$\mathcal{L}(f * g) = \hat{f}(p) \hat{g}(p).$$

Proof. Write out the double integral and swap the order (both orders describe the wedge $0 \leq t' \leq t < \infty$ of the (t, t') plane):

$$\mathcal{L}(f * g)(p) = \int_0^\infty \int_0^t f(t - t')g(t')e^{-pt} \, dt' \, dt = \int_0^\infty g(t') \left(\int_{t'}^\infty f(t - t')e^{-pt} \, dt \right) dt'.$$

Substituting $u = t - t'$ in the inner integral factors it as $e^{-pt'} \hat{f}(p)$, and the remaining integral over t' gives $\hat{g}(p)$. $\square$

This is how forced systems are solved once and for all. If a system has *transfer function* $\frac{1}{Q(p)}$ – meaning the transform of the equation reads $Q(p)\hat{y} = \hat{f}$ for forcing f – then

$$y = (\mathcal{L}^{-1}(1/Q)) * f,$$

a single convolution against a kernel computed once by residues.

Remark (Impulses and Transfer Functions). The kernel $\mathcal{L}^{-1}(1/Q)$ has a physical name: the **impulse response**. Allowing the (IB Methods) delta function into the formalism, $\mathcal{L}(\delta(t - t_0)) = e^{-pt_0}$ for $t_0 \geq 0$, so in particular $\mathcal{L}(\delta) = 1$: an impulsive kick at $t = 0$ has transform 1, and the response it provokes – the Green's function $g = \mathcal{L}^{-1}(1/Q)$ – is what the convolution then smears over the actual forcing history. The pole diagram of the transfer function $\frac{1}{Q(p)}$ is precisely the engineer's stability picture: all poles in the left half-plane means every impulse response decays.

Example 11.8.15 (Forced Oscillator via Convolution)

Solve $\ddot{y} + y = f(t)$ with $y(0) = \dot{y}(0) = 0$, for arbitrary forcing f . Transforming, $(p^2 + 1)\hat{y} = \hat{f}$, so $\hat{y} = \frac{\hat{f}}{p^2 + 1}$. Since $\mathcal{L}^{-1}\left(\frac{1}{p^2 + 1}\right) = \sin t$,

$$y(t) = \int_0^t \sin(t - t')f(t') \, dt'.$$

This is exactly the Green's function solution of IB Methods, derived in three lines.

The convolution theorem also works as an *inversion* device, splitting a complicated transform into a convolution of simple ones.

Example 11.8.16

Let's find $\mathcal{L}^{-1}\left(\frac{1}{p^2(p^2+1)}\right)$. Rather than partial fractions or a fourth-order residue computation, write it as $\frac{1}{p^2} \cdot \frac{1}{p^2+1}$, the product of the transforms of t and $\sin t$. So the inverse is their convolution:

$$\int_0^t (t-t') \sin t' dt' = \left[-(t-t') \cos t' \right]_0^t - \int_0^t \cos t' dt' = t - \sin t.$$

(Partial fractions, $\frac{1}{p^2(p^2+1)} = \frac{1}{p^2} - \frac{1}{p^2+1}$, confirms this instantly – as usual there are several routes, and it pays to pick the shortest.)

§11.8.6 Solving PDEs with Transforms

Finally, let's see a transform dispose of a partial differential equation. The strategy: transform in *time*, reducing the PDE to an ODE in the spatial variable with p as a parameter; solve it; invert.

Example 11.8.17 (Waves on a Half-Line)

A semi-infinite string lies along $x \geq 0$, initially at rest ($u = u_t = 0$ at $t = 0$), and from time zero its end is waggled: $u(0, t) = f(t)$. The displacement obeys the wave equation

$$\frac{\partial^2 u}{\partial t^2} = c^2 \frac{\partial^2 u}{\partial x^2}.$$

Transform in t , writing $\hat{u}(x, p) = \mathcal{L}(u(x, \cdot))(p)$. The time derivatives become multiplications, and the zero initial conditions kill the boundary terms:

$$p^2 \hat{u} = c^2 \frac{\partial^2 \hat{u}}{\partial x^2}.$$

For each fixed p this is a constant-coefficient ODE in x , with general solution

$$\hat{u}(x, p) = A(p)e^{-px/c} + B(p)e^{px/c}.$$

For $\text{Re } p > 0$ the second solution grows as $x \rightarrow \infty$, so boundedness forces $B = 0$; the boundary condition gives $A(p) = \hat{f}(p)$. Hence

$$\hat{u}(x, p) = \hat{f}(p) e^{-px/c},$$

and we recognise the translation property from our table – no contour needed:

$$u(x, t) = f\left(t - \frac{x}{c}\right) H\left(t - \frac{x}{c}\right).$$

The physics falls out of the formula: the end's motion propagates rightward at speed c , and a point at distance x sits perfectly still until the signal arrives at time x/c .

Causality, which we built into the Laplace transform by fiat ($f = 0$ for $t < 0$), emerges in the solution. Had we transformed the heat equation instead, the same procedure would produce a $\sqrt{p}$ – and its branch point would send us back to the Bromwich keyhole. Since this is the last computation of the course, let's see it through.

Example 11.8.18 (Heat Conduction into a Half-Line)

A semi-infinite rod along $x \geq 0$ starts at temperature 0, and from $t = 0$ its end is held at constant temperature u_0 . The temperature obeys the heat equation $u_t = \kappa u_{xx}$. Transforming in t (zero initial data, so $\mathcal{L}(u_t) = p\hat{u}$):

$$p\hat{u} = \kappa \frac{\partial^2 \hat{u}}{\partial x^2} \implies \hat{u}(x, p) = \frac{u_0}{p} e^{-x\sqrt{p/\kappa}},$$

taking the branch of $\sqrt{p}$ positive on the positive real axis (cut along the negative real axis), discarding the growing solution $e^{+x\sqrt{p/\kappa}}$, and fitting the boundary condition $\hat{u}(0, p) = \frac{u_0}{p}$.

Now invert with the Bromwich keyhole. The pole at $p = 0$ sits at the branch point's doorstep; shrinking the little circle around it contributes its residue-like term $u_0 \cdot e^0 = u_0$ (on the small circle $e^{-x\sqrt{p/\kappa}} \rightarrow 1$, and $\frac{1}{2\pi i} \oint \frac{dp}{p} = 1$ counting the full loop). The two legs of the cut give, with $p = se^{\pm i\pi}$ so that $\sqrt{p} = \pm i\sqrt{s}$,

$$-\frac{u_0}{2\pi i} \int_0^\infty \frac{e^{-st}}{s} \left(e^{-ix\sqrt{s/\kappa}} - e^{ix\sqrt{s/\kappa}} \right) ds = -\frac{u_0}{\pi} \int_0^\infty \frac{e^{-st}}{s} \sin(x\sqrt{s/\kappa}) ds.$$

Substituting $s = \kappa v^2$ (so $\frac{ds}{s} = \frac{2dv}{v}$), the solution assembles as

$$u(x, t) = u_0 \left(1 - \frac{2}{\pi} \int_0^\infty e^{-\kappa v^2 t} \frac{\sin xv}{v} dv \right).$$

The remaining integral is a Gaussian classic. Writing $F(x) = \int_0^\infty e^{-\kappa v^2 t} \frac{\sin xv}{v} dv$ and differentiating under the integral sign,

$$F'(x) = \int_0^\infty e^{-\kappa v^2 t} \cos(xv) dv = \frac{1}{2} \sqrt{\frac{\pi}{\kappa t}} e^{-x^2/4\kappa t};$$

integrating back up from $F(0) = 0$ then yields $F(x) = \frac{\pi}{2} \operatorname{erf}\left(\frac{x}{2\sqrt{\kappa t}}\right)$, where $\operatorname{erf}(y) = \frac{2}{\sqrt{\pi}} \int_0^y e^{-w^2} dw$ is the error function. Hence

$$u(x, t) = u_0 \left(1 - \operatorname{erf}\left(\frac{x}{2\sqrt{\kappa t}}\right) \right) = u_0 \operatorname{erfc}\left(\frac{x}{2\sqrt{\kappa t}}\right).$$

Contrast this with the string: there is no wavefront – for any $t > 0$ the temperature is (slightly) positive at *every* x , and the solution depends on x and t only through the diffusive similarity variable $x/\sqrt{\kappa t}$. All of that physics was encoded in the branch cut: a continuum of decaying modes rather than a clean travelling pole.

And that is the course. Looking back, the through-line is a single idea: analyticity is rigidity, and rigidity is exploitable. The Cauchy–Riemann equations turned complex

functions into conformal maps and harmonic solvers; Cauchy's theorem turned integration into a game of counting singularities; and residues turned that game into a machine for real integrals, transforms, and differential equations. The Complex Analysis course makes all of this bulletproof; here, we have made it *work*.

12 Electromagnetism

Electromagnetism is the theory of two vector fields – the electric field and the magnetic field – and of the charges which produce them and are pushed around by them. Between them, these fields are responsible for very nearly every phenomenon we encounter that is not gravity: the binding of electrons to nuclei and of atoms into molecules, the rigidity of solid objects, chemistry, electricity, magnets, and light itself.

What makes the subject beautiful, rather than merely useful, is that all of this is encoded in *four* equations. Maxwell’s equations are a system of linear partial differential equations relating the fields to their sources, and essentially the whole of this course consists of finding and interpreting their solutions. We will start with the static solutions – stationary charges (electrostatics) and steady currents (magnetostatics) – where the equations decouple and a great deal can be computed by hand. We will then let things depend on time, at which point the electric and magnetic fields become inextricably linked: changing magnetic fields drive currents, and the equations acquire wave solutions which travel at precisely the speed of light. Finally we will discover that the whole structure is really a relativistic one. Written in the language of special relativity, Maxwell’s four equations collapse into two, and the magnetic field turns out to be nothing but the electric field seen by a moving observer.

This article constitutes my notes for the ‘Electromagnetism’ course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered. The reader is assumed to be comfortable with the vector calculus of the IA course – gradients, divergences, curls, and the integral theorems of Green, Stokes and Gauss¹. If you spot any errors or have any feedback, I can be contacted at ak2316@cam.ac.uk.

§12.1 Charges, Fields and Maxwell’s Equations

We begin by setting up the objects the theory is about. There are two kinds: the *sources*, which are electric charges and their motion, and the *fields*, which the sources produce and which in turn exert forces on the sources. The whole theory then amounts to two statements – a force law telling us how fields push charges, and Maxwell’s equations telling us how charges make fields.

§12.1.1 Charge and Charge Density

Every particle carries a number, its **electric charge**, which measures how strongly it couples to the electromagnetic force. Charge is measured in Coulombs, and in this course we will happily allow it to be any real number. This is a lie, but a harmless one: at the fundamental level charge is quantised, and every particle carries $q = ne$ for some $n \in \mathbb{Z}$, where

$$e \approx 1.6 \times 10^{-19} \text{ C}$$

¹The final section also uses special relativity at the level of the IA ‘Dynamics and Relativity’ course, though we will review everything we need.

is the charge on a proton. The electron has $n = -1$, the proton $n = +1$, the neutron $n = 0$. Since e is so tiny compared to the charges we deal with in practice, treating charge as a continuum is an excellent approximation, in exactly the same way that treating water as a continuous fluid is.

Rather than track individual particles, we therefore describe charge by a density.

Definition 12.1.1 (Charge density)

The **charge density** $\rho(\mathbf{x}, t)$ is the charge per unit volume, so that the total charge contained in a region $V \subseteq \mathbb{R}^3$ is

$$Q = \int_V \rho(\mathbf{x}, t) \, dV.$$

We will also want to consider idealised charge distributions which are concentrated on a surface, on a curve, or at a single point. In those cases the appropriate object is a charge per unit area σ , a charge per unit length η , or simply a charge Q together with a delta function. Which one is meant will always be clear from context.

§12.1.2 Current and Current Density

Charge that moves is a *current*. Again the natural object is a density.

Definition 12.1.2 (Current density)

The **current density** $\mathbf{J}(\mathbf{x}, t)$ is a vector field with the property that, for any surface S ,

$$I = \int_S \mathbf{J} \cdot d\mathbf{S}$$

is the charge crossing S per unit time. The number I is the **current** through S .

So $\mathbf{J}$ points in the direction that charge is flowing, and its magnitude is the current per unit area. If the charge density ρ is moving with velocity $\mathbf{v}(\mathbf{x}, t)$, then in time δt the charge crossing a small patch of area δA with unit normal $\hat{\mathbf{n}}$ is the charge in a slanted cylinder of volume $(\mathbf{v} \cdot \hat{\mathbf{n}})\delta A \delta t$, and so

$$\mathbf{J} = \rho \mathbf{v}.$$

This is worth remembering; it is the bridge between the field description and the particle description.

Example 12.1.3 (Current in a wire)

Consider a wire: a cylinder of cross-sectional area A containing n mobile electrons per unit volume, each of charge $q = -e$, all drifting along the wire with speed v . Then

$$\rho = nq = -ne, \quad \mathbf{J} = nq\mathbf{v}, \quad I = |nqvA| = nevA.$$

It is worth noting how slow this drift is in practice. For a copper wire of a square millimetre carrying an amp, v works out at less than a tenth of a millimetre per sec-

ond. The *signal* travels essentially at the speed of light, but the electrons themselves shuffle along at a snail's pace.

§12.1.3 Conservation of Charge

It is a fact of nature that charge cannot be created or destroyed. But this statement, as usually phrased, is much weaker than the truth. ‘The total charge in the universe is constant’ would permit a charge to vanish from Cambridge and simultaneously appear on the Moon. What actually happens is that charge is conserved *locally*: if the charge in some region decreases, it is because charge flowed out through the boundary.

The mathematical expression of this is a continuity equation, exactly as in the IA Vector Calculus course.

Law 12.1.4 (Continuity equation)

The charge density and current density satisfy

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J} = 0.$$

To see that this says what we claimed, fix a region V with boundary $S = \partial V$ and let $Q(t) = \int_V \rho \, dV$ be the charge inside. Then differentiating under the integral sign and applying the divergence theorem,

$$\frac{dQ}{dt} = \int_V \frac{\partial \rho}{\partial t} \, dV = - \int_V \nabla \cdot \mathbf{J} \, dV = - \int_S \mathbf{J} \cdot d\mathbf{S} = -I,$$

where I is the total current flowing out through S . In other words – the charge in V decreases at exactly the rate at which charge leaves through the boundary. Nothing teleports.

Taking $V = \mathbb{R}^3$ and assuming, as we always shall, that $\mathbf{J}$ decays at infinity, the surface term vanishes and we recover the global statement $dQ/dt = 0$. So local conservation implies global conservation, but not conversely.

§12.1.4 Fields and the Lorentz Force Law

In modern physics we do not believe in action at a distance. Instead, forces are mediated by *fields*: dynamical objects which assign a value to every point of space and time, and which carry energy and momentum in their own right. Electromagnetism has two of them,

$\mathbf{E}(\mathbf{x}, t)$ the **electric field**, $\mathbf{B}(\mathbf{x}, t)$ the **magnetic field**,

both vector fields on $\mathbb{R}^3$.

The fields interact with charges in two directions, and it is worth keeping the two firmly separate in one's head.

- Fields push charges. This is governed by the Lorentz force law.
- Charges make fields. This is governed by Maxwell's equations.

The first is quickly stated.

Law 12.1.5 (Lorentz force law)

A particle of charge q moving with velocity $\mathbf{v}$ in fields $\mathbf{E}$ and $\mathbf{B}$ experiences a force

$$\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}).$$

Two features deserve immediate comment. The electric part $q\mathbf{E}$ acts on a charge whether or not it is moving, and points along $\mathbf{E}$. The magnetic part $q\mathbf{v} \times \mathbf{B}$ acts only on moving charges, and is perpendicular to the velocity. In particular

$$\mathbf{F} \cdot \mathbf{v} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}) \cdot \mathbf{v} = q\mathbf{E} \cdot \mathbf{v},$$

so *magnetic fields do no work*. They can bend a particle's trajectory but never change its speed. Every bit of energy a charged particle gains comes from the electric field.

For a continuous distribution of charge rather than a single particle, we should integrate. A volume element dV carries charge ρdV moving with velocity $\mathbf{v}$, so it feels a force $(\rho\mathbf{E} + \rho\mathbf{v} \times \mathbf{B}) dV$, giving

$$\mathbf{F} = \int_V (\rho\mathbf{E} + \mathbf{J} \times \mathbf{B}) dV$$

using $\mathbf{J} = \rho\mathbf{v}$. We will use the magnetic half of this repeatedly when we compute forces between wires.

§12.1.5 Maxwell's Equations

Now for the other half of the story: how charges produce fields. Remarkably, the answer fits on one line each.

Law 12.1.6 (Maxwell's equations)

The electromagnetic fields produced by a charge density ρ and current density $\mathbf{J}$ obey

$$\nabla \cdot \mathbf{E} = \frac{\rho}{\epsilon_0}, \quad (\text{M1})$$

$$\nabla \cdot \mathbf{B} = 0, \quad (\text{M2})$$

$$\nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = \mathbf{0}, \quad (\text{M3})$$

$$\nabla \times \mathbf{B} - \mu_0 \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} = \mu_0 \mathbf{J}. \quad (\text{M4})$$

Here ϵ_0 and μ_0 are constants of nature, the **electric constant** and the **magnetic constant**^a, with numerical values

$$\epsilon_0 \approx 8.85 \times 10^{-12} \text{ m}^{-3} \text{ kg}^{-1} \text{ s}^2 \text{ C}^2, \quad \mu_0 = 4\pi \times 10^{-7} \text{ m kg C}^{-2}.$$

^aThese are also called the permittivity and permeability of free space, which sound more impressive but mean the same thing.

That is the entire content of classical electromagnetism. Everything that follows in this course – Coulomb's law, capacitors, solenoids, induction, light – is a consequence of these four equations together with the Lorentz force law. It is genuinely astonishing that so much should follow from so little, and the reader is encouraged to keep the equations somewhere visible while reading the rest of these notes.

A few structural remarks before we start solving them.

They are linear. If $(\mathbf{E}_1, \mathbf{B}_1)$ solves the equations with sources $(\rho_1, \mathbf{J}_1)$ and $(\mathbf{E}_2, \mathbf{B}_2)$ solves them with sources $(\rho_2, \mathbf{J}_2)$, then the sum solves them with the summed sources. This is the **principle of superposition**, and it is why electromagnetism is tractable at all. Of the four fundamental forces, it is the only one with this property.

They are inconsistent without the last term. Take the divergence of (M4). Since $\nabla \cdot (\nabla \times \mathbf{B}) = 0$ always,

$$0 = \mu_0 \epsilon_0 \frac{\partial}{\partial t} (\nabla \cdot \mathbf{E}) + \mu_0 \nabla \cdot \mathbf{J} = \mu_0 \left(\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J} \right),$$

where we used (M1) in the last step. So Maxwell's equations do not merely permit charge conservation – they *imply* it. We will see in Section 12.4.4 that had we written (M4) without the $\partial \mathbf{E} / \partial t$ term (which is what Ampère originally wrote), the same computation would have forced $\partial \rho / \partial t = 0$, which is plainly false. The extra term is Maxwell's, and it is also, as we shall see, the term responsible for light.

They come in pairs. Equations (M2) and (M3) contain no sources at all: they are constraints on the fields themselves, and they are exactly the conditions which allow us to introduce potentials. Equations (M1) and (M4) are the ones that say where the fields come from.

They have an integral form. Applying the integral theorems to each gives a statement with a direct physical reading; we will derive each in turn as we meet it, but for reference the four integral forms are

$$\begin{aligned} \int_{\partial V} \mathbf{E} \cdot d\mathbf{S} &= \frac{Q}{\epsilon_0}, & (\text{Gauss' law}) \\ \int_{\partial V} \mathbf{B} \cdot d\mathbf{S} &= 0, & (\text{no magnetic monopoles}) \\ \oint_{\partial S} \mathbf{E} \cdot d\mathbf{x} &= -\frac{d}{dt} \int_S \mathbf{B} \cdot d\mathbf{S}, & (\text{Faraday's law}) \\ \oint_{\partial S} \mathbf{B} \cdot d\mathbf{x} &= \mu_0 \int_S \mathbf{J} \cdot d\mathbf{S} + \mu_0 \epsilon_0 \frac{d}{dt} \int_S \mathbf{E} \cdot d\mathbf{S}. & (\text{Ampère's law}) \end{aligned}$$

The reader who has done the IA Vector Calculus course will have seen a version of this already; we now do the whole thing properly.

§12.1.6 The Static Limit

The most important simplification is to look for solutions which do not depend on time. Setting all time derivatives to zero, Maxwell's equations fall apart into two entirely independent systems:

$$\begin{cases} \nabla \cdot \mathbf{E} = \rho / \epsilon_0, \\ \nabla \times \mathbf{E} = \mathbf{0}, \end{cases} \quad \begin{cases} \nabla \cdot \mathbf{B} = 0, \\ \nabla \times \mathbf{B} = \mu_0 \mathbf{J}. \end{cases}$$

The first pair involves only $\mathbf{E}$ and ρ ; the second only $\mathbf{B}$ and $\mathbf{J}$. This is the sense in which electricity and magnetism are separate phenomena in the static world – they only become entangled once things start changing in time. Accordingly we spend the next two sections on **electrostatics** (stationary charges, $\rho = \rho(\mathbf{x})$, $\mathbf{J} = \mathbf{0}$) and **magnetostatics** (steady currents, $\rho = 0$, $\mathbf{J} = \mathbf{J}(\mathbf{x})$) respectively, and only afterwards let time back in.

§12.2 Electrostatics

In electrostatics nothing moves. We take $\mathbf{J} = \mathbf{0}$, we take $\rho = \rho(\mathbf{x})$ independent of time, and we look for a time-independent electric field with $\mathbf{B} = \mathbf{0}$. As we saw, the equations we have to solve are

$$\nabla \cdot \mathbf{E} = \frac{\rho}{\epsilon_0}, \quad \nabla \times \mathbf{E} = \mathbf{0},$$

and (M2) and (M4) are satisfied trivially. The goal of this section is to determine $\mathbf{E}$ from ρ : first in highly symmetric situations, where a single application of the divergence theorem does everything, and then in general.

§12.2.1 Gauss' Law

The integral form of (M1) is so useful that it gets its own name. Let V be a region with boundary $S = \partial V$. Integrating (M1) over V ,

$$\int_V \nabla \cdot \mathbf{E} \, dV = \frac{1}{\epsilon_0} \int_V \rho \, dV,$$

and applying the divergence theorem on the left gives the following.

Law 12.2.1 (Gauss' law)

For any closed surface S bounding a region V ,

$$\int_S \mathbf{E} \cdot d\mathbf{S} = \frac{Q}{\epsilon_0},$$

where $Q = \int_V \rho \, dV$ is the total charge enclosed by S .

Definition 12.2.2 (Flux)

The **flux** of $\mathbf{E}$ through a surface S is $\int_S \mathbf{E} \cdot d\mathbf{S}$.

Gauss' law says something slightly surprising. The flux out of S depends only on the charge *inside* S , and not at all on the charge outside. This is not to say that external charges make no field on S – of course they do – but their field lines enter through one part of the surface and leave through another, and the two contributions cancel exactly.

The reason Gauss' law is so powerful is that, when the charge distribution has enough symmetry, symmetry alone determines the direction of $\mathbf{E}$ and the surfaces on which $|\mathbf{E}|$ is constant. Gauss' law then determines the one remaining unknown function. Let's see this in action.

Example 12.2.3 (Coulomb's law)

Take a spherically symmetric charge distribution $\rho = \rho(r)$ with $\rho(r) = 0$ for $r > R$, so all the charge lies inside a ball of radius R , and let Q be the total charge. We take for S a sphere of radius $r > R$ centred at the origin.

By symmetry the field can only point radially and can only depend on r , so

$$\mathbf{E} = E(r)\hat{\mathbf{r}}.$$

(Note this automatically has $\nabla \times \mathbf{E} = \mathbf{0}$, so we need only worry about (M1).) The flux is then

$$\int_S \mathbf{E} \cdot d\mathbf{S} = \int_S E(r) \hat{\mathbf{r}} \cdot d\mathbf{S} = E(r) \cdot 4\pi r^2,$$

since $\hat{\mathbf{r}}$ is precisely the outward normal to S and $E(r)$ is constant on S . Gauss' law now gives $4\pi r^2 E(r) = Q/\epsilon_0$, so

$$\mathbf{E}(\mathbf{r}) = \frac{Q}{4\pi\epsilon_0 r^2} \hat{\mathbf{r}}, \quad r > R.$$

Combining with the Lorentz force law, a second charge q placed at $\mathbf{r}$ feels a force

$$\mathbf{F} = \frac{Qq}{4\pi\epsilon_0 r^2} \hat{\mathbf{r}},$$

which is **Coulomb's law**: an inverse square law, repulsive for like charges and attractive for unlike ones. It is worth pausing over the fact that we never needed to know $\rho(r)$, only the total charge Q . From outside, any spherically symmetric lump of charge is indistinguishable from a point charge at its centre.

Example 12.2.4 (Inside a uniformly charged ball)

Now take the charge to be uniformly spread through the ball,

$$\rho(r) = \begin{cases} \rho_0 & r < R, \\ 0 & r > R, \end{cases}$$

with total charge $Q = \frac{4}{3}\pi R^3 \rho_0$, and ask what happens *inside*. Take S to be a sphere of radius $r < R$.

The charge enclosed is now only Qr^3/R^3 , so Gauss' law reads

$$4\pi r^2 E(r) = \frac{Q}{\epsilon_0} \frac{r^3}{R^3},$$

giving

$$\mathbf{E}(\mathbf{r}) = \frac{Qr}{4\pi\epsilon_0 R^3} \hat{\mathbf{r}}, \quad r < R.$$

So inside the ball the field grows *linearly* with r , reaching its maximum on the surface $r = R$, where it matches continuously onto the exterior solution $Q/4\pi\epsilon_0 r^2$ found above. It vanishes at the centre, as it must by symmetry.

Example 12.2.5 (Line charge)

Consider an infinite straight line of charge along the z -axis, with uniform charge per unit length η . We use cylindrical polars (r, φ, z) .

By symmetry (translations along z , rotations about z , and reflection in any plane containing the axis) the field must be radial and depend only on r :

$$\mathbf{E} = E(r) \hat{\mathbf{r}}.$$

Take S to be a cylinder of radius r and length L about the axis. The end caps contribute nothing, since $\mathbf{E}$ is tangent to them, and the curved part has area $2\pi rL$ with outward normal $\hat{\mathbf{r}}$. So

$$\int_S \mathbf{E} \cdot d\mathbf{S} = 2\pi rL E(r) = \frac{\eta L}{\epsilon_0},$$

giving

$$\mathbf{E} = \frac{\eta}{2\pi\epsilon_0 r} \hat{\mathbf{r}}.$$

Note that the field falls off like $1/r$ rather than $1/r^2$. This is exactly what one should expect: we have one extra dimension's worth of charge contributing, so the field dies away more slowly.

Example 12.2.6 (Plane of charge)

Finally, let all the charge sit on the plane $z = 0$ with uniform charge per unit area σ .

By symmetry the field is vertical and depends only on z , and reflection in the plane forces it to be odd:

$$\mathbf{E} = E(z)\hat{\mathbf{z}}, \quad E(-z) = -E(z).$$

Take for S a cylinder (a ‘Gaussian pillbox’) of cross-sectional area A with its flat faces at heights $\pm z$. Now it is the curved side that contributes nothing, and the two caps that do:

$$\int_S \mathbf{E} \cdot d\mathbf{S} = E(z)A - E(-z)A = 2E(z)A = \frac{\sigma A}{\epsilon_0}.$$

Hence

$$E(z) = \frac{\sigma}{2\epsilon_0} \quad \text{for } z > 0,$$

which is *constant* – the field of an infinite charged plane does not decay at all. (Each successive dimension of charge costs us one power of r , and we have run out of powers.)

The last example exhibits an important general phenomenon: $\mathbf{E}$ jumps across a layer of surface charge. Here

$$E(0^+) - E(0^-) = \frac{\sigma}{\epsilon_0},$$

and this is not special to the plane.

Proposition 12.2.7 (Discontinuity across a surface charge)

Let S be a surface carrying surface charge density σ , with unit normal $\hat{\mathbf{n}}$ pointing

from the $-$ side to the $+$ side. Then

$$\hat{\mathbf{n}} \cdot \mathbf{E}_+ - \hat{\mathbf{n}} \cdot \mathbf{E}_- = \frac{\sigma}{\epsilon_0},$$

while the components of $\mathbf{E}$ tangential to S are continuous.

Proof. For the normal component, apply Gauss' law to a small pillbox straddling S , with flat faces of area δA parallel to S on either side, and then shrink the height of the pillbox to zero. The contribution of the curved side vanishes in the limit, the enclosed charge tends to $\sigma \delta A$, and the two faces contribute $(\hat{\mathbf{n}} \cdot \mathbf{E}_+ - \hat{\mathbf{n}} \cdot \mathbf{E}_-) \delta A$. Dividing by δA gives the result.

For the tangential component, use $\nabla \times \mathbf{E} = \mathbf{0}$ instead. Take a small rectangular loop C straddling S , with two sides of length $\delta \ell$ parallel to S (one either side) and two short sides crossing it, and let $\hat{\mathbf{t}}$ be the unit tangent along the long sides. By Stokes' theorem $\oint_C \mathbf{E} \cdot d\mathbf{x} = \int (\nabla \times \mathbf{E}) \cdot d\mathbf{S} = 0$. Shrinking the short sides to zero length leaves $(\hat{\mathbf{t}} \cdot \mathbf{E}_+ - \hat{\mathbf{t}} \cdot \mathbf{E}_-) \delta \ell = 0$, and since $\hat{\mathbf{t}}$ was an arbitrary tangent direction, the tangential components agree. $\square$

§12.2.2 The Electrostatic Potential

Symmetry will only take us so far. To handle a general ρ we must actually solve

$$\nabla \cdot \mathbf{E} = \frac{\rho}{\epsilon_0}, \quad \nabla \times \mathbf{E} = \mathbf{0}.$$

The trick, familiar from vector calculus, is that the second equation solves itself. A curl-free field on $\mathbb{R}^3$ (which is simply connected) is a gradient.

Definition 12.2.8 (Electrostatic potential)

If $\mathbf{E} = -\nabla\phi$, we call the scalar field ϕ the **electrostatic potential**.

The minus sign is a convention, and a sensible one: it makes ϕ agree with potential energy per unit charge, so that positive charges roll downhill. Substituting into (M1) turns the whole of electrostatics into a single scalar equation.

Proposition 12.2.9 (Poisson's equation)

The electrostatic potential satisfies

$$\nabla^2 \phi = -\frac{\rho}{\epsilon_0}.$$

In a region free of charge this reduces to **Laplace's equation** $\nabla^2 \phi = 0$.

Two remarks. First, ϕ is only determined up to an additive constant, since ∇ kills constants. We fix this in the usual way by demanding $\phi(\mathbf{r}) \rightarrow 0$ as $r \rightarrow \infty$, which is possible whenever the charge is confined to a bounded region. Secondly, Poisson's equation is linear, which is superposition again: the potential of a collection of charges is the sum of the individual potentials.

Poisson's equation was studied at length in the IA Vector Calculus course, and we will

lean on it heavily. The single most useful fact is the uniqueness theorem, which is worth recalling in full since we will use it to justify some outrageous-looking guesses later on.

Theorem 12.2.10 (Uniqueness for Poisson's equation)

Let V be a bounded region with boundary ∂V , and consider the problem

$$\nabla^2 \phi = -\frac{\rho}{\epsilon_0} \quad \text{in } V,$$

subject to either ϕ specified on ∂V (Dirichlet conditions) or $\partial\phi/\partial n = \hat{\mathbf{n}} \cdot \nabla \phi$ specified on ∂V (Neumann conditions). Then the solution is unique – in the Dirichlet case outright, and in the Neumann case up to an additive constant.

Proof. Suppose ϕ_1 and ϕ_2 are both solutions, and set $\psi = \phi_1 - \phi_2$. Then $\nabla^2 \psi = 0$ in V , and on ∂V we have either $\psi = 0$ (Dirichlet) or $\partial\psi/\partial n = 0$ (Neumann). Now consider

$$\int_V \nabla \cdot (\psi \nabla \psi) \, dV = \int_V (|\nabla \psi|^2 + \psi \nabla^2 \psi) \, dV = \int_V |\nabla \psi|^2 \, dV,$$

using harmonicity of ψ . On the other hand, by the divergence theorem the left hand side is

$$\int_{\partial V} \psi \nabla \psi \cdot d\mathbf{S} = \int_{\partial V} \psi \frac{\partial \psi}{\partial n} \, dS = 0,$$

since one factor or the other vanishes on ∂V in each case. Hence $\int_V |\nabla \psi|^2 \, dV = 0$, and as the integrand is non-negative and continuous, $\nabla \psi = \mathbf{0}$ throughout V . So ψ is constant, and in the Dirichlet case that constant is zero. $\square$

The theorem also holds on unbounded regions provided we impose a decay condition at infinity, which for us will always be $\phi \rightarrow 0$ as $r \rightarrow \infty$. The moral is a practical one: if by any means whatsoever – inspired guesswork included – we produce a function satisfying the equation and the boundary conditions, we have found *the* answer, and are not obliged to explain how we found it.

Example 12.2.11 (The point charge, again)

A point charge Q at the origin has

$$\rho(\mathbf{r}) = Q \delta^3(\mathbf{r}),$$

where δ^3 is the three-dimensional delta function. Away from the origin we must solve Laplace's equation with spherical symmetry, and the general such solution is $\phi = \alpha/r + \text{const}$; the constant is zero by our boundary condition at infinity.

To fix α , integrate Poisson's equation over a ball V of radius r . The left hand side is

$$\int_V \nabla^2 \phi \, dV = \int_S \nabla \phi \cdot d\mathbf{S} = \int_S \left(-\frac{\alpha}{r^2}\right) \hat{\mathbf{r}} \cdot d\mathbf{S} = -4\pi\alpha,$$

while the right hand side is $-Q/\epsilon_0$. Hence $\alpha = Q/4\pi\epsilon_0$, and

$$\phi = \frac{Q}{4\pi\epsilon_0 r}, \quad \mathbf{E} = -\nabla \phi = \frac{Q}{4\pi\epsilon_0 r^2} \hat{\mathbf{r}},$$

which is Coulomb's law once more, now derived by a completely different route.

§12.2.3 General Charge Distributions

The point charge solution is the key to everything else, because it is (up to a constant) the Green's function for the Laplacian. Recall that this is the function G solving

$$\nabla^2 G(\mathbf{r}; \mathbf{r}') = \delta^3(\mathbf{r} - \mathbf{r}'),$$

and the calculation we just did says

$$G(\mathbf{r}; \mathbf{r}') = -\frac{1}{4\pi} \frac{1}{|\mathbf{r} - \mathbf{r}'|}.$$

Proposition 12.2.12 (Potential of a general distribution)

Let ρ be a charge distribution confined to a bounded region V . Then

$$\phi(\mathbf{r}) = \frac{1}{4\pi\epsilon_0} \int_V \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} dV',$$

and correspondingly

$$\mathbf{E}(\mathbf{r}) = \frac{1}{4\pi\epsilon_0} \int_V \rho(\mathbf{r}') \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3} dV'.$$

Proof. Since $\nabla^2 \phi = -\rho/\epsilon_0$ and G is the Green's function,

$$\phi(\mathbf{r}) = -\frac{1}{\epsilon_0} \int_V \rho(\mathbf{r}') G(\mathbf{r}; \mathbf{r}') dV' = \frac{1}{4\pi\epsilon_0} \int_V \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} dV'.$$

For the field we differentiate under the integral sign, noting that ∇ acts on $\mathbf{r}$ only, and

$$\nabla \left(\frac{1}{|\mathbf{r} - \mathbf{r}'|} \right) = -\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3}.$$

Then $\mathbf{E} = -\nabla \phi$ gives the stated formula. $\square$

This is a complete answer, but for a complicated ρ it is a complete answer of the least useful kind: an integral one cannot do. What saves us is that we are usually far away from the charge, and then we can expand.

§12.2.4 The Multipole Expansion and Dipoles

Suppose all the charge lies within some bounded region near the origin, and we look at the potential at $|\mathbf{r}| \gg |\mathbf{r}'|$. Taylor expanding the Green's function in $\mathbf{r}'$,

$$\frac{1}{|\mathbf{r} - \mathbf{r}'|} = \frac{1}{r} + \frac{\mathbf{r} \cdot \mathbf{r}'}{r^3} + O\left(\frac{r'^2}{r^3}\right),$$

and substituting into Proposition 12.2.12 gives

$$\phi(\mathbf{r}) = \frac{1}{4\pi\epsilon_0} \left(\frac{Q}{r} + \frac{\mathbf{p} \cdot \hat{\mathbf{r}}}{r^2} + \cdots \right),$$

where

$$Q = \int_V \rho(\mathbf{r}') \, dV', \quad \mathbf{p} = \int_V \mathbf{r}' \rho(\mathbf{r}') \, dV'.$$

This is the beginning of the **multipole expansion**. The leading term says that from far enough away any lump of charge looks like a point charge with the same total charge. The correction $\mathbf{p}$ is the first thing you see when the total charge vanishes.

Definition 12.2.13 (Electric dipole moment)

The **electric dipole moment** of a charge distribution is

$$\mathbf{p} = \int \mathbf{r}' \rho(\mathbf{r}') \, dV'.$$

Note that $\mathbf{p}$ depends on the choice of origin in general – but if $Q = 0$, shifting the origin by $\mathbf{a}$ changes $\mathbf{p}$ by $-\mathbf{a}Q = \mathbf{0}$, so for a neutral distribution the dipole moment is well defined. This is the case of interest.

The cleanest example is a pair of equal and opposite point charges.

Example 12.2.14 (The dipole)

Put a charge $+Q$ at the origin and $-Q$ at $-\mathbf{d}$. By superposition,

$$\phi(\mathbf{r}) = \frac{Q}{4\pi\epsilon_0} \left(\frac{1}{r} - \frac{1}{|\mathbf{r} + \mathbf{d}|} \right).$$

This is exact but unenlightening; we expand for $r \gg d$. Using the general Taylor expansion $f(\mathbf{r} + \mathbf{d}) = f(\mathbf{r}) + \mathbf{d} \cdot \nabla f + \frac{1}{2}(\mathbf{d} \cdot \nabla)^2 f + \dots$ with $f = 1/r$,

$$\frac{1}{|\mathbf{r} + \mathbf{d}|} = \frac{1}{r} - \frac{\mathbf{d} \cdot \mathbf{r}}{r^3} + O\left(\frac{d^2}{r^3}\right),$$

so the $1/r$ terms cancel and

$$\phi(\mathbf{r}) \approx \frac{Q}{4\pi\epsilon_0} \frac{\mathbf{d} \cdot \mathbf{r}}{r^3} = \frac{\mathbf{p} \cdot \hat{\mathbf{r}}}{4\pi\epsilon_0 r^2}, \quad \mathbf{p} = Q\mathbf{d}.$$

This agrees with our general formula, as it must. Note the convention: $\mathbf{p}$ points from the negative charge to the positive one.

Differentiating, and using $\nabla(\mathbf{p} \cdot \mathbf{r}) = \mathbf{p}$ and $\nabla(r^{-3}) = -3\hat{\mathbf{r}}/r^4$,

$$\mathbf{E} = -\nabla\phi = \frac{1}{4\pi\epsilon_0} \left(\frac{3(\mathbf{p} \cdot \hat{\mathbf{r}})\hat{\mathbf{r}} - \mathbf{p}}{r^3} \right).$$

So the dipole field falls off like $1/r^3$, faster than a point charge, which is unsurprising: at large distances the two charges nearly cancel.

Dipoles are not only things that produce fields; they are also things that respond to them, and the way they do so explains a good deal of everyday physics.

Proposition 12.2.15 (Dipole in an external field)

A dipole $\mathbf{p}$ sitting in an external field $\mathbf{E}$ has potential energy

$$U = -\mathbf{p} \cdot \mathbf{E},$$

experiences a torque

$$\boldsymbol{\tau} = \mathbf{p} \times \mathbf{E}$$

about its centre, and (if the field is non-uniform) a net force

$$\mathbf{F} = \nabla(\mathbf{p} \cdot \mathbf{E}).$$

Proof. Model the dipole as charges $\pm Q$ at $\mathbf{r} \pm \frac{1}{2}\mathbf{d}$, with $\mathbf{p} = Q\mathbf{d}$. The total energy in the external potential ϕ is

$$U = Q\phi(\mathbf{r} + \frac{1}{2}\mathbf{d}) - Q\phi(\mathbf{r} - \frac{1}{2}\mathbf{d}) = Q\mathbf{d} \cdot \nabla\phi(\mathbf{r}) + O(d^2) = -\mathbf{p} \cdot \mathbf{E}(\mathbf{r}),$$

Taylor expanding and using $\mathbf{E} = -\nabla\phi$. The force is minus the gradient of the energy, $\mathbf{F} = -\nabla U = \nabla(\mathbf{p} \cdot \mathbf{E})$, which indeed vanishes for a uniform field. For the torque, the two charges feel forces $\pm Q\mathbf{E}$, so about the centre

$$\boldsymbol{\tau} = \frac{1}{2}\mathbf{d} \times (Q\mathbf{E}) + (-\frac{1}{2}\mathbf{d}) \times (-Q\mathbf{E}) = Q\mathbf{d} \times \mathbf{E} = \mathbf{p} \times \mathbf{E}. \quad \square$$

The energy $-\mathbf{p} \cdot \mathbf{E}$ is minimised when $\mathbf{p}$ is aligned with $\mathbf{E}$, and the torque is exactly what rotates it into alignment. This is the mechanism behind a great deal of chemistry – a water molecule is a permanent dipole, and it is why microwave ovens work and why water is such a good solvent. The force formula also explains why a charged comb picks up small neutral pieces of paper: the field of the comb *induces* a dipole in the paper, and being non-uniform, then pulls on it.

§12.2.5 Field Lines and Equipotentials

Drawing a vector field is awkward – we cannot draw an arrow at every point. The standard device is to draw *field lines* instead.

Definition 12.2.16 (Field lines and equipotentials)

A **field line** is a curve everywhere tangent to $\mathbf{E}$, drawn with the convention that the density of lines is proportional to $|\mathbf{E}|$. An **equipotential** is a surface on which ϕ is constant.

Field lines begin on positive charges and end on negative charges (or run off to infinity), and they never cross, since $\mathbf{E}$ has a well-defined direction at each point. Equipotentials always meet field lines at right angles, since $\mathbf{E} = -\nabla\phi$ is normal to the level sets of ϕ .

Example 12.2.17 (Point charges and dipoles)

For a single positive charge the lines run radially outward and the equipotentials are concentric spheres; for a negative charge everything reverses.

For a dipole the lines leave the positive charge and curl round to the negative one.

§12.2.6 Electrostatic Energy

How much energy does it take to assemble a configuration of charges? Recall from IA Dynamics and Relativity that a charge q sitting at $\mathbf{r}$ in a potential ϕ has potential energy $U = q\phi(\mathbf{r})$; this is the work done in bringing it in from infinity, since

$$W = - \int_{\infty}^{\mathbf{r}} \mathbf{F} \cdot d\mathbf{x} = -q \int_{\infty}^{\mathbf{r}} \mathbf{E} \cdot d\mathbf{x} = q \int_{\infty}^{\mathbf{r}} \nabla \phi \cdot d\mathbf{x} = q [\phi(\mathbf{r}) - \phi(\infty)] = q\phi(\mathbf{r}).$$

Now consider N point charges q_i at positions $\mathbf{r}_i$, and build the configuration up one charge at a time. Bringing in the first costs nothing. The second must be dragged in against the field of the first, costing

$$W_2 = \frac{1}{4\pi\epsilon_0} \frac{q_1 q_2}{|\mathbf{r}_1 - \mathbf{r}_2|},$$

the third must fight both of its predecessors, and so on. Summing,

$$U = \frac{1}{4\pi\epsilon_0} \sum_{i < j} \frac{q_i q_j}{|\mathbf{r}_i - \mathbf{r}_j|} = \frac{1}{8\pi\epsilon_0} \sum_{i \neq j} \frac{q_i q_j}{|\mathbf{r}_i - \mathbf{r}_j|},$$

the second form counting each pair twice and compensating with a factor of $\frac{1}{2}$. Since the potential at $\mathbf{r}_i$ due to all the *other* charges is $\phi(\mathbf{r}_i) = \frac{1}{4\pi\epsilon_0} \sum_{j \neq i} q_j / |\mathbf{r}_i - \mathbf{r}_j|$, we can write this more compactly as

$$U = \frac{1}{2} \sum_{i=1}^N q_i \phi(\mathbf{r}_i),$$

which generalises to a continuous distribution as

$$U = \frac{1}{2} \int \rho(\mathbf{r}) \phi(\mathbf{r}) dV.$$

This is already a nice formula, but we can do better and remove the charges entirely.

Proposition 12.2.18 (Energy in the electric field)

The energy of an electrostatic configuration is

$$U = \frac{\epsilon_0}{2} \int_{\mathbb{R}^3} |\mathbf{E}|^2 dV.$$

Proof. Using $\rho = \epsilon_0 \nabla \cdot \mathbf{E}$ and the product rule $\nabla \cdot (\phi \mathbf{E}) = \phi \nabla \cdot \mathbf{E} + \mathbf{E} \cdot \nabla \phi$,

$$U = \frac{\epsilon_0}{2} \int (\nabla \cdot \mathbf{E}) \phi dV = \frac{\epsilon_0}{2} \int [\nabla \cdot (\phi \mathbf{E}) - \mathbf{E} \cdot \nabla \phi] dV.$$

The first term is a total divergence, so by the divergence theorem it becomes a surface integral over a sphere at infinity. For a bounded charge distribution $\phi \sim 1/r$ and $|\mathbf{E}| \sim 1/r^2$ while the area grows like r^2 , so the integrand decays like $1/r$ and the term vanishes. In the second, $\nabla \phi = -\mathbf{E}$, leaving

$$U = \frac{\epsilon_0}{2} \int \mathbf{E} \cdot \mathbf{E} dV. \quad \square$$

This is a genuinely different picture of where the energy lives. The formula $U = \frac{1}{2} \int \rho \phi$ suggests the energy is stored ‘in the charges’, while $U = \frac{\epsilon_0}{2} \int |\mathbf{E}|^2$ says it is stored in the field, spread out through all of space with energy density $\frac{\epsilon_0}{2} |\mathbf{E}|^2$. The second picture is the correct one, though our derivation of it from the first is not a proof of that.

Remark. The two formulae are not quite equivalent, and it is instructive to see how they differ. For a single point charge the discrete formula gives $U = 0$ (there are no pairs), but the field is non-zero, so $\frac{\epsilon_0}{2} \int |\mathbf{E}|^2$ certainly is not – indeed it diverges, since $|\mathbf{E}|^2 \sim r^{-4}$ near the origin. The discrepancy is the (infinite) *self-energy* of the point charge, which the discrete sum quietly discards. This is the first hint of a genuine difficulty with point particles in classical field theory, and we will say no more about it here.

§12.2.7 Conductors

Definition 12.2.19 (Conductor)

A **conductor** is a region of space containing charges which are free to move.

The single fact that governs everything about conductors in electrostatics is this: inside a conductor, $\mathbf{E} = \mathbf{0}$. The argument is a one-liner. If $\mathbf{E}$ were non-zero anywhere inside, the free charges there would feel a force and move; so we would not be in a static situation. In equilibrium the charges have rearranged themselves precisely so as to cancel the field inside. That is the whole story, and a surprising number of consequences follow from it.

Proposition 12.2.20 (Properties of conductors)

In electrostatic equilibrium, a conductor satisfies:

- (i) ϕ is constant throughout the conductor;
- (ii) $\rho = 0$ inside the conductor, so any net charge lives on the surface;
- (iii) the surface of the conductor is an equipotential, and $\mathbf{E}$ just outside it is perpendicular to the surface;

(iv) just outside the surface, $\mathbf{E} = \frac{\sigma}{\epsilon_0} \hat{\mathbf{n}}$, where σ is the surface charge density and $\hat{\mathbf{n}}$ the outward normal.

Proof. (i) is immediate from $\mathbf{E} = -\nabla\phi = \mathbf{0}$. For (ii), $\rho = \epsilon_0 \nabla \cdot \mathbf{E} = 0$. Statement (iii) follows from (i), since the surface is part of the conductor and hence has ϕ constant on it, and $\mathbf{E}$ is normal to equipotentials. Physically, a tangential component of $\mathbf{E}$ at the surface would push the surface charges around. Finally (iv) is Proposition 12.2.7 with $\mathbf{E}_{\text{inside}} = \mathbf{0}$. $\square$

Part (iv) is extremely convenient in practice: it lets us read off the induced surface charge from the field, or vice versa.

Example 12.2.21 (Induced surface charge)

Take a neutral spherical conductor and place it in a uniform external field, say produced by a positively charged plate on the left and a negatively charged one on the right. Far away, the field lines are straight. Near the conductor they must bend so as to meet the surface perpendicularly, and since field lines terminate on charges, there must be negative charge on the left of the sphere and positive charge on the right.

The total induced charge is of course zero – the conductor was neutral and stays so – but it has been redistributed. This is why a conductor screens its interior: a hollow conductor (a ‘Faraday cage’) has $\mathbf{E} = \mathbf{0}$ inside no matter what is going on outside.

Example 12.2.22 (The method of images)

Let a conductor fill the half-space $x < 0$, grounded so that $\phi = 0$ throughout it, and place a point charge q at $\mathbf{d} = (d, 0, 0)$ with $d > 0$.

We must solve $\nabla^2\phi = -\rho/\epsilon_0$ in $x > 0$ with the boundary condition $\phi = 0$ on $x = 0$. By the uniqueness theorem, *any* solution we can find is *the* solution, so we are entitled to guess.

Here is the guess. Forget the conductor and instead put an *image charge* $-q$ at $(-d, 0, 0)$. By symmetry the potential of this pair vanishes on the plane $x = 0$, which is exactly the boundary condition we want. So we set

$$\phi = \begin{cases} \frac{q}{4\pi\epsilon_0} \left[\frac{1}{|\mathbf{r} - \mathbf{d}|} - \frac{1}{|\mathbf{r} + \mathbf{d}|} \right] & x > 0, \\ 0 & x \leq 0. \end{cases}$$

In $x > 0$ this satisfies Poisson's equation with the single source at $\mathbf{d}$ (the image charge lies outside the region, so contributes no source there), it satisfies Laplace's equation in $x < 0$, and it is continuous across $x = 0$. Uniqueness does the rest.

It remains to find the surface charge that makes this consistent. We need E_x at $x = 0^+$:

$$E_x = -\frac{\partial\phi}{\partial x} = \frac{q}{4\pi\epsilon_0} \left(\frac{x-d}{|\mathbf{r} - \mathbf{d}|^3} - \frac{x+d}{|\mathbf{r} + \mathbf{d}|^3} \right),$$

and setting $x = 0$ gives $E_x|_{x=0} = -\frac{q}{2\pi\epsilon_0} \frac{d}{(d^2 + y^2 + z^2)^{3/2}}$. The outward normal of the conductor is $\hat{\mathbf{n}} = \hat{\mathbf{x}}$, so

$$\sigma = \epsilon_0 E_x|_{x=0} = -\frac{q}{2\pi} \frac{d}{(d^2 + y^2 + z^2)^{3/2}}.$$

Integrating over the plane (most easily in polar coordinates $s^2 = y^2 + z^2$),

$$\int \sigma \, dy \, dz = -qd \int_0^\infty \frac{s \, ds}{(d^2 + s^2)^{3/2}} = -q,$$

so the induced charge is exactly $-q$: every field line leaving the charge terminates on the conductor. As a byproduct, the force on the charge is the force exerted by the image, namely $q^2/16\pi\epsilon_0 d^2$ towards the plane – a charge is always attracted to a nearby grounded conductor.

Example 12.2.23 (A charge outside an earthed sphere)

The method is not limited to planes. Take an earthed conducting sphere of radius a centred at the origin, and a charge q at $\mathbf{d}$ with $d > a$. We look for a potential vanishing on $|\mathbf{r}| = a$ and on the sphere's interior.

Try a single image charge q' placed at $\mathbf{d}' = \lambda\mathbf{d}$ for some λ to be determined, so that

$$\phi(\mathbf{r}) = \frac{1}{4\pi\epsilon_0} \left(\frac{q}{|\mathbf{r} - \mathbf{d}|} + \frac{q'}{|\mathbf{r} - \lambda\mathbf{d}|} \right).$$

On the sphere $|\mathbf{r}| = a$, writing θ for the angle between $\mathbf{r}$ and $\mathbf{d}$,

$$|\mathbf{r} - \mathbf{d}|^2 = a^2 + d^2 - 2ad \cos \theta, \quad |\mathbf{r} - \lambda\mathbf{d}|^2 = a^2 + \lambda^2 d^2 - 2\lambda ad \cos \theta.$$

For ϕ to vanish for *all* θ we need the ratio of these to be a constant, and inspection shows that taking $\lambda = a^2/d^2$ works: then

$$|\mathbf{r} - \lambda\mathbf{d}|^2 = a^2 + \frac{a^4}{d^2} - \frac{2a^3 \cos \theta}{d} = \frac{a^2}{d^2} (d^2 + a^2 - 2ad \cos \theta) = \frac{a^2}{d^2} |\mathbf{r} - \mathbf{d}|^2.$$

So $|\mathbf{r} - \lambda \mathbf{d}| = (a/d)|\mathbf{r} - \mathbf{d}|$ on the sphere, and $\phi = 0$ there provided

$$q' = -\frac{a}{d}q.$$

The image charge therefore sits at distance a^2/d from the centre – inside the sphere, hence outside the region where we are solving, as required – and carries charge $-qa/d$.

By uniqueness this is the answer. Two consequences are worth noting: the total induced charge on the sphere is $-qa/d$ (not $-q$, since the sphere is earthed and can exchange charge with the ground), and the force on q is the attraction towards the image,

$$F = \frac{1}{4\pi\epsilon_0} \frac{q|q'|}{(d - a^2/d)^2} = \frac{q^2 ad}{4\pi\epsilon_0(d^2 - a^2)^2},$$

directed towards the sphere.

§12.2.8 Capacitance

A pair of conductors carrying equal and opposite charges $\pm Q$ makes a **capacitor**. Since Poisson's equation is linear, doubling all the charges doubles all the potentials, so the potential difference V between the two conductors is proportional to Q .

Definition 12.2.24 (Capacitance)

The **capacitance** of a capacitor is $C = Q/V$, where $\pm Q$ are the charges on the two conductors and V is the potential difference between them. It depends only on the geometry.

Example 12.2.25 (Parallel plate capacitor)

Take two parallel plates of area A , a distance d apart, carrying charges $\pm Q$, and suppose $d \ll \sqrt{A}$ so we may pretend the plates are infinite and ignore what happens at the edges.

Each plate carries surface charge $\sigma = \pm Q/A$, and by our earlier calculation each produces a field of magnitude $\sigma/2\epsilon_0$ pointing away from the positive plate and towards the negative one. Between the plates these add; outside, they cancel. So

$$\mathbf{E} = \frac{Q}{\epsilon_0 A} \hat{\mathbf{n}}$$

between the plates, pointing from $+$ to $-$, and $\mathbf{E} = \mathbf{0}$ outside. The potential

difference is then

$$V = \int \mathbf{E} \cdot d\mathbf{x} = \frac{Qd}{\epsilon_0 A},$$

so

$$C = \frac{Q}{V} = \frac{\epsilon_0 A}{d}.$$

To make a large capacitance one wants large plates very close together, which is exactly what a real capacitor looks like.

We can also compute the energy stored, and it is a good check on Proposition 12.2.18. The field occupies a volume Ad and has magnitude $Q/\epsilon_0 A$, so

$$U = \frac{\epsilon_0}{2} |\mathbf{E}|^2 \cdot Ad = \frac{\epsilon_0}{2} \frac{Q^2}{\epsilon_0^2 A^2} Ad = \frac{Q^2 d}{2\epsilon_0 A} = \frac{Q^2}{2C} = \frac{1}{2} CV^2,$$

which is the formula every physicist knows. Alternatively one can get it directly: to move a further charge dq from one plate to the other against the existing potential difference q/C costs $dW = (q/C) dq$, and integrating from 0 to Q gives $Q^2/2C$ again.

Example 12.2.26 (Spherical capacitor)

For a slightly less trivial geometry, take two concentric spherical conducting shells of radii $a < b$, the inner carrying charge Q and the outer $-Q$.

Between the shells, Gauss' law on a sphere of radius $a < r < b$ encloses charge Q , so

$$\mathbf{E} = \frac{Q}{4\pi\epsilon_0 r^2} \hat{\mathbf{r}},$$

while inside the inner shell and outside the outer shell the enclosed charge is zero and $\mathbf{E} = \mathbf{0}$. The potential difference is

$$V = \int_a^b \frac{Q}{4\pi\epsilon_0 r^2} dr = \frac{Q}{4\pi\epsilon_0} \left(\frac{1}{a} - \frac{1}{b} \right),$$

so

$$C = 4\pi\epsilon_0 \frac{ab}{b-a}.$$

Two limits are worth noting. If $b = a + d$ with $d \ll a$, then $C \approx 4\pi\epsilon_0 a^2/d = \epsilon_0 A/d$ where $A = 4\pi a^2$: we recover the parallel plate answer, as we should, since a thin shell looks locally flat. And if we let $b \rightarrow \infty$, we get $C = 4\pi\epsilon_0 a$, the 'self-capacitance' of an isolated sphere.

§12.3 Magnetostatics

We now turn on currents and turn off time dependence. In magnetostatics we take $\rho = 0$ and $\mathbf{J} = \mathbf{J}(\mathbf{x})$ a steady current, and look for a time-independent magnetic field. As we noted, Maxwell's equations then reduce to

$$\nabla \cdot \mathbf{B} = 0, \quad \nabla \times \mathbf{B} = \mu_0 \mathbf{J},$$

with $\mathbf{E} = \mathbf{0}$.

It is worth being clear about what $\rho = 0$ means here. It does *not* mean there are no charges around – we certainly need charges, or there would be no current. It means

the positive and negative charges balance everywhere, and continue to do so. In a copper wire, the mobile electrons drift along while the positive ions stay put, and the two densities cancel; charge does not pile up anywhere. Mathematically, the continuity equation with $\partial\rho/\partial t = 0$ says

$$\nabla \cdot \mathbf{J} = 0,$$

which is the precise statement that current does not accumulate: whatever flows into a region flows out again. This condition is essential – indeed, taking the divergence of $\nabla \times \mathbf{B} = \mu_0 \mathbf{J}$ forces it.

§12.3.1 Ampère's Law

Just as Gauss' law is the integral form of (M1), the integral form of $\nabla \times \mathbf{B} = \mu_0 \mathbf{J}$ is Ampère's law. Take a surface S with boundary $C = \partial S$, integrate over S and apply Stokes' theorem:

$$\oint_C \mathbf{B} \cdot d\mathbf{x} = \int_S (\nabla \times \mathbf{B}) \cdot d\mathbf{S} = \mu_0 \int_S \mathbf{J} \cdot d\mathbf{S}.$$

Law 12.3.1 (Ampère's law)

For any closed curve C bounding a surface S ,

$$\oint_C \mathbf{B} \cdot d\mathbf{x} = \mu_0 I,$$

where I is the total current passing through S , with orientations related by the right-hand rule.

Note that, because $\nabla \cdot \mathbf{J} = 0$, the current through S depends only on the boundary curve C and not on which surface we span it with – a fact we will have cause to revisit when we come to the displacement current. As with Gauss' law, the utility of Ampère's law lies in exploiting symmetry.

Example 12.3.2 (The straight wire)

Take an infinite straight wire along the z -axis carrying current I , and use cylindrical polars (r, φ, z) .

Symmetry under translations in z and rotations about the axis says $\mathbf{B}$ can depend only on r . It can have no z component (reflect in a plane perpendicular to the wire), and no radial component, since $\nabla \cdot \mathbf{B} = 0$ applied to a cylinder about the axis would

then be violated. So

$$\mathbf{B} = B(r)\hat{\phi}.$$

Take C to be a circle of radius r about the axis. Then $d\mathbf{x} = r d\phi \hat{\phi}$, so

$$\oint_C \mathbf{B} \cdot d\mathbf{x} = 2\pi r B(r) = \mu_0 I,$$

and hence

$$\mathbf{B} = \frac{\mu_0 I}{2\pi r} \hat{\phi}.$$

The field circles the wire, falling off as $1/r$, with a direction given by the right-hand rule: point your right thumb along the current and your fingers curl the way $\mathbf{B}$ does.

Example 12.3.3 (Surface current)

Take the plane $z = 0$ to carry a **surface current density** $\mathbf{k}$ – current per unit length, measured across a line in the plane perpendicular to the flow – with $\mathbf{k} = k\hat{\mathbf{x}}$.

Think of this as infinitely many parallel wires laid side by side. Each produces a field circling it, and adding them up, the components perpendicular to the sheet cancel in pairs while those parallel to it survive. So $\mathbf{B}$ points in the $\pm\hat{\mathbf{y}}$ direction, depends only on z , and is odd in z :

$$\mathbf{B} = -B(z)\hat{\mathbf{y}}, \quad B(-z) = -B(z).$$

Take a rectangular loop C of height $2z$ and width L , lying in the y - z plane and straddling the sheet. Only the two horizontal sides contribute, and the current through the loop is kL , so

$$\oint_C \mathbf{B} \cdot d\mathbf{x} = LB(z) - LB(-z) = 2LB(z) = \mu_0 kL,$$

giving

$$B(z) = \frac{\mu_0 k}{2} \quad \text{for } z > 0.$$

Once again the field is constant, and once again there is a discontinuity across the sheet – this time in the *tangential* component of $\mathbf{B}$. The general statement, proved by shrinking an Ampèrian loop across an arbitrary surface exactly as in Proposition 12.2.7, is

$$\hat{\mathbf{n}} \times \mathbf{B}_+ - \hat{\mathbf{n}} \times \mathbf{B}_- = \mu_0 \mathbf{k},$$

with the normal component of $\mathbf{B}$ continuous.

Example 12.3.4 (The solenoid)

A **solenoid** is a wire wound tightly into a cylindrical helix, so that it approximates a cylindrical surface current. Let there be N turns per unit length, each carrying current I .

Symmetry (translation in z , rotation about the axis) together with $\nabla \cdot \mathbf{B} = 0$ gives $\mathbf{B} = B(r)\hat{\mathbf{z}}$. Outside the solenoid there is no current, so $\nabla \times \mathbf{B} = \mathbf{0}$, and for a field of this form that says $\partial B/\partial r = 0$. So B is constant outside; since it must vanish at infinity, it vanishes everywhere outside.

Now apply Ampère's law to the rectangle C shown, with one vertical side of length L inside the solenoid and the other outside. The outside side contributes nothing (the field is zero there) and the horizontal sides contribute nothing (they are perpendicular to $\mathbf{B}$, or lie where $\mathbf{B} = \mathbf{0}$). The number of wires threading the rectangle is NL , so

$$BL = \mu_0 INL \implies B = \mu_0 NI.$$

So the field inside a solenoid is uniform, parallel to the axis, and independent of the radius. This is how one makes a uniform magnetic field in practice.

§12.3.2 The Vector Potential and Gauge

For a general current distribution we need to deal with both equations at once, and as in electrostatics we begin by solving one of them identically. This time it is $\nabla \cdot \mathbf{B} = 0$, and a divergence-free field on $\mathbb{R}^3$ is a curl.

Definition 12.3.5 (Vector potential)

If $\mathbf{B} = \nabla \times \mathbf{A}$, then the vector field $\mathbf{A}$ is a **vector potential** for $\mathbf{B}$.

Before going on it is worth appreciating what (M2) is telling us. In electrostatics the analogous equation was $\nabla \cdot \mathbf{E} = \rho/\epsilon_0$, with a source on the right. The magnetic equation has a zero there instead, and the physical content of that zero is that there are no *magnetic charges*: no isolated north pole has ever been found. Break a bar magnet in half and you get two smaller magnets, never a lone north and a lone south.

Substituting $\mathbf{B} = \nabla \times \mathbf{A}$ into the remaining equation and using the identity $\nabla \times (\nabla \times \mathbf{A}) = \nabla(\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A}$ gives

$$\nabla(\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A} = \mu_0 \mathbf{J}. \quad (*)$$

This looks unpleasant. What rescues us is that $\mathbf{A}$ is far from unique.

Definition 12.3.6 (Gauge transformation)

Given a vector potential $\mathbf{A}$ and any scalar function $\chi(\mathbf{x})$, the field

$$\mathbf{A}' = \mathbf{A} + \nabla\chi$$

is another vector potential for the same $\mathbf{B}$, since $\nabla \times \nabla\chi = \mathbf{0}$. The map $\mathbf{A} \mapsto \mathbf{A} + \nabla\chi$ is a **gauge transformation**, and a choice of $\mathbf{A}$ is a choice of **gauge**.

So $\mathbf{A}$ carries redundant information: only the gauge-invariant combination $\nabla \times \mathbf{A}$ is physical. We may exploit this freedom to make (*) as simple as possible, and the obvious thing to try is to kill the first term.

Definition 12.3.7 (Coulomb gauge)

A vector potential with $\nabla \cdot \mathbf{A} = 0$ is said to be in **Coulomb gauge**.

Proposition 12.3.8

Any vector potential can be brought into Coulomb gauge.

Proof. Suppose $\nabla \cdot \mathbf{A} = \psi(\mathbf{x})$. Under a gauge transformation,

$$\nabla \cdot \mathbf{A}' = \nabla \cdot \mathbf{A} + \nabla^2\chi = \psi + \nabla^2\chi,$$

so we need χ with $\nabla^2\chi = -\psi$. This is Poisson's equation, which we know always has a solution (write it down with the Green's function if you like). So such a χ exists. $\square$

In Coulomb gauge, (*) collapses to

$$\nabla^2\mathbf{A} = -\mu_0\mathbf{J},$$

or in Cartesian components, $\nabla^2 A_i = -\mu_0 J_i$: three independent copies of Poisson's equation, one for each component. We solved that in electrostatics, so we can simply write down the answer.

Proposition 12.3.9

In Coulomb gauge, the vector potential of a localised steady current $\mathbf{J}$ is

$$\mathbf{A}(\mathbf{r}) = \frac{\mu_0}{4\pi} \int \frac{\mathbf{J}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} dV'.$$

Proof. Applying the Green's function solution of Poisson's equation componentwise gives this formula, so all that remains is to check the result really is in Coulomb gauge – otherwise it would not solve the original equation (*). Taking the divergence (with ∇ acting on $\mathbf{r}$),

$$\nabla \cdot \mathbf{A}(\mathbf{r}) = \frac{\mu_0}{4\pi} \int \mathbf{J}(\mathbf{r}') \cdot \nabla \left(\frac{1}{|\mathbf{r} - \mathbf{r}'|} \right) dV' = -\frac{\mu_0}{4\pi} \int \mathbf{J}(\mathbf{r}') \cdot \nabla' \left(\frac{1}{|\mathbf{r} - \mathbf{r}'|} \right) dV',$$

using the fact that differentiating $|\mathbf{r} - \mathbf{r}'|^{-1}$ with respect to $\mathbf{r}'$ is minus differentiating with respect to $\mathbf{r}$. Now that the derivative acts on the primed variable we may integrate by parts:

$$\nabla \cdot \mathbf{A} = -\frac{\mu_0}{4\pi} \int \left[\nabla' \cdot \left(\frac{\mathbf{J}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \right) - \frac{\nabla' \cdot \mathbf{J}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \right] dV'.$$

The first term is a total divergence, and becomes a surface integral at infinity which vanishes because the current is localised. The second vanishes because the current is steady, $\nabla' \cdot \mathbf{J} = 0$. So $\nabla \cdot \mathbf{A} = 0$. $\square$

Taking the curl gives the magnetostatic analogue of the Coulomb integral.

Law 12.3.10 (Biot–Savart law)

The magnetic field of a localised steady current is

$$\mathbf{B}(\mathbf{r}) = \frac{\mu_0}{4\pi} \int \mathbf{J}(\mathbf{r}') \times \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3} dV'.$$

If the current is confined to a thin wire along a curve C , then $\mathbf{J} dV' \rightarrow I d\mathbf{r}'$ and this becomes

$$\mathbf{B}(\mathbf{r}) = \frac{\mu_0 I}{4\pi} \oint_C d\mathbf{r}' \times \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3}.$$

Proof. Take the curl of Proposition 12.3.9. Since ∇ acts on $\mathbf{r}$ and $\mathbf{J}$ depends on $\mathbf{r}'$,

$$\nabla \times \left(\frac{\mathbf{J}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \right) = \nabla \left(\frac{1}{|\mathbf{r} - \mathbf{r}'|} \right) \times \mathbf{J}(\mathbf{r}') = -\frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3} \times \mathbf{J}(\mathbf{r}') = \mathbf{J}(\mathbf{r}') \times \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3},$$

and the result follows. $\square$

The Biot–Savart law is the exact analogue, for magnetostatics, of the formula $\mathbf{E} = \frac{1}{4\pi\epsilon_0} \int \rho(\mathbf{r} - \mathbf{r}')/|\mathbf{r} - \mathbf{r}'|^3$ we found in electrostatics – with the cross product accounting for the fact that magnetic fields circulate rather than radiate.

§12.3.3 Magnetic Dipoles

There are no magnetic monopoles, so the leading behaviour of a magnetic field far from its source is a dipole. Let us compute it.

Example 12.3.11 (The current loop)

Take a planar loop of wire C carrying current I , and look at the field far away.

By Proposition 12.3.9 specialised to a wire,

$$\mathbf{A}(\mathbf{r}) = \frac{\mu_0 I}{4\pi} \oint_C \frac{d\mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|},$$

and expanding as before,

$$\mathbf{A}(\mathbf{r}) = \frac{\mu_0 I}{4\pi} \oint_C \left(\frac{1}{r} + \frac{\mathbf{r} \cdot \mathbf{r}'}{r^3} + \dots \right) d\mathbf{r}'.$$

The leading term is a constant times $\oint_C d\mathbf{r}' = \mathbf{0}$, so it drops out – exactly as we should expect, since a $1/r$ term in $\mathbf{A}$ would be a magnetic monopole.

For the next term we use a corollary of Stokes' theorem: for any scalar f ,

$$\oint_C f d\mathbf{r}' = \int_S d\mathbf{S}' \times \nabla' f.$$

(To see this, dot both sides with a constant vector $\mathbf{c}$; the left becomes $\oint_C (f\mathbf{c}) \cdot d\mathbf{r}'$, which by Stokes' theorem is $\int_S \nabla' \times (f\mathbf{c}) \cdot d\mathbf{S}' = \int_S (\nabla' f \times \mathbf{c}) \cdot d\mathbf{S}'$, and rearranging the triple product gives $\mathbf{c} \cdot \int_S d\mathbf{S}' \times \nabla' f$.)

Taking $f(\mathbf{r}') = \mathbf{g} \cdot \mathbf{r}'$ for a constant vector $\mathbf{g}$ gives $\nabla' f = \mathbf{g}$, so

$$\oint_C (\mathbf{g} \cdot \mathbf{r}') d\mathbf{r}' = \int_S d\mathbf{S}' \times \mathbf{g} = \mathbf{S} \times \mathbf{g}, \quad \text{where } \mathbf{S} = \int_S d\mathbf{S}'$$

is the vector area of the loop. Applying this with $\mathbf{g} = \mathbf{r}/r^3$,

$$\mathbf{A}(\mathbf{r}) \approx \frac{\mu_0}{4\pi} \frac{\mathbf{m} \times \mathbf{r}}{r^3},$$

where we have defined the following.

Definition 12.3.12 (Magnetic dipole moment)

The **magnetic dipole moment** of a current loop is $\mathbf{m} = I\mathbf{S}$, with $\mathbf{S}$ the vector area of the loop.

Taking the curl (a slightly tedious but routine index computation) gives

$$\mathbf{B} = \nabla \times \mathbf{A} = \frac{\mu_0}{4\pi} \left(\frac{3(\mathbf{m} \cdot \hat{\mathbf{r}})\hat{\mathbf{r}} - \mathbf{m}}{r^3} \right),$$

which is precisely the same shape as the electric field of an electric dipole, with $\mathbf{p}/\epsilon_0$ replaced by $\mu_0 \mathbf{m}$. The difference is that the magnetic expansion has no $1/r^2$ monopole term at all.

The same conclusion holds for an arbitrary localised current, though the computation takes a little more care.

Proposition 12.3.13 (Dipole moment of a general current)

For a localised steady current $\mathbf{J}$,

$$\mathbf{A}(\mathbf{r}) = \frac{\mu_0}{4\pi} \frac{\mathbf{m} \times \mathbf{r}}{r^3} + O(r^{-3}), \quad \mathbf{m} = \frac{1}{2} \int \mathbf{r}' \times \mathbf{J}(\mathbf{r}') dV'.$$

Proof. Expanding Proposition 12.3.9 in components,

$$A_i(\mathbf{r}) = \frac{\mu_0}{4\pi} \int \left(\frac{J_i(\mathbf{r}')}{r} + \frac{J_i(\mathbf{r}')(\mathbf{r} \cdot \mathbf{r}')}{r^3} + \dots \right) dV'.$$

For the first term, note that since $\partial'_j J_j = \nabla' \cdot \mathbf{J} = 0$ and $\partial'_j r'_i = \delta_{ij}$,

$$\partial'_j (J_j r'_i) = (\partial'_j J_j) r'_i + J_j \delta_{ij} = J_i,$$

so J_i is a total derivative and its integral vanishes.

For the second, apply the same trick to $J_j r'_i r'_k$:

$$\partial'_j (J_j r'_i r'_k) = J_i r'_k + J_k r'_i,$$

so the symmetric part of $J_i r'_k$ integrates to zero, and only the antisymmetric part survives:

$$\int J_i(\mathbf{r} \cdot \mathbf{r}') dV' = \int \frac{r_k}{2} (J_i r'_k - J_k r'_i) dV' = \frac{1}{2} \int [\mathbf{r} \times (\mathbf{J} \times \mathbf{r}')]_i dV'.$$

Rearranging the triple product and comparing with $(\mathbf{m} \times \mathbf{r})_i$ gives the result with the stated $\mathbf{m}$. $\square$

For a planar loop the two definitions agree: $\frac{1}{2} \oint \mathbf{r}' \times I d\mathbf{r}'$ is I times the vector area, which is $I\mathbf{S}$.

§12.3.4 Magnetic Forces

Currents make magnetic fields, and magnetic fields push currents. Hence currents push each other. The relevant formula is the continuum Lorentz force law from Section 1,

$$\mathbf{F} = \int \mathbf{J} \times \mathbf{B} dV,$$

which for a thin wire becomes $\mathbf{F} = I \oint_C d\mathbf{r} \times \mathbf{B}$.

Example 12.3.14 (Force between parallel wires)

Take two infinite parallel wires a distance d apart, carrying currents I_1 and I_2 in the same direction, say along $\hat{\mathbf{z}}$, and separated along $\hat{\mathbf{x}}$.

The first wire produces at the location of the second a field of magnitude

$$B_1 = \frac{\mu_0 I_1}{2\pi d},$$

pointing in the $\hat{\phi}$ direction, which at the second wire is $-\hat{\mathbf{y}}$ (taking the wires along $\hat{\mathbf{z}}$ separated in $\hat{\mathbf{x}}$). The force per unit length on the second wire is then

$$\frac{\mathbf{F}}{L} = I_2 \hat{\mathbf{z}} \times \mathbf{B}_1 = -\frac{\mu_0 I_1 I_2}{2\pi d} \hat{\mathbf{z}} \times \hat{\mathbf{y}} = \frac{\mu_0 I_1 I_2}{2\pi d} \hat{\mathbf{x}},$$

which points from the second wire towards the first. So parallel currents *attract*, and (reversing I_2) antiparallel currents repel. This is exactly backwards from the electrostatic case, where like charges repel, and it is the reason the definition of the Ampere used to be phrased in terms of the force between two wires.

Example 12.3.15 (General force between current loops)

More generally, a current I_1 on a loop C_1 produces, by Biot–Savart,

$$\mathbf{B}(\mathbf{r}) = \frac{\mu_0 I_1}{4\pi} \oint_{C_1} d\mathbf{r}_1 \times \frac{\mathbf{r} - \mathbf{r}_1}{|\mathbf{r} - \mathbf{r}_1|^3},$$

and a second loop C_2 carrying I_2 then feels

$$\mathbf{F} = \frac{\mu_0 I_1 I_2}{4\pi} \oint_{C_2} \oint_{C_1} d\mathbf{r}_2 \times \left(d\mathbf{r}_1 \times \frac{\mathbf{r}_2 - \mathbf{r}_1}{|\mathbf{r}_2 - \mathbf{r}_1|^3} \right).$$

This double integral is not something one wants to evaluate. If the loops are far apart, though, each looks like a dipole, and the force can be shown to be

$$\mathbf{F} = \frac{\mu_0}{4\pi} \nabla \left(\frac{3(\mathbf{m}_1 \cdot \hat{\mathbf{r}})(\mathbf{m}_2 \cdot \hat{\mathbf{r}}) - \mathbf{m}_1 \cdot \mathbf{m}_2}{r^3} \right),$$

the gradient of an interaction energy of exactly the same form as for two electric dipoles. We omit the (long) proof.

There is one more result worth recording, on a small current loop placed in an *external* field. It is the exact magnetic analogue of Proposition 12.2.15.

Proposition 12.3.16 (Magnetic dipole in an external field)

A small current loop of dipole moment $\mathbf{m}$ in an external field $\mathbf{B}$ experiences a torque

$$\boldsymbol{\tau} = \mathbf{m} \times \mathbf{B},$$

and has interaction energy $U = -\mathbf{m} \cdot \mathbf{B}$, so that in a non-uniform field it feels a force $\mathbf{F} = \nabla(\mathbf{m} \cdot \mathbf{B})$.

Proof. If $\mathbf{B}$ is essentially constant over the loop, the net force is

$$\mathbf{F} = I \oint_C d\mathbf{r} \times \mathbf{B} = I \left(\oint_C d\mathbf{r} \right) \times \mathbf{B} = \mathbf{0},$$

since the integral of $d\mathbf{r}$ round a closed curve vanishes. The torque about the centre of the loop is

$$\boldsymbol{\tau} = I \oint_C \mathbf{r} \times (d\mathbf{r} \times \mathbf{B}) = I \oint_C [d\mathbf{r} (\mathbf{r} \cdot \mathbf{B}) - \mathbf{B} (\mathbf{r} \cdot d\mathbf{r})],$$

by the vector triple product. The second term vanishes, since $\oint_C \mathbf{r} \cdot d\mathbf{r} = \oint_C d(\frac{1}{2}r^2) = 0$. For the first, apply the identity $\oint_C (\mathbf{g} \cdot \mathbf{r}) d\mathbf{r} = \mathbf{S} \times \mathbf{g}$ established in the current loop example, with $\mathbf{g} = \mathbf{B}$:

$$\boldsymbol{\tau} = I \mathbf{S} \times \mathbf{B} = \mathbf{m} \times \mathbf{B},$$

as claimed. Finally, $U = -\mathbf{m} \cdot \mathbf{B}$ is the energy function whose angular derivative reproduces this torque, and whose spatial gradient gives the force. $\square$

This is why a compass needle turns to point along the field, and why an electric motor turns: a current loop in a magnetic field twists until its moment aligns, and if you flip the current at the right moment it keeps twisting. A bar magnet is, at bottom, an enormous number of microscopic current loops – electron spins, really – whose dipole moments have lined up, and the force $\nabla(\mathbf{m} \cdot \mathbf{B})$ is what makes it stick to a fridge.

We have now spent a whole section on ‘magnets’ which look nothing at all like the ones in a kitchen drawer. The bridge between the two is the observation just made, and the details belong to a course on the electromagnetism of media.

§12.4 Electrodynamics

We now allow the fields to depend on time, and the two halves of the theory become inseparable. A changing magnetic field produces an electric field, and a changing electric field produces a magnetic field; put the two together and you get a self-sustaining disturbance which propagates through empty space at the speed of light.

§12.4.1 Induction and Faraday’s Law

We begin with the Maxwell equation we have so far ignored,

$$\nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = \mathbf{0}.$$

Integrate it over a fixed surface S with boundary C , and apply Stokes' theorem:

$$\oint_C \mathbf{E} \cdot d\mathbf{x} = - \int_S \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{S} = - \frac{d}{dt} \int_S \mathbf{B} \cdot d\mathbf{S},$$

the last step being legitimate because S is not moving. Both sides deserve names.

Definition 12.4.1 (Electromotive force and magnetic flux)

The **electromotive force** (emf) around a closed curve C is

$$\mathcal{E} = \oint_C \mathbf{E} \cdot d\mathbf{x},$$

and the **magnetic flux** through a surface S is

$$\Phi = \int_S \mathbf{B} \cdot d\mathbf{S}.$$

The name 'electromotive force' is a historical embarrassment: $\mathcal{E}$ is not a force but a work done per unit charge, and it is measured in volts. If C is a loop of wire, $\mathcal{E}$ is the voltage that the loop sees.

Law 12.4.2 (Faraday's law of induction)

$$\mathcal{E} = - \frac{d\Phi}{dt}.$$

So changing the flux through a circuit drives a current around it. There are many ways to change the flux – move a magnet towards the loop, switch an electromagnet on or off, rotate the loop – and all of them work. Essentially every electrical generator in the world runs on this principle.

The minus sign is worth dwelling on. It says that the induced current flows in the direction whose own magnetic field *opposes* the change in flux. This is **Lenz's law**, and it is a statement about stability: were the sign the other way, an increase in flux would induce a current reinforcing the increase, which would induce more current, and so on. The world would rapidly become unpleasant.

Example 12.4.3 (A loop in a decreasing field)

Consider a circular loop of wire with a magnetic field passing up through it, and suppose we decrease $|\mathbf{B}|$.

Then $d\Phi/dt < 0$, so $\mathcal{E} > 0$ and the current flows anticlockwise when viewed from above. By the right-hand rule this current produces a magnetic field pointing *up* through the loop, which is to say it tries to maintain the flux that we are removing.

Lenz's law in action.

There is a second, superficially quite different, way to change the flux: keep $\mathbf{B}$ fixed and move the circuit. Remarkably, the same formula holds.

Example 12.4.4 (The sliding bar)

Take a conducting bar of length d sliding with speed v along a pair of rails, in a uniform field $\mathbf{B}$ perpendicular to the plane of the circuit.

Here nothing is changing in time at any fixed point of space, so the Maxwell equation we used above has nothing to say. Instead, use the Lorentz force law directly: each charge q in the bar is being carried along at velocity $\mathbf{v}$, so it feels a force $q\mathbf{v} \times \mathbf{B}$ of magnitude qvB directed along the bar. The work done per unit charge in going once round the circuit is therefore

$$\mathcal{E} = vBd,$$

since only the charges in the moving bar have any force on them. Meanwhile the area of the circuit is shrinking at rate vd , so

$$\frac{d\Phi}{dt} = -vBd,$$

and once again $\mathcal{E} = -d\Phi/dt$. The same law, but for a completely different reason – one is Maxwell's equation, the other is the Lorentz force law. That these two conspire to give the same answer is a strong hint that something deeper is going on, and in Section 12.5 we will see what.

Let us do the general case, in which both effects occur at once.

Theorem 12.4.5 (The flux rule)

Let $C(t)$ be a moving closed curve bounding a moving surface $S(t)$, with the curve moving with local velocity $\mathbf{v}$. Define the emf as

$$\mathcal{E} = \oint_{C(t)} (\mathbf{E} + \mathbf{v} \times \mathbf{B}) \cdot d\mathbf{x}.$$

Then $\mathcal{E} = -d\Phi/dt$.

Proof. As the curve moves from time t to $t + \delta t$, it sweeps out a cylindrical surface S_c , and $S(t)$, $S(t + \delta t)$ and S_c together bound a volume.

Now compute the change in flux, expanding $\mathbf{B}(t + \delta t) = \mathbf{B}(t) + \delta t \partial \mathbf{B} / \partial t + O(\delta t^2)$:

$$\begin{aligned} \Phi(t + \delta t) - \Phi(t) &= \int_{S(t+\delta t)} \mathbf{B}(t + \delta t) \cdot d\mathbf{S} - \int_{S(t)} \mathbf{B}(t) \cdot d\mathbf{S} \\ &= \delta t \int_{S(t)} \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{S} + \left[\int_{S(t+\delta t)} - \int_{S(t)} \right] \mathbf{B}(t) \cdot d\mathbf{S} + O(\delta t^2). \end{aligned}$$

Since $\nabla \cdot \mathbf{B} = 0$, the flux of $\mathbf{B}(t)$ out of the closed surface formed by $S(t + \delta t)$, $S(t)$ and S_c is zero, which says exactly

$$\left[\int_{S(t+\delta t)} - \int_{S(t)} \right] \mathbf{B}(t) \cdot d\mathbf{S} = - \int_{S_c} \mathbf{B}(t) \cdot d\mathbf{S}.$$

On S_c , an element of the curve $d\mathbf{x}$ sweeps out area $d\mathbf{S} = d\mathbf{x} \times \mathbf{v} \delta t$, so $\mathbf{B} \cdot d\mathbf{S} = \delta t (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{x}$. Dividing by δt and letting $\delta t \rightarrow 0$,

$$\frac{d\Phi}{dt} = \int_{S(t)} \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{S} - \oint_{C(t)} (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{x}.$$

Finally substitute $\partial \mathbf{B} / \partial t = -\nabla \times \mathbf{E}$ from (M3) and apply Stokes' theorem to the first term:

$$\frac{d\Phi}{dt} = - \oint_{C(t)} \mathbf{E} \cdot d\mathbf{x} - \oint_{C(t)} (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{x} = -\mathcal{E}. \quad \square$$

So the two mechanisms are two terms of one formula, and the flux rule is completely general.

§12.4.2 Inductance and Magnetic Energy

Consider a loop of wire C carrying current I . This produces a magnetic field, and hence a flux through the loop itself. By linearity, the flux is proportional to the current.

Definition 12.4.6 (Inductance)

The **inductance** of a circuit C is $L = \Phi/I$, the flux through C per unit current flowing in C . It depends only on the geometry of C .

Example 12.4.7 (Inductance of a solenoid)

Take a solenoid of length ℓ and cross-sectional area A , with N turns per unit length, and suppose $\ell \gg \sqrt{A}$ so that we may use $B = \mu_0 N I$ throughout. The flux through

a single turn is $\Phi_0 = \mu_0 N I A$, and there are $N\ell$ turns in total, so

$$\Phi = \mu_0 N^2 I A \ell = \mu_0 N^2 I V,$$

where $V = A\ell$ is the volume. Hence

$$L = \mu_0 N^2 V.$$

There is also a version of this for two circuits, which is what makes transformers possible.

Definition 12.4.8 (Mutual inductance)

Given two circuits C_1 and C_2 , the **mutual inductance** M is defined by $\Phi_2 = M I_1$, where Φ_2 is the flux through C_2 produced by a current I_1 in C_1 .

It is a small miracle – and a very useful one – that M is symmetric in the two circuits.

Proposition 12.4.9

The flux through C_2 due to unit current in C_1 equals the flux through C_1 due to unit current in C_2 .

Proof. Using $\mathbf{B} = \nabla \times \mathbf{A}$, Stokes' theorem, and the expression for the vector potential of a wire,

$$\Phi_2 = \int_{S_2} \mathbf{B}_1 \cdot d\mathbf{S} = \oint_{C_2} \mathbf{A}_1 \cdot d\mathbf{r}_2 = \frac{\mu_0 I_1}{4\pi} \oint_{C_2} \oint_{C_1} \frac{d\mathbf{r}_1 \cdot d\mathbf{r}_2}{|\mathbf{r}_1 - \mathbf{r}_2|}.$$

The right hand side is manifestly symmetric under exchanging the roles of C_1 and C_2 , so M is too. (This is the **Neumann formula**.) $\square$

Inductance is the key to computing the energy stored in a magnetic field, by the following argument. To build up a current we must change it, and by Faraday's law a changing current induces an emf

$$\mathcal{E} = -\frac{d\Phi}{dt} = -L \frac{dI}{dt}$$

which, by Lenz's law, opposes what we are trying to do. So we must do work against it. In a time δt a charge $I\delta t$ goes round the loop, and the work we must do against the induced emf is

$$\delta W = -\mathcal{E} I \delta t = L I \frac{dI}{dt} \delta t = \frac{L}{2} \frac{d(I^2)}{dt} \delta t.$$

Integrating from zero current up to I ,

$$W = \frac{1}{2} L I^2 = \frac{1}{2} I \Phi.$$

Proposition 12.4.10 (Energy in the magnetic field)

The energy stored in a magnetic field is

$$U = \frac{1}{2\mu_0} \int_{\mathbb{R}^3} |\mathbf{B}|^2 dV.$$

Proof. Start from $U = \frac{1}{2}I\Phi$, write $\mathbf{B} = \nabla \times \mathbf{A}$ and use Stokes' theorem:

$$U = \frac{1}{2}I \int_S \mathbf{B} \cdot d\mathbf{S} = \frac{1}{2}I \int_S (\nabla \times \mathbf{A}) \cdot d\mathbf{S} = \frac{1}{2}I \oint_C \mathbf{A} \cdot d\mathbf{x} = \frac{1}{2} \int_{\mathbb{R}^3} \mathbf{J} \cdot \mathbf{A} dV,$$

the last step because the current is confined to the wire, where $\mathbf{J} dV = I d\mathbf{x}$. Now use $\mathbf{J} = (\nabla \times \mathbf{B})/\mu_0$ and the identity $\nabla \cdot (\mathbf{B} \times \mathbf{A}) = \mathbf{A} \cdot (\nabla \times \mathbf{B}) - \mathbf{B} \cdot (\nabla \times \mathbf{A})$:

$$U = \frac{1}{2\mu_0} \int (\nabla \times \mathbf{B}) \cdot \mathbf{A} dV = \frac{1}{2\mu_0} \int [\nabla \cdot (\mathbf{B} \times \mathbf{A}) + \mathbf{B} \cdot (\nabla \times \mathbf{A})] dV.$$

The first term is a total divergence and integrates to a surface term at infinity, which vanishes provided $\mathbf{B} \times \mathbf{A}$ decays fast enough. The second is $|\mathbf{B}|^2$, giving the result. $\square$

Comparing with Proposition 12.2.18, the total energy stored in the electromagnetic field is

$$U = \int_{\mathbb{R}^3} \left(\frac{\epsilon_0}{2} |\mathbf{E}|^2 + \frac{1}{2\mu_0} |\mathbf{B}|^2 \right) dV.$$

It is worth flagging that this does not follow logically from the two separate results: in principle, when both fields are present, they might interact and contribute cross terms $\mathbf{E} \cdot \mathbf{B}$ to the energy. They do not, but seeing why requires the Poynting theorem, which we prove below.

§12.4.3 Resistance and Circuits

So far our story is: change the flux, get an emf, accelerate the charges. But charges that accelerate forever would give infinite currents, and in reality they do not. What stops them is a form of friction: the charges collide with the atoms of the wire, losing energy. The upshot is that the emf ends up proportional to the charges' *velocity* rather than their acceleration.

Law 12.4.11 (Ohm's law)

For most materials, the current is proportional to the applied emf:

$$\mathcal{E} = IR,$$

where R is the **resistance** of the circuit. In terms of fields, this reads $\mathbf{J} = \sigma \mathbf{E}$, where σ is the **conductivity** of the material.

Since $\mathcal{E} = \oint \mathbf{E} \cdot d\mathbf{x}$ is the potential difference V in the static case, this is the familiar $V = IR$. For a wire of length ℓ and cross-section A made of a material of **resistivity** $\varrho = 1/\sigma$, one finds $R = \varrho \ell / A$; the resistivity is a property of the substance alone, while the resistance depends on the shape.

Resistance costs energy. In time δt a charge $I \delta t$ moves round the circuit through a potential difference $\mathcal{E}$, so

$$\frac{dW}{dt} = \mathcal{E}I = I^2 R.$$

This is **Joule heating**: the energy lost to the collisions, which reappears as heat. It is how an electric kettle works, and why a computer needs a fan.

Example 12.4.12 (The decelerating bar)

Return to the sliding bar, and now give the bar resistance R (taking the rails to be perfect conductors).

There are two unknowns: the position $x(t)$ of the bar and the current $I(t)$. A current I in the bar feels a force $I\ell B$ along the rails, so

$$m\ddot{x} = I\ell B.$$

Meanwhile the emf is $\mathcal{E} = -d\Phi/dt = -B\ell\dot{x}$, so Ohm's law gives $IR = -B\ell\dot{x}$. Eliminating I ,

$$m\ddot{x} = -\frac{B^2\ell^2}{R}\dot{x},$$

which integrates to

$$\dot{x}(t) = -v e^{-B^2\ell^2 t/mR}.$$

The bar decelerates exponentially. This is Lenz's law again – the induced current opposes the motion that produced it – and its kinetic energy is dissipated as Joule heating in the bar. It is exactly the mechanism behind magnetic braking.

Example 12.4.13 (The LR circuit)

Put an inductor L , a resistor R and a battery of emf $\mathcal{E}_0$ in series, and close the switch at $t = 0$.

Going round the loop, the battery supplies $\mathcal{E}_0$, the inductor opposes with $-L dI/dt$, and the resistor drops IR :

$$\mathcal{E}_0 - L \frac{dI}{dt} = IR.$$

This is a first order linear ODE with solution

$$I(t) = \frac{\mathcal{E}_0}{R} \left(1 - e^{-Rt/L}\right),$$

so the current does not jump to its final value $\mathcal{E}_0/R$ instantly but rises on a timescale L/R . Inductors resist changes in current, in exactly the way that masses resist

changes in velocity.

§12.4.4 The Displacement Current

We have now used every one of Maxwell's equations except for the final term in (M4),

$$\nabla \times \mathbf{B} = \mu_0 \left(\mathbf{J} + \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} \right),$$

in which the quantity $\epsilon_0 \partial \mathbf{E} / \partial t$ is called, for historical reasons, the **displacement current**. It is the smallest looking term in Maxwell's equations and by far the most consequential.

Its necessity is a matter of pure mathematics, and was noticed as such. Suppose we drop it, as Ampère did, and write $\nabla \times \mathbf{B} = \mu_0 \mathbf{J}$. Taking the divergence, and using that the divergence of a curl vanishes,

$$\mu_0 \nabla \cdot \mathbf{J} = \nabla \cdot (\nabla \times \mathbf{B}) = 0.$$

But charge conservation says $\dot{\rho} + \nabla \cdot \mathbf{J} = 0$, so this forces $\dot{\rho} = 0$ everywhere and always. That is absurd – we can perfectly well pick up a charge and carry it somewhere else, changing ρ as we go. So the equations as they stood were inconsistent with the conservation of charge.

With the extra term the computation instead reads

$$0 = \nabla \cdot \left(\mathbf{J} + \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} \right) = \nabla \cdot \mathbf{J} + \epsilon_0 \frac{\partial}{\partial t} (\nabla \cdot \mathbf{E}) = \nabla \cdot \mathbf{J} + \frac{\partial \rho}{\partial t},$$

using (M1). So not only is the theory now consistent with charge conservation, it *implies* it. This is a beautiful piece of physics: Maxwell found the term by demanding mathematical consistency, and it turned out to predict light.

Example 12.4.14 (The charging capacitor)

Here is the standard illustration of why the term is needed. Take a wire carrying current I into one plate of a capacitor, and consider Ampère's law on a circle C around the wire. We may span C with a flat disc S_1 cut by the wire, or with a bulging surface S_2 that passes between the plates.

Through S_1 the current is I ; through S_2 it is zero, since no charge crosses the gap. Without the displacement current Ampère's law would give two different answers, which is not acceptable. With it, we note that the charge Q on the plate gives a

field $E = Q/\epsilon_0 A$ in the gap, so the displacement current through S_2 is

$$\epsilon_0 \frac{d}{dt} \int_{S_2} \mathbf{E} \cdot d\mathbf{S} = \epsilon_0 A \frac{d}{dt} \left(\frac{Q}{\epsilon_0 A} \right) = \frac{dQ}{dt} = I,$$

exactly making up the difference. The two surfaces agree, as they must.

§12.4.5 Electromagnetic Waves

Now for the payoff. We look for solutions of Maxwell's equations in vacuum, so $\rho = 0$ and $\mathbf{J} = \mathbf{0}$:

$$\nabla \cdot \mathbf{E} = 0, \quad \nabla \cdot \mathbf{B} = 0, \quad \nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \quad \nabla \times \mathbf{B} = \mu_0 \epsilon_0 \frac{\partial \mathbf{E}}{\partial t}.$$

Notice that this system is not empty: the source-free equations couple $\mathbf{E}$ and $\mathbf{B}$ to each other, so we can have fields with no charges anywhere at all.

Theorem 12.4.15 (The wave equation)

In vacuum, each of $\mathbf{E}$ and $\mathbf{B}$ satisfies the wave equation

$$\frac{1}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} - \nabla^2 \mathbf{E} = \mathbf{0}, \quad \frac{1}{c^2} \frac{\partial^2 \mathbf{B}}{\partial t^2} - \nabla^2 \mathbf{B} = \mathbf{0},$$

with wave speed

$$c = \frac{1}{\sqrt{\mu_0 \epsilon_0}}.$$

Proof. Differentiate (M4) with respect to t and commute the derivatives:

$$\begin{aligned} \mu_0 \epsilon_0 \frac{\partial^2 \mathbf{E}}{\partial t^2} &= \frac{\partial}{\partial t} (\nabla \times \mathbf{B}) = \nabla \times \frac{\partial \mathbf{B}}{\partial t} = -\nabla \times (\nabla \times \mathbf{E}) \\ &= \nabla^2 \mathbf{E} - \nabla (\nabla \cdot \mathbf{E}) = \nabla^2 \mathbf{E}, \end{aligned}$$

using (M3), then the vector identity, then (M1) with $\rho = 0$. The computation for $\mathbf{B}$ is identical with the roles of (M3) and (M4) exchanged. $\square$

Now put in the numbers. With $\epsilon_0 \approx 8.85 \times 10^{-12}$ and $\mu_0 = 4\pi \times 10^{-7}$ in SI units,

$$c = \frac{1}{\sqrt{\mu_0 \epsilon_0}} \approx 3 \times 10^8 \text{ m s}^{-1},$$

which is the speed of light. This is not a coincidence, and it was not regarded as one at the time: two constants measured in table-top experiments with wires and capacitors, combined in this particular way, reproduce the speed at which light travels. Maxwell's conclusion was the correct one – light *is* an electromagnetic wave.

Let us find the solutions explicitly. Look for a wave travelling in the x direction and independent of y and z , so $\mathbf{E} = \mathbf{E}(x, t)$. Then $\nabla \cdot \mathbf{E} = \partial E_x / \partial x = 0$, so E_x is constant, and we may take it to be zero. Choosing axes so that the field oscillates along $\hat{\mathbf{y}}$,

$$\mathbf{E} = (0, E(x, t), 0), \quad \frac{1}{c^2} \frac{\partial^2 E}{\partial t^2} - \frac{\partial^2 E}{\partial x^2} = 0,$$

whose general solution, as we know, is

$$E(x, t) = f(x - ct) + g(x + ct)$$

for arbitrary functions f, g : a wave travelling right and a wave travelling left. The most important special case is a **monochromatic** wave

$$E = E_0 \sin(kx - \omega t).$$

Definition 12.4.16 (Amplitude, wavenumber, frequency)

In the above, E_0 is the **amplitude**, k the **wavenumber** and ω the (angular) **frequency**. The wavelength is $\lambda = 2\pi/k$, and the wave equation forces the **dispersion relation**

$$\omega^2 = c^2 k^2.$$

To find the accompanying magnetic field, use (M3). With $\mathbf{E}$ as above, $\nabla \times \mathbf{E} = (\partial E / \partial x) \hat{\mathbf{z}}$, so $\mathbf{B} = (0, 0, B)$ with

$$\frac{\partial B}{\partial t} = -\frac{\partial E}{\partial x} \implies B = \frac{E_0}{c} \sin(kx - \omega t).$$

So $\mathbf{E}$ and $\mathbf{B}$ oscillate in phase, perpendicular to one another and to the direction of travel, with $|\mathbf{B}| = |\mathbf{E}|/c$. The magnetic field is not free to be chosen: it is determined entirely by the electric one.

For general directions of propagation it is cleaner to use complex exponentials, and take real parts at the end. Write

$$\mathbf{E} = \mathbf{E}_0 e^{i(\mathbf{k} \cdot \mathbf{x} - \omega t)}, \quad \mathbf{B} = \mathbf{B}_0 e^{i(\mathbf{k} \cdot \mathbf{x} - \omega t)},$$

where $\mathbf{k}$ is the (real) **wavevector** with $\omega = c|\mathbf{k}|$. Maxwell's equations then impose

$$\nabla \cdot \mathbf{E} = 0 \implies \mathbf{k} \cdot \mathbf{E}_0 = 0,$$

$$\nabla \cdot \mathbf{B} = 0 \implies \mathbf{k} \cdot \mathbf{B}_0 = 0,$$

$$\nabla \times \mathbf{E} = -\partial_t \mathbf{B} \implies \mathbf{k} \times \mathbf{E}_0 = \omega \mathbf{B}_0.$$

So both fields are transverse – perpendicular to the direction of propagation – and if $\mathbf{E}_0, \mathbf{B}_0$ are real then $\mathbf{k}, \mathbf{E}_0$ and $\mathbf{B}_0$ form a right-handed orthogonal triad.

§12.4.6 Polarisation

The vector $\mathbf{E}_0$ has two remaining degrees of freedom (it must be perpendicular to $\mathbf{k}$), and how it uses them is the **polarisation** of the wave.

Definition 12.4.17 (Linear polarisation)

A wave with $\mathbf{E}_0$, $\mathbf{B}_0$ and $\mathbf{k}$ all real is **linearly polarised**.

Such a wave oscillates back and forth in a fixed plane containing $\mathbf{k}$, and this is what polarising sunglasses filter for.

If instead $\mathbf{E}_0$ is complex, we may write $\mathbf{E}_0 = \alpha + i\beta$ with $\alpha, \beta \in \mathbb{R}^3$, and taking the real part,

$$\text{Re } \mathbf{E} = \alpha \cos(\mathbf{k} \cdot \mathbf{x} - \omega t) - \beta \sin(\mathbf{k} \cdot \mathbf{x} - \omega t).$$

At a fixed point in space, as t increases the tip of $\mathbf{E}$ traces out an ellipse in the plane spanned by α and β (both of which must be perpendicular to $\mathbf{k}$).

Definition 12.4.18 (Elliptic and circular polarisation)

A wave with complex $\mathbf{E}_0$ is **elliptically polarised**. In the special case $|\alpha| = |\beta|$ and $\alpha \cdot \beta = 0$, the ellipse is a circle and the wave is **circularly polarised**.

Example 12.4.19 (Why metals are shiny)

Let a conductor fill the region $x > 0$, and shine a linearly polarised light wave at it:

$$\mathbf{E}_{\text{inc}} = E_0 \hat{\mathbf{y}} e^{i(kx - \omega t)}, \quad \omega = ck.$$

Inside a conductor $\mathbf{E} = \mathbf{0}$, and the tangential component of $\mathbf{E}$ is continuous, so we need $\mathbf{E} \cdot \hat{\mathbf{y}} = 0$ at $x = 0$. The incident wave alone certainly does not satisfy this.

The fix is to add a reflected wave travelling the other way,

$$\mathbf{E}_{\text{ref}} = -E_0 \hat{\mathbf{y}} e^{i(-kx - \omega t)},$$

so that the total field $\mathbf{E} = \mathbf{E}_{\text{inc}} + \mathbf{E}_{\text{ref}}$ solves Maxwell's equations (by linearity) and vanishes on $x = 0$ (by construction). So a wave *must* be reflected – there is no consistent solution without one, and that is why metals are shiny.

Working out the corresponding magnetic fields from (M3) gives

$$\mathbf{B}_{\text{inc}} = \frac{E_0}{c} \hat{\mathbf{z}} e^{i(kx - \omega t)}, \quad \mathbf{B}_{\text{ref}} = \frac{E_0}{c} \hat{\mathbf{z}} e^{i(-kx - \omega t)},$$

so at the surface $\mathbf{B} \cdot \hat{\mathbf{z}}|_{x=0^-} = (2E_0/c)e^{-i\omega t}$, while $\mathbf{B} = \mathbf{0}$ inside. That is a discontinuity in the tangential magnetic field, which we know signals a surface current: from the jump condition,

$$\mathbf{k}_{\text{surf}} = \frac{2E_0}{\mu_0 c} \hat{\mathbf{y}} e^{-i\omega t}.$$

So the physical picture is that the incoming light drives an oscillating current in the surface of the metal, and it is that oscillating current which radiates the reflected wave.

§12.4.7 Energy Transport and the Poynting Vector

Electromagnetic waves carry energy – this is how sunlight warms the Earth. Let us make that precise by asking how the field energy in a region changes with time.

Theorem 12.4.20 (Poynting's theorem)

Let $U = \int_V \left(\frac{\epsilon_0}{2} |\mathbf{E}|^2 + \frac{1}{2\mu_0} |\mathbf{B}|^2 \right) dV$ be the field energy in a region V with boundary S . Then

$$\underbrace{\frac{dU}{dt} + \int_V \mathbf{J} \cdot \mathbf{E} dV}_{\text{rate of change of energy in } V} = \underbrace{- \int_S \mathbf{S}_P \cdot d\mathbf{S}}_{\text{energy flowing out through } \partial V}, \quad \mathbf{S}_P = \frac{1}{\mu_0} \mathbf{E} \times \mathbf{B}.$$

Proof. Differentiate under the integral sign and substitute Maxwell's equations for the time derivatives:

$$\begin{aligned} \frac{dU}{dt} &= \int_V \left(\epsilon_0 \mathbf{E} \cdot \frac{\partial \mathbf{E}}{\partial t} + \frac{1}{\mu_0} \mathbf{B} \cdot \frac{\partial \mathbf{B}}{\partial t} \right) dV \\ &= \int_V \left(\frac{1}{\mu_0} \mathbf{E} \cdot (\nabla \times \mathbf{B}) - \mathbf{E} \cdot \mathbf{J} - \frac{1}{\mu_0} \mathbf{B} \cdot (\nabla \times \mathbf{E}) \right) dV, \end{aligned}$$

using (M4) for $\partial \mathbf{E} / \partial t$ and (M3) for $\partial \mathbf{B} / \partial t$. Now the vector identity

$$\nabla \cdot (\mathbf{E} \times \mathbf{B}) = \mathbf{B} \cdot (\nabla \times \mathbf{E}) - \mathbf{E} \cdot (\nabla \times \mathbf{B})$$

turns the first and third terms into a total divergence, and the divergence theorem gives

$$\frac{dU}{dt} = - \int_V \mathbf{J} \cdot \mathbf{E} dV - \frac{1}{\mu_0} \int_S (\mathbf{E} \times \mathbf{B}) \cdot d\mathbf{S},$$

which rearranges to the stated form. $\square$

The interpretation is exactly a conservation law for energy, of the same shape as the continuity equation for charge. The term $\int_V \mathbf{J} \cdot \mathbf{E}$ is the rate at which the field does work on the charges in V (recall the work done on a charge q is $q\mathbf{v} \cdot \mathbf{E} \delta t$), so the left hand side is the total rate of change of energy in V , fields and particles together. The right hand side must therefore be the energy flowing in through the boundary.

Definition 12.4.21 (Poynting vector)

The **Poynting vector** is

$$\mathbf{S}_P = \frac{1}{\mu_0} \mathbf{E} \times \mathbf{B},$$

the flux of electromagnetic energy: energy per unit time per unit area.

Example 12.4.22 (Energy carried by a wave)

For a linearly polarised plane wave,

$$\mathbf{E} = \mathbf{E}_0 \sin(\mathbf{k} \cdot \mathbf{x} - \omega t), \quad \mathbf{B} = \frac{1}{c} (\hat{\mathbf{k}} \times \mathbf{E}_0) \sin(\mathbf{k} \cdot \mathbf{x} - \omega t),$$

so, using $\mathbf{E}_0 \times (\hat{\mathbf{k}} \times \mathbf{E}_0) = |\mathbf{E}_0|^2 \hat{\mathbf{k}}$ since $\mathbf{E}_0 \perp \hat{\mathbf{k}}$,

$$\mathbf{S}_P = \frac{E_0^2}{c\mu_0} \hat{\mathbf{k}} \sin^2(\mathbf{k} \cdot \mathbf{x} - \omega t).$$

Averaging over one period $T = 2\pi/\omega$, and using $\langle \sin^2 \rangle = \frac{1}{2}$,

$$\langle \mathbf{S}_P \rangle = \frac{E_0^2}{2c\mu_0} \hat{\mathbf{k}}.$$

The energy flows in the direction of propagation, as it should, at a rate proportional to the square of the amplitude.

Example 12.4.23 (Charging a capacitor)

Here is a more surprising application. Consider a parallel plate capacitor being charged at a steady rate, so the charge is $Q(t)$ and the current into the plates is $I = \dot{Q}$.

Between the plates $\mathbf{E}$ points from the positive plate to the negative one and has magnitude $Q/\epsilon_0 A$. The displacement current generates a magnetic field circulating around the axis; by Ampère's law applied to a circle of radius r between the plates,

$$2\pi r B = \mu_0 \epsilon_0 \frac{d}{dt} \left(\frac{Q}{\epsilon_0 A} \pi r^2 \right) \implies B = \frac{\mu_0 I r}{2\pi R^2},$$

where R is the radius of the plates. So at the rim $r = R$ we find $\mathbf{S}_P = \frac{1}{\mu_0} \mathbf{E} \times \mathbf{B}$ pointing radially *inwards*, with magnitude

$$|\mathbf{S}_P| = \frac{1}{\mu_0} \frac{Q}{\epsilon_0 \pi R^2} \cdot \frac{\mu_0 I}{2\pi R} = \frac{QI}{2\pi^2 \epsilon_0 R^3}.$$

Multiplying by the area of the rim, $2\pi R d$, the total power flowing in is

$$P = \frac{QId}{\pi \epsilon_0 R^2} = \frac{d}{dt} \left(\frac{Q^2 d}{2\pi \epsilon_0 R^2} \right) = \frac{d}{dt} \left(\frac{Q^2}{2C} \right),$$

which is exactly the rate at which the stored energy increases. So the energy does not flow *down the wires* into the capacitor at all – it flows in sideways through the gap, carried by the fields. This is a striking demonstration that the field picture is the right one.

Remark (Radiation pressure). Electromagnetic fields carry momentum as well as energy, with momentum density $\epsilon_0 \mathbf{E} \times \mathbf{B} = \mathbf{S}_P/c^2$. A wave absorbed by a surface therefore delivers momentum at a rate $\langle |\mathbf{S}_P| \rangle / c$ per unit area, exerting a **radiation pressure**

$$P = \frac{\langle |\mathbf{S}_P| \rangle}{c} = \frac{E_0^2}{2c^2 \mu_0}$$

(and twice that if the surface is a perfect reflector, since the momentum is reversed rather than absorbed). Sunlight at the Earth delivers roughly 1.4 kW m^{-2} , so the pressure is

about 5×10^{-6} Pa – utterly negligible for everyday purposes, but quite enough to push a solar sail, and quite enough to blow the tail of a comet away from the Sun.

§12.5 Electromagnetism and Relativity

We have already seen two hints that special relativity is lurking. The first is that Maxwell's equations have wave solutions travelling at a definite speed c , and the natural question is: with respect to which frame? The answer, and Einstein's starting point, is: all of them. The second is that the flux rule came out the same whether we moved the magnet or moved the loop – as though the split between 'electric' and 'magnetic' effects were frame-dependent.

In this final section we make this precise. We will rewrite Maxwell's equations in relativistic notation, at which point four equations become two and the theory becomes almost embarrassingly simple. Along the way we will discover that the magnetic field is not really an independent object at all: it is what the electric field looks like to a moving observer.

§12.5.1 A Review of Special Relativity

Recall from the IA Dynamics and Relativity course that in special relativity we treat space and time as a single four-dimensional object, and events are labelled by a **4-vector**

$$X^\mu = \begin{pmatrix} ct \\ x \\ y \\ z \end{pmatrix}, \quad \mu = 0, 1, 2, 3.$$

We use Greek indices μ, ν, ρ, σ for the range $0, \dots, 3$ and Roman indices i, j, k when we mean only the spatial components $1, 2, 3$. The summation convention is in force throughout.

The geometry of spacetime is encoded in the **Minkowski metric**

$$\eta_{\mu\nu} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix},$$

which plays the role of the dot product, so that

$$X \cdot X = \eta_{\mu\nu} X^\mu X^\nu = (ct)^2 - (x^2 + y^2 + z^2)$$

is the spacetime interval. This is not positive definite – vectors can have zero or negative 'length squared' – but it is invertible, with inverse $\eta^{\mu\nu}$ numerically the same matrix.

The failure of positive-definiteness means we must be more careful than in Euclidean space about the position of indices, and it is worth understanding why. A vector, informally, is a direction; a *covector* is a linear map eating a vector and returning a number. In Euclidean space with an orthonormal basis, the metric is the identity and one can identify the two without noticing. In Minkowski space one cannot, because the metric has minus signs, and a vector's components and its associated covector's components genuinely differ. We therefore write vector components with upper indices V^μ and covector components with lower indices V_μ , and adopt the following rule.

Definition 12.5.1 (Raising and lowering)

The metric converts between the two:

$$V_\mu = \eta_{\mu\nu} V^\nu, \quad V^\mu = \eta^{\mu\nu} V_\nu.$$

Concretely, lowering an index flips the sign of the spatial components and leaves the time component alone.

The rule of the summation convention now becomes sharper: *an upper index may only be contracted with a lower index*. Contracting two upper indices is meaningless – it corresponds to trying to feed a vector to a vector.

Definition 12.5.2 (Lorentz transformation)

A **Lorentz transformation** is a change of basis Λ preserving the metric,

$$\Lambda^\mu{}_\rho \eta_{\mu\nu} \Lambda^\nu{}_\sigma = \eta_{\rho\sigma},$$

equivalently $\Lambda^T \eta \Lambda = \eta$.

The Lorentz transformations are exactly the boosts, rotations, reflections and time reversals. For instance the standard boost with velocity v along the x -axis,

$$ct' = \gamma \left(ct - \frac{v}{c} x \right), \quad x' = \gamma(x - vt), \quad y' = y, \quad z' = z, \quad \gamma = \frac{1}{\sqrt{1 - v^2/c^2}},$$

corresponds to

$$\Lambda^\mu{}_\nu = \begin{pmatrix} \gamma & -\gamma v/c & 0 & 0 \\ -\gamma v/c & \gamma & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix},$$

while a spatial rotation R corresponds to $\Lambda = \text{diag}(1, R)$ in block form.

We can now give the working definition of these objects, which is the one we will actually use: an object is a vector, covector, or tensor according to how its components transform.

Definition 12.5.3 (Vectors, covectors, tensors)

A **4-vector** is an assignment of four numbers V^μ to each inertial frame, transforming as $V^\mu \mapsto \Lambda^\mu{}_\nu V^\nu$. A **covector** transforms as $V_\mu \mapsto \Lambda_\mu{}^\nu V_\nu$. More generally, a **tensor** of type (m, n) is an object $T^{\mu_1 \dots \mu_m}{}_{\nu_1 \dots \nu_n}$ transforming with one factor of Λ for each index, in the appropriate position.

By assumption X^μ is a vector, and by differentiating along a worldline so is dX^μ/ds for any invariant parameter s . Two derived objects we will need:

Definition 12.5.4 (4-velocity and 4-momentum)

For a particle with worldline $X^\mu(\tau)$ parameterised by proper time τ (so $dt/d\tau =$

$\gamma(\mathbf{u})$ where $\mathbf{u}$ is the ordinary velocity), the **4-velocity** and **4-momentum** are

$$U^\mu = \frac{dX^\mu}{d\tau} = \gamma \begin{pmatrix} c \\ \mathbf{u} \end{pmatrix}, \quad P^\mu = mU^\mu = \begin{pmatrix} E/c \\ \mathbf{p} \end{pmatrix},$$

where E is the relativistic energy and $\mathbf{p} = m\gamma\mathbf{u}$.

Definition 12.5.5 (4-derivative)

The **4-derivative** is

$$\partial_\mu = \frac{\partial}{\partial X^\mu} = \left(\frac{1}{c} \frac{\partial}{\partial t}, \nabla \right).$$

The index on ∂_μ is naturally a *lower* one, i.e. the derivative is a covector, which we can check by the chain rule: under $X \mapsto X' = \Lambda X$,

$$\frac{\partial}{\partial X'^\mu} = \frac{\partial X^\nu}{\partial X'^\mu} \frac{\partial}{\partial X^\nu} = (\Lambda^{-1})^\nu{}_\mu \partial_\nu = \Lambda_\mu{}^\nu \partial_\nu,$$

which is exactly the covector transformation rule. This matches the intuition from the IA courses that the derivative of a function eats a direction and returns a rate of change.

§12.5.2 The 4-Current and Charge Conservation

Our first job is to package the sources relativistically. The natural guess is to combine the charge density and current density into a single object.

Definition 12.5.6 (4-current)

The **4-current** is

$$J^\mu = \begin{pmatrix} \rho c \\ \mathbf{J} \end{pmatrix}.$$

Of course, writing four numbers in a column does not make them a 4-vector; we should check that they transform correctly. The full verification is a good exercise, but the following special case makes it entirely believable. Suppose in frame S we have a static charge density $\rho_0(\mathbf{x})$ with no current, so $J^\mu = (\rho_0 c, \mathbf{0})$. In a frame S' boosted with velocity $\mathbf{v}$, the transformation rule would give

$$J'^\mu = \Lambda^\mu{}_\nu J^\nu = \begin{pmatrix} \gamma \rho_0 c \\ -\gamma \rho_0 \mathbf{v} \end{pmatrix}.$$

Both entries are exactly what we would expect physically. The charge density has gone up by a factor of γ , which is right: charge is invariant, but lengths in the direction of motion are Lorentz contracted, so the same charge occupies less volume. And the current density is that charge density times the velocity $-\mathbf{v}$ at which the charge now appears to move.

With this notation, local charge conservation takes a startlingly compact form.

Proposition 12.5.7

The continuity equation is

$$\partial_\mu J^\mu = 0,$$

and this equation is Lorentz invariant.

Proof. Expanding, $\partial_\mu J^\mu = \frac{1}{c} \frac{\partial(\rho c)}{\partial t} + \nabla \cdot \mathbf{J} = \frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J}$, which is the continuity equation. Invariance is immediate from the index structure: every index is contracted, one up with one down, so the object is a scalar. $\square$

This is the first indication of how much the relativistic notation buys us. The statement ‘charge is conserved locally’ and the statement ‘all observers agree that charge is conserved locally’ are now the same statement, and both are one symbol long.

§12.5.3 Gauge Potentials and the Field Tensor

In the static case we introduced potentials ϕ with $\mathbf{E} = -\nabla\phi$ and $\mathbf{A}$ with $\mathbf{B} = \nabla \times \mathbf{A}$. In the time-dependent case the first of these fails, since $\nabla \times \mathbf{E} \neq \mathbf{0}$ in general. But (M3) says $\nabla \times \mathbf{E} = -\partial_t(\nabla \times \mathbf{A})$, i.e. $\nabla \times (\mathbf{E} + \partial_t \mathbf{A}) = \mathbf{0}$, so it is $\mathbf{E} + \partial_t \mathbf{A}$ which is a gradient. Hence we should define the potentials by

$$\mathbf{E} = -\nabla\phi - \frac{\partial \mathbf{A}}{\partial t}, \quad \mathbf{B} = \nabla \times \mathbf{A}.$$

With this definition, (M2) and (M3) hold automatically, and the whole content of Maxwell’s equations sits in (M1) and (M4).

The potentials are still not unique. For any function $\chi(\mathbf{x}, t)$, the transformation

$$\mathbf{A} \mapsto \mathbf{A} + \nabla\chi, \quad \phi \mapsto \phi - \frac{\partial\chi}{\partial t}$$

leaves both $\mathbf{E}$ and $\mathbf{B}$ unchanged, as one checks directly. This is the time-dependent version of the gauge transformations we met in magnetostatics.

Now, we have one scalar and one 3-vector, which is four functions. The obvious thing to do is the right thing.

Definition 12.5.8 (4-potential)

The **gauge potential** is the 4-vector

$$A^\mu = \begin{pmatrix} \phi/c \\ \mathbf{A} \end{pmatrix}.$$

Lowering the index gives $A_\mu = (\phi/c, -\mathbf{A})$, and the gauge transformation becomes simply

$$A_\mu \mapsto A_\mu - \partial_\mu \chi.$$

This one line contains both of the transformations above; the reader is encouraged to check it.

Since $\mathbf{E}$ and $\mathbf{B}$ are built from derivatives of A_μ , and since we want a gauge-invariant object, the following definition suggests itself.

Definition 12.5.9 (Electromagnetic field tensor)

The **electromagnetic field tensor** is

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu.$$

This is antisymmetric, $F_{\mu\nu} = -F_{\nu\mu}$, so its diagonal vanishes and it has $(16 - 4)/2 = 6$ independent components – precisely the right number to hold the three components of $\mathbf{E}$ and the three of $\mathbf{B}$. It is gauge invariant, since under $A_\mu \mapsto A_\mu - \partial_\mu \chi$,

$$F_{\mu\nu} \mapsto F_{\mu\nu} - \partial_\mu \partial_\nu \chi + \partial_\nu \partial_\mu \chi = F_{\mu\nu}$$

by the symmetry of mixed partials. So F is a genuinely physical object, while A is not.

Let us identify the components. Taking $\mu = 0, \nu = 1$ and remembering that the spatial part of A_μ carries a minus sign,

$$F_{01} = \frac{1}{c} \frac{\partial}{\partial t} (-A_x) - \frac{\partial}{\partial x} \left(\frac{\phi}{c} \right) = \frac{1}{c} \left(-\frac{\partial A_x}{\partial t} - \frac{\partial \phi}{\partial x} \right) = \frac{E_x}{c},$$

and similarly $F_{02} = E_y/c$, $F_{03} = E_z/c$. For the purely spatial components,

$$F_{12} = \frac{\partial}{\partial x} (-A_y) - \frac{\partial}{\partial y} (-A_x) = -(\nabla \times \mathbf{A})_z = -B_z,$$

and cyclically. Assembling,

$$F_{\mu\nu} = \begin{pmatrix} 0 & E_x/c & E_y/c & E_z/c \\ -E_x/c & 0 & -B_z & B_y \\ -E_y/c & B_z & 0 & -B_x \\ -E_z/c & -B_y & B_x & 0 \end{pmatrix}.$$

Raising both indices with $F^{\mu\nu} = \eta^{\mu\rho} \eta^{\nu\sigma} F_{\rho\sigma}$ flips the sign of any component with exactly one spatial index, so

$$F^{\mu\nu} = \begin{pmatrix} 0 & -E_x/c & -E_y/c & -E_z/c \\ E_x/c & 0 & -B_z & B_y \\ E_y/c & B_z & 0 & -B_x \\ E_z/c & -B_y & B_x & 0 \end{pmatrix}.$$

The electric entries change sign (one spatial index) and the magnetic ones do not (two spatial indices, so two sign flips).

§12.5.4 Transformation of the Fields

The whole point of assembling $F^{\mu\nu}$ is that we now know how $\mathbf{E}$ and $\mathbf{B}$ transform: as a tensor,

$$F'^{\mu\nu} = \Lambda^\mu_\rho \Lambda^\nu_\sigma F^{\rho\sigma}.$$

Let us extract what this means in familiar language.

For a rotation $\Lambda = \text{diag}(1, R)$ one gets, unsurprisingly, $\mathbf{E}' = R\mathbf{E}$ and $\mathbf{B}' = R\mathbf{B}$: both fields are ordinary 3-vectors as far as rotations are concerned. For a boost with speed v along the x -axis, grinding through the matrix multiplication gives the following.

Proposition 12.5.10 (Transformation of $\mathbf{E}$ and $\mathbf{B}$)

Under a boost with velocity v along $\hat{\mathbf{x}}$,

$$\begin{aligned} E'_x &= E_x, & B'_x &= B_x, \\ E'_y &= \gamma(E_y - vB_z), & B'_y &= \gamma\left(B_y + \frac{v}{c^2}E_z\right), \\ E'_z &= \gamma(E_z + vB_y), & B'_z &= \gamma\left(B_z - \frac{v}{c^2}E_y\right). \end{aligned}$$

The components along the boost are unchanged, and the transverse components mix. Crucially, they mix $\mathbf{E}$ with $\mathbf{B}$: a purely electric field in one frame has a magnetic part in another. This is the sense in which the two fields are not separate things.

Example 12.5.11 (The boosted line charge)

Consider an infinite line of charge along the x -axis with charge per unit length η , at rest in frame S . We computed its field long ago:

$$\mathbf{E} = \frac{\eta}{2\pi\epsilon_0(y^2 + z^2)} \begin{pmatrix} 0 \\ y \\ z \end{pmatrix}, \quad \mathbf{B} = \mathbf{0}.$$

Now boost with velocity v along the wire. Applying the transformation rules, and noting that $y' = y$ and $z' = z$ since the boost is along x ,

$$\mathbf{E}' = \frac{\gamma\eta}{2\pi\epsilon_0(y'^2 + z'^2)} \begin{pmatrix} 0 \\ y' \\ z' \end{pmatrix}, \quad \mathbf{B}' = \frac{\gamma\eta v}{2\pi\epsilon_0 c^2(y'^2 + z'^2)} \begin{pmatrix} 0 \\ z' \\ -y' \end{pmatrix}.$$

Look at what these say. The electric field is that of a line charge with density $\gamma\eta$ – which is right, because in S' the charge is Lorentz contracted. And writing $s' = \sqrt{y'^2 + z'^2}$ and $\hat{\phi}' = (0, -z', y')/s'$, and using $\epsilon_0 c^2 = 1/\mu_0$, the magnetic field is

$$\mathbf{B}' = \frac{\mu_0 I'}{2\pi s'} \hat{\phi}', \quad I' = -\gamma\eta v,$$

which is precisely the field of a straight wire carrying current I' , exactly as we computed from Ampère's law.

It is worth being clear about how remarkable this is. We did not use Ampère's law, or the Biot–Savart law, or anything magnetic at all. We used Gauss' law and a Lorentz boost. Magnetism, in other words, is what you get when you look at electrostatics from a moving frame. Relativity is not only a theory of things going very fast; it is there every time you stick a magnet on the fridge.

§12.5.5 The Field of a Moving Charge

Let us do the same for a point charge, which is a more delicate calculation but gives a memorable answer.

Example 12.5.12 (Boosted point charge)

A charge Q at rest at the origin of S has

$$\mathbf{E} = \frac{Q}{4\pi\epsilon_0(x^2 + y^2 + z^2)^{3/2}} \begin{pmatrix} x \\ y \\ z \end{pmatrix}, \quad \mathbf{B} = \mathbf{0}.$$

Boosting with velocity v along $\hat{\mathbf{x}}$, the transformation rules give $E'_x = E_x$ and $E'_{y,z} = \gamma E_{y,z}$, so

$$\mathbf{E}' = \frac{Q}{4\pi\epsilon_0(x^2 + y^2 + z^2)^{3/2}} \begin{pmatrix} x \\ \gamma y \\ \gamma z \end{pmatrix},$$

but this is expressed in the wrong coordinates. Substituting $x = \gamma(x' + vt')$, $y = y'$, $z = z'$,

$$\mathbf{E}' = \frac{\gamma Q}{4\pi\epsilon_0(\gamma^2(x' + vt')^2 + y'^2 + z'^2)^{3/2}} \begin{pmatrix} x' + vt' \\ y' \\ z' \end{pmatrix}.$$

In S' the particle sits at $(-vt', 0, 0)$, so this is a radial field centred on the particle, as it should be. Evaluate at $t' = 0$, where the particle is at the origin of S' and $\mathbf{r}' = (x', y', z')$. Writing θ for the angle between $\mathbf{r}'$ and the x' -axis, the denominator simplifies:

$$\begin{aligned} \gamma^2 x'^2 + y'^2 + z'^2 &= (\gamma^2 - 1)x'^2 + r'^2 = \frac{v^2\gamma^2}{c^2}x'^2 + r'^2 \\ &= \left(\frac{v^2\gamma^2}{c^2} \cos^2 \theta + 1\right) r'^2 = \gamma^2 \left(1 - \frac{v^2}{c^2} \sin^2 \theta\right) r'^2, \end{aligned}$$

using $\gamma^2 - 1 = \gamma^2 v^2/c^2$ in the second step and $\gamma^{-2} = 1 - v^2/c^2$ in the last. Hence

$$\mathbf{E}' = \frac{1}{\gamma^2 \left(1 - \frac{v^2}{c^2} \sin^2 \theta\right)^{3/2}} \frac{Q}{4\pi\epsilon_0 r'^2} \hat{\mathbf{r}}'.$$

The field is still radial, but no longer isotropic. The prefactor is smallest at $\theta = 0$ (ahead of and behind the charge) and largest at $\theta = \pi/2$ (to the sides), so the field is squashed in the direction of motion and enhanced perpendicular to it. Drawing field lines, the effect is a ‘pancaking’ of the field:

There is also a magnetic field, which one obtains from the same transformation rules:

$$\mathbf{B}' = \frac{\mu_0 \gamma Q v}{4\pi(\gamma^2(x' + vt')^2 + y'^2 + z'^2)^{3/2}} \begin{pmatrix} 0 \\ z' \\ -y' \end{pmatrix},$$

circulating around the direction of motion, as one would expect of a moving charge.

As a historical aside: this squashing of the field of a moving charge was found by Lorentz by solving Maxwell's equations directly, before relativity existed, and it is precisely what led him to write down the transformations that bear his name.

§12.5.6 Lorentz Invariants

Since $\mathbf{E}$ and $\mathbf{B}$ mix under boosts, it is natural to ask whether any combination of them is agreed upon by all observers. With index notation this is easy to answer: we need to contract all indices away.

The first candidate is the obvious one.

Proposition 12.5.13

The quantity

$$\frac{1}{2}F_{\mu\nu}F^{\mu\nu} = |\mathbf{B}|^2 - \frac{|\mathbf{E}|^2}{c^2}$$

is Lorentz invariant.

Proof. Invariance is automatic, since all indices are contracted. The evaluation is a direct computation from the matrices above: the electric entries appear as (something) $\times$ (−something), contributing negatively, and the magnetic ones contribute positively. $\square$

For the second invariant we need a new object. Define the totally antisymmetric symbol in four dimensions,

$$\varepsilon^{\mu\nu\rho\sigma} = \begin{cases} +1 & \mu\nu\rho\sigma \text{ an even permutation of } 0123, \\ -1 & \text{an odd permutation,} \\ 0 & \text{otherwise,} \end{cases}$$

the spacetime analogue of ϵ_{ijk} . Is it a tensor? Transforming it gives another totally antisymmetric object, and (exactly as in $\mathbb{R}^3$) the space of such objects is one-dimensional, so $\varepsilon'^{\mu\nu\rho\sigma} = a \varepsilon^{\mu\nu\rho\sigma}$ for some constant a . Testing on a single component,

$$\varepsilon'^{0123} = \Lambda^0_{\kappa} \Lambda^1_{\lambda} \Lambda^2_{\alpha} \Lambda^3_{\beta} \varepsilon^{\kappa\lambda\alpha\beta} = \det \Lambda,$$

by the definition of the determinant. Lorentz transformations have $\det \Lambda = \pm 1$, and restricting to the ones continuously connected to the identity (rotations and boosts, but not reflections or time reversal) we have $\det \Lambda = 1$ and ε is indeed invariant.

Definition 12.5.14 (Dual field tensor)

The **dual electromagnetic tensor** is

$$\tilde{F}^{\mu\nu} = \frac{1}{2} \varepsilon^{\mu\nu\rho\sigma} F_{\rho\sigma} = \begin{pmatrix} 0 & -B_x & -B_y & -B_z \\ B_x & 0 & E_z/c & -E_y/c \\ B_y & -E_z/c & 0 & E_x/c \\ B_z & E_y/c & -E_x/c & 0 \end{pmatrix}.$$

The factor of $\frac{1}{2}$ is there because each pair $\{\rho, \sigma\}$ is counted twice in the sum. Comparing with $F^{\mu\nu}$, the dual is obtained by the substitution

$$\mathbf{E} \mapsto c\mathbf{B}, \quad \mathbf{B} \mapsto -\mathbf{E}/c,$$

and the reader should note the minus sign: the duality is like a rotation by ninety degrees, and doing it twice gives minus the identity. In particular $\tilde{F}_{\mu\nu}\tilde{F}^{\mu\nu} = -F_{\mu\nu}F^{\mu\nu}$, so contracting the dual with itself gives nothing new. Contracting it with F , however, does.

Proposition 12.5.15

The quantity

$$\frac{1}{4}\tilde{F}^{\mu\nu}F_{\mu\nu} = \frac{\mathbf{E} \cdot \mathbf{B}}{c}$$

is Lorentz invariant.

So all observers agree on $|\mathbf{B}|^2 - |\mathbf{E}|^2/c^2$ and on $\mathbf{E} \cdot \mathbf{B}$. In particular, if the fields are perpendicular in one frame they are perpendicular in every frame, and if $|\mathbf{E}| = c|\mathbf{B}|$ in one frame – as for a plane wave – then the same holds in all frames.

§12.5.7 Maxwell's Equations in Covariant Form

We now have everything we need to write down the theory in its final form.

Theorem 12.5.16 (Maxwell's equations, relativistic form)

Maxwell's four equations are equivalent to the pair

$$\partial_\mu F^{\mu\nu} = \mu_0 J^\nu, \quad \partial_\mu \tilde{F}^{\mu\nu} = 0.$$

Proof. We check each equation component by component. Take the first, with $\nu = 0$. Since $F^{00} = 0$, only spatial μ contribute, and $F^{i0} = E_i/c$, so

$$\partial_i F^{i0} = \nabla \cdot \left(\frac{\mathbf{E}}{c} \right) = \mu_0 J^0 = \mu_0 \rho c,$$

i.e. $\nabla \cdot \mathbf{E} = \mu_0 c^2 \rho = \rho/\epsilon_0$, which is (M1). Taking instead $\nu = i$ spatial, the $\mu = 0$ term gives $\frac{1}{c}\partial_t(-E_i/c)$ and the spatial terms assemble into $(\nabla \times \mathbf{B})_i$, so

$$-\frac{1}{c^2}\frac{\partial \mathbf{E}}{\partial t} + \nabla \times \mathbf{B} = \mu_0 \mathbf{J},$$

which is (M4).

Now the second equation. With $\nu = 0$ we get $\partial_i \tilde{F}^{i0} = \nabla \cdot \mathbf{B} = 0$, which is (M2); with $\nu = i$ we get $\frac{\partial \mathbf{B}}{\partial t} + \nabla \times \mathbf{E} = \mathbf{0}$, which is (M3). $\square$

Two equations, each one line long, replacing four. It is hard to overstate how much cleaner this is: the constants c , ϵ_0 , μ_0 have been almost entirely absorbed into the definitions, and the equations are manifestly Lorentz covariant, since both sides carry a single free upper index and so transform the same way.

Several facts we worked for now become immediate.

First, charge conservation. Since $F^{\mu\nu}$ is antisymmetric and $\partial_\nu\partial_\mu$ is symmetric, $\partial_\nu\partial_\mu F^{\mu\nu} = 0$ identically, and hence

$$\partial_\nu J^\nu = 0.$$

Compare this with the fiddly computation we did in Section 12.4.4.

Secondly, the second equation is automatic once we have potentials. If $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ then

$$\partial_\mu \tilde{F}^{\mu\nu} = \frac{1}{2} \varepsilon^{\mu\nu\rho\sigma} \partial_\mu F_{\rho\sigma} = \frac{1}{2} \varepsilon^{\mu\nu\rho\sigma} \partial_\mu (\partial_\rho A_\sigma - \partial_\sigma A_\rho) = 0,$$

since ε is antisymmetric in $\mu\rho$ while $\partial_\mu\partial_\rho$ is symmetric. So the entire theory reduces to

$$\partial_\mu F^{\mu\nu} = \mu_0 J^\nu \quad \text{where} \quad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu.$$

Thirdly, the asymmetry between the two equations – a source on one, zero on the other – is exactly the statement that there are electric charges but no magnetic ones.

§12.5.8 The Lorenz Gauge

In magnetostatics we exploited the freedom in $\mathbf{A}$ by choosing Coulomb gauge, $\nabla \cdot \mathbf{A} = 0$, which turned the field equation into Poisson's equation. There is a relativistic version of the same trick, and it is prettier.

Definition 12.5.17 (Lorenz gauge)

A gauge potential satisfying

$$\partial_\mu A^\mu = 0$$

is said to be in **Lorenz gauge**^a. In three-dimensional language this reads $\nabla \cdot \mathbf{A} + \frac{1}{c^2} \frac{\partial \phi}{\partial t} = 0$.

^aAfter Ludvig Lorenz, who is not Hendrik Lorentz of the Lorentz transformations. The near-coincidence of names is one of the crueller accidents in the history of physics.

Unlike Coulomb gauge, this condition is Lorentz invariant: it involves only a contracted pair of indices, so an observer in any frame will agree that it holds.

Proposition 12.5.18

Any gauge potential can be brought into Lorenz gauge.

Proof. Suppose $\partial_\mu A^\mu = \psi$. Under a gauge transformation $A_\mu \mapsto A_\mu - \partial_\mu \chi$ we get

$$\partial_\mu A^\mu \mapsto \psi - \partial_\mu \partial^\mu \chi,$$

so we need to solve $\square \chi = \psi$, where $\square = \partial_\mu \partial^\mu = \frac{1}{c^2} \frac{\partial^2}{\partial t^2} - \nabla^2$ is the **d'Alembertian**. This is the inhomogeneous wave equation, which always has solutions. $\square$

The payoff is immediate. Substituting $F^{\mu\nu} = \partial^\mu A^\nu - \partial^\nu A^\mu$ into the Maxwell equation,

$$\mu_0 J^\nu = \partial_\mu F^{\mu\nu} = \partial_\mu \partial^\mu A^\nu - \partial^\nu (\partial_\mu A^\mu) = \square A^\nu,$$

the second term vanishing precisely because we are in Lorenz gauge. So the whole of electromagnetism reduces to

Theorem 12.5.19

In Lorenz gauge, Maxwell's equations are

$$\square A^\nu = \mu_0 J^\nu.$$

Four decoupled wave equations, one for each component of the potential, sourced by the corresponding component of the current. In empty space $J^\nu = \mathbf{0}$ and this is $\square A^\nu = 0$: the potential propagates as a wave at speed c , which is our electromagnetic waves reappearing in a much more economical form. And the fact that the equation is a *wave* equation rather than Poisson's equation says something physically important – changing a charge here does not instantaneously change the field there. Influence propagates at the speed of light.

Remark. The Lorenz gauge does not fix A^μ completely. We may still perform a further gauge transformation with any χ satisfying $\square\chi = 0$, and remain in Lorenz gauge. This residual freedom is what allows one to argue that an electromagnetic wave has only two physical polarisation states, rather than the four one might naively count from A^μ – exactly the two we found in Section 4.

§12.5.9 The Lorentz Force in Covariant Form

One thing remains: the force law. In non-relativistic notation it is

$$\frac{d\mathbf{p}}{dt} = q(\mathbf{E} + \mathbf{u} \times \mathbf{B}),$$

and we should like a version which is manifestly covariant. The right hand side involves $\mathbf{E}$, $\mathbf{B}$ and $\mathbf{u}$, which we now know how to package as $F^{\mu\nu}$ and U^μ ; the left is a rate of change of momentum, which becomes $dP^\mu/d\tau$. There is essentially only one way to combine these.

Law 12.5.20 (Lorentz force law, relativistic form)

A particle of charge q obeys

$$\frac{dP^\mu}{d\tau} = q F^{\mu\nu} U_\nu.$$

Proposition 12.5.21

This is equivalent to the Lorentz force law together with the work-energy relation.

Proof. Take $\mu = i$ spatial. Using $U_\nu = \gamma(c, -\mathbf{u})$ and reading off $F^{i\nu}$ from the matrix,

$$\frac{d\mathbf{p}}{d\tau} = q\gamma(\mathbf{E} + \mathbf{u} \times \mathbf{B}),$$

and since $dt/d\tau = \gamma$, the chain rule gives

$$\frac{d\mathbf{p}}{dt} = q(\mathbf{E} + \mathbf{u} \times \mathbf{B}),$$

the familiar law – with the understanding that $\mathbf{p} = m\gamma\mathbf{u}$ is the relativistic momentum.

Now take $\mu = 0$. Then $F^{0\nu}U_\nu = -\frac{\mathbf{E}}{c} \cdot (-\gamma\mathbf{u}) = \frac{\gamma}{c}\mathbf{E} \cdot \mathbf{u}$, so

$$\frac{dP^0}{d\tau} = \frac{1}{c} \frac{dE}{d\tau} = \frac{q\gamma}{c} \mathbf{E} \cdot \mathbf{u} \implies \frac{dE}{dt} = q\mathbf{E} \cdot \mathbf{u},$$

which is the statement that the electric field does work at a rate $q\mathbf{E} \cdot \mathbf{u}$ – and, incidentally, that the magnetic field does none. $\square$

So the time component of the covariant force law, which has no non-relativistic analogue as a separate statement, is the energy equation. This is a recurring theme in relativity: equations that look independent in three dimensions turn out to be components of a single four-dimensional statement.

We close with two standard applications.

Example 12.5.22 (Motion in a constant electric field)

Take $\mathbf{E} = (E, 0, 0)$ and start the particle from rest, so the motion stays along $\hat{\mathbf{x}}$. The equation of motion is

$$m \frac{d(\gamma u)}{dt} = qE \implies m\gamma u = qEt,$$

taking $u = 0$ at $t = 0$. Solving for u ,

$$u = \frac{dx}{dt} = \frac{qEt}{\sqrt{m^2 + q^2 E^2 t^2 / c^2}}.$$

Note that $u \rightarrow c$ as $t \rightarrow \infty$, but never reaches it: no amount of pushing gets a massive particle to the speed of light. Integrating,

$$x = \frac{mc^2}{qE} \left(\sqrt{1 + \frac{q^2 E^2 t^2}{m^2 c^2}} - 1 \right),$$

and for small t this expands as $x \approx \frac{qE}{2m} t^2$, which is the Newtonian answer, as it must be.

Example 12.5.23 (Motion in a constant magnetic field)

Take $\mathbf{B} = (0, 0, B)$ with $\mathbf{E} = \mathbf{0}$. The $\mu = 0$ equation gives

$$\frac{dP^0}{d\tau} = 0 \implies E = m\gamma c^2 \text{ is constant,}$$

so γ , and hence $|\mathbf{u}|$, is constant – as we knew, since magnetic fields do no work. The spatial equation is then

$$m\gamma \frac{d\mathbf{u}}{dt} = q\mathbf{u} \times \mathbf{B},$$

the γ coming outside the derivative because it is constant. This is the equation we solved in Dynamics and Relativity, except for the factor of γ : the particle moves in

a circle (or a helix, if it also has velocity along $\mathbf{B}$) with angular frequency

$$\omega = \frac{qB}{m\gamma}.$$

The relativistic correction is what makes a cyclotron stop working at high energies, and is why one builds synchrotrons instead.

That is the end of the course. It is worth taking stock of where we have got to. We began with four experimental laws about wires and magnets and charges, wrote them as differential equations, and found that they contained – as inevitable consequences – the existence of light, the impossibility of magnetic monopoles, the conservation of charge, and finally the structure of spacetime itself. Very little in mathematics repays this kind of attention so generously.

13 Fluid Dynamics

Fluids are everywhere. Air, water, blood, magma, the interstellar medium and the honey on your toast are all fluids, and the same handful of equations governs all of them. What makes something a fluid rather than a solid is a matter of how it responds to being pushed sideways: lean on a wall and it deforms a little and then stops, but lean on air or water and it simply keeps on moving. A solid resists shear with a finite deformation; a fluid cannot resist shear at all, and so we stop asking how far a fluid has moved and start asking how fast it is moving. Velocity, not displacement, is the central object of this subject.

This course is an introduction to that story. We will begin with the simplest flows imaginable – fluid dragged between two flat plates – and derive their equations of motion from scratch. We will then develop the general kinematic language of fluid motion, state the Navier–Stokes equations, and spend most of our time exploiting the two great simplifications available to us: that many flows of interest are effectively *inviscid* (viscosity is negligible), and that many inviscid flows are *irrotational* (they carry no local spin), in which case the whole problem collapses to Laplace’s equation and the machinery of vector calculus takes over. Along the way we will find out why aeroplanes fly, why a spinning ball swerves, how fast a tsunami travels, and why cyclones go around the wrong way in Australia.

This article constitutes my notes for the ‘Fluid Dynamics’ course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered¹. If you spot any errors or have any feedback, I can be contacted at ak2316@cam.ac.uk.

§13.1 What is a Fluid?

Before we can do any mathematics we need to decide what it is that we are modelling, and the honest answer is that we are going to model something that does not quite exist.

§13.1.1 The Continuum Hypothesis

A real fluid is made of molecules. A cubic millimetre of air at room temperature contains something like 2.5×10^{16} of them, each careering about at several hundred metres per second and colliding with its neighbours every nanosecond or so. Nobody wants to solve 10^{16} coupled equations of motion, and in any case we are almost never interested in the answer: what we want to know is how the air as a whole moves, on scales of centimetres and seconds.

So we make an idealisation.

¹We assume throughout a working knowledge of the material in the ‘Vector Calculus’ course – in particular the divergence theorem, Stokes’ theorem, the vector identities for $\nabla \times (\mathbf{a} \times \mathbf{b})$ and friends, and the expressions for ∇ , $\nabla \cdot$ and ∇^2 in cylindrical and spherical coordinates. Cross-references to my notes for that course appear throughout.

Definition 13.1.1 (Continuum Hypothesis)

The **continuum hypothesis** is the assumption that a fluid may be treated as a continuous medium, so that at every point $\mathbf{x}$ of the region occupied by the fluid and at every time t we may speak of a density $\rho(\mathbf{x}, t)$, a pressure $p(\mathbf{x}, t)$ and a velocity $\mathbf{u}(\mathbf{x}, t)$, all varying smoothly with $\mathbf{x}$ and t .

What justifies this? The idea is that we choose a length scale ℓ which is enormous compared with the spacing between molecules, but tiny compared with the scale L on which the flow varies. A blob of side ℓ then contains so many molecules that its average density is a perfectly well-defined and steady number – the statistical fluctuations are of relative size $N^{-1/2}$, which for $N \sim 10^{10}$ is utterly negligible – and yet the blob is so small compared with L that we may pretend it is a point. The ‘fluid particle’ at $\mathbf{x}$ is really such a blob, and $\mathbf{u}(\mathbf{x}, t)$ is the mean velocity of the molecules within it.

For everyday flows this works beautifully. It begins to fail in very rarefied gases (the upper atmosphere, where the mean free path is metres) and at very small scales, and we will say no more about that.

Two properties of the fluid enter our equations, and we should say what they are. The **density** ρ is the mass per unit volume; for water $\rho \approx 1000 \text{ kg m}^{-3}$ and for air $\rho \approx 1 \text{ kg m}^{-3}$. The other is the viscosity, which we come to in a moment.

§13.1.2 Stress, Strain and Newtonian Fluids

Forces in a fluid come in two flavours. A **body force** acts on the bulk of the fluid, and is specified as a force per unit volume $\mathbf{f}$; gravity, with $\mathbf{f} = \rho\mathbf{g}$, is the only one we shall meet. A **surface force** acts across a surface – either a genuine physical boundary, or an imaginary surface that we have drawn inside the fluid for the purposes of calculation – and is specified as a force per unit area.

Definition 13.1.2 (Stress)

A **stress** is a force per unit area exerted across a surface. If $\mathbf{n}$ is the unit normal to the surface, the stress is resolved into a **normal stress** parallel to $\mathbf{n}$ and a **tangential** (or **shear**) **stress** perpendicular to it.

The normal stress is one we already know about. If a fluid of pressure p lies on one side of a surface with unit normal $\mathbf{n}$ pointing *into* the fluid, then the fluid pushes on the surface with a force per unit area

$$\boldsymbol{\tau}_p = -p\mathbf{n}.$$

Pressure by itself does nothing very interesting: it pushes equally in all directions and the net effect on a small blob cancels. What drives a flow is a pressure *gradient*. Integrating the pressure force over the surface of a small volume and applying the divergence

theorem, the net force per unit volume is $-\nabla p$, so fluid is pushed from high pressure towards low pressure.

Tangential stresses are the new ingredient, and they are what distinguishes a fluid from an ideal ‘no friction’ medium. Consider the classic experiment: two large parallel plates a distance h apart with fluid in between, the lower held fixed and the upper dragged along at speed U .

To keep the upper plate moving we must keep pushing it, so the fluid exerts a retarding tangential stress on it. Experiment tells us that for air, water, oil and most other simple fluids this stress is directly proportional to U/h .

Definition 13.1.3 (Newtonian Fluid, Viscosity)

A **Newtonian fluid** is one in which the tangential stress is proportional to the rate of strain, that is, to the velocity gradient. In the configuration above the tangential stress is

$$\tau_s = \mu \frac{U}{h},$$

and the constant of proportionality μ is the **dynamic viscosity** of the fluid.

The word ‘strain’ here means extension per unit length, and the *rate* of strain is its time derivative, which is exactly a velocity gradient. Air, water and oil are Newtonian. Paint, toothpaste, blood and shampoo are **non-Newtonian**: their long chain molecules give them stress-strain relationships that are nonlinear, or that depend on the history of the flow, and they are far harder to model. Sand and rice are **granular** and are not really fluids at all, though they sometimes behave like them. We will only ever consider Newtonian fluids.

Dimensionally, $[\tau_s] = ML^{-1}T^{-2}$ and $[U/h] = T^{-1}$, so

$$[\mu] = ML^{-1}T^{-1},$$

measured in $\text{kg m}^{-1} \text{s}^{-1}$. It is a property of the fluid alone. For water $\mu \approx 10^{-3} \text{ kg m}^{-1} \text{s}^{-1}$ and for air $\mu \approx 10^{-5} \text{ kg m}^{-1} \text{s}^{-1}$.

In general, for a flow with velocity u_T tangential to some surface with inward normal $\mathbf{n}$, the tangential stress exerted by the fluid on the surface is

$$\tau_s = \mu \frac{\partial u_T}{\partial n},$$

directed along the tangential component of the velocity. This is the definition we shall actually use.

Remark. In full generality the stress is a rank-2 tensor field σ_{ij} , and the Newtonian constitutive relation reads $\sigma_{ij} = -p\delta_{ij} + 2\mu e_{ij}$ where e_{ij} is the rate-of-strain tensor. We will not need this machinery in this course – we will only ever consider situations simple enough that we can identify ‘the’ shear stress by inspection – but it is what makes the arguments below rigorous, and it is the starting point of the Part II course.

§13.2 Parallel Viscous Flow

We are going to begin with the simplest flows there are, and derive their equations of motion honestly from a force balance. This has the great virtue that when we later write down the Navier–Stokes equations without deriving them, we will at least recognise them as a generalisation of something we understand.

Definition 13.2.1 (Steady, Parallel Flow)

A flow is **steady** if the velocity at each fixed point does not change in time, so that $\partial \mathbf{u} / \partial t = \mathbf{0}$. A flow is **parallel** if the fluid moves in one direction only, so that (choosing axes appropriately)

$$\mathbf{u} = (u(y, t), 0, 0).$$

Note the claim buried in the definition: the velocity of a parallel flow does not depend on x . This is forced on us by incompressibility. If u increased with x then fluid would be leaving any given slab faster than it arrives, and fluid would have to be created or destroyed to compensate. We will prove this properly in Section 13.3; for now we take it as read.

§13.2.1 The Equations of Parallel Flow

Consider a small rectangular box of fluid, of side δx by δy and unit width in the z direction, sitting inside a steady parallel flow.

The box moves in the x direction without accelerating, so the forces on it must balance. In the x direction there are normal stresses (pressures) on the two vertical faces, and tangential stresses on the two horizontal faces. Being careful with signs, the net force per unit width is

$$p(x) \delta y - p(x + \delta x) \delta y + \tau_s(y + \delta y) \delta x + \tau_s(y) \delta x = 0.$$

Now the normal to the top face points upwards *into* the fluid above, and the normal to the bottom face points downwards, so by our sign convention

$$\tau_s(y + \delta y) = \mu \frac{\partial u}{\partial y}(y + \delta y), \quad \tau_s(y) = -\mu \frac{\partial u}{\partial y}(y).$$

Dividing through by $\delta x \delta y$ we get

$$-\frac{p(x + \delta x) - p(x)}{\delta x} + \mu \frac{1}{\delta y} \left(\frac{\partial u}{\partial y}(y + \delta y) - \frac{\partial u}{\partial y}(y) \right) = 0,$$

and letting $\delta x, \delta y \rightarrow 0$,

$$-\frac{\partial p}{\partial x} + \mu \frac{\partial^2 u}{\partial y^2} = 0.$$

The same argument in the y direction, where nothing at all is happening, gives $\partial p / \partial y = 0$.

There is no reason to restrict ourselves to steady flow with no body forces. If the flow is unsteady, the left hand side of the force balance becomes mass times acceleration, $\rho \delta x \delta y \partial u / \partial t$; and if there is a body force per unit volume $(f_x, f_y, 0)$ we should add $f_x \delta x \delta y$ and $f_y \delta x \delta y$ to the two equations. Doing so gives the following.

Proposition 13.2.2 (Equations of Parallel Flow)

For a parallel flow $\mathbf{u} = (u(y, t), 0, 0)$ of a Newtonian fluid of constant density ρ and viscosity μ , subject to a body force per unit volume $(f_x, f_y, 0)$,

$$\begin{aligned} \rho \frac{\partial u}{\partial t} &= -\frac{\partial p}{\partial x} + \mu \frac{\partial^2 u}{\partial y^2} + f_x, \\ 0 &= -\frac{\partial p}{\partial y} + f_y. \end{aligned}$$

Notice what the second equation says: across the flow, the pressure is purely hydrostatic. All the dynamics is in the first equation, which is a diffusion equation for u forced by the pressure gradient. Notice too that these equations are *linear* in u , so we may superpose solutions – a fact we will use immediately.

Finally, we need boundary conditions. There are two possibilities.

Definition 13.2.3 (Boundary Conditions for Viscous Flow)

At a boundary, a viscous fluid satisfies one of:

- (i) the **no-slip condition**, that the tangential velocity of the fluid equals the tangential velocity of the boundary. In particular $u_T = 0$ at a stationary rigid boundary.
- (ii) the **stress condition**, that a prescribed tangential stress τ is applied, so that $-\mu \partial u_T / \partial n = \tau$.

No-slip is the appropriate condition at a solid boundary: fluid really does stick to solids, which is why dust does not blow off a fan blade. The stress condition is appropriate at a boundary between two fluids, where the stresses must match; in the important special case of a liquid with air above it, the air is so much less viscous that we may take $\tau = 0$ and speak of a **free surface**.

§13.2.2 Couette and Poiseuille Flow

The two canonical parallel flows are driven, respectively, by a moving boundary and by a pressure gradient.

Example 13.2.4 (Plane Couette Flow)

Fluid occupies $0 < y < h$ between two plates; the lower is at rest, the upper moves with speed U . There is no pressure gradient and no body force, and the flow is steady, so our equation reduces to

$$\frac{\partial^2 u}{\partial y^2} = 0.$$

Hence u is linear in y . The no-slip conditions are $u(0) = 0$ and $u(h) = U$, so

$$u = \frac{Uy}{h},$$

a uniform shear. The velocity gradient, and hence the stress, is the same everywhere in the fluid.

Example 13.2.5 (Plane Poiseuille Flow)

Now hold both plates at rest and instead drive the flow with a pressure difference: the pressure is P_1 at $x = 0$ and $P_0 < P_1$ at $x = L$. We will include gravity, taking $\mathbf{f} = (0, -g\rho, 0)$. Our equations read

$$\begin{aligned} -\frac{\partial p}{\partial x} + \mu \frac{\partial^2 u}{\partial y^2} &= 0, \\ -\frac{\partial p}{\partial y} - g\rho &= 0. \end{aligned}$$

Integrating the second, $p = -g\rho y + F(x)$ for some function F . Substituting into the first,

$$\mu \frac{\partial^2 u}{\partial y^2} = F'(x).$$

The left hand side is a function of y alone, the right of x alone, so both are equal to some constant G . Since $F(L) - F(0) = P_0 - P_1$ we identify

$$G = -\frac{P_1 - P_0}{L},$$

and integrating twice with $u(0) = u(h) = 0$ gives

$$u = \frac{P_1 - P_0}{2\mu L} y(h - y).$$

This is the famous parabolic profile, fastest in the middle at $y = h/2$ where $u = (P_1 - P_0)h^2/8\mu L$.

Since the equations are linear, a flow driven by *both* a moving boundary and a pressure gradient is simply the sum of the two solutions above.

It is worth extracting a couple of derived quantities from these solutions, since they are the things one actually measures.

Definition 13.2.6 (Volume Flux)

The **volume flux** q across a cross-section is the volume of fluid crossing it per unit time. For a parallel flow, per unit transverse width,

$$q = \int_0^h u(y) \, dy.$$

Example 13.2.7

For the Couette flow,

$$q = \int_0^h \frac{Uy}{h} \, dy = \frac{Uh}{2},$$

which is just what we would get by moving all the fluid at the average of the two plate speeds. For the Poiseuille flow, writing $G = (P_1 - P_0)/L$,

$$q = \int_0^h \frac{G}{2\mu} y(h-y) \, dy = \frac{Gh^3}{12\mu}.$$

The h^3 here is worth remembering: doubling the width of a pipe increases its throughput eightfold at fixed pressure gradient, which is why arterial narrowing is so serious.

We can also ask how much local rotation there is in these flows.

Definition 13.2.8 (Vorticity)

The **vorticity** of a flow is

$$\boldsymbol{\omega} = \nabla \times \mathbf{u}.$$

We will have a great deal to say about vorticity later. For a parallel flow $\mathbf{u} = (u(y, t), 0, 0)$ we simply have

$$\boldsymbol{\omega} = \left(0, 0, -\frac{\partial u}{\partial y}\right).$$

Example 13.2.9

For the Couette flow, $\boldsymbol{\omega} = (0, 0, -U/h)$ is uniform: every fluid particle is spinning at the same rate, clockwise. This is a little counterintuitive, since the flow is perfectly straight, but a small paddle-wheel placed in the fluid would indeed turn, because the fluid is faster above it than below.

For the Poiseuille flow,

$$\boldsymbol{\omega} = \left(0, 0, \frac{G}{\mu} \left(y - \frac{h}{2}\right)\right),$$

which vanishes on the centre-line and has opposite signs in the two halves of the channel – the flow spins one way below the centre-line and the other way above it.

Lastly, the tangential stress exerted *on the boundaries*, which is what we would feel if we

tried to hold the plates in place, is $\tau_s = \mu \partial u / \partial n$ with $\mathbf{n}$ into the fluid. For Couette flow this is $\mu U/h$ at $y = 0$ and $-\mu U/h$ at $y = h$: the fluid drags the stationary lower plate forwards and drags backwards on the moving upper plate, as it must. For Poiseuille flow it is $Gh/2$ at both walls, pulling both forwards, and – strikingly – independent of μ . That makes sense: the total force on the walls must balance the pressure force driving the flow, which knows nothing about the fluid.

813 2 3 Two More Examples

Example 13.2.10 (Gravity-Driven Flow Down a Slope)

Suppose a layer of liquid of depth h flows steadily down a plane inclined at angle α to the horizontal, with air above.

We take x down the slope and y normal to it, so that the body force is

$$\rho \mathbf{g} = (\rho g \sin \alpha, -\rho g \cos \alpha, 0).$$

The y equation then gives

$$\frac{\partial p}{\partial y} = -\rho g \cos \alpha \implies p = p_0 - \rho g \cos \alpha (y - h),$$

using $p = p_0$ at the free surface $y = h$ (air is so light that we may treat its pressure as uniform). Note that p is independent of x , so there is no pressure gradient driving the flow – gravity does it all. The x equation is

$$\mu \frac{\partial^2 u}{\partial y^2} = -\rho g \sin \alpha.$$

The boundary conditions are no-slip at the bottom, $u(0) = 0$, and *no stress* at the free surface, $\partial u / \partial y = 0$ at $y = h$, since air is so much less viscous that it cannot exert any appreciable drag. Integrating,

$$u = \frac{\rho g \sin \alpha}{2\mu} y(2h - y).$$

This is exactly half of a Poiseuille profile: instead of returning to zero at $y = h$ it turns over there and would return to zero at $y = 2h$. That is precisely what we should expect, since a free surface is a plane of symmetry for the shear stress.

The volume flux is

$$q = \int_0^h u \, dy = \frac{\rho g \sin \alpha}{2\mu} \left(h^3 - \frac{h^3}{3} \right) = \frac{\rho g h^3 \sin \alpha}{3\mu}.$$

Everything so far has been steady. Let us do one unsteady problem, which will teach us something important about how viscosity actually operates.

Example 13.2.11 (Impulsively Started Plate)

Fluid is initially at rest in $y > 0$, above a flat plate at $y = 0$. At $t = 0$ the plate is suddenly set moving with constant speed U in the x direction. There is no pressure gradient and no body force, so our equation is

$$\frac{\partial u}{\partial t} = \nu \frac{\partial^2 u}{\partial y^2}, \quad \nu := \frac{\mu}{\rho}.$$

This is the diffusion equation!

Definition 13.2.12 (Kinematic Viscosity)

The **kinematic viscosity** is $\nu = \mu/\rho$, with dimensions L^2T^{-1} .

So ν is a diffusivity, and what it diffuses is momentum – or, equivalently, vorticity. This is the single most useful way to think about viscosity.

Before solving, let us extract the answer by dimensional analysis. The only quantities in the problem are U , ν , y and t ; there is no imposed length scale at all, since the fluid is infinitely deep. Suppose that after a time T the motion has penetrated a distance δ into the fluid. Balancing the two sides of the equation on those scales,

$$\frac{U}{T} \sim \nu \frac{U}{\delta^2} \implies \delta \sim \sqrt{\nu T}.$$

The U has cancelled, as it must, since the equation is linear.

This is a very small number. For water $\nu \approx 10^{-6} \text{ m}^2 \text{ s}^{-1}$ and for air $\nu \approx 10^{-5} \text{ m}^2 \text{ s}^{-1}$, so after a full minute the disturbance has spread only a few millimetres. Viscous effects are confined to thin layers near boundaries – a fact which will dominate the rest of the course.

Now let us solve it properly. Since there is no extrinsic length scale, we look for a **similarity solution**: we guess that the profile always has the same shape, merely stretched by the growing thickness $\sqrt{\nu t}$. Write

$$u(y, t) = U f(\eta), \quad \eta = \frac{y}{\sqrt{\nu t}}.$$

Then $\partial u / \partial t = -U f'(\eta) \eta / (2t)$ and $\partial^2 u / \partial y^2 = U f''(\eta) / (\nu t)$, so the equation becomes an ordinary differential equation,

$$f'' + \frac{1}{2} \eta f' = 0,$$

with $f(0) = 1$ and $f \rightarrow 0$ as $\eta \rightarrow \infty$. This integrates at once: $f' = C e^{-\eta^2/4}$, and imposing the boundary conditions gives

$$u = U \operatorname{erfc}\left(\frac{y}{2\sqrt{\nu t}}\right),$$

where $\operatorname{erfc}(s) = 1 - \frac{2}{\sqrt{\pi}} \int_0^s e^{-r^2} dr$ is the complementary error function.

The stress on the plate is

$$\tau_s = \mu \left. \frac{\partial u}{\partial y} \right|_{y=0} = -\frac{\mu U}{\sqrt{\pi \nu t}} = -U \sqrt{\frac{\rho \mu}{\pi t}},$$

which is infinite at $t = 0$ (we did, after all, ask for an infinite acceleration) and decays like $t^{-1/2}$ thereafter.

The combination $\sqrt{\rho \mu}$ appearing here is worth a comment. It is about 1 for water and about $10^{-2.5}$ for air, so for a given surface velocity, water transmits far more stress than air does. This is why the wind blowing across the ocean generates a surface current a hundred times slower than itself, rather than dragging the sea along with it.

§13.3 Kinematics

So far we have looked at one very special family of flows. We now build up the general language needed to describe any flow at all. This section contains no dynamics whatsoever – no forces appear – it is purely about how to describe motion and what conservation of mass has to say about it.

§13.3.1 The Material Derivative

Suppose we want to measure how some quantity f – pressure, temperature, the concentration of a dye – is changing. There are two natural things we might mean, and they are not the same.

We could fix a probe at a point in space and watch the reading change. This gives us $\partial f / \partial t$, the rate of change at fixed $\mathbf{x}$, and it is called the **Eulerian** time derivative. Alternatively we could climb into a boat, let ourselves drift with the current, and watch the reading change as we go. This is the **Lagrangian** derivative, and it is the one which physics actually cares about: Newton's second law is about the acceleration of a *particle*, not about the rate of change of velocity at a fixed point in the room.

Relating them is an application of the chain rule. If $\mathbf{x}(t)$ is any path through the flow, then

$$\frac{d}{dt} f(\mathbf{x}(t), t) = \frac{\partial f}{\partial t} + \dot{\mathbf{x}} \cdot \nabla f.$$

If the path is that of a fluid particle, then by definition $\dot{\mathbf{x}} = \mathbf{u}$.

Definition 13.3.1 (Material Derivative)

The **material derivative** (or convective, or Lagrangian derivative) of a field f is

$$\frac{Df}{Dt} = \frac{\partial f}{\partial t} + \mathbf{u} \cdot \nabla f.$$

It is the rate of change of f experienced by a fluid particle moving with the flow.

The two terms have names. The first, $\partial f / \partial t$, is the local or Eulerian rate of change: how fast things are changing at a fixed point. The second, $\mathbf{u} \cdot \nabla f$, is the **advective** term: the change we experience because we have been carried somewhere where f is different.

The picture to have in mind is a river which widens as it flows. The flow is steady, so a probe fixed to the bank sees nothing changing at all and $\partial \mathbf{u} / \partial t = \mathbf{0}$. But a leaf drifting downstream visibly *decelerates* as the river widens, and this deceleration is entirely due to the advective term $\mathbf{u} \cdot \nabla \mathbf{u}$. Steady does not mean unaccelerated.

The material derivative is where all the difficulty of fluid dynamics comes from, incidentally: applied to $\mathbf{u}$ itself, the term $\mathbf{u} \cdot \nabla \mathbf{u}$ is quadratic in the unknown, and it is this nonlinearity which makes the equations of fluid dynamics so intractable (and which is responsible for turbulence).

§13.3.2 Streamlines, Pathlines and Streaklines

There are three natural families of curves associated with a flow, and they coincide only for steady flows – confusing them is a classic source of error.

Definition 13.3.2 (Streamlines, Pathlines, Streaklines)

Let $\mathbf{u}(\mathbf{x}, t)$ be a velocity field.

- (i) A **streamline** at time t_0 is a curve which is everywhere parallel to $\mathbf{u}(\cdot, t_0)$; that is, a solution of

$$\frac{d\mathbf{x}}{ds} = \mathbf{u}(\mathbf{x}, t_0)$$

with t_0 held *fixed*. Streamlines give an instantaneous snapshot of the flow direction.

- (ii) A **pathline** (or particle path) is the trajectory actually followed by a given fluid particle, a solution of

$$\frac{d\mathbf{x}}{dt} = \mathbf{u}(\mathbf{x}, t).$$

- (iii) A **streakline** is the locus at a given time of all particles which have previously

passed through some fixed point – the curve you see when you release dye continuously from a nozzle.

If the flow is steady then $\mathbf{u}$ does not depend on t and the two differential equations above are identical, so streamlines, pathlines and streaklines all coincide. If the flow is unsteady they can be wildly different.

Example 13.3.3 (Streamlines Need Not Be Pathlines)

Consider the (rather artificial) unsteady flow

$$\mathbf{u} = (t, 1, 0).$$

At any instant the velocity is uniform in space, so the streamlines are parallel straight lines: vertical at $t = 0$, at 45° at $t = 1$, and steadily flattening thereafter.

Yet no fluid particle follows any of these lines. A particle released at (x_0, y_0) obeys $\dot{x} = t$, $\dot{y} = 1$, so

$$x = \frac{1}{2}t^2 + x_0, \quad y = t + y_0,$$

and eliminating t , its pathline is the parabola

$$x - x_0 = \frac{1}{2}(y - y_0)^2.$$

Not a straight line in sight.

§13.3.3 Conservation of Mass

Now for our first real physical law. Fix an arbitrary region of space $\mathcal{D}$, with boundary $\partial\mathcal{D}$ and outward unit normal $\mathbf{n}$, and let fluid flow through it.

The mass inside $\mathcal{D}$ can change only because fluid flows in or out across $\partial\mathcal{D}$. In a time δt , the fluid crossing a patch δS of the boundary occupies a slanted cylinder of volume $(\mathbf{u} \cdot \mathbf{n}) \delta S \delta t$, carrying mass $\rho(\mathbf{u} \cdot \mathbf{n}) \delta S \delta t$. Hence

$$\frac{d}{dt} \int_{\mathcal{D}} \rho \, dV = - \int_{\partial\mathcal{D}} \rho \mathbf{u} \cdot \mathbf{n} \, dS,$$

the minus sign because $\mathbf{n}$ points out. Since $\mathcal{D}$ is a *fixed* region we may take the derivative inside the integral, and by the divergence theorem we may convert the right hand side

to a volume integral:

$$\int_{\mathcal{D}} \left(\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) \right) dV = 0.$$

This holds for every region $\mathcal{D}$, and the integrand is continuous, so the integrand must vanish identically.

Proposition 13.3.4 (Conservation of Mass)

At every point of the fluid,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0.$$

This is the prototype of a conservation law: the rate of change of the density of some quantity, plus the divergence of its flux, is zero. Exactly the same structure appears for charge in electromagnetism, and for probability in quantum mechanics.

Expanding the divergence, $\nabla \cdot (\rho \mathbf{u}) = \mathbf{u} \cdot \nabla \rho + \rho \nabla \cdot \mathbf{u}$, and recognising a material derivative, we may write this as

$$\frac{D\rho}{Dt} + \rho \nabla \cdot \mathbf{u} = 0.$$

This form makes the physical content much clearer. A fluid particle's density changes exactly when the flow is locally expanding or contracting.

§13.3.4 Incompressibility

We are now in a position to say precisely what we mean by an incompressible fluid.

Definition 13.3.5 (Incompressible Fluid)

A fluid is **incompressible** if the density of each fluid particle is constant, i.e. $D\rho/Dt = 0$. By conservation of mass this is equivalent to the **continuity equation**

$$\nabla \cdot \mathbf{u} = 0.$$

Notice this is weaker than saying the density is uniform: a stably stratified ocean, denser at the bottom, can perfectly well be incompressible in this sense. In this course we will almost always take ρ to be a constant as well, and we will say so when we do not.

Two immediate remarks. First, this justifies our claim about parallel flow: if $\mathbf{u} = (u, 0, 0)$ then $\nabla \cdot \mathbf{u} = \partial u / \partial x$, so incompressibility forces u to be independent of x .

Secondly, incompressibility is an approximation, and it is worth knowing when it is a good one. Nothing is truly incompressible – sound waves are compression waves, and if air were incompressible we could not hear. A cleaner way to say it is that incompressibility amounts to assuming that the speed of sound is infinite, so that pressure changes are communicated instantaneously. That is a good approximation precisely when the flow speed is small compared to the sound speed, which is 340 m s^{-1} in air and 1500 m s^{-1} in water. Almost everything we will do is safely in this regime.

§13.3.5 Kinematic Boundary Conditions

Whatever the dynamics, there is one thing fluid may never do: cross a boundary.

Suppose a boundary moves with velocity $\mathbf{U}$ (which may vary from place to place along it) and has unit normal $\mathbf{n}$. In a frame moving with the boundary, the fluid velocity is $\mathbf{u} - \mathbf{U}$, and the requirement that no fluid crosses the boundary is that this relative velocity has no normal component. Thus:

Definition 13.3.6 (Kinematic Boundary Condition)

At a boundary moving with velocity $\mathbf{U}$ and unit normal $\mathbf{n}$,

$$\mathbf{u} \cdot \mathbf{n} = \mathbf{U} \cdot \mathbf{n}.$$

At a stationary rigid boundary this reduces to $\mathbf{u} \cdot \mathbf{n} = 0$.

This is a purely kinematic statement – no forces, no viscosity – and it holds whether or not we are making the inviscid approximation. It should not be confused with the no-slip condition, which is a statement about the *tangential* component and only holds for a viscous fluid.

Free surfaces are more interesting, since we do not know in advance where they are. Suppose the surface of the water is given by $z = \zeta(x, y, t)$; think of an oil-water interface, or of a water wave.

Define $F(x, y, z, t) = z - \zeta(x, y, t)$, so that the surface is the level set $F = 0$. Since F is a material surface – the same fluid particles remain on it forever – we must have

$$\frac{DF}{Dt} = 0 \quad \text{on } F = 0.$$

Writing this out with $\mathbf{u} = (u, v, w)$,

$$\frac{\partial}{\partial t}(z - \zeta) + \mathbf{u} \cdot \nabla(z - \zeta) = -\frac{\partial \zeta}{\partial t} + w - u \frac{\partial \zeta}{\partial x} - v \frac{\partial \zeta}{\partial y} = 0,$$

that is,

$$w = \frac{\partial \zeta}{\partial t} + u \frac{\partial \zeta}{\partial x} + v \frac{\partial \zeta}{\partial y} = \frac{D\zeta}{Dt} \quad \text{on } z = \zeta.$$

In words: the vertical velocity of the fluid at the surface equals the rate at which the surface height changes, following the fluid. We will lean heavily on this when we do water waves.

§13.3.6 The Streamfunction

Incompressibility, $\nabla \cdot \mathbf{u} = 0$, is a constraint on three unknown functions. It would be nice to solve it once and for all, and vector calculus tells us how: a divergence-free field on a suitable domain is a curl.

Definition 13.3.7 (Vector Potential)

A **vector potential** for an incompressible flow is a field $\mathbf{A}$ with $\mathbf{u} = \nabla \times \mathbf{A}$.

In three dimensions this trades three unknowns for three unknowns and is not obviously progress. In two dimensions it is a genuine simplification. Suppose the flow is two-dimensional,

$$\mathbf{u} = (u(x, y, t), v(x, y, t), 0).$$

Then we may take $\mathbf{A} = (0, 0, \psi(x, y, t))$, and computing the curl,

$$\mathbf{u} = \left(\frac{\partial \psi}{\partial y}, -\frac{\partial \psi}{\partial x}, 0 \right).$$

Definition 13.3.8 (Streamfunction)

For a two-dimensional incompressible flow, the **streamfunction** is the scalar $\psi(x, y, t)$ with

$$u = \frac{\partial \psi}{\partial y}, \quad v = -\frac{\partial \psi}{\partial x}.$$

So a two-dimensional incompressible flow is described by a *single* scalar function, and any ψ whatsoever gives an incompressible flow, since $\nabla \cdot (\nabla \times \mathbf{A}) = 0$ automatically. That is a genuine reduction in the difficulty of the problem. The streamfunction has three lovely properties, which we now establish.

Proposition 13.3.9 (Properties of the Streamfunction)

Let ψ be the streamfunction of a two-dimensional incompressible flow. Then

- (i) The streamlines of the flow are exactly the contours of ψ .
- (ii) The volume flux (per unit length in z) across any curve from $\mathbf{x}_0$ to $\mathbf{x}_1$ is $\psi(\mathbf{x}_1) - \psi(\mathbf{x}_0)$, and in particular depends only on the endpoints.
- (iii) ψ is constant on any stationary rigid boundary.

Proof. For (i), a contour of ψ has normal $\mathbf{n} \parallel \nabla \psi = (\psi_x, \psi_y, 0)$, and

$$\mathbf{u} \cdot \nabla \psi = \frac{\partial \psi}{\partial y} \frac{\partial \psi}{\partial x} - \frac{\partial \psi}{\partial x} \frac{\partial \psi}{\partial y} = 0.$$

So $\mathbf{u}$ is everywhere tangent to the contours, which is exactly the definition of a streamline.

For (ii), parameterise the curve by arclength. A line element $d\boldsymbol{\ell} = (dx, dy)$ has (rightward) normal $\mathbf{n} d\ell = (dy, -dx)$, so the flux across the curve is

$$q = \int_{\mathbf{x}_0}^{\mathbf{x}_1} \mathbf{u} \cdot \mathbf{n} d\ell = \int_{\mathbf{x}_0}^{\mathbf{x}_1} (u dy - v dx) = \int_{\mathbf{x}_0}^{\mathbf{x}_1} \left(\frac{\partial \psi}{\partial y} dy + \frac{\partial \psi}{\partial x} dx \right) = \int_{\mathbf{x}_0}^{\mathbf{x}_1} d\psi,$$

which is $\psi(\mathbf{x}_1) - \psi(\mathbf{x}_0)$.

For (iii), a stationary rigid boundary satisfies $\mathbf{u} \cdot \mathbf{n} = 0$, so no flux crosses it, so by (ii) ψ takes the same value at any two of its points. $\square$

Part (ii) is the one to remember, and it has a very useful visual consequence. Suppose we draw streamlines at equally spaced values $\psi = c_0, c_0 + \Delta, c_0 + 2\Delta, \dots$. Then the volume flux between any two adjacent streamlines is the same, so where the streamlines are close together, the fluid must be moving faster.

By property (iii) we can always choose the constant so that $\psi = 0$ on a boundary, and it is conventional to do so.

It is often convenient to work in plane polar coordinates (r, θ) , viewed as cylindrical polars with the z direction ignored. Then $\mathbf{A} = (0, 0, \psi)$ and

$$\mathbf{u} = \nabla \times \mathbf{A} = \frac{1}{r} \begin{vmatrix} \mathbf{e}_r & r\mathbf{e}_\theta & \mathbf{e}_z \\ \partial_r & \partial_\theta & \partial_z \\ 0 & 0 & \psi \end{vmatrix} = \left(\frac{1}{r} \frac{\partial \psi}{\partial \theta}, -\frac{\partial \psi}{\partial r}, 0 \right).$$

One checks directly that this is divergence free using the polar form

$$\nabla \cdot \mathbf{u} = \frac{1}{r} \frac{\partial}{\partial r}(ru_r) + \frac{1}{r} \frac{\partial u_\theta}{\partial \theta}.$$

There is a third case which comes up often enough to be worth recording, namely axisymmetric flow. If in spherical polars (r, θ, φ) the flow has no φ component and no φ dependence, we may take $\mathbf{A} = (0, 0, \Psi/(r \sin \theta))$, giving

$$u_r = \frac{1}{r^2 \sin \theta} \frac{\partial \Psi}{\partial \theta}, \quad u_\theta = -\frac{1}{r \sin \theta} \frac{\partial \Psi}{\partial r}.$$

Definition 13.3.10 (Stokes Streamfunction)

The function $\Psi(r, \theta)$ above is the **Stokes streamfunction**. Its contours are again streamlines, and $2\pi(\Psi(\mathbf{x}_1) - \Psi(\mathbf{x}_0))$ is the volume flux through the annular surface swept out by rotating a curve from $\mathbf{x}_0$ to $\mathbf{x}_1$ about the axis.

The factor of $r \sin \theta$ is there precisely to make the flux interpretation work: it is the distance from the axis, so that $2\pi r \sin \theta$ is the circumference of the circle traced out by a point.

§13.4 Dynamics

We have spent long enough describing motion; it is time to explain it. In this section we write down the general equation of motion for a fluid, work out when we are allowed to throw parts of it away, and then extract two of the most useful results in the subject: the momentum integral and Bernoulli's equation.

§13.4.1 The Navier–Stokes Equations

The general equation of motion for a Newtonian fluid is the following. Deriving it properly requires the stress tensor, and is a job for the Part II course; what we can say is that it is exactly Newton’s second law, with the same three forces we met in the parallel case, and that it reduces to our parallel-flow equations in that special case.

Law 13.4.1 (Navier–Stokes Equation)

For an incompressible Newtonian fluid of constant density ρ and viscosity μ ,

$$\rho \frac{D\mathbf{u}}{Dt} = \rho \left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right) = -\nabla p + \mu \nabla^2 \mathbf{u} + \mathbf{f},$$

together with the continuity equation $\nabla \cdot \mathbf{u} = 0$.

Let us read this off term by term. On the left is mass per unit volume times acceleration – and note carefully that the acceleration of a fluid *particle* is the material derivative of $\mathbf{u}$, not the partial derivative. On the right are the three forces per unit volume: the pressure gradient, the viscous force, and any body force $\mathbf{f}$ (for us, always gravity, $\mathbf{f} = \rho \mathbf{g}$).

A few remarks are in order.

- (i) The equation is *nonlinear*, because of the advective term $\mathbf{u} \cdot \nabla \mathbf{u}$. This is the source of essentially all the difficulty in fluid dynamics, and the reason that the existence and smoothness of solutions in three dimensions is an open problem with a million dollar prize attached.
- (ii) Together with $\nabla \cdot \mathbf{u} = 0$ we have four scalar equations for four unknowns (u, v, w and p), which is at least the right count. Note that there is no separate equation for the pressure: the pressure is whatever it has to be in order to keep the flow incompressible.
- (iii) In Cartesian coordinates the viscous term acts componentwise, so that $\nabla^2 \mathbf{u}$ has components $(\nabla^2 u_x, \nabla^2 u_y, \nabla^2 u_z)$. In other coordinate systems it emphatically does not, and it is then safest to use the identity

$$\nabla^2 \mathbf{u} = \nabla(\nabla \cdot \mathbf{u}) - \nabla \times (\nabla \times \mathbf{u}) = -\nabla \times \boldsymbol{\omega}$$

for an incompressible flow. This exhibits the viscous force as being entirely due to gradients of vorticity, a fact we will return to.

- (iv) Setting $\mathbf{u} = (u(y, t), 0, 0)$ recovers exactly the parallel flow equations of Section 2, as the reader should check.

§13.4.2 Pressure, Gravity and Reduced Pressure

Before doing anything hard, let us dispose of gravity.

Suppose the fluid is at rest, $\mathbf{u} = \mathbf{0}$. Then Navier–Stokes reduces to $\nabla p_H = \rho \mathbf{g}$, where we write p_H for the pressure in this static case. Taking $\mathbf{g} = (0, 0, -g)$ and ρ constant, this integrates to

Definition 13.4.2 (Hydrostatic Pressure)

The **hydrostatic pressure** in a fluid of constant density at rest is

$$p_H = p_0 - g\rho z,$$

where p_0 is the pressure at $z = 0$.

This says exactly what you would expect: the pressure at a point is the weight of fluid above it. It has one famous consequence.

Proposition 13.4.3 (Archimedes' Principle)

A body $\mathcal{D}$ immersed in a fluid at rest experiences a net pressure force equal to minus the weight of the fluid it displaces.

Proof. The force is the integral of $-p_H \mathbf{n}$ over the surface of the body, and by the divergence theorem

$$\mathbf{F} = - \int_{\partial \mathcal{D}} p_H \mathbf{n} \, dS = - \int_{\mathcal{D}} \nabla p_H \, dV = - \int_{\mathcal{D}} \rho \mathbf{g} \, dV = -M \mathbf{g},$$

where $M = \rho \, \text{vol}(\mathcal{D})$ is the mass of fluid displaced. $\square$

So a body denser than the fluid sinks, one less dense floats, and one of exactly the same density is neutrally buoyant and just sits there.

Now suppose the fluid is moving. The pressure will not be hydrostatic, but we may always split it up,

$$p = p_H + p',$$

where p' is the deviation from hydrostatic caused by (or causing) the motion. Substituting into Navier–Stokes, the term $-\nabla p_H$ cancels precisely against $\rho \mathbf{g}$, leaving

$$\rho \frac{D\mathbf{u}}{Dt} = -\nabla p' + \mu \nabla^2 \mathbf{u}.$$

Definition 13.4.4 (Reduced Pressure)

The **reduced** (or **modified**) **pressure** is $p' = p - p_H = p + g\rho z$.

This is a genuinely useful trick, and it deserves to be stated loudly: *if the density is constant, gravity has no dynamical effect at all*. Every fluid particle is neutrally buoyant, and we may drop gravity from the equations entirely provided we agree to work with the reduced pressure. From now on we will usually drop the prime and simply write p , understanding that we mean the reduced pressure.

The one place where we cannot do this is when there is a density difference in the problem – most importantly, at a free surface, where water meets air. There, gravity matters enormously, and it is the restoring force for water waves. We will restore it when we get there.

§13.4.3 The Reynolds Number

The Navier–Stokes equations are hard, so we would like to know when we can throw a term away. The systematic way to do this is to estimate the size of each term.

Suppose the flow has a characteristic speed U and a characteristic length scale L , both externally imposed by the geometry – for flow in a pipe, U might be the mean speed and L the diameter. The natural time scale is then $T = L/U$, the time taken to traverse the region. Dividing Navier–Stokes by ρ and writing $\nu = \mu/\rho$,

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = -\frac{1}{\rho} \nabla p + \nu \nabla^2 \mathbf{u},$$

and the four terms have magnitudes of order

$$\frac{U}{L/U}, \quad \frac{U^2}{L}, \quad \frac{P}{\rho L}, \quad \frac{\nu U}{L^2},$$

where P is a characteristic pressure *difference* (only differences drive flow). Dividing throughout by U^2/L ,

$$1, \quad 1, \quad \frac{P}{\rho U^2}, \quad \frac{\nu}{UL}.$$

Definition 13.4.5 (Reynolds Number)

The **Reynolds number** of a flow is the dimensionless quantity

$$Re = \frac{UL}{\nu}.$$

The two inertial terms are both of relative size 1, and the viscous term of relative size $1/Re$. So the Reynolds number measures the importance of inertia relative to viscosity, and it is the single most important number in the subject. We need not worry about the pressure term: the pressure will always scale so as to balance whatever the dominant terms are, since its job is to enforce incompressibility.

Definition 13.4.6 (Dynamic Similarity)

Two flows with geometrically similar boundaries and the same Reynolds number are **dynamically similar**: they are described by the same dimensionless solution.

This is why wind tunnels work. It is also why lava, despite being fabulously viscous, flows down a mountain looking very much like water flowing down a river – the length scales are so much larger that the Reynolds numbers are comparable. It is the Reynolds number, not U , L or ν separately, that determines the character of a flow.

Example 13.4.7

An aircraft has $U \sim 250 \text{ m s}^{-1}$, $L \sim 10 \text{ m}$ and (in air) $\nu \sim 10^{-5} \text{ m}^2 \text{ s}^{-1}$, so $Re \sim 10^8$: viscosity is utterly negligible on the scale of the wing. A bacterium swimming in water has $U \sim 10^{-5} \text{ m s}^{-1}$, $L \sim 10^{-6} \text{ m}$, $\nu \sim 10^{-6} \text{ m}^2 \text{ s}^{-1}$, so $Re \sim 10^{-5}$: for the bacterium, inertia is meaningless and water feels like treacle.

The two limiting cases are worth naming. When $Re \ll 1$ the inertial terms are negligible, the pressure scales as $P \sim \mu U/L$ to balance the viscous stress, and we obtain the linear **Stokes equations**

$$\mathbf{0} = -\nabla p + \mu \nabla^2 \mathbf{u}, \quad \nabla \cdot \mathbf{u} = 0.$$

When $Re \gg 1$ the viscous term is negligible, the pressure scales as $P \sim \rho U^2$ to balance inertia, and we obtain the **Euler equations**

$$\rho \frac{D\mathbf{u}}{Dt} = -\nabla p, \quad \nabla \cdot \mathbf{u} = 0.$$

The rest of this course is essentially about the second of these.

There is however a serious catch, and we should be honest about it. Dropping the viscous term reduces the order of the equation from two to one, so we can no longer impose as many boundary conditions – and the one we must give up is no-slip. An inviscid fluid is allowed to slide along a solid wall. Since real fluids do not, our approximation must be failing somewhere near the boundary.

Where? At the scale δ on which the viscous and inertial terms are comparable:

$$\frac{U^2}{\delta} \sim \frac{\nu U}{\delta^2} \implies \delta \sim \frac{\nu}{U}, \quad \text{equivalently} \quad \frac{\delta}{L} \sim \frac{1}{Re}.$$

So when Re is large there is a thin **boundary layer** of thickness $\delta \ll L$ hugging the wall, inside which viscosity matters and the velocity adjusts rapidly from zero at the wall to the inviscid ‘slip’ value just outside. Away from that layer the inviscid solution is excellent. This is the picture to keep in mind whenever we set $\nu = 0$ in what follows.

§13.4.4 A Case Study: Stagnation Point Flow

Let us make all of that concrete with a single carefully worked example, which is well worth the effort because it displays the boundary layer explicitly.

Example 13.4.8 (Stagnation Point Flow)

We look for a solution of the Navier–Stokes equations in the half-plane $y \geq 0$ with $\mathbf{u} = \mathbf{0}$ on $y = 0$ and

$$\mathbf{u} \rightarrow (Ex, -Ey, 0) \quad \text{as } y \rightarrow \infty,$$

for a constant $E > 0$. The far field here is fluid falling onto a plate and spreading sideways, with the streamlines being hyperbolae $xy = \text{const}$.

Notice there is no imposed length scale in this problem: $[E] = T^{-1}$ and $[\nu] = L^2 T^{-1}$,

so the only length we can build is

$$\delta = \sqrt{\frac{\nu}{E}},$$

and we look for a similarity solution in $\eta = y/\delta$. Incompressibility suggests we posit a streamfunction of the form

$$\psi = \sqrt{\nu E} x g(\eta),$$

which gives

$$u = \frac{\partial \psi}{\partial y} = E x g'(\eta), \quad v = -\frac{\partial \psi}{\partial x} = -\sqrt{\nu E} g(\eta) = -E \delta g(\eta).$$

Substituting into the two components of Navier–Stokes gives

$$\begin{aligned} E^2 x (g'^2 - g g'') &= -\frac{1}{\rho} \frac{\partial p}{\partial x} + E^2 x g''', \\ E \sqrt{\nu E} g g' &= -\frac{1}{\rho} \frac{\partial p}{\partial y} - E \sqrt{\nu E} g''. \end{aligned}$$

To eliminate the pressure we cross-differentiate: take $\partial/\partial y$ of the first and $\partial/\partial x$ of the second and subtract. The second equation has no x dependence at all, so we simply get

$$g' g'' - g g''' = g^{(4)},$$

a single fourth order ordinary differential equation. The boundary conditions are $g(0) = g'(0) = 0$ from no-slip, and $g'(\eta) \rightarrow 1$, $g(\eta) \sim \eta$ as $\eta \rightarrow \infty$ to match the far field.

We do not need to solve this (it has no closed form), and that is rather the point: all the dimensional parameters have been absorbed into g and η , so one numerical solution serves for every E and ν . Its shape is easy to guess.

The horizontal velocity rises from zero at the wall to its inviscid value Ex over a distance $y \sim \delta$, and is essentially inviscid beyond that. So δ is the boundary layer thickness, and at that scale $Re_\delta = U\delta/\nu = O(1)$, exactly as advertised.

Outside the boundary layer we may drop viscosity, and one checks directly that $\mathbf{u} = (Ex, -Ey, 0)$ solves the Euler equations exactly, with

$$p = p_0 - \frac{1}{2} \rho E^2 (x^2 + y^2).$$

The isobars are the semicircles drawn in the figure. As fluid falls in from above it moves into regions of higher pressure, so the pressure gradient is **adverse** and it decelerates; as it turns and moves outwards it moves into regions of lower pressure, so the gradient is **favourable** and it accelerates. At the origin the velocity vanishes and the pressure attains its maximum p_0 . This is a **stagnation point**, and the association it displays – high pressure with low velocity and vice versa – is a foretaste of Bernoulli's equation.

§13.4.5 The Euler Momentum Equation

We stated Navier–Stokes without proof, but in the inviscid case we can do better and derive it honestly, by considering the momentum budget of a fixed region of space. This is worth doing because the intermediate result – the momentum integral – is a powerful tool in its own right.

Fix a region $\mathcal{D}$ with boundary $\partial\mathcal{D}$ and outward normal $\mathbf{n}$. The momentum inside $\mathcal{D}$ changes for three reasons (ignoring viscous surface forces, which is our inviscid approximation): momentum is carried across the boundary by the flow, pressure acts on the boundary, and body forces act throughout. So

$$\frac{d}{dt} \int_{\mathcal{D}} \rho \mathbf{u} \, dV = - \int_{\partial\mathcal{D}} \rho \mathbf{u} (\mathbf{u} \cdot \mathbf{n}) \, dS - \int_{\partial\mathcal{D}} p \mathbf{n} \, dS + \int_{\mathcal{D}} \mathbf{f} \, dV.$$

The first term on the right is the momentum flux: fluid crossing the boundary at rate $(\mathbf{u} \cdot \mathbf{n}) \, dS$ per unit volume carries momentum $\rho \mathbf{u}$ with it.

To make progress, switch to suffix notation, since the divergence theorem applies to each component separately:

$$\frac{d}{dt} \int_{\mathcal{D}} \rho u_i \, dV = - \int_{\partial\mathcal{D}} \rho u_i u_j n_j \, dS - \int_{\partial\mathcal{D}} p n_i \, dS + \int_{\mathcal{D}} f_i \, dV.$$

Applying the divergence theorem to the surface integrals and collecting everything on one side,

$$\int_{\mathcal{D}} \left(\rho \frac{\partial u_i}{\partial t} + \rho \frac{\partial}{\partial x_j} (u_i u_j) + \frac{\partial p}{\partial x_i} - f_i \right) dV = 0.$$

Since $\mathcal{D}$ is arbitrary the integrand vanishes. Finally

$$\frac{\partial}{\partial x_j} (u_i u_j) = u_j \frac{\partial u_i}{\partial x_j} + u_i \frac{\partial u_j}{\partial x_j} = u_j \frac{\partial u_i}{\partial x_j},$$

the last term vanishing by incompressibility, and we recognise the material derivative.

Proposition 13.4.9 (Euler Momentum Equation)

For an inviscid incompressible fluid of constant density,

$$\rho \frac{D\mathbf{u}}{Dt} = -\nabla p + \mathbf{f}.$$

This is of course exactly Navier–Stokes with $\mu = 0$, but it is reassuring to have got it from momentum conservation directly.

Very often the body force is conservative, $\mathbf{f} = -\nabla\chi$. For gravity with constant ρ we have $\mathbf{f} = \rho\mathbf{g} = -\nabla(-\rho\mathbf{g} \cdot \mathbf{x})$, so

$$\chi = -\rho\mathbf{g} \cdot \mathbf{x} = g\rho z$$

when $\mathbf{g} = (0, 0, -g)$. (Of course, by the discussion of reduced pressure we could equally absorb χ into p and forget about it.)

Specialising the integral form to a *steady* flow, the left hand side vanishes, and converting the body force integral back to a surface integral gives a result which is extremely useful for practical problems.

Proposition 13.4.10 (Momentum Integral for Steady Flow)

For a steady inviscid flow with conservative body force $\mathbf{f} = -\nabla\chi$, and any fixed region $\mathcal{D}$,

$$\int_{\partial\mathcal{D}} (\rho\mathbf{u}(\mathbf{u} \cdot \mathbf{n}) + p\mathbf{n} + \chi\mathbf{n}) \, dS = \mathbf{0}.$$

The power of this is that it involves only surface integrals: if we can choose a control surface on which we know the flow, we can compute forces without knowing anything about the messy interior.

§13.4.6 Bernoulli's Equation

The other classical consequence of the Euler equation comes from the vector identity

$$\mathbf{u} \cdot \nabla\mathbf{u} = \nabla\left(\frac{1}{2}|\mathbf{u}|^2\right) - \mathbf{u} \times (\nabla \times \mathbf{u}) = \nabla\left(\frac{1}{2}|\mathbf{u}|^2\right) - \mathbf{u} \times \boldsymbol{\omega}.$$

Substituting this into the Euler equation with $\mathbf{f} = -\nabla\chi$ and rearranging,

$$\rho \frac{\partial\mathbf{u}}{\partial t} - \rho \mathbf{u} \times \boldsymbol{\omega} = -\nabla\left(\frac{1}{2}\rho|\mathbf{u}|^2 + p + \chi\right).$$

This is worth a name.

Definition 13.4.11 (Bernoulli Quantity)

The **Bernoulli quantity** of a flow is

$$H = \frac{1}{2}\rho|\mathbf{u}|^2 + p + \chi.$$

Now dot the rearranged equation with $\mathbf{u}$. The term $\mathbf{u} \cdot (\mathbf{u} \times \boldsymbol{\omega})$ vanishes identically, and we are left with the following.

Theorem 13.4.12 (Bernoulli's Theorem)

For an inviscid incompressible flow of constant density with conservative body force,

$$\frac{1}{2}\rho \frac{\partial}{\partial t}|\mathbf{u}|^2 = -\mathbf{u} \cdot \nabla H.$$

In particular:

- (i) If the flow is *steady*, then $\mathbf{u} \cdot \nabla H = 0$, so H is constant along streamlines.
- (ii) If the flow is *irrotational* ($\boldsymbol{\omega} = \mathbf{0}$) and steady, then $\nabla H = \mathbf{0}$, so H is constant

everywhere.

Proof. The displayed equation is what we derived. For (i), a steady flow has $\partial \mathbf{u} / \partial t = \mathbf{0}$, so $\mathbf{u} \cdot \nabla H = 0$, which says exactly that H does not change as we move along a streamline. For (ii), if $\boldsymbol{\omega} = \mathbf{0}$ then the term $\rho \mathbf{u} \times \boldsymbol{\omega}$ was absent to begin with, so the rearranged Euler equation reads $\rho \partial \mathbf{u} / \partial t = -\nabla H$, and if additionally the flow is steady then $\nabla H = \mathbf{0}$. $\square$

The distinction between (i) and (ii) is important and frequently muddled. In a general steady flow, H is constant on each streamline but may take different values on different streamlines. Only if the flow is irrotational may we compare H at two points which are not joined by a streamline. Since (as we will see in Section 13.5) flows which start from rest are irrotational, we will usually be in the happy case (ii).

The content of Bernoulli's theorem is the trade-off between speed and pressure: where a steady flow speeds up, the pressure must fall. This is the single most-used fact in fluid dynamics, and it is worth pausing to see *why* it is true, since it often gets mystified. It is nothing but energy conservation. H is (up to the constant χ) the sum of kinetic energy density and pressure, and a fluid particle can only speed up if something pushes it, i.e. if it is moving from high pressure to low.

Remark. Even when the flow is unsteady, H retains a meaning. Integrating Bernoulli's theorem over a fixed region $\mathcal{D}$ and using incompressibility,

$$\frac{d}{dt} \int_{\mathcal{D}} \frac{1}{2} \rho |\mathbf{u}|^2 dV = - \int_{\partial \mathcal{D}} H \mathbf{u} \cdot \mathbf{n} dS,$$

so H is the density of *transportable energy*: the rate at which the kinetic energy in a region changes is the flux of H across its boundary.

§13.4.7 Applications of Bernoulli and the Momentum Integral

Let us put these two results to work. The examples below are all worked in the same style: identify the streamline, apply Bernoulli at two points on it, and use conservation of mass to relate the speeds.

Example 13.4.13 (The Venturi Meter)

Consider a horizontal pipe of cross-sectional area A with a constriction of area $a < A$ in the middle, and two vertical tubes let into it so that we may read off the pressure.

Conservation of mass gives the volume flux

$$q = UA = ua.$$

Now apply Bernoulli along the central streamline. The pipe is horizontal so the χ terms are equal and cancel, giving

$$\frac{1}{2}\rho U^2 + P = \frac{1}{2}\rho u^2 + p.$$

Substituting $U = q/A$ and $u = q/a$,

$$\left(\frac{1}{A^2} - \frac{1}{a^2}\right) q^2 = \frac{2(p - P)}{\rho}.$$

Since $a < A$ the left hand side is negative, so $p < P$: the fluid is faster and hence at lower pressure in the constriction. The vertical tubes are hydrostatic, so $p - P = -\rho gh$, and rearranging,

$$q = \sqrt{2gh} \frac{Aa}{\sqrt{A^2 - a^2}}.$$

So by measuring a height difference with a ruler we can measure the flow rate through the pipe. This is a Venturi meter, and it is how the fuel flow in a carburettor is metered.

Example 13.4.14 (The Pitot Tube)

How does an aircraft measure its airspeed? Point a tube directly into the oncoming flow and seal the far end. The fluid at the mouth of the tube is brought to rest – it is a stagnation point – while fluid passing a second, side-facing opening is still moving at the free stream speed U .

Bernoulli along the central streamline, from far upstream to the stagnation point S , gives

$$p_S = p_\infty + \frac{1}{2}\rho U^2.$$

The pressure p_S is called the **stagnation** or **total** pressure, and $\frac{1}{2}\rho U^2$ the **dynamic** pressure. At the side opening B the fluid is still moving at essentially U , so it reads $p_B \approx p_\infty$. Hence

$$U = \sqrt{\frac{2(p_S - p_B)}{\rho}},$$

and a differential pressure gauge between the two openings is an airspeed indicator.

Example 13.4.15 (Torricelli's Law)

A large tank of water has a small hole of area a in its side, a depth H below the free surface. How fast does the water come out?

Apply Bernoulli along the streamline running from the free surface down to the hole, and now we must *not* drop gravity, since we are comparing two points at different heights on a free surface. At the surface the pressure is atmospheric and (the tank being large) the velocity is negligible. At the hole the pressure is again atmospheric, since the emerging jet is surrounded by air. So with $\chi = \rho g z$,

$$p_{\text{atm}} + \rho g H = p_{\text{atm}} + \frac{1}{2} \rho u^2,$$

giving

$$u = \sqrt{2gH}.$$

This is Torricelli's law, and it is precisely the speed a particle would reach falling freely through a height H – which is no coincidence, Bernoulli being energy conservation in disguise.

The next example uses the momentum integral instead, and shows off its real advantage: we compute a force on a body whose shape we never specify.

Example 13.4.16 (Force on a Fire Hose Nozzle)

Water enters a nozzle with speed U , area A and gauge pressure P , and leaves as a jet with speed u , area a and gauge pressure 0 (the jet is open to the atmosphere). With what force does the water try to tear the nozzle off the hose?

Apply the steady momentum integral in the x direction over the dashed control surface, which consists of the inlet (1), the walls (2) and (3), and the outlet (4). We may ignore gravity (χ contributes nothing net to a horizontal force).

- On the inlet (1), $\mathbf{n} = -\hat{\mathbf{x}}$, so the momentum flux contributes $\rho U(-U)A = -\rho U^2 A$ and the pressure contributes $-PA$.
- On the cylindrical wall (2), the velocity is parallel to the surface so there is no momentum flux, and the pressure force is purely radial: nothing in the x direction.
- On the tapering wall (3), again no momentum flux, but the pressure force does have an x component. Its total is $\int_{\text{nozzle}} p \mathbf{n} \cdot \hat{\mathbf{x}} \, dS$, which is exactly (minus) the force F that we want.
- On the outlet (4), the momentum flux is $\rho u \cdot ua = \rho u^2 a$ and the pressure is zero.

Summing to zero, the force exerted by the water on the nozzle in the x direction is

$$F = \rho A U^2 - \rho a u^2 + P A.$$

We still have P in there, but Bernoulli along the central streamline gives $\frac{1}{2} \rho U^2 + P =$

$\frac{1}{2}\rho u^2$, and with $q = UA = ua$ this simplifies, after a little algebra, to

$$F = \frac{\rho q^2}{2a} \left(1 - \frac{a}{A}\right)^2.$$

Let us put numbers in. A hose of radius 10 cm with a nozzle of radius 5 cm has $A/a = 4$, and a typical flow rate is $q = 0.01 \text{ m}^3 \text{ s}^{-1}$. Then

$$F = \frac{1000 \times 10^{-4}}{2 \times (0.05)^2 \pi} \left(\frac{3}{4}\right)^2 \approx 14 \text{ N},$$

a couple of kilograms' worth. That is why fire hoses have handles.

Remark. It is instructive to see what would have happened if we had tried to get this force by integrating the pressure over the nozzle directly. We would have needed to know the shape of the nozzle, and the flow inside it, in complete detail. The momentum integral lets us put a box around our ignorance.

The last example in this vein is a favourite, because it is one where Bernoulli's equation is *wrong* and only the momentum integral will do.

Example 13.4.17 (The Hydraulic Jump)

Turn on a kitchen tap onto a flat sink and look at the bottom. There is a disc of very fast, very thin water around the point of impact, bounded by an abrupt circular step beyond which the water is slower and deeper. That step is a **hydraulic jump**, and something similar happens at the foot of a spillway or a weir.

Take a control volume straddling the jump, with the flow uniform and parallel on each side. Conservation of mass (per unit width) gives

$$q = u_1 h_1 = u_2 h_2.$$

For the momentum, the pressure on each face is hydrostatic, $p = p_{\text{atm}} + \rho g(h_i - z)$, and integrating over the depth gives a total pressure force per unit width of $\frac{1}{2}\rho g h_i^2$ (above atmospheric). Balancing horizontal momentum flux plus pressure force,

$$\rho u_1^2 h_1 + \frac{1}{2}\rho g h_1^2 = \rho u_2^2 h_2 + \frac{1}{2}\rho g h_2^2.$$

Substituting $u_i = q/h_i$ and dividing by ρ ,

$$\frac{q^2}{h_1} - \frac{q^2}{h_2} = \frac{g}{2} (h_2^2 - h_1^2) \implies \frac{q^2(h_2 - h_1)}{h_1 h_2} = \frac{g}{2} (h_2 - h_1)(h_2 + h_1).$$

The trivial root $h_2 = h_1$ is 'no jump'; cancelling it gives

$$q^2 = \frac{1}{2} g h_1 h_2 (h_1 + h_2),$$

a quadratic determining h_2 from h_1 and q . Writing this in terms of the upstream Froude number $Fr_1 = u_1/\sqrt{gh_1}$ and solving,

$$\frac{h_2}{h_1} = \frac{1}{2} \left(\sqrt{1 + 8Fr_1^2} - 1 \right).$$

So a jump ($h_2 > h_1$) is possible only if $Fr_1 > 1$: the upstream flow must be *super-critical*, moving faster than shallow-water waves can propagate, so that it cannot be warned of the obstruction ahead. Downstream one checks that $Fr_2 < 1$, so the flow is subcritical.

Where does Bernoulli go? Computing $H = \frac{1}{2}\rho u^2 + \rho gh$ on the two sides, one finds it *decreases* across the jump, by

$$\Delta H = \frac{\rho g(h_2 - h_1)^3}{4h_1 h_2} > 0.$$

Energy has been lost, to the turbulent churning that is so visible at a real jump. This is precisely why we had to use momentum: momentum is conserved across the jump but energy is not, and applying Bernoulli here would give a flatly wrong answer. It is a useful reminder that Bernoulli's theorem was derived for a smooth inviscid flow, and a hydraulic jump is neither.

§13.5 Vorticity

We met the vorticity $\boldsymbol{\omega} = \nabla \times \mathbf{u}$ briefly in Section 2. It is time to take it seriously, because it turns out to be the quantity which really controls the character of a flow. In particular, we are going to prove that a flow which starts out with no vorticity keeps none – which is the licence we need to spend the second half of the course on potential flow.

§13.5.1 What Vorticity Measures

A good way to see the meaning of $\boldsymbol{\omega}$ is to look at a general flow very close to a chosen point $\mathbf{x}_0$. Taylor expanding,

$$\mathbf{u}(\mathbf{x}) = \mathbf{u}_0 + \mathbf{r} \cdot \nabla \mathbf{u}_0 + O(|\mathbf{r}|^2), \quad \mathbf{r} = \mathbf{x} - \mathbf{x}_0,$$

so to first order the flow is described by the matrix $\partial u_i / \partial x_j$. Any matrix splits uniquely into symmetric and antisymmetric parts,

$$\frac{\partial u_i}{\partial x_j} = E_{ij} + \Omega_{ij}, \quad E_{ij} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right), \quad \Omega_{ij} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x_j} - \frac{\partial u_j}{\partial x_i} \right),$$

and the antisymmetric part is precisely the vorticity in disguise. Indeed, using $\varepsilon_{ijk}\varepsilon_{klm} = \delta_{il}\delta_{jm} - \delta_{im}\delta_{jl}$,

$$(\boldsymbol{\omega} \times \mathbf{r})_i = \varepsilon_{ijk}\varepsilon_{jlm} \frac{\partial u_m}{\partial x_l} r_k = \left(\frac{\partial u_i}{\partial x_k} - \frac{\partial u_k}{\partial x_i} \right) r_k = 2\Omega_{ik}r_k.$$

Hence the local structure of any flow is

Proposition 13.5.1 (Decomposition of a Linear Flow)

Near any point,

$$\mathbf{u} = \underbrace{\mathbf{u}_0}_{\text{uniform flow}} + \underbrace{E\mathbf{r}}_{\text{pure strain}} + \underbrace{\frac{1}{2}\boldsymbol{\omega} \times \mathbf{r}}_{\text{rigid rotation}} + O(|\mathbf{r}|^2).$$

uniform flow

pure strain, $E\mathbf{r}$ rotation, $\frac{1}{2}\boldsymbol{\omega} \times \mathbf{r}$

So the vorticity at a point is *twice the local angular velocity* of the fluid there. A tiny paddle-wheel dropped into the flow spins at angular velocity $\frac{1}{2}\boldsymbol{\omega}$. Meanwhile E , the rate-of-strain tensor, describes how a small blob is stretched and squashed; incompressibility says $\text{tr } E = \nabla \cdot \mathbf{u} = 0$, so in principal axes $E = \text{diag}(E_1, E_2, E_3)$ with $E_1 + E_2 + E_3 = 0$, and any stretching in one direction must be paid for by compression in another.

Definition 13.5.2 (Irrotational Flow, Circulation)

A flow is **irrotational** if $\boldsymbol{\omega} = \mathbf{0}$ everywhere. The **circulation** around a closed curve C is

$$\Gamma = \oint_C \mathbf{u} \cdot d\boldsymbol{\ell} \stackrel{\text{Stokes}}{=} \int_S \boldsymbol{\omega} \cdot \mathbf{n} \, dS$$

for any surface S spanning C .

Circulation is the integrated form of vorticity, and Stokes' theorem relating them is the reason both are useful. Notice that an irrotational flow has zero circulation around every curve which bounds a surface lying in the fluid – but *not* necessarily around every curve, if the region is not simply connected. That loophole is exactly where lift comes from, as we shall see.

§13.5.2 The Vorticity Equation

We know how $\mathbf{u}$ evolves; let us find out how $\boldsymbol{\omega}$ evolves. Start from Navier–Stokes with a conservative body force, in the form

$$\frac{\partial \mathbf{u}}{\partial t} + \nabla \left(\frac{1}{2} |\mathbf{u}|^2 \right) - \mathbf{u} \times \boldsymbol{\omega} = -\frac{1}{\rho} \nabla p - \frac{1}{\rho} \nabla \chi + \nu \nabla^2 \mathbf{u},$$

and take the curl. Every gradient dies, leaving

$$\frac{\partial \boldsymbol{\omega}}{\partial t} - \nabla \times (\mathbf{u} \times \boldsymbol{\omega}) = \nu \nabla^2 \boldsymbol{\omega}.$$

Now expand the remaining curl using the standard identity

$$\nabla \times (\mathbf{u} \times \boldsymbol{\omega}) = (\nabla \cdot \boldsymbol{\omega}) \mathbf{u} + \boldsymbol{\omega} \cdot \nabla \mathbf{u} - (\nabla \cdot \mathbf{u}) \boldsymbol{\omega} - \mathbf{u} \cdot \nabla \boldsymbol{\omega}.$$

The first term vanishes because a curl is divergence free, and the third because the flow is incompressible. Rearranging and recognising the material derivative gives the following.

Proposition 13.5.3 (Vorticity Equation)

For an incompressible Newtonian fluid of constant density,

$$\frac{D\boldsymbol{\omega}}{Dt} = \boldsymbol{\omega} \cdot \nabla \mathbf{u} + \nu \nabla^2 \boldsymbol{\omega}.$$

Two things are remarkable about this equation. First, the pressure has vanished completely: vorticity does not care about pressure. Secondly, in the inviscid case the equation is *homogeneous* in $\boldsymbol{\omega}$ – there is no source term. Vorticity cannot be created out of nothing in the interior of an inviscid flow; it can only be moved around and stretched.

Let us read the two surviving terms.

The term $\nu \nabla^2 \boldsymbol{\omega}$ is diffusion: viscosity spreads vorticity out, exactly as we saw in the impulsively started plate problem, and eventually dissipates it. It is also, importantly, the only mechanism by which vorticity can be *generated*, and this happens at boundaries: the no-slip condition forces a steep velocity gradient at a wall, which is to say a sheet of vorticity, and viscosity then diffuses it into the fluid. Every bit of vorticity in the world was born at a boundary.

The term $\boldsymbol{\omega} \cdot \nabla \mathbf{u}$ is more interesting and is called **vortex stretching**. To see what it does, take the inviscid case and dot with $\boldsymbol{\omega}$:

$$\frac{D}{Dt} \left(\frac{1}{2} |\boldsymbol{\omega}|^2 \right) = \omega_i (E_{ij} + \Omega_{ij}) \omega_j = \omega_i E_{ij} \omega_j,$$

the antisymmetric part dropping out against the symmetric $\omega_i \omega_j$. In principal axes,

$$\frac{D}{Dt} \left(\frac{1}{2} |\boldsymbol{\omega}|^2 \right) = E_1 \omega_1^2 + E_2 \omega_2^2 + E_3 \omega_3^2.$$

Suppose the flow is being stretched along $\mathbf{e}_1$, so $E_1 > 0$ and (since the E_i sum to zero) $E_2, E_3 < 0$. A vortex aligned with the stretching, $\boldsymbol{\omega} = (\omega_1, 0, 0)$, then obeys

$$\frac{D}{Dt} \left(\frac{1}{2} \omega_1^2 \right) = E_1 \omega_1^2,$$

so $|\boldsymbol{\omega}|$ grows exponentially. Stretching a vortex tube spins it up.

This is nothing but conservation of angular momentum: squeezing a rotating tube of fluid radially inwards brings its mass closer to the axis, and it must spin faster to compensate. It is the same physics as an ice skater pulling in their arms, and it is why bath plugholes, tornadoes and dust devils are all so vigorous.

In fact, this is a special case of a beautiful general statement. Let $\mathbf{x}_1(t)$ and $\mathbf{x}_2(t)$ be two neighbouring fluid particles and let $\delta \boldsymbol{\ell} = \mathbf{x}_2 - \mathbf{x}_1$ be the material line element joining them. Then

$$\frac{D\delta \boldsymbol{\ell}}{Dt} = \mathbf{u}(\mathbf{x}_2) - \mathbf{u}(\mathbf{x}_1) = \delta \boldsymbol{\ell} \cdot \nabla \mathbf{u}$$

to first order. But this is *exactly* the same equation as the inviscid vorticity equation. So in an inviscid flow, vorticity behaves exactly like a material line element: vortex lines are frozen into the fluid and are stretched and rotated along with it.

Remark. If the density is not constant then the derivation above picks up an extra term, and one finds

$$\frac{D\boldsymbol{\omega}}{Dt} = \boldsymbol{\omega} \cdot \nabla \mathbf{u} + \frac{1}{\rho^2} \nabla \rho \times \nabla p + \nu \nabla^2 \boldsymbol{\omega}.$$

The new term is called the **baroclinic** term, and it *does* generate vorticity from nothing whenever the surfaces of constant density and constant pressure are not parallel. It is what drives convection: a heater at one end of a room produces a horizontal density gradient which, crossed with the vertical (hydrostatic) pressure gradient, spins the air up into a circulation.

§13.5.3 Kelvin's Circulation Theorem

Circulation obeys a conservation law of its own, which is arguably the most elegant result in the subject.

Theorem 13.5.4 (Kelvin's Circulation Theorem)

Let $C(t)$ be a closed *material* curve – one which moves with the fluid – in an inviscid, incompressible flow of constant density with conservative body forces. Then the circulation

$$\Gamma = \oint_{C(t)} \mathbf{u} \cdot d\boldsymbol{\ell}$$

is independent of t .

Proof. Differentiate following the fluid. Both the velocity and the line element change, so

$$\frac{d\Gamma}{dt} = \oint_{C(t)} \frac{D\mathbf{u}}{Dt} \cdot d\boldsymbol{\ell} + \oint_{C(t)} \mathbf{u} \cdot \frac{D(d\boldsymbol{\ell})}{Dt}.$$

For the first integral, the Euler equation gives $D\mathbf{u}/Dt = -\nabla(p/\rho + \chi/\rho)$, and the integral of a gradient around a closed curve vanishes.

For the second, we showed above that a material line element obeys $D(d\boldsymbol{\ell})/Dt = d\boldsymbol{\ell} \cdot \nabla \mathbf{u}$, so

$$\mathbf{u} \cdot \frac{D(d\boldsymbol{\ell})}{Dt} = u_i d\ell_j \frac{\partial u_i}{\partial x_j} = d\boldsymbol{\ell} \cdot \nabla \left(\frac{1}{2} |\mathbf{u}|^2 \right),$$

which is again the integral of a gradient around a closed curve, and vanishes. Hence $d\Gamma/dt = 0$. $\square$

By Stokes' theorem this says that the flux of vorticity through any material surface is constant, which is a precise version of the statement that vortex lines are frozen into an inviscid fluid. Viscosity is what allows vortex lines to slip through the fluid and reconnect, and its absence is why inviscid flows have such long memories.

§13.5.4 Irrotational Flow Stays Irrotational

Here is the payoff, and it is a corollary of either of the last two results.

Corollary 13.5.5 (Persistence of Irrotational Flow)

Suppose an inviscid, incompressible flow of constant density with conservative body force is irrotational at some initial time. Then it is irrotational for all time.

Proof. In the inviscid case the vorticity equation reads $D\boldsymbol{\omega}/Dt = \boldsymbol{\omega} \cdot \nabla \mathbf{u}$. This is a linear ordinary differential equation for $\boldsymbol{\omega}$ along each particle path, homogeneous in $\boldsymbol{\omega}$, so if $\boldsymbol{\omega} = \mathbf{0}$ at $t = 0$ on a given particle path then $\boldsymbol{\omega} = \mathbf{0}$ on it for all time.

Alternatively: by Kelvin's theorem the circulation around every material curve is preserved, and initially every such circulation is zero. $\square$

This is enormously useful, because the great majority of the flows we care about *do* start from rest. Water in a tank before we disturb it; air far upstream of an aeroplane; the ocean before a storm. All of these are at rest, hence trivially irrotational, hence – to the extent that we may neglect viscosity – irrotational forever.

We should be honest about the limits of this. Real fluids are viscous, and viscosity generates vorticity at boundaries. What actually happens at high Reynolds number is that vorticity is confined to thin boundary layers on solid surfaces and to the wakes shed behind bodies, while the bulk of the fluid remains beautifully irrotational. So the irrotational model is excellent away from surfaces and wakes, and hopeless inside them – an assessment we will have cause to remember when we compute the drag on a sphere and get zero.

§13.6 Inviscid Irrotational Flow

We now specialise, for the rest of the course, to flows which are incompressible, inviscid *and* irrotational. We have just seen that the last assumption is self-consistent, so let us see what it buys us.

If $\boldsymbol{\omega} = \nabla \times \mathbf{u} = \mathbf{0}$ on a simply connected region, then $\mathbf{u}$ is a gradient.

Definition 13.6.1 (Velocity Potential)

A **velocity potential** for an irrotational flow is a scalar ϕ with

$$\mathbf{u} = \nabla \phi.$$

(Note the sign: unlike gravity or electrostatics, we do not put a minus sign in front. Fluid dynamicists are lazy.) Now impose incompressibility:

$$\nabla \cdot \mathbf{u} = \nabla^2 \phi = 0.$$

Definition 13.6.2 (Potential Flow)

A **potential flow** is an incompressible irrotational flow, described by a velocity

potential satisfying Laplace's equation $\nabla^2\phi = 0$.

This is a spectacular simplification. We have replaced a nonlinear system of four coupled partial differential equations by a single *linear* equation, and moreover the best-understood linear equation in all of mathematics. In particular we may superpose solutions, so we can build up complicated flows by adding simple ones. The velocity comes from $\mathbf{u} = \nabla\phi$ and the pressure afterwards from Bernoulli, which (the flow being irrotational) holds globally, not just along streamlines.

Boundary conditions are as follows: at a stationary rigid boundary, $\mathbf{u} \cdot \mathbf{n} = \partial\phi/\partial n = 0$, a Neumann condition. We have already given up no-slip.

It is worth pausing on the relationship between ϕ and the streamfunction ψ , since students often confuse them. In two dimensions both exist, and

$$u = \frac{\partial\phi}{\partial x} = \frac{\partial\psi}{\partial y}, \quad v = \frac{\partial\phi}{\partial y} = -\frac{\partial\psi}{\partial x}.$$

These are the Cauchy–Riemann equations! We will exploit that fact in Section 13.6.5. But note that ψ exists whenever the flow is incompressible (whether or not it is irrotational), while ϕ exists whenever it is irrotational (whether or not it is incompressible). It is only when we have both that they come as a pair. Their contours are the streamlines and the equipotentials respectively, and they meet at right angles.

§13.6.1 Three-Dimensional Potential Flows

We solve Laplace's equation by separation of variables, exactly as in the Methods course. In spherical polars (r, θ, φ) ,

$$\nabla^2\phi = \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial\phi}{\partial r} \right) + \frac{1}{r^2 \sin\theta} \frac{\partial}{\partial\theta} \left(\sin\theta \frac{\partial\phi}{\partial\theta} \right) + \frac{1}{r^2 \sin^2\theta} \frac{\partial^2\phi}{\partial\varphi^2},$$

and the velocity is

$$\mathbf{u} = \nabla\phi = \left(\frac{\partial\phi}{\partial r}, \frac{1}{r} \frac{\partial\phi}{\partial\theta}, \frac{1}{r \sin\theta} \frac{\partial\phi}{\partial\varphi} \right).$$

Start with the simplest possible case, $\phi = \phi(r)$. Then Laplace's equation is $(r^2\phi')' = 0$, so $\phi' = A/r^2$ and

$$\phi = -\frac{A}{r}$$

(discarding an irrelevant additive constant). The velocity is purely radial and falls off like r^{-2} .

What is A ? Compute the volume flux out of the sphere $r = a$:

$$q = \int_S \mathbf{u} \cdot \mathbf{n} \, dS = \int_S \frac{\partial\phi}{\partial r} \, dS = \frac{A}{a^2} \cdot 4\pi a^2 = 4\pi A.$$

Definition 13.6.3 (Point Source)

A **point source** of strength q at the origin has potential

$$\phi = -\frac{q}{4\pi r}, \quad u_r = \frac{q}{4\pi r^2}.$$

If $q < 0$ we call it a **sink**.

We could have found this without any calculus: incompressibility says the flux through every sphere about the origin is the same, and the area grows like r^2 , so the velocity must fall like r^{-2} . Note that $\nabla^2 \phi = q \delta(\mathbf{x})$, so up to a constant ϕ is the Green's function for the Laplacian – the source is really a singularity that we have inserted by hand, and the flow is genuinely a potential flow only away from the origin.

Allowing θ dependence but keeping axisymmetry, separation of variables gives the general solution

$$\phi = \sum_{n=0}^{\infty} (A_n r^n + B_n r^{-n-1}) P_n(\cos \theta),$$

where P_n are the Legendre polynomials, with $P_0 = 1$, $P_1(x) = x$, $P_2(x) = \frac{1}{2}(3x^2 - 1)$. The $n = 1$ decaying solution, $\phi \propto \cos \theta / r^2$, is a **dipole**, and it is the workhorse of what follows.

Example 13.6.4 (Uniform Flow Past a Sphere)

Let us find the flow past a fixed sphere of radius a , with uniform stream $\mathbf{u} \rightarrow U \hat{\mathbf{x}}$ at infinity. Since $\phi = Ux = Ur \cos \theta$ generates the uniform stream, we must solve

$$\begin{aligned} \nabla^2 \phi &= 0 & r > a, \\ \phi &\rightarrow Ur \cos \theta & r \rightarrow \infty, \\ \frac{\partial \phi}{\partial r} &= 0 & r = a, \end{aligned}$$

the last being the condition that no fluid enters the sphere.

The far-field condition is proportional to $P_1(\cos \theta)$, and the P_n are orthogonal, so only the $n = 1$ terms can appear:

$$\phi = \left(Ar + \frac{B}{r^2} \right) \cos \theta.$$

Matching at infinity gives $A = U$, and the boundary condition at $r = a$ gives $U - 2B/a^3 = 0$, so $B = Ua^3/2$. Thus

$$\phi = U \left(r + \frac{a^3}{2r^2} \right) \cos \theta.$$

The flow is a uniform stream plus the dipole response of the sphere. Differentiating,

$$\begin{aligned} u_r &= U \left(1 - \frac{a^3}{r^3} \right) \cos \theta, \\ u_\theta &= -U \left(1 + \frac{a^3}{2r^3} \right) \sin \theta. \end{aligned}$$

At $\theta = 0$ and $\theta = \pi$ on the surface both components vanish: these are the front and rear stagnation points A and A' . At the ‘poles’ $\theta = \pm\pi/2$ we have $u_r = 0$ and $|u_\theta| = \frac{3}{2}U$, so the flow over the top of the sphere is fifty percent faster than the free stream. (This is why it is windier at the top of a hill than in the valley, and why the streamlines in the figure bunch together there.)

Now for the pressure. Bernoulli applies globally, so comparing the surface with infinity,

$$p_\infty + \frac{1}{2}\rho U^2 = p + \frac{1}{2}\rho \cdot \frac{9}{4}U^2 \sin^2 \theta,$$

giving the surface pressure

$$p = p_\infty + \frac{1}{2}\rho U^2 \left(1 - \frac{9}{4} \sin^2 \theta\right).$$

At the stagnation points A and A' this is $p_\infty + \frac{1}{2}\rho U^2$, the maximum; at the poles it is $p_\infty - \frac{5}{8}\rho U^2$, the minimum.

And now something has gone wrong. The pressure depends only on $\sin^2 \theta$, so it is exactly the same at the front and the back of the sphere. Integrating $-p\mathbf{n}$ over the surface gives *zero net force*. The fluid exerts no drag whatsoever.

Remark (d’Alembert’s Paradox). The conclusion of the last example is completely general: a body moving steadily through an inviscid, irrotational, incompressible fluid experiences no drag. This is **d’Alembert’s paradox**, and it is obviously false – if it were true, cycling would be effortless.

The resolution is that we threw away viscosity. What happens in reality at high Reynolds number is that the flow does look very much like our solution over the front of the sphere, but the adverse pressure gradient at the rear (the pressure is rising as the fluid moves from the poles towards A') causes the boundary layer to *separate*. Behind the sphere is a turbulent wake in which the pressure is roughly p_∞ rather than recovering to $p_\infty + \frac{1}{2}\rho U^2$, and this fore-aft asymmetry is the drag.

Empirically one writes the drag force as

$$F = C_D \cdot \frac{1}{2}\rho U^2 \pi a^2,$$

defining a dimensionless **drag coefficient** C_D which is a function of Re alone (by dynamic similarity), and which must be measured.

Not everything about the sphere solution is wrong, though. The kinetic energy it carries is a real and measurable thing.

Example 13.6.5 (Added Mass and the Rising Bubble)

Change frame so that the sphere moves at speed U through fluid at rest; we simply subtract $U\hat{\mathbf{x}}$ from the velocity field of Example 13.6.4, leaving only the dipole part

$$\phi = \frac{Ua^3}{2r^2} \cos \theta.$$

The kinetic energy of the fluid is then

$$\int_{r>a} \frac{1}{2}\rho|\mathbf{u}|^2 dV = \frac{\pi}{3}a^3\rho U^2 = \frac{1}{2}M_A U^2,$$

where

$$M_A = \frac{2}{3}\pi a^3\rho = \frac{1}{2}M_D$$

is the **added mass** and $M_D = \frac{4}{3}\pi a^3\rho$ is the mass of fluid displaced. In other words, to move a sphere through a fluid you must also accelerate the fluid around it, and the sphere behaves as if it had an extra $\frac{1}{2}M_D$ of inertia.

Here is a cute application. A small spherical bubble rises through water. It is essentially massless, so the only energy in the problem is the kinetic energy of the water and the potential energy released as the bubble rises a distance h :

$$\frac{1}{2}M_A U^2 - M_D gh = \text{const.}$$

Differentiating with respect to time and using $\dot{h} = U$,

$$M_A U \dot{U} = M_D g U \implies \dot{U} = \frac{M_D}{M_A} g = 2g.$$

So an inviscid bubble accelerates upwards at *twice* the acceleration due to gravity. (In practice viscosity and deformation intervene long before the bubble gets very fast, but the factor of two is real and has been measured.)

§13.6.2 Potential Flows in Two Dimensions

Two-dimensional flows are where most of the classical theory lives, partly because they are easier, and partly because a long thin wing is nearly two-dimensional. In plane polars

$$\nabla^2 \phi = \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial \phi}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 \phi}{\partial \theta^2}, \quad \mathbf{u} = \left(\frac{\partial \phi}{\partial r}, \frac{1}{r} \frac{\partial \phi}{\partial \theta} \right),$$

and separation of variables gives the general solution

$$\phi = A \log r + B\theta + \sum_{n=1}^{\infty} (A_n r^n + B_n r^{-n}) \begin{Bmatrix} \cos n\theta \\ \sin n\theta \end{Bmatrix}.$$

Let us go through the building blocks one at a time.

Example 13.6.6 (Line Source)

Take $\phi = A \log r$. By conservation of mass, if q is the volume flux per unit length in the z direction then $2\pi r u_r = q$, so $u_r = q/2\pi r$ and

$$\phi = \frac{q}{2\pi} \log r, \quad \psi = \frac{q}{2\pi} \theta.$$

The streamlines are radial lines and the equipotentials are circles, meeting at right angles as promised.

Example 13.6.7 (Line Vortex)

Take $\phi = B\theta$. Then $u_r = 0$ and $u_\theta = B/r$: the flow goes round in circles, faster near the centre.

source

line vortex

To fix B , compute the circulation around a circle of radius a :

$$\kappa = \oint_{r=a} \mathbf{u} \cdot d\boldsymbol{\ell} = \int_0^{2\pi} \frac{B}{a} a d\theta = 2\pi B.$$

So

$$\phi = \frac{\kappa}{2\pi} \theta, \quad u_\theta = \frac{\kappa}{2\pi r}, \quad \psi = -\frac{\kappa}{2\pi} \log r.$$

Now, this flow *looks* rotational – everything is going round in circles – but it is not. One checks directly that $\nabla \times \mathbf{u} = \mathbf{0}$ for $r \neq 0$: a paddle-wheel placed off-centre translates around the vortex without spinning, because the shear on its inner side exactly cancels the shear on its outer side. All the vorticity is concentrated at the singular point $r = 0$.

This has a consequence which we cannot stress enough. For any simple closed curve C ,

$$\oint_C \mathbf{u} \cdot d\boldsymbol{\ell} = \begin{cases} \kappa & \text{if } C \text{ encloses the origin,} \\ 0 & \text{otherwise,} \end{cases}$$

so the circulation is not zero, even though the vorticity vanishes everywhere in the fluid. There is no contradiction with Stokes' theorem, because the region occupied by the fluid ($r > 0$) is not simply connected and no surface spanning C lies entirely in the fluid. Note also that $\phi = \kappa\theta/2\pi$ is not single-valued: it increases by κ each time we go round.

Example 13.6.8 (Line Dipole)

Place a source of strength q at $(\varepsilon, 0)$ and a sink of strength $-q$ at $(-\varepsilon, 0)$, and let

$\varepsilon \rightarrow 0$ with $q\varepsilon$ held fixed. Then

$$\phi = \frac{q}{2\pi} (\log |\mathbf{x} - \varepsilon \hat{\mathbf{x}}| - \log |\mathbf{x} + \varepsilon \hat{\mathbf{x}}|) \rightarrow -\frac{q\varepsilon}{\pi} \cdot \frac{\cos \theta}{r},$$

so up to normalisation a two-dimensional dipole has $\phi \propto \cos \theta / r$. This is precisely the $n = 1$ decaying term in our general solution, and it is what a cylinder in a stream will generate.

§13.6.3 Flow Past a Cylinder, and Lift

We now assemble the pieces into the most important example in the course.

Example 13.6.9 (Uniform Flow Past a Cylinder with Circulation)

We solve

$$\begin{aligned} \nabla^2 \phi &= 0 & r > a, \\ \phi &\rightarrow Ur \cos \theta & r \rightarrow \infty, \\ \frac{\partial \phi}{\partial r} &= 0 & r = a. \end{aligned}$$

As with the sphere, the far field picks out the $\cos \theta$ terms; but now we are also allowed to add a line vortex, since the region $r > a$ is not simply connected and a circulation κ round the cylinder is perfectly consistent with irrotational flow. So

$$\phi = U \left(r + \frac{a^2}{r} \right) \cos \theta + \frac{\kappa}{2\pi} \theta,$$

with

$$\begin{aligned} u_r &= U \left(1 - \frac{a^2}{r^2} \right) \cos \theta, \\ u_\theta &= -U \left(1 + \frac{a^2}{r^2} \right) \sin \theta + \frac{\kappa}{2\pi r}, \end{aligned}$$

and streamfunction

$$\psi = Ur \sin \theta \left(1 - \frac{a^2}{r^2} \right) - \frac{\kappa}{2\pi} \log r.$$

Physically, the circulation κ is a stand-in for the vorticity trapped in the viscous boundary layer on the cylinder – for instance because the cylinder is spinning.

Stagnation points. We need $u_r = u_\theta = 0$. The first gives $r = a$ or $\theta = \pm\pi/2$. On $r = a$ the second gives

$$\sin \theta = \frac{\kappa}{4\pi a U}.$$

So provided $|\kappa| \leq 4\pi a U$ there are two stagnation points on the surface of the cylinder, symmetrically placed about the vertical axis. As κ increases from zero they start at $\theta = 0, \pi$ and migrate upwards (for $\kappa > 0$) until they merge at the top when

$\kappa = 4\pi aU$. Beyond that they leave the cylinder altogether: the remaining solution is on $\theta = \pi/2$ with

$$\frac{\kappa}{2\pi r} = U \left(1 + \frac{a^2}{r^2} \right),$$

a single stagnation point above the cylinder, with a region of fluid trapped circulating around it.

The force. On the surface $r = a$ the speed is $|u_\theta| = |-2U \sin \theta + \kappa/2\pi a|$, so Bernoulli (globally valid, the flow being irrotational and steady) gives

$$p_\infty + \frac{1}{2}\rho U^2 = p + \frac{1}{2}\rho \left(\frac{\kappa}{2\pi a} - 2U \sin \theta \right)^2,$$

that is,

$$p = p_\infty + \frac{1}{2}\rho U^2 - \frac{\rho \kappa^2}{8\pi^2 a^2} + \frac{\rho \kappa U \sin \theta}{\pi a} - 2\rho U^2 \sin^2 \theta.$$

This is still symmetric under $\theta \mapsto \pi - \theta$, so there is still no drag – d’Alembert has not gone away. But it is *not* symmetric under $\theta \mapsto -\theta$, and computing the transverse force per unit length,

$$F_y = - \int_0^{2\pi} p \sin \theta \, a \, d\theta = - \int_0^{2\pi} \frac{\rho \kappa U}{\pi a} \sin^2 \theta \, a \, d\theta = -\rho U \kappa,$$

every other term integrating to zero by parity. So there is a sideways force, at right angles to the oncoming stream, directly proportional to the circulation.

This is the central fact of aerodynamics, and it deserves to be stated on its own.

Theorem 13.6.10 (Magnus Force / Kutta–Joukowski Lift)

A two-dimensional body in a uniform stream $\mathbf{U}$ with circulation κ about it experiences a force per unit length

$$\mathbf{F} = \rho \mathbf{U} \times \boldsymbol{\kappa},$$

where $\boldsymbol{\kappa} = \kappa \hat{\mathbf{z}}$. There is no drag.

The mechanism is now transparent: the circulation adds to the free stream on one side of the body and subtracts on the other, so the flow is faster above than below, so by Bernoulli the pressure is lower above than below, so there is a net upward force. This is why a sliced tennis ball swerves, why a spinning cricket ball dips, and – with a little more work – why an aerofoil generates lift. (For an aerofoil the circulation is not imposed by spinning it; it is generated automatically by the sharp trailing edge, via the Kutta condition, and comes with an equal and opposite ‘starting vortex’ shed downstream, in accordance with Kelvin’s theorem.)

§13.6.4 The Method of Images

Laplace’s equation is linear, and boundaries are just conditions we have to satisfy. Sometimes we can satisfy them by adding an extra singularity outside the fluid, exactly as in electrostatics.

Example 13.6.11 (Source Next to a Plane Wall)

Suppose there is a rigid wall along $y = 0$ and a line source of strength q at $(0, d)$, with fluid in $y > 0$. The wall requires $v = 0$ on $y = 0$.

Place an image source, also of strength q , at $(0, -d)$ – outside the fluid, so it does not disturb Laplace’s equation where we need it. By symmetry the two vertical velocities on $y = 0$ are equal and opposite, so $v = 0$ there automatically.

Hence in $y > 0$,

$$\phi = \frac{q}{4\pi} \log(x^2 + (y - d)^2) + \frac{q}{4\pi} \log(x^2 + (y + d)^2),$$

and the flow in the physical region $y > 0$ is exactly that of two equal sources. Notice we have solved a problem with a boundary by solving a problem without one.

The same idea handles a vortex next to a wall (image vortex of *opposite* sign, so that the wall is a streamline; the pair then translates parallel to the wall, which is why smoke rings bounce along ceilings), and a source outside a circular cylinder (the Milne–Thomson

circle theorem, which puts an image at the inverse point a^2/d .

§13.6.5 Complex Potentials

We noted earlier that in two dimensions,

$$\frac{\partial \phi}{\partial x} = \frac{\partial \psi}{\partial y}, \quad \frac{\partial \phi}{\partial y} = -\frac{\partial \psi}{\partial x},$$

which are exactly the Cauchy–Riemann equations for $\phi + i\psi$ as a function of $z = x + iy$. This is not a coincidence, and it is the doorway to an enormously powerful set of techniques.

Definition 13.6.12 (Complex Potential)

The **complex potential** of a two-dimensional potential flow is the holomorphic function

$$w(z) = \phi(x, y) + i\psi(x, y),$$

and its derivative is the **complex velocity**

$$\frac{dw}{dz} = u - iv.$$

Every one of our building blocks is now a one-line formula: a uniform stream is $w = Uz$; a source of strength q at the origin is $w = (q/2\pi) \log z$; a line vortex of circulation κ is $w = -(i\kappa/2\pi) \log z$; a dipole is $w = m/z$; and flow past a cylinder with circulation is

$$w(z) = U \left(z + \frac{a^2}{z} \right) - \frac{i\kappa}{2\pi} \log z,$$

whose real and imaginary parts the reader may check reproduce the ϕ and ψ of Example 13.6.9. Better still, if $\zeta = f(z)$ is a conformal map then $w(\zeta(z))$ is again a complex potential, so we can transplant the solution for a cylinder onto any shape a conformal map can reach – including, via the Joukowski map, an aerofoil.

We will not develop this here, since it is properly the business of the ‘Complex Methods’ course, and the reader is referred to my notes for that course ([../part-ib/complex-methods/](#)), where conformal mapping and its fluid applications are treated at length. The only point to take away now is that potential flow in two dimensions and complex analysis are the same subject.

§13.6.6 Unsteady Potential Flows

Everything so far has been steady. If the flow is unsteady but still irrotational, Bernoulli takes a slightly different and very useful form. Starting from Euler in the form

$$\rho \left(\frac{\partial \mathbf{u}}{\partial t} + \nabla \left(\frac{1}{2} |\mathbf{u}|^2 \right) - \mathbf{u} \times \boldsymbol{\omega} \right) = -\nabla p - \nabla \chi$$

and setting $\boldsymbol{\omega} = \mathbf{0}$, $\mathbf{u} = \nabla \phi$, everything becomes a gradient:

$$\nabla \left(\rho \frac{\partial \phi}{\partial t} + \frac{1}{2} \rho |\nabla \phi|^2 + p + \chi \right) = \mathbf{0}.$$

Proposition 13.6.13 (Unsteady Bernoulli)

For an unsteady irrotational flow of an inviscid incompressible fluid of constant density,

$$\rho \frac{\partial \phi}{\partial t} + \frac{1}{2} \rho |\nabla \phi|^2 + p + \chi = f(t)$$

for some function f of time alone.

The point is that f is the same at every point in space, so we may equate the left hand side at two different places, however far apart, and thereby couple the dynamics of distant parts of the flow. Two classic examples follow.

Example 13.6.14 (Oscillations in a Manometer)

A U-tube of uniform cross section contains liquid, with the equilibrium level a height H above the bottom bend, and we displace the level in the left arm up by $h(t)$.

Dimensional analysis already tells us a lot: the only parameters are g and H , so the frequency must be a multiple of $\sqrt{g/H}$. Let us get the constant.

Take the reservoir at the bottom to be wide, so the fluid there is essentially at rest and $\phi = 0$ there. In the left arm the fluid moves vertically at $\dot{h}$, so $\phi = \dot{h}y$ and $\partial\phi/\partial t = \ddot{h}y$; in the right arm the fluid moves down at $\dot{h}$, so $\phi = -\dot{h}y$ and $\partial\phi/\partial t = -\ddot{h}y$. The free surfaces are at $y = H + h$ and $y = H - h$, both at atmospheric pressure.

Applying unsteady Bernoulli at each free surface and equating (both equal $f(t)$),

$$\rho \ddot{h}(H + h) + \frac{1}{2} \rho \dot{h}^2 + p_{\text{atm}} + g\rho(H + h) = -\rho \ddot{h}(H - h) + \frac{1}{2} \rho \dot{h}^2 + p_{\text{atm}} + g\rho(H - h).$$

A great deal cancels, leaving $2\rho H\ddot{h} + 2g\rho h = 0$, that is,

$$\ddot{h} + \frac{g}{H}h = 0.$$

Simple harmonic motion with frequency exactly $\sqrt{g/H}$ – the dimensionless constant is 1.

Example 13.6.15 (Oscillations of a Bubble)

A spherical bubble of radius $a(t)$ sits in an infinite fluid and pulses radially. The induced flow is spherically symmetric, so

$$\nabla^2 \phi = 0 \quad (r > a), \quad \phi \rightarrow 0 \quad (r \rightarrow \infty), \quad \frac{\partial \phi}{\partial r} = \dot{a} \quad (r = a).$$

The decaying spherically symmetric solution is $\phi = A(t)/r$, so $u_r = -A/r^2$, and the boundary condition gives $-A/a^2 = \dot{a}$. Hence

$$\phi = -\frac{a^2\dot{a}}{r}, \quad \left. \frac{\partial\phi}{\partial t} \right|_{r=a} = -(a\ddot{a} + 2\dot{a}^2).$$

Neglect gravity and apply unsteady Bernoulli at $r = a$ and at infinity:

$$-\rho(a\ddot{a} + 2\dot{a}^2) + \frac{1}{2}\rho\dot{a}^2 + p(a, t) = p_\infty,$$

that is, the **Rayleigh–Plesset equation**

$$\rho(a\ddot{a} + \frac{3}{2}\dot{a}^2) = p(a, t) - p_\infty.$$

This is nonlinear, so linearise: put $a = a_0 + \eta$ with $\eta \ll a_0$, and to first order

$$\rho a_0 \ddot{\eta} = p(a, t) - p_\infty = \delta p.$$

To relate δp to η we need thermodynamics. If the oscillation is fast there is no time for heat exchange, so it is adiabatic and pV^γ is constant, where γ is the ratio of specific heats. Taking logarithms and varying,

$$\frac{\delta p}{p_\infty} = -\gamma \frac{\delta V}{V_0} = -3\gamma \frac{\eta}{a_0},$$

using $V = \frac{4}{3}\pi a^3$. Therefore

$$\rho a_0 \ddot{\eta} = -\frac{3\gamma p_\infty}{a_0} \eta,$$

simple harmonic motion with frequency

$$\omega = \left(\frac{3\gamma p_\infty}{\rho a_0^2} \right)^{1/2}.$$

Putting numbers in for a bubble of radius 1 mm in water gives $\omega \sim 2 \times 10^4 \text{ s}^{-1}$, comfortably inside the human audible range of 20 to 20 000 s^{-1} . This is the sound of a babbling brook, or of a glass of fizzy water: we are literally hearing individual bubbles ring.

§13.7 Water Waves

We now apply the machinery of potential flow to what is probably the most familiar fluid phenomenon of all. The set-up is a layer of water of undisturbed depth H over a flat bottom, with air above, and a free surface at $z = h(x, y, t)$.

We will start with dimensional analysis, which gets us surprisingly far, and then solve the problem properly.

§13.7.1 What Dimensional Analysis Tells Us

Consider waves of wavenumber $k = 2\pi/\lambda$ on water of depth H , and suppose the fluid is inviscid. The wave speed c can depend only on k , g and H , so dimensionally

$$c = \sqrt{gH} f(kH)$$

for some dimensionless function f .

Now consider the two extreme regimes.

Deep water, $kH \gg 1$: the wavelength is short compared with the depth, so the wave has no way of knowing how deep the water is, and c cannot depend on H . The only way to arrange that is $f(s) \propto s^{-1/2}$, giving

$$c = \alpha \sqrt{\frac{g}{k}}$$

for some constant α . Long waves travel faster than short ones.

Shallow water, $kH \ll 1$: the wavelength is enormous compared with the depth, and the wave cannot resolve individual wavelengths, so c cannot depend on k . Hence f is a constant β and

$$c = \beta \sqrt{gH}.$$

All waves travel at the same speed, set by the depth.

We cannot get α and β this way, nor can we interpolate between the two regimes; for that we need to solve the equations, and we will find that $\alpha = \beta = 1$. But two well-known phenomena already follow.

First, *why wave crests are always parallel to the beach*. Approaching a shore the water gets shallower, so waves slow down. If a wavefront comes in at an angle, the end that is further out is in deeper water and travels faster, so the front swings round until it is parallel to the shore. It is refraction, exactly as in optics.

Secondly, *why waves break*. In shallow water $c = \sqrt{gH}$, so where the water is deeper the wave moves faster. But at a crest the water *is* deeper, by the wave amplitude. When the amplitude becomes comparable with the depth, the crest overtakes the trough in front of it, the front face steepens, and the wave breaks.

§13.7.2 The Linearised Problem

Now let us set the problem up properly. The water starts at rest, so by the persistence of irrotationality it is irrotational forever, and being incompressible it has a potential satisfying

$$\nabla^2 \phi = 0, \quad -H < z < h.$$

There are three boundary conditions.

- (i) *No flow through the bottom*: $\frac{\partial \phi}{\partial z} = 0$ on $z = -H$.
- (ii) *Kinematic condition at the free surface*: by Section 3.5, the surface is a material surface, so

$$\frac{\partial \phi}{\partial z} = \frac{Dh}{Dt} = \frac{\partial h}{\partial t} + u \frac{\partial h}{\partial x} + v \frac{\partial h}{\partial y} \quad \text{on } z = h.$$

- (iii) *Dynamic condition at the free surface*: the pressure there must equal the (constant) atmospheric pressure p_0 . By unsteady Bernoulli, with $\chi = g\rho z$,

$$\rho \frac{\partial \phi}{\partial t} + \frac{1}{2} \rho |\nabla \phi|^2 + g\rho h + p_0 = f(t) \quad \text{on } z = h.$$

Note that gravity has come back, and had to: at a free surface the density is not constant across the boundary, so the reduced-pressure trick is unavailable. Gravity is the restoring force for these waves.

The equation is easy; the boundary conditions are horrible. They are nonlinear, and worse, they are imposed on a surface $z = h$ whose location we do not know until we have solved the problem. So we linearise. Assume:

- small amplitude, $h \ll H$;
- small slope, $|\partial h / \partial x|, |\partial h / \partial y| \ll 1$;

and throw away everything quadratic in small quantities. The velocities are themselves small (the water would be at rest if h were), so $u \partial h / \partial x$ goes, and so does all of $|\nabla \phi|^2$. Finally, Taylor expanding about $z = 0$,

$$\left. \frac{\partial \phi}{\partial z} \right|_{z=h} = \left. \frac{\partial \phi}{\partial z} \right|_{z=0} + h \left. \frac{\partial^2 \phi}{\partial z^2} \right|_{z=0} + \cdots \approx \left. \frac{\partial \phi}{\partial z} \right|_{z=0},$$

so we may apply the surface conditions on the fixed plane $z = 0$ instead. We are left with a completely linear problem.

Proposition 13.7.1 (Linear Water Wave Equations)

$$\begin{aligned}
\nabla^2 \phi &= 0 & -H < z \leq 0, \\
\frac{\partial \phi}{\partial z} &= 0 & z = -H, \\
\frac{\partial \phi}{\partial z} &= \frac{\partial h}{\partial t} & z = 0, \\
\frac{\partial \phi}{\partial t} + gh &= 0 & z = 0,
\end{aligned}$$

the last after absorbing constants into ϕ .

§13.7.3 The Dispersion Relation

Consider straight-crested waves travelling in the x direction, so nothing depends on y . Try a travelling wave

$$h = h_0 e^{i(kx - \omega t)},$$

(with the convention that we take real parts at the end), and correspondingly

$$\phi = \hat{\phi}(z) e^{i(kx - \omega t)}.$$

Laplace's equation gives $\hat{\phi}'' - k^2 \hat{\phi} = 0$, so $\hat{\phi}$ is a combination of $e^{\pm kz}$; the bottom condition $\hat{\phi}'(-H) = 0$ picks out

$$\hat{\phi} = \phi_0 \cosh k(z + H).$$

There are now three unknowns h_0, ϕ_0, ω and two conditions left. The kinematic condition at $z = 0$ gives

$$k\phi_0 \sinh kH = -i\omega h_0,$$

and the dynamic condition gives

$$-i\omega\phi_0 \cosh kH + gh_0 = 0.$$

Eliminating ϕ_0 and h_0 (the alternative being the trivial solution) gives $\omega^2 \cosh kH = gk \sinh kH$.

Theorem 13.7.2 (Dispersion Relation for Water Waves)

Linear surface gravity waves on water of depth H satisfy

$$\omega^2 = gk \tanh kH,$$

and hence travel with phase speed

$$c = \frac{\omega}{k} = \sqrt{\frac{g}{k} \tanh kH}.$$

Let us check our limits. As $kH \rightarrow \infty$, $\tanh kH \rightarrow 1$, so in deep water

$$\omega^2 = gk, \quad c = \sqrt{\frac{g}{k}} = \sqrt{\frac{g\lambda}{2\pi}}.$$

As $kH \rightarrow 0$, $\tanh kH \rightarrow kH$, so in shallow water

$$\omega^2 = gHk^2, \quad c = \sqrt{gH}.$$

Exactly as dimensional analysis predicted, with $\alpha = \beta = 1$.

Several things follow from the shape of this curve.

The wave speed decreases monotonically with k : long waves are fast, short waves are slow. Hence a disturbance of a general shape – a square wave, say, or the splash of a stone – disperses, its long components racing ahead and its short ones lagging behind. That is what the word ‘dispersion’ means.

There is a *maximum* wave speed $\sqrt{gH}$, attained in the shallow-water limit. Nothing on the surface can travel faster than this. If a boat travels faster than $\sqrt{gH}$ then all the waves it produces are left behind, and it produces a wake with a sharp bow shock, exactly like a supersonic aircraft. The relevant dimensionless number is

Definition 13.7.3 (Froude Number)

The **Froude number** of a flow of speed U over depth H is

$$Fr = \frac{U}{\sqrt{gH}},$$

the analogue of the Mach number for surface waves.

Example 13.7.4 (Tsunami)

A tsunami has wavelength $\lambda \sim 400$ km in an ocean of depth $H \sim 4$ km, so $kH \sim 0.06 \ll 1$ and we are firmly in the shallow water regime. Hence

$$c = \sqrt{gH} = \sqrt{10 \times 4 \times 10^3} = 200 \text{ m s}^{-1},$$

roughly the speed of a jet aircraft, crossing the Pacific in under a day. Note that the speed depends only on the depth, so the topography of the ocean floor refracts and focusses tsunamis – knowing the bathymetry lets one predict where a tsunami will strike hardest, which saves lives.

Note also that in deep water a tsunami has an amplitude of perhaps half a metre spread over 400 km: a ship at sea would not notice it passing. It is only as H decreases near the coast, so that c decreases and (by conservation of energy flux) the amplitude must grow, that it becomes destructive.

§13.7.4 Particle Paths

What do individual fluid particles do as a wave passes? They certainly do not travel with the wave – a cork bobs, it does not surf.

Take the deep water case for cleanliness. With $h = h_0 \cos(kx - \omega t)$ (real part taken), the relations above give

$$\phi = \frac{h_0 g}{\omega} e^{kz} \sin(kx - \omega t),$$

so

$$u = \frac{\partial \phi}{\partial x} = h_0 \omega e^{kz} \cos(kx - \omega t), \quad w = \frac{\partial \phi}{\partial z} = h_0 \omega e^{kz} \sin(kx - \omega t),$$

using $\omega^2 = gk$. To leading order a particle near (x_0, z_0) therefore has

$$x - x_0 = -h_0 e^{kz_0} \sin(kx_0 - \omega t), \quad z - z_0 = h_0 e^{kz_0} \cos(kx_0 - \omega t).$$

So each particle moves in a *circle* of radius $h_0 e^{kz_0}$, traversed once per wave period. The radius decays exponentially with depth, with e-folding scale $1/k = \lambda/2\pi$: at one wavelength down the motion is only $e^{-2\pi} \approx 0.2\%$ of that at the surface, which is why submarines are calm in a storm.

In shallow water the story is different: the exponentials become cosh and sinh, the horizontal motion is nearly independent of depth and the vertical motion vanishes at the bottom, so the circles flatten into ellipses which become more and more elongated as we descend, degenerating into pure horizontal to-and-fro at the bed.

§13.7.5 Group Velocity

Suppose we superpose two waves of nearly equal wavenumber. Using a trigonometric identity,

$$\cos k_1 x + \cos k_2 x = 2 \cos \left(\frac{k_1 + k_2}{2} x \right) \cos \left(\frac{k_1 - k_2}{2} x \right).$$

The first factor oscillates rapidly at the mean wavenumber; the second oscillates slowly and acts as an envelope. The result is a train of wave ‘packets’.

The crests move at the phase speed $c = \omega/k$, but the envelope – and hence the energy, and hence the information – moves at a different speed.

Definition 13.7.5 (Group Velocity)

The **group velocity** of a wave with dispersion relation $\omega(k)$ is

$$c_g = \frac{d\omega}{dk}.$$

To see why, write the envelope factor above with $\Delta k = (k_1 - k_2)/2$ and restore the time dependence: the envelope is $\cos(\Delta k x - \Delta \omega t)$, which moves at speed $\Delta \omega / \Delta k \rightarrow d\omega / dk$.

For deep water waves, $\omega = \sqrt{gk}$, so

$$c_g = \frac{1}{2} \sqrt{\frac{g}{k}} = \frac{1}{2} c.$$

The group travels at half the speed of the individual crests. If you watch a group of swell in the open sea carefully you can see this: crests appear at the back of the group, race forward through it, and vanish at the front. For shallow water waves, on the other hand, $\omega = k\sqrt{gH}$ is linear in k , so $c_g = c = \sqrt{gH}$ and the waves are *non-dispersive*: a shallow water wave keeps its shape.

§13.7.6 Standing Waves and Instability

Example 13.7.6 (Standing Waves in a Container)

Take a rectangular tank $0 < x < L$ with vertical end walls, where the condition is $u = \partial\phi/\partial x = 0$. Superposing left- and right-moving waves of the same wavenumber gives a standing wave

$$\phi = \phi_0 \cosh k(z + H) \cos kx \cos \omega t,$$

which satisfies the wall conditions provided $\sin kL = 0$, that is,

$$k = \frac{n\pi}{L}, \quad n = 1, 2, \dots$$

So the tank has a discrete set of normal modes, with frequencies $\omega_n^2 = gk_n \tanh k_n H$. This is exactly the phenomenon of *sloshing* in a bath or a fuel tank, and the $n = 1$ mode is the one with the longest period and the largest amplitude. (In a harbour the same modes are called *seiches*, and they can be excited resonantly by tides or by tsunamis, sometimes with dramatic results.)

Example 13.7.7 (Rayleigh–Taylor Instability)

Here is a delightful use of the dispersion relation. Suppose we turn the problem upside down and put the water *above* the air. Every equation is the same, except that gravity now points from the water into the air, so we replace g by $-g$.

In the deep water limit this turns $\omega^2 = gk$ into

$$\omega^2 = -gk \implies \omega = \pm i\sqrt{gk},$$

so that

$$h \propto Ae^{\sqrt{gk}t} + Be^{-\sqrt{gk}t}.$$

One of these solutions grows exponentially: the configuration is **unstable**, and the water falls. This is the **Rayleigh–Taylor instability**, and note that the growth rate $\sqrt{gk}$ increases with k , so the shortest wavelengths grow fastest – which is why the interface breaks up into a fine-scale mess of fingers rather than tipping over in one piece. (In reality surface tension, which we have neglected throughout, cuts the instability off at short wavelengths, which is why you can hold water in an upside-down glass covered with a fine mesh.)

§13.8 Flow in a Rotating Frame

The Earth rotates, so anyone who wants to describe the ocean or the atmosphere must work in a rotating frame. This turns out to change everything: rotating fluids behave in ways that are, at first sight, deeply counterintuitive.

§13.8.1 Equations of Motion in a Rotating Frame

From the Dynamics and Relativity course, the acceleration of a particle in a frame rotating with angular velocity $\boldsymbol{\Omega}$ is

$$\frac{D\mathbf{u}}{Dt} + 2\boldsymbol{\Omega} \times \mathbf{u} + \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{x}),$$

the extra terms being the Coriolis and centrifugal accelerations. So the Euler equation becomes

$$\rho \left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} + 2\boldsymbol{\Omega} \times \mathbf{u} \right) = -\nabla p - \rho \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{x}) + \rho \mathbf{g}.$$

This is worse than what we started with, so let us simplify it.

First, the centrifugal term. For the Earth $|\boldsymbol{\Omega}| = 2\pi/(1 \text{ day}) \approx 7 \times 10^{-5} \text{ s}^{-1}$, and taking the largest relevant scale $|\mathbf{x}| \sim 10^7 \text{ m}$,

$$\frac{|\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{x})|}{|\mathbf{g}|} \lesssim \frac{(7 \times 10^{-5})^2 \times 10^7}{10} \approx 5 \times 10^{-3}.$$

Utterly negligible compared with gravity. (In any case it is a gradient, $\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{x}) = -\nabla \left(\frac{1}{2} |\boldsymbol{\Omega} \times \mathbf{x}|^2 \right)$, so we could absorb it into the pressure. It is, in effect, already inside what we call ‘gravity’ – it is why the Earth is an oblate spheroid.)

Secondly, the nonlinear term. Comparing it with the Coriolis term, their scales are U^2/L and ΩU , so we may drop the nonlinearity provided

Definition 13.8.1 (Rossby Number)

The **Rossby number** is

$$Ro = \frac{U}{\Omega L},$$

measuring inertia relative to Coriolis effects.

For the atmosphere, $U \sim 10 \text{ m s}^{-1}$ and $L \sim 10^6 \text{ m}$, giving $Ro \approx 0.1$: small, so rotation dominates. (For your bath, $U \sim 0.1$ and $L \sim 0.3$, giving $Ro \sim 5000$; rotation is irrelevant, and the direction your bath drains has nothing whatsoever to do with the Coriolis force.)

Proposition 13.8.2 (Euler’s Equation in a Rotating Frame)

For small Rossby number,

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{f} \times \mathbf{u} = -\frac{1}{\rho} \nabla p + \mathbf{g}, \quad \mathbf{f} := 2\boldsymbol{\Omega}.$$

Definition 13.8.3 (Coriolis Parameter)

The vector $\mathbf{f} = 2\boldsymbol{\Omega}$ is the **planetary vorticity**. Since only the component of $\boldsymbol{\Omega}$ perpendicular to the flow matters, and geophysical flows are nearly horizontal, the relevant quantity is the local vertical component

$$f = 2\Omega \sin \theta,$$

where θ is the latitude. This is the **Coriolis parameter**.

Note that $f > 0$ in the northern hemisphere, $f < 0$ in the southern, and $f = 0$ on the equator. This sign change is the reason cyclones spin the other way in Australia.

§13.8.2 The Shallow Water Equations

Geophysical flows are shallow: the Atlantic is 4 km deep and 5000 km across, giving an aspect ratio like a sheet of paper. Let us exploit this.

Consider a layer of fluid with a free surface at $z = h(x, y, t)$ and $p = p_0$ there. Write $\mathbf{u} = (u, v, w)$ and suppose horizontal scales L vastly exceed the vertical scale H . Incompressibility gives

$$\frac{\partial w}{\partial z} = -\frac{\partial u}{\partial x} - \frac{\partial v}{\partial y},$$

whose terms scale as W/H , U/L and V/L . Since $H \ll L$ we find $W \ll U, V$: the motion is overwhelmingly horizontal, which is intuitively obvious – there is nowhere to go vertically.

So take $\mathbf{u} = (u, v, 0)$ and $\mathbf{f} = (0, 0, f)$. The three components of the rotating Euler equation are then

$$\begin{aligned}\frac{\partial u}{\partial t} - fv &= -\frac{1}{\rho} \frac{\partial p}{\partial x}, \\ \frac{\partial v}{\partial t} + fu &= -\frac{1}{\rho} \frac{\partial p}{\partial y}, \\ 0 &= -\frac{1}{\rho} \frac{\partial p}{\partial z} - g.\end{aligned}$$

The last is the **hydrostatic approximation**: the vertical momentum equation has collapsed to a statement of hydrostatic balance, because vertical accelerations are so tiny. Integrating it with $p = p_0$ at $z = h$,

$$p = p_0 + g\rho(h - z).$$

Substituting into the horizontal equations, the z dependence drops out entirely and we obtain

Proposition 13.8.4 (Shallow Water Momentum Equations)

$$\begin{aligned}\frac{\partial u}{\partial t} - fv &= -g \frac{\partial h}{\partial x}, \\ \frac{\partial v}{\partial t} + fu &= -g \frac{\partial h}{\partial y}.\end{aligned}$$

The right hand sides are independent of z , so if the velocities are initially independent of z they remain so. Pressure gradients have been replaced entirely by *gradients of the free surface height*: the weather is driven by the shape of the surface.

We also need mass conservation. Taking a fixed horizontal region $\mathcal{D}$ and noting that the mass per unit area is ρh ,

$$\frac{d}{dt} \int_{\mathcal{D}} \rho h \, dA = - \int_{\partial \mathcal{D}} \rho h \mathbf{u} \cdot \mathbf{n} \, d\ell,$$

and applying the (two-dimensional) divergence theorem and taking $\mathcal{D}$ arbitrary gives

Proposition 13.8.5 (Shallow Water Continuity Equation)

$$\frac{\partial h}{\partial t} + \nabla \cdot (h\mathbf{u}) = 0.$$

If fluid converges horizontally at a point, the surface there rises. That is the whole content.

§13.8.3 Geostrophic Balance

Now specialise to steady flow, so the time derivatives vanish:

$$-fv = -g \frac{\partial h}{\partial x}, \quad fu = -g \frac{\partial h}{\partial y},$$

which we may rearrange as

$$u = \frac{\partial}{\partial y} \left(-\frac{gh}{f} \right), \quad v = -\frac{\partial}{\partial x} \left(-\frac{gh}{f} \right).$$

But these are exactly the equations defining a streamfunction!

Definition 13.8.6 (Geostrophic Balance)

A flow in which the Coriolis force exactly balances the horizontal pressure gradient is in **geostrophic balance**. The **shallow water streamfunction** is

$$\psi = -\frac{gh}{f} = -\frac{p}{\rho f},$$

so that the streamlines are the contours of constant surface height, equivalently the isobars.

This is a genuinely strange conclusion, and it is worth stating in plain words: *in a rotating fluid, the flow runs along the isobars, not across them*. Naively one expects fluid to flow from high pressure to low, and in a non-rotating fluid it does. Here, instead, fluid accelerating down the pressure gradient is deflected by the Coriolis force until it is moving at right angles to that gradient, at which point the two forces balance and the motion is steady.

This is why a weather map is useful: the isobars *are* the streamlines, so you can read the wind straight off the chart. Around a low pressure system in the northern hemisphere the flow is anticlockwise (a cyclone); around a high it is clockwise. In the southern hemisphere $f < 0$ and both are reversed.

§13.8.4 Potential Vorticity and the Rossby Radius

Finally, let us find the conserved quantity that governs how a rotating fluid adjusts. Linearise about a state of rest with uniform depth, writing

$$h = h_0 + \eta, \quad \eta \ll h_0,$$

so that the equations become

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{f} \times \mathbf{u} = -g \nabla \eta \quad (*)$$

and, dropping products of small quantities,

$$\frac{\partial \eta}{\partial t} + h_0 \nabla \cdot \mathbf{u} = 0. \quad (\dagger)$$

Take the curl of (*), writing $\boldsymbol{\zeta} = \nabla \times \mathbf{u}$ for the (vertical) relative vorticity. Using $\nabla \times (\mathbf{f} \times \mathbf{u}) = \mathbf{f}(\nabla \cdot \mathbf{u})$ for constant $\mathbf{f}$ and horizontal $\mathbf{u}$,

$$\frac{\partial \boldsymbol{\zeta}}{\partial t} + \mathbf{f} \nabla \cdot \mathbf{u} = 0,$$

and substituting $\nabla \cdot \mathbf{u} = -\eta_t/h_0$ from (†) gives

$$\frac{\partial}{\partial t} \left(\zeta - \frac{\eta}{h_0} f \right) = 0.$$

Definition 13.8.7 (Potential Vorticity)

The **potential vorticity** is

$$Q = \zeta - \frac{\eta}{h_0} f,$$

and it is conserved: $\partial Q / \partial t = 0$.

The interpretation is that a column of fluid which is stretched (larger η) must spin up (larger ζ) to compensate – exactly the vortex stretching of Section 13.5, with the planetary vorticity f supplying the ambient rotation. This single conservation law explains an enormous amount of atmospheric and oceanic dynamics.

To see it in action, take the divergence of (*) and use (†) again:

$$-\frac{1}{h_0} \frac{\partial^2 \eta}{\partial t^2} - f \zeta = -g \nabla^2 \eta,$$

and eliminating ζ using $\zeta = Q_0 + f\eta/h_0$,

$$\frac{\partial^2 \eta}{\partial t^2} - gh_0 \nabla^2 \eta + f^2 \eta = -h_0 f Q_0,$$

where Q_0 is the (time-independent, hence known from the initial data) potential vorticity.

Example 13.8.8 (Rossby Adjustment)

Suppose we start with a step in the surface height: $\eta = -\eta_0$ for $x < 0$ and $\eta = +\eta_0$ for $x > 0$, with the fluid at rest. What is the final state?

Without rotation, the answer is obvious: the water sloshes about and eventually settles flat, with no flow. With rotation, that answer is *impossible*, because a flat surface with no flow has $Q = 0$ everywhere, and the initial data has (since $\zeta = 0$ initially)

$$Q_0 = \mp \frac{\eta_0}{h_0} f \quad \text{for } x \gtrless 0,$$

which is not zero. Conservation of Q forbids the naive answer.

Look for a steady final state independent of y . Then our equation reduces to

$$\frac{d^2 \eta}{dx^2} - \frac{f^2}{gh_0} \eta = \frac{f}{g} Q_0 = \mp \frac{f^2}{gh_0} \eta_0.$$

Definition 13.8.9 (Rossby Radius of Deformation)

The length scale

$$R = \frac{\sqrt{gh_0}}{f}$$

is the **Rossby radius of deformation** – the distance a shallow water wave travels in one rotation time.

In terms of R the equation is $\eta'' - \eta/R^2 = \mp\eta_0/R^2$, and requiring $\eta \rightarrow \pm\eta_0$ as $x \rightarrow \pm\infty$ with η, η' continuous at the origin gives

$$\eta = \eta_0 \begin{cases} 1 - e^{-x/R} & x > 0, \\ -\left(1 - e^{x/R}\right) & x < 0. \end{cases}$$

So the step does not flatten out; it slumps into a smooth front of width $2R$, and it stops there. Computing the velocity from geostrophic balance,

$$u = -\frac{g}{f} \frac{\partial \eta}{\partial y} = 0, \quad v = \frac{g}{f} \frac{\partial \eta}{\partial x} = \eta_0 \sqrt{\frac{g}{h_0}} e^{-|x|/R},$$

there is a jet flowing along the front, whose Coriolis force holds up the remaining pressure gradient. The final state is not rest; it is geostrophic balance.

Putting numbers in, the Rossby radius in the atmosphere is

$$R = \frac{\sqrt{10 \times 10^4}}{10^{-4}} \approx 10^6 \text{ m} = 1000 \text{ km},$$

which is precisely the scale of the weather systems on a synoptic chart – that is why cyclones are the size they are. In the ocean, h_0 is effectively much smaller (one should use the depth of the thermocline), and one finds $R \sim 100 \text{ km}$: ocean eddies are ten times smaller than atmospheric ones, and correspondingly much harder to observe. The Rossby radius is the fundamental length scale of any rotating system in which gravity also matters, and it is a good note on which to end.

14 Geometry

Geometry is the study of shapes – but shapes viewed with an eye towards *measurement*. In this course we will study surfaces: spaces which locally look like the plane, but which globally can be curved, twisted or glued together in interesting ways. We will begin by pinning down what a surface actually is, and then gradually add structure: smoothness, ways of measuring lengths, angles and areas, and finally curvature. Along the way we will meet the three classical two-dimensional geometries – Euclidean, spherical and hyperbolic – and the course will culminate in the Gauss–Bonnet theorem, a genuinely remarkable result linking the curvature of a surface to its topology.

This article constitutes my notes for the ‘Geometry’ course, held in Lent 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§14.1 Topological and Smooth Surfaces

§14.1.1 Topological Surfaces

We will begin immediately with a definition that will occupy us for some time.

Definition 14.1.1 (Topological Surface)

A topological surface is a topological space Σ such that

- (i) Each $p \in \Sigma$ has an open neighborhood U with $p \in U$ such that U is homeomorphic to $\mathbb{R}^2$, with its usual Euclidean topology.
- (ii) Σ is Hausdorff and second countable.

Recall that a space X is Hausdorff if for $p \neq q$ in X there exist disjoint open sets $p \in U$ and $q \in V$ in X , and that a space is second countable if its topology has a countable basis. In some ways, the real nature of topological surfaces comes from the condition (i), and the condition (ii) is really there for technical honesty.

§14.1.2 Examples of Topological Surfaces

Let’s now take some time to consider some examples of topological surfaces.

Example 14.1.2 ($\mathbb{R}^2$)

The plane $\mathbb{R}^2$ is a topological surface.

Example 14.1.3 (Subsets of $\mathbb{R}^2$)

Any open subset of $\mathbb{R}^2$ is a topological surface. For example

- (i) $\mathbb{R}^2 \setminus \{0\}$ is a topological surface;

(ii) Let $Z = \{(0, 0)\} \cup \{(1, 1/n) \mid n \in \mathbb{N}\}$, then $\mathbb{R}^2 \setminus Z$ is a topological surface.

Example 14.1.4 (Graphs)

Let $f : \mathbb{R}^2 \rightarrow \mathbb{R}$ be a continuous function. Then the **graph**

$$\Gamma_f = \{(x, y, f(x, y)) \mid (x, y) \in \mathbb{R}^2\} \subseteq \mathbb{R}^3,$$

taken with the subspace topology, is a topological surface. Let's see why.

Recall that if X and Y are topological spaces, the product topology on $X \times Y$ has basis open sets $U \times V$ with $U \subseteq X$ and $V \subseteq Y$ both open sets.

It has the feature that $f : Z \rightarrow X \times Y$ is continuous if and only if $\pi_x \circ f : Z \rightarrow X$ and $\pi_y \circ f : Z \rightarrow Y$ are continuous.

So if $\Gamma_f \subseteq X \times Y$ and $f : X \rightarrow Y$ is continuous then Γ_f is homeomorphic to X , with the map $s : x \mapsto (x, f(x))$, so that $\pi|_{\Gamma_f}$ and s are inverse homeomorphisms.

So $\Gamma_f \cong \mathbb{R}^2$ for *any* continuous $f : \mathbb{R}^2 \rightarrow \mathbb{R}$, and Γ_f is a topological surface.

As a note, the topological surface Γ_f is independent of f . Later on as we develop more tools in geometry we will be able to better reflect the structure of the function f .

Example 14.1.5 (Stereographic Projection)

Consider the sphere

$$S^2 = \{(x, y, t) \in \mathbb{R}^3 \mid x^2 + y^2 + t^2 = 1\}.$$

We can consider the stereographic projection

$$\begin{aligned} \pi_+ : S^2 \setminus \{(0, 0, 1)\} &\rightarrow \mathbb{R}^2 (z = 0) \subseteq \mathbb{R}^3 \\ (x, y, t) &\mapsto \left(\frac{x}{1-t}, \frac{y}{1-t} \right). \end{aligned}$$

Such a projection is shown below.

Note that π_+ is continuous and has an inverse

$$(u, v) \mapsto \left(\frac{2u}{u^2 + v^2 + 1}, \frac{2v}{u^2 + v^2 + 1}, \frac{u^2 + v^2 - 1}{u^2 + v^2 + 1} \right).$$

So π_+ is a continuous bijection with continuous inverse and hence a homeomorphism.

Of course we could also have projected from the south pole, to get a homeomorphism π_- from $S^2 \setminus \{(0, 0, -1)\}$ to $\mathbb{R}^2$, so indeed every point lies in an open set which is homeomorphic through either π_+ or π_- to $\mathbb{R}^2$. So S^2 is a topological surface.

Remark. S^2 is compact as a topological space, since it is a closed bounded set in $\mathbb{R}^3$.

Example 14.1.6 (Real Projective Plane)

The group $\mathbb{Z}/2\mathbb{Z}$ acts on S^2 by homeomorphisms via the **antipodal map** $a : S^2 \rightarrow S^2$ with

$$a(x, y, t) = (-x, -y, -t).$$

That is, there exists a homomorphism $\mathbb{Z}/2\mathbb{Z} \rightarrow \text{Homeo}(S^2)$ sending the non-identity element to a .

The **real projective plane** is the quotient space of S^2 given by identifying every point with its antipodal image: $\mathbb{RP}^2 = S^2/(\mathbb{Z}/2\mathbb{Z}) = S^2/\sim$ with $x \sim a(x)$.

Note that $\sim$ is the equivalence relation of belonging to the same orbit under the given action.

As a set, $\mathbb{RP}^2$ is naturally in bijection with the set of straight lines in $\mathbb{R}^3$ through the origin, with the bijection given by mapping lines with the identified points on the sphere that they pass through.

We can also check that $\mathbb{RP}^2$ is a topological surface.

We must first check that it is Hausdorff. Recall that if X is a space and $q : X \rightarrow Y$ is a quotient map, then $V \subseteq Y$ is open if and only if $q^{-1}(V) \subseteq X$ is open.

If $[p] \neq [q] \in \mathbb{RP}^2$ then $\pm p$ and $\pm q \in S^2$ are distinct antipodal points. We can then take small open discs^a about these in S^2 as in the picture, which give us disjoint open neighborhoods of $[p]$ or $[q]$ in $\mathbb{RP}^2$. That is, it's Hausdorff.

We can also check that $\mathbb{RP}^2$ is second countable. Let U be a countable basis for the topology on S^2 , and without loss of generality for all $u \in U$, the antipodal image is in U . Let $\overline{U}$ be the family of open sets in $\mathbb{RP}^2$ of the form $q(u) \cup q(-u)$, $u \in U$. Now if $V \subseteq \mathbb{RP}^2$ is open, by definition $q^{-1}(V)$ is open in S^2 , and so $q^{-1}(V)$ contains

some $u \in U$ and hence contains $u \cup (-u)$. So $\overline{U}$ is a countable base for the quotient topology on $\mathbb{RP}^2$.

Finally, let $p \in S^2$ and let $[p] \in \mathbb{RP}^2$ be its image. Let $\overline{D}$ be a small^b closed disc neighborhood of $p \in S^2$.

Then the quotient map $q|_{\overline{D}} : \overline{D} \rightarrow q(\overline{D}) \subseteq \mathbb{RP}^2$ is a continuous map from a compact space to a Hausdorff space. Also, on $\overline{D}$ the map q is injective. So by the topological inverse function theorem, this map $q|_{\overline{D}}$ is a homeomorphism. This induces (by taking interiors) a homeomorphism $q|_D : D \rightarrow q(D) \subseteq \mathbb{RP}^2$. So $[p] \in q(D)$ has an open neighborhood in $\mathbb{RP}^2$ homeomorphic to an open disk, and we are done.

^aWe could take small balls $B_{\pm p}(\delta)$ and $B_{\pm q}(\delta)$ ($\delta \ll 1$ small), which meet S^2 in open sets. If $q : S^2 \rightarrow \mathbb{RP}^2$ is the quotient map, then $q(B_p(\delta))$ is open since $q^{-1}(q(B_p(\delta))) = B_p(\delta) \cup (-B_p(\delta))$, the union with the antipodal image.

^bContained in an open hemisphere

Example 14.1.7 (Torus)

Let $S^1 = \{z \in \mathbb{C} \mid |z| = 1\}$, and define the **torus** $S^1 \times S^1$ with the subspace topology from $\mathbb{C}^2$ (which is the product topology). We will show that the torus is a topological surface.

Consider the map

$$\begin{aligned} \mathbb{R}^2 &\xrightarrow{e} S^1 \times S^1 \subseteq \mathbb{C} \times \mathbb{C} \\ (s, t) &\mapsto (e^{2\pi i s}, e^{2\pi i t}). \end{aligned}$$

Note that this induces a map (in a set theoretic sense)

$$\begin{array}{ccc} \mathbb{R}^2 & \xrightarrow{e} & S^1 \times S^1 \\ \downarrow & \nearrow \hat{e} & \\ \mathbb{R}^2/\mathbb{Z}^2 & & \end{array}$$

that is, on the equivalence relation on $\mathbb{R}^2$ given by translating by $\mathbb{Z}^2$, e is constant on equivalence classes and so induces a map of sets $\mathbb{R}^2/\mathbb{Z}^2 \rightarrow S^1 \times S^1$. Note we are viewing $\mathbb{R}^2/\mathbb{Z}^2$ as the quotient space for $q : \mathbb{R}^2 \rightarrow \mathbb{R}^2/\mathbb{Z}^2$.

So the map $[0, 1]^2 \hookrightarrow \mathbb{R}^2 \xrightarrow{q} \mathbb{R}^2/\mathbb{Z}^2$ is onto, so $\mathbb{R}^2/\mathbb{Z}^2$ is compact. So $\hat{e}$ is a continuous map from a compact space to a Hausdorff space and is a bijection, and is thus a homeomorphism by the topological inverse function theorem.

Note we already know that $S^1 \times S^1$ is compact and Hausdorff (closed and bounded

in $\mathbb{R}^4$). As for $S^2 \rightarrow \mathbb{RP}^2$, pick $[p] = q(p)$ for $p \in \mathbb{R}^2$ and some small closed disc $\overline{D}(p) \subseteq \mathbb{R}^2$ such that for all integers $(n, m) \neq (0, 0)$ we have $\overline{D}(p) \cap (\overline{D}(p) + (n, m)) = \emptyset$. Then $e|_{\overline{D}(p)}$ is injective and $q|_{\overline{D}(p)}$ is injective. Now restricting to the open disc as before, we get an open disc neighborhood of $[p] \in S^1 \times S^1$. Since $[p]$ is arbitrary, $S^1 \times S^1$ is a topological surface.

Another viewpoint: $\mathbb{R}^2/\mathbb{Z}^2$ is also given by imposing on $[0, 1]^2$ the equivalence relation generated by $(x, 0) \sim (x, 1)$, $(0, y) \sim (1, y)$.

Example 14.1.8 (Gluing Edges)

Let P be a planar Euclidean polygon. We will assume the edges are *oriented* and paired. For simplicity, we can suppose that e and e' have the same Euclidean length whenever $\{e, e'\}$ are paired.

If $\{e, e'\}$ are paired edges, there is a unique isometry from e to e' respecting their orientations, say $f_{ee'} : e \rightarrow e'$. These maps generate an equivalence relation on P , where I identify $x \in P$ with $f_{ee'}(x)$ whenever $x \in e$.

Lemma. $P/\sim$ (with the quotient topology) is a topological surface.

Before we prove this, we will consider the specific example of the torus as $[0, 1]^2/\sim$.

If $P = [0, 1]^2$ and p is in the interior of P , then we can pick $\delta > 0$ sufficiently small so that $B_p(\delta)$ and $\overline{B_p(\delta)}$ in $\mathbb{R}^2$ lie in the interior of P . Now we argue as before: the quotient map is injective on $\overline{B_p(\delta)}$ and a homeomorphism on its interior. If p is on an edge of P , then we take two half disks of sufficiently small radius δ so that they don't meet a vertex of P .

Then we can define a map f from the union of these half disks to the disk of the same radius at the origin of $\mathbb{R}^2$ as above.

Explicitly, we define f_U and f_V such that they are continuous on the half disks $U, V \in [0, 1]^2$. These induce a continuous map on $q(U)$ and $q(V) \subseteq T^2$, ($q : [0, 1]^2 \rightarrow [0, 1]^2 / \sim = T^2$). In T^2 , the half disks $q(U)$ and $q(V)$ overlap *but* overlaps agree on the closed intersection locus (as f_U and f_V are compatible with the equivalence relation). So f_U and f_V glue to define a continuous map f on an open neighborhood $[p] \in T^2$ to $B_0(\delta) \subseteq \mathbb{R}^2$.

Now we can apply our ‘usual argument’ (pass to a closed disk, apply the topological inverse function theorem, pass back to the interior) to show that if $[q] \in T^2$ lies on the image of an edge of $[0, 1]^2$, it has an open neighborhood homeomorphic to a disk.

Analogously, at a vertex of $[0, 1]^2$, the same argument with a slight modification works.

This shows that $[0, 1]^2 / \sim$ is a topological surface.

For a general planar polygon P . We will now see how to address the general case. We again are trying to show that each point has an open neighborhood that is homeomorphic to a disk. For interior points, a suitably sized disk (chosen so that it does not intersect any edges or vertices) works exactly as before.

Now we have our equivalence relation on points in the polygon $x \sim f_{ee'}(x)$ where $x \in e \in \text{Edge}(P)$ and e, e' are paired with $f : e \rightarrow e'$ compatible with orientation. This relation induces an equivalence relation on $\text{Vert}(P)$.

If $v \in \text{Vert}(P)$ has r vertices in its equivalence class, then these contribute r sectors in P , of total angle α_v say. Rescaling angles by a factor of $2\pi/\alpha_v$, these sectors can be glued around the image of v to give a full sector $\{(\rho, \theta) \mid 0 \leq \rho < \delta, \theta \in [0, 2\pi]\}$, which is homeomorphic to a disk.

To see that $P / \sim$ is Hausdorff, we can take disks on the interior with a sufficiently small radius and distinct points will have disjoint disks. For second countable, consider disks on the interior of P with rational radii and centre, and if $e \in \text{Edge}(P)$ then $e \mapsto [0, \text{length}(e)]$ is an isometry, so take only half disks on e which are centred

at rational points, with rational radii. And at vertices, allow rational radius sectors. This gives a countable basis.

Example 14.1.9 (Connect Sum)

Given topological surfaces Σ_1 and Σ_2 , we can remove an open disk from each and glue the resulting boundary circles.

Explicitly, I take $\Sigma_1 \setminus D_1$ and $\Sigma_2 \setminus D_2$ and impose an equivalence relation

$$\theta \in \partial D_1 \sim \theta \in \partial D_2,$$

where θ parameterises the boundary circles $S^1 \cong \partial D_i$.

The result $\Sigma_1 \# \Sigma_2$ is the **connect sum** of Σ_1 and Σ_2 . Note that in principle this connect sum depends on a number of choices, but we suppress this from the notation.

Indeed, the connect sum of topological surfaces is a topological surface. This is proved as before.

§14.1.3 Subdivisions and Triangulations

Before discussing smooth surfaces, we want to talk a bit about subdivisions and triangulations of compact surfaces.

Definition 14.1.10 (Subdivision)

A **subdivision** of a compact topological surface Σ consists of

- (i) A finite set $V \subseteq \Sigma$ of **vertices**;
- (ii) A finite collection of continuous embeddings $\{e_i : [0, 1] \rightarrow \Sigma\}$ called **edges**, each of which has endpoints in V , and any two of which meet at endpoints;
- (iii) The connected components of $\Sigma \setminus [V \cup \bigcup_i e_i([0, 1])]$ are each homeomorphic to an open disk called a **face**.

Definition 14.1.11 (Triangulation)

A subdivision is a **triangulation** if each *closed* face (the closure of a face) contains exactly 3 edges and two closed faces are either disjoint or meet in exactly one edge.

Example 14.1.12 (Subdivisions and Triangulations of S^2 and T^2)

The cube displays a subdivision of the sphere S^2 , and the tetrahedron displays a triangulation of the sphere S^2 .

Subdivision of S^2 Triangulation of S^2

One convenient way of displaying a subdivision is with the diagrams we had for specifying surfaces by gluing edges. For example, the below shows a subdivision of T^2 with 1 vertex, 2 edges and 1 face.

Subdivision of T^2

2 Edges, 1 Vertex

As a more degenerate example, a single vertex of S^2 is indeed a subdivision, leaving 1 vertex, 0 edges and 1 face.

Indeed, the notion of subdivisions gives us an interesting topological invariant for compact topological surfaces.

Definition 14.1.13 (Euler Characteristic)

The **Euler characteristic** of a subdivision is the number

$$V - E + F$$

where V is number of vertices, E is the number of edges and F is the number of faces.

Theorem 14.1.14 (Euler's Relation)

- (i) Every compact topological surface admits subdivisions, and indeed triangulations.

- (ii) The Euler characteristic, denoted $\chi(\Sigma)$, does not depend on the choice of subdivision, and thus defines a topological invariant of the surface.

We aren't going to prove this theorem because it's relatively hard and won't really say anything about the true nature of what is going on. A nice proof will be given in a course on Algebraic Topology.

Example 14.1.15 (Euler's Relation for Various Surfaces)

Considering some of our previous examples, we can see that

- (i) $\chi(S^2) = 2$;
- (ii) $\chi(T^2) = 0$;
- (iii) If Σ_1 and Σ_2 are compact topological surfaces, we can form $\Sigma_1 \# \Sigma_2$ by removing an open disk which is the face of a triangulation, and gluing the boundary circles gives us that

$$\chi(\Sigma_1 \# \Sigma_2) = \chi(\Sigma_1) + \chi(\Sigma_2) - 2.$$

In particular, if a surface has g holes, then considering it as homeomorphic to connect sum of g copies of T^2 , we get that $\chi(\Sigma_g) = 2 - 2g$. The number g is called the **genus** of Σ .

§14.1.4 Charts and Atlases

Recall that if Σ is a topological surface, each $p \in \Sigma$ lies in an open neighbourhood $p \in U \subseteq \Sigma$ with U homeomorphic to an open disk.

Definition 14.1.16 (Chart)

A pair (U, ϕ) where $U \subseteq \Sigma$ and ϕ is a homeomorphism $\phi : U \rightarrow V$ where V is open in $\mathbb{R}^2$ is called a **chart** for Σ .

Definition 14.1.17 (Atlas)

A collection of charts $\{(U_i, \phi_i) \mid i \in I\}$ such that $\bigcup_{i \in I} U_i = \Sigma$ is called an **atlas** for Σ .

Example 14.1.18 (Trivial Example of an Atlas)

Recall that any open subset U of $\mathbb{R}^2$ is a topological surface. Then taking (U, Id) gives us an atlas with one chart.

Example 14.1.19 (Atlas for S^2)

For S^2 , we have an atlas with 2 charts, the 2 stereographic projections.

Definition 14.1.20 (Transition Maps)

Let (U_1, ϕ_1) and (U_2, ϕ_2) be charts containing a point p on a topological surface Σ .

Considering the intersection, we get a map $\phi_1(U_1 \cap U_2) \rightarrow \phi_2(U_1 \cap U_2)$. Such a map is called a **transition map** between the charts, and this is a homeomorphism of open sets in $\mathbb{R}^2$.

§14.1.5 Smooth Surfaces

Recall that if V and V' are open subsets of $\mathbb{R}^n$, then a map $f : V \rightarrow V'$ is **smooth** if it is infinitely differentiable. If f is a homeomorphism between V and V' , then we call it a **diffeomorphism** if it's smooth and has a smooth inverse.

Definition 14.1.21 (Abstract Smooth Surface)

An **abstract smooth surface** Σ is a topological surface with an atlas of charts $\{(U_i, \phi_i) \mid i \in I\}$ with $\bigcup_{i \in I} U_i = \Sigma$ such that all of the transition maps $\phi_j(U_i \cap U_j) \rightarrow \phi_i(U_i \cap U_j)$ are diffeomorphisms of open sets in $\mathbb{R}^2$.

Remark. It would *not* make sense to ask for the maps ϕ_i themselves to be smooth, as Σ is just a topological space.

Example 14.1.22 (S^2 with Stereographic Projection)

The atlas of 2 charts with stereographic projection gives S^2 the structure of an abstract smooth surface.

Remark (Philosophical). Being a topological surface is *structure*, one can ask if a topological space X is a topological surface or not. But being an abstract smooth surface is *data*, in that one has to be given an atlas of charts with smooth transition maps with smooth inverses, and there could be many.

Definition 14.1.23 (Smooth at a Point)

Let Σ be an abstract smooth surface, and if $f : \Sigma \rightarrow \mathbb{R}^n$ is a continuous map then we say that f is **smooth** at $p \in \Sigma$ if whenever (U, ϕ) is a chart at p belonging to the smooth atlas for Σ , the map $f \circ \phi^{-1} : \phi(U) \rightarrow \mathbb{R}^n$ is smooth.

Note that smoothness of f at p is *independent* of the choice of chart since the transition maps between two such are diffeomorphisms.

Definition 14.1.24 (Smoothness of Maps Between Surfaces)

If Σ_1 and Σ_2 are abstract smooth surfaces, a map $f : \Sigma_1 \rightarrow \Sigma_2$ is smooth if “it is smooth in the local charts”. That is, given charts (U, ϕ) at p and (U', ϕ') at $f(p)$ in our chosen smooth atlases, we want $\phi' \circ f \circ \phi^{-1}$ to be smooth at $\phi(p)$.

Again, smoothness of f does not depend on our choice of charts at p and $f(p)$ provided we take charts from our smooth atlas.

We can now say what it means for abstract smooth surfaces to be diffeomorphic.

Definition 14.1.25 (Diffeomorphic)

Two abstract smooth surfaces Σ_1 and Σ_2 are **diffeomorphic** if there exists a homeomorphism $f : \Sigma_1 \rightarrow \Sigma_2$ which is smooth and has a smooth inverse.

Remark. We often pass from a given smooth atlas for an abstract smooth surfaces Σ to the maximal ‘compatible’ such atlas, that is, I add to the atlas $\{(U_i, \phi_i) \mid i \in I\}$ for Σ all charts (V, ψ) with the property that the transition maps are still all diffeomorphisms. Such a process technically involves Zorn’s lemma.

§14.2 Smooth Surfaces in $\mathbb{R}^3$

So far, this has all been rather abstract, but in this course what we really care about is smooth surfaces in $\mathbb{R}^3$, where we can do honest calculus. Recall if $V \subseteq \mathbb{R}^n$ and $V' \subseteq \mathbb{R}^m$ are open subsets then $f : V \rightarrow V'$ is smooth if it is infinitely differentiable.

Definition 14.2.1 (Smoothness of Maps on Subsets of $\mathbb{R}^n$)

If $Z \subseteq \mathbb{R}^n$ is an arbitrary subset, we say that a continuous map $f : Z \rightarrow \mathbb{R}^m$ is **smooth** at a point $p \in Z$ if there exists an open set $B \subseteq \mathbb{R}^n$ with $p \in B$ and a smooth map $F : B \rightarrow \mathbb{R}^m$ such that

$$F|_{B \cap Z} = f|_{B \cap Z}.$$

That is, f is *locally* the restriction of a smooth map defined on an open set.

With this notion in hand, it makes sense to talk about subsets of Euclidean spaces being diffeomorphic.

Definition 14.2.2 (Diffeomorphic Subsets)

If $X \subseteq \mathbb{R}^n$ and $Y \subseteq \mathbb{R}^m$ are arbitrary subsets, we say that X and Y are **diffeomorphic** if there is a homeomorphism $f : X \rightarrow Y$ such that both f and f^{-1} are smooth.

§14.2.1 Definitions and Equivalent Characterisations

We can now say what it means for a subset of $\mathbb{R}^3$ to be a smooth surface.

Definition 14.2.3 (Smooth Surface in $\mathbb{R}^3$)

A **smooth surface in $\mathbb{R}^3$** is a subset $\Sigma \subseteq \mathbb{R}^3$ such that each point $p \in \Sigma$ has an open neighbourhood $U \subseteq \Sigma$ which is diffeomorphic to an open set in $\mathbb{R}^2$.

Unpacking the definitions, this says: for each $p \in \Sigma$ there is an open ball $p \in B \subseteq \mathbb{R}^3$ and an open set $V \subseteq \mathbb{R}^2$ such that, setting $U = B \cap \Sigma$, there is a homeomorphism $\phi : U \rightarrow V$ which is smooth (in the sense of the previous definition), and whose inverse $V \rightarrow U \subseteq \mathbb{R}^3$ is also smooth.

There are several other ways one might have tried to define a smooth surface in $\mathbb{R}^3$ – as a level set of a smooth function, as a graph, or via nice parametrisations – and thankfully they all agree. Before stating this, we single out the parametrisations that will do most of the work in this course.

Definition 14.2.4 (Allowable Parametrisation)

Let $V \subseteq \mathbb{R}^2$ be open and let $U \subseteq \Sigma \subseteq \mathbb{R}^3$ be open in Σ . A map $\sigma : V \rightarrow U$ is an **allowable parametrisation** if σ is a homeomorphism, is smooth as a map $V \rightarrow \mathbb{R}^3$, and $D\sigma|_x$ has rank 2 for every $x \in V$. If moreover $\sigma(0) = p$, we say σ is an allowable parametrisation *near* p .

The rank condition is what stops the parametrisation from degenerating – it guarantees that the two partial derivatives σ_u and σ_v are linearly independent, so the image genuinely looks two-dimensional.

Theorem 14.2.5 (Characterisations of Smooth Surfaces)

For a subset $\Sigma \subseteq \mathbb{R}^3$, the following are equivalent.

- (i) Σ is a smooth surface in $\mathbb{R}^3$.
- (ii) Σ is *locally a graph* over one of the three coordinate planes: for each $p \in \Sigma$ there is an open ball $p \in B \subseteq \mathbb{R}^3$ and an open set $V \subseteq \mathbb{R}^2$ such that

$$\Sigma \cap B = \{(x, y, g(x, y)) \mid (x, y) \in V\}$$

for some smooth $g : V \rightarrow \mathbb{R}$, or the same with the roles of the coordinates permuted.

- (iii) Σ is *locally cut out* by a smooth function: for each $p \in \Sigma$ there is an open ball $p \in B \subseteq \mathbb{R}^3$ and a smooth $f : B \rightarrow \mathbb{R}$ such that

$$\Sigma \cap B = f^{-1}(0), \quad \text{with } Df|_x \neq 0 \text{ for all } x \in B.$$

- (iv) Σ is locally the image of an allowable parametrisation near each of its points.

Remark. Characterisation (ii) implies that every $p \in \Sigma$ lies in a chart (U, ϕ) where ϕ is the restriction of one of the coordinate projections $\pi_{xy}, \pi_{yz}, \pi_{xz} : \mathbb{R}^3 \rightarrow \mathbb{R}^2$. The transition map between two graphical charts over the *same* plane is the identity, and between charts over different planes it looks like

$$(x, y) \mapsto (x, y, g(x, y)) \mapsto (y, g(x, y)),$$

which is smooth with smooth inverse of the same shape. So a smooth surface in $\mathbb{R}^3$ carries a natural atlas whose transition maps are diffeomorphisms – that is, it is an abstract smooth surface, and the two uses of the word ‘smooth’ are consistent.

Some of the implications in this theorem are easy, but the substantial ones rest on the inverse function theorem, which we now recall (a proof is given in Analysis and Topology).

§14.2.2 The Inverse and Implicit Function Theorems

Theorem 14.2.6 (Inverse Function Theorem)

Let $U \subseteq \mathbb{R}^n$ be open and $f : U \rightarrow \mathbb{R}^n$ be continuously differentiable. Let $p \in U$, $q = f(p)$, and suppose the derivative $Df|_p$ is invertible. Then there exists an open neighbourhood V of q and a continuously differentiable map $g : V \rightarrow \mathbb{R}^n$ with $g(q) = p$, whose image is an open neighbourhood $U' \subseteq U$ of p , such that $f \circ g = \text{Id}_V$. Moreover if f is smooth then so is g .

By the chain rule, the inverse satisfies $Dg|_q = (Df|_p)^{-1}$. The inverse function theorem deals with maps $\mathbb{R}^n \rightarrow \mathbb{R}^n$ whose derivative is an isomorphism. If instead we have $f : \mathbb{R}^{k+\ell} \rightarrow \mathbb{R}^\ell$ whose derivative is *surjective*, we can say something about the level sets of f – this is the implicit function theorem.

Theorem 14.2.7 (Implicit Function Theorem)

Let $p = (x_0, y_0) \in U$ where $U \subseteq \mathbb{R}^k \times \mathbb{R}^\ell$ is open, and let $f : U \rightarrow \mathbb{R}^\ell$ be continuously differentiable with $f(p) = 0$, such that the $\ell \times \ell$ matrix of partial derivatives $(\partial f_i / \partial y_j)$ is invertible at p . Then there is an open neighbourhood V of x_0 in $\mathbb{R}^k$ and a continuously differentiable map $g : V \rightarrow \mathbb{R}^\ell$ with $g(x_0) = y_0$ such that, for $(x, y) \in U$ sufficiently close to p ,

$$f(x, y) = 0 \iff y = g(x).$$

Moreover if f is smooth then so is g .

Proof. Define $F : U \rightarrow \mathbb{R}^k \times \mathbb{R}^\ell$ by $F(x, y) = (x, f(x, y))$. Then in block form

$$DF = \begin{pmatrix} I & 0 \\ * & \partial f_i / \partial y_j \end{pmatrix},$$

which is invertible at (x_0, y_0) . So by the inverse function theorem, F is locally invertible near $F(x_0, y_0) = (x_0, 0)$; let $G : V \times V' \rightarrow U' \subseteq U$ be a continuously differentiable local inverse, defined on a product of open sets. Writing $G(x, y) = (\varphi(x, y), \psi(x, y))$, the relation $F \circ G = \text{Id}$ gives

$$(\varphi(x, y), f(\varphi(x, y), \psi(x, y))) = (x, y),$$

so $\varphi(x, y) = x$ and $f(x, \psi(x, y)) = y$ for $(x, y) \in V \times V'$. In particular $f(x, y) = 0$ exactly when $y = \psi(x, 0)$, so we may take $g(x) = \psi(x, 0)$. $\square$

Example 14.2.8 (Level Sets in $\mathbb{R}^3$)

Let $f : \mathbb{R}^3 \rightarrow \mathbb{R}$ be smooth with $f(x_0, y_0, z_0) = 0$, and consider the level set $\Sigma = f^{-1}(0)$. Suppose $Df \neq 0$ at (x_0, y_0, z_0) ; permuting coordinates, we may assume $\partial f / \partial z \neq 0$ there. The implicit function theorem (with $k = 2$, $\ell = 1$) then provides an open neighbourhood V of (x_0, y_0) and a smooth $g : V \rightarrow \mathbb{R}$ such that near (x_0, y_0, z_0) , the level set Σ is exactly the graph $\{(x, y, g(x, y)) \mid (x, y) \in V\}$. In other words – near a point where its defining function has non-vanishing derivative, a level set is locally a graph.

§14.2.3 Proof of the Characterisation Theorem

We can now assemble the proof of Theorem 14.2.5.

Proof of Theorem 14.2.5. We first show that (ii) implies all of the other conditions. Suppose Σ is locally the graph $\{(x, y, g(x, y))\}$ over (say) the xy -plane. Then the coordinate projection π_{xy} restricts to a homeomorphism from this graph to V , it is defined and smooth on an open neighbourhood in $\mathbb{R}^3$, and its inverse $\sigma(x, y) = (x, y, g(x, y))$ is smooth. So Σ is a smooth surface in $\mathbb{R}^3$, giving (i). Also, the graph is cut out by the function $f(x, y, z) = z - g(x, y)$, which has $\partial f / \partial z = 1 \neq 0$, giving (iii). Finally $\sigma(x, y) = (x, y, g(x, y))$ is an allowable parametrisation: it is a smooth homeomorphism, and its derivative contains the 2×2 identity block in the first two rows, so has rank 2. This gives (iv).

Next, (i) implies (iv): if $\phi : U \rightarrow V$ is a diffeomorphism as in the definition of a smooth surface, then near a given point, ϕ^{-1} extends implicitly to a smooth map on an open subset of $\mathbb{R}^2$, and (shrinking if necessary) $\sigma = \phi^{-1}$ is a smooth homeomorphism. Its derivative has rank 2: writing F for a local smooth extension of ϕ to an open set $B \subseteq \mathbb{R}^3$, we have $F \circ \sigma = \text{Id}$ near a point of V , so by the chain rule $DF|_p \circ D\sigma|_x = I_2$, which forces $D\sigma|_x$ to be injective, i.e. of rank 2. So σ is allowable.

That (iii) implies (ii) is exactly the level set example of the implicit function theorem above.

Finally we show (iv) implies (ii) and (i), which completes the cycle. Let $\sigma : V \rightarrow U$ be an allowable parametrisation with $\sigma(0) = p$, and write $\sigma = (\sigma_1, \sigma_2, \sigma_3)$, so

$$D\sigma = \begin{pmatrix} \partial\sigma_1/\partial u & \partial\sigma_1/\partial v \\ \partial\sigma_2/\partial u & \partial\sigma_2/\partial v \\ \partial\sigma_3/\partial u & \partial\sigma_3/\partial v \end{pmatrix}.$$

This matrix has rank 2, so some two rows form an invertible 2×2 matrix – without loss of generality the first two rows. Let $\text{pr} = \pi_{xy}$, and consider $\text{pr} \circ \sigma : V \rightarrow \mathbb{R}^2$. Its derivative at 0 is an isomorphism, so by the inverse function theorem it has a smooth local inverse, and hence Σ is locally the graph of the smooth function $\sigma_3 \circ (\text{pr} \circ \sigma)^{-1}$ over the xy -plane. This gives (ii). For (i), the map $(x, y, z) \mapsto (\text{pr} \circ \sigma)^{-1}(x, y)$ is defined and smooth on an open ball about p in $\mathbb{R}^3$, and restricts on Σ to a local inverse of σ . So σ^{-1} is smooth, and Σ is a smooth surface in $\mathbb{R}^3$. $\square$

Let's see some examples.

Example 14.2.9 (The Sphere)

The unit sphere $S^2 \subseteq \mathbb{R}^3$ is $f^{-1}(0)$ for $f(x, y, z) = x^2 + y^2 + z^2 - 1$. At any point of S^2 we have $Df = (2x, 2y, 2z) \neq 0$, so S^2 is a smooth surface in $\mathbb{R}^3$ by criterion (iii).

Example 14.2.10 (Surfaces of Revolution)

Let $\gamma : (a, b) \rightarrow \mathbb{R}^3$ be a smooth injective curve in the xz -plane, say

$$\gamma(t) = (f(t), 0, g(t)), \quad \text{with } f > 0 \text{ and } \gamma' \neq 0 \text{ everywhere.}$$

The **surface of revolution** obtained by rotating γ about the z -axis is covered by parametrisations

$$\sigma(u, v) = (f(u) \cos v, f(u) \sin v, g(u)),$$

with $(u, v) \in (a, b) \times (\theta, \theta + 2\pi)$ for fixed θ . Here

$$\sigma_u = (f' \cos v, f' \sin v, g'), \quad \sigma_v = (-f \sin v, f \cos v, 0),$$

and one computes $\|\sigma_u \times \sigma_v\|^2 = f^2((f')^2 + (g')^2) \neq 0$, so these are allowable parametrisations and the surface of revolution is a smooth surface in $\mathbb{R}^3$.

Example 14.2.11 ($O(3)$ Acting on S^2)

The orthogonal group $O(3)$ acts on S^2 by diffeomorphisms: any $A \in O(3)$ defines a linear (hence smooth) map $\mathbb{R}^3 \rightarrow \mathbb{R}^3$ preserving S^2 , whose restriction to S^2 is a homeomorphism that is smooth with smooth inverse in the sense above. This is analogous to the action of the Möbius group on $\mathbb{C} \cup \{\infty\} \cong S^2$, which we shall meet again when we study hyperbolic geometry.

§14.2.4 Orientability

There is one more piece of global structure we should discuss before we start measuring things: *orientation*. Intuitively, an orientation of a surface is a consistent choice of what ‘anticlockwise’ means at each point, and the Möbius band shows this is not always possible.

Definition 14.2.12 (Orientation-Preserving)

Let V, V' be open sets in $\mathbb{R}^2$ and $f : V \rightarrow V'$ a diffeomorphism, so $Df|_x \in \text{GL}(2, \mathbb{R})$ for every $x \in V$. We say f is **orientation-preserving** if $\det Df|_x > 0$ for all $x \in V$.

Definition 14.2.13 (Orientable)

An abstract smooth surface Σ is **orientable** if it admits an atlas in which all transition maps are orientation-preserving. A choice of such an atlas is an **orientation** of Σ , and Σ equipped with an orientation is **oriented**.

Orientability behaves well under diffeomorphism, as one would hope.

Lemma 14.2.14

If Σ_1 and Σ_2 are diffeomorphic abstract smooth surfaces, then Σ_1 is orientable if and only if Σ_2 is orientable.

Proof. Let $f : \Sigma_1 \rightarrow \Sigma_2$ be a diffeomorphism and suppose Σ_2 is equipped with an oriented atlas. Consider the atlas on Σ_1 whose charts are $(f^{-1}(U), \psi \circ f)$ for charts (U, ψ) in the oriented atlas of Σ_2 . The transition map between two such charts,

$$(\psi_1 \circ f) \circ (\psi_2 \circ f)^{-1} = \psi_1 \circ \psi_2^{-1},$$

is exactly a transition map of the oriented atlas on Σ_2 , so is orientation-preserving. Hence Σ_1 is orientable, and the claim follows by symmetry. $\square$

Example 14.2.15 (The Möbius Band)

The **Möbius band** is the surface obtained from the square by gluing a pair of opposite open edges with a flip:

where the dashed edges are omitted (so this is a surface without boundary). One can check that the Möbius band is *not* orientable, and in fact a surface is orientable if and only if it contains no open subsurface homeomorphic to the Möbius band. This gives a way of extending the notion of orientability to topological surfaces, where the definition through determinants of derivatives makes no sense.

Example 14.2.16 (S^2 and T^2 are Orientable)

For S^2 with the atlas of two stereographic projections, the transition map works out to be

$$(u, v) \mapsto \left(\frac{u}{u^2 + v^2}, \frac{v}{u^2 + v^2} \right)$$

on $\mathbb{R}^2 \setminus \{0\}$, which does not have positive determinant everywhere (it is a reflection composed with an inversion). But replacing π_- by its composite with the reflection $(u, v) \mapsto (u, -v)$ fixes this, and the resulting atlas is oriented. So S^2 is orientable. For the torus $T^2 = \mathbb{R}^2 / \mathbb{Z}^2$, we found an atlas whose transition maps are restrictions of translations of $\mathbb{R}^2$, and translations certainly have positive determinant. So T^2 is orientable.

Remark. One can define other classes of surfaces by restricting which subgroup of $\text{GL}(2, \mathbb{R})$ the derivatives of transition maps may lie in. Asking for derivatives in $\text{GL}^+(2, \mathbb{R})$ gives oriented surfaces; asking for transition maps that are restrictions of translations gives *Euclidean* surfaces (like the torus above); asking for derivatives in $\text{GL}(1, \mathbb{C}) \subseteq \text{GL}(2, \mathbb{R})$ gives *Riemann surfaces*.

§14.2.5 Tangent Planes

If a smooth surface is the collection of points that locally looks like a plane, its tangent plane at p is the best flat approximation at p .

Definition 14.2.17 (Tangent Plane)

Let Σ be a smooth surface in $\mathbb{R}^3$, $p \in \Sigma$, and let $\sigma : V \rightarrow U$ be an allowable parametrisation near p (so $\sigma(0) = p$). The **tangent plane** is

$$T_p\Sigma = \text{Image}(D\sigma|_0) = \langle \sigma_u, \sigma_v \rangle \subseteq \mathbb{R}^3,$$

a two-dimensional vector subspace of $\mathbb{R}^3$. The **affine tangent plane** at p is the translate $p + T_p\Sigma$.

Of course, we should check that this does not depend on which allowable parametrisation we picked.

Lemma 14.2.18

$T_p\Sigma$ is independent of the choice of allowable parametrisation.

Proof. Suppose $\sigma : V \rightarrow U$ and $\tilde{\sigma} : \tilde{V} \rightarrow \tilde{U}$ are allowable parametrisations with $\sigma(0) = \tilde{\sigma}(0) = p$. The transition map $\sigma^{-1} \circ \tilde{\sigma}$ is a diffeomorphism of open sets of $\mathbb{R}^2$ (shrinking domains so both parametrise the same neighbourhood), and

$$\tilde{\sigma} = \sigma \circ (\sigma^{-1} \circ \tilde{\sigma}).$$

Applying the chain rule at 0, $D\tilde{\sigma}|_0 = D\sigma|_0 \circ D(\sigma^{-1} \circ \tilde{\sigma})|_0$, and the second factor is an isomorphism of $\mathbb{R}^2$. So the images of $D\tilde{\sigma}|_0$ and $D\sigma|_0$ agree. $\square$

There is a more geometric way to think about the tangent plane. If $\gamma : (-\epsilon, \epsilon) \rightarrow \mathbb{R}^3$ is any smooth curve with image in Σ and $\gamma(0) = p$, then writing $\gamma(t) = \sigma(u(t), v(t))$ for smooth u, v we get

$$\gamma'(0) = \sigma_u u'(0) + \sigma_v v'(0) \in T_p\Sigma,$$

and conversely every vector of $T_p\Sigma$ arises this way. So $T_p\Sigma$ is precisely the set of velocity vectors at p of smooth curves on Σ through p – which makes it visibly independent of any parametrisation.

Definition 14.2.19 (Normal Direction)

If Σ is a smooth surface in $\mathbb{R}^3$ and $p \in \Sigma$, the **normal direction** at p is $(T_p\Sigma)^\perp$, the Euclidean orthogonal complement of the tangent plane. There are exactly two

unit vectors in the normal direction.

Definition 14.2.20 (Two-Sided)

A smooth surface in $\mathbb{R}^3$ is **two-sided** if it admits a continuous global choice of unit normal vector $p \mapsto n(p)$.

Two-sidedness is how orientability manifests itself for surfaces sitting in $\mathbb{R}^3$.

Lemma 14.2.21

A smooth surface Σ in $\mathbb{R}^3$ is orientable if and only if it is two-sided.

Proof. Given an allowable parametrisation $\sigma : V \rightarrow U$ near p , define the *positive unit normal with respect to σ*

$$n_\sigma(p) = \frac{\sigma_u \times \sigma_v}{\|\sigma_u \times \sigma_v\|},$$

which is the unit normal making $\{\sigma_u, \sigma_v, n_\sigma\}$ a positively oriented basis of $\mathbb{R}^3$. Now suppose $\tilde{\sigma}$ is another allowable parametrisation near p and $\sigma = \tilde{\sigma} \circ \varphi$ for the transition map φ . Writing $D\varphi|_0 = \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}$, the chain rule gives $\sigma_u = \alpha\tilde{\sigma}_u + \gamma\tilde{\sigma}_v$ and $\sigma_v = \beta\tilde{\sigma}_u + \delta\tilde{\sigma}_v$, and hence

$$\sigma_u \times \sigma_v = \det(D\varphi|_0) \tilde{\sigma}_u \times \tilde{\sigma}_v. \quad (\dagger)$$

So if Σ is oriented and we only use parametrisations compatible with the orientation, the determinant above is positive and the positive unit normal is independent of the parametrisation. Since n_σ is manifestly continuous on each U , these local normals patch to a global continuous unit normal, and Σ is two-sided.

Conversely, suppose Σ has a global continuous unit normal n . Consider the collection of all allowable parametrisations σ such that $\{\sigma_u, \sigma_v, n\}$ is a positively oriented basis of $\mathbb{R}^3$ at every point (any allowable parametrisation can be corrected to have this property by precomposing with $(u, v) \mapsto (v, u)$ if needed, so these charts cover Σ). By $(\dagger)$, the transition map φ between two such parametrisations satisfies $\det D\varphi > 0$. So this atlas is oriented and Σ is orientable. $\square$

The following little lemma gets used constantly: symmetries of a surface act on its tangent planes.

Lemma 14.2.22

Let Σ be a smooth surface in $\mathbb{R}^3$, and let $A : \mathbb{R}^3 \rightarrow \mathbb{R}^3$ be a smooth map with $A(\Sigma) \subseteq \Sigma$. Then for $p \in \Sigma$, the derivative $DA|_p$ maps $T_p\Sigma$ into $T_{A(p)}\Sigma$.

Proof. Recall $T_p\Sigma$ is spanned by vectors $\gamma'(0)$ for smooth curves $\gamma : (-\epsilon, \epsilon) \rightarrow \Sigma$ with $\gamma(0) = p$. For such a curve, $A \circ \gamma$ is a smooth curve on Σ through $A(p)$, and by the chain rule

$$DA|_p(\gamma'(0)) = (A \circ \gamma)'(0) \in T_{A(p)}\Sigma. \quad \square$$

Example 14.2.23 (The Sphere is Two-Sided)

For the unit sphere S^2 , the normal direction at p is spanned by p itself: the rotation group $\text{SO}(3)$ acts transitively on S^2 and preserves tangent planes by Lemma 14.2.22, so it suffices to check this at the north pole, where it is clear. So $n(p) = p$ (the outward normal) is a global continuous choice of unit normal, and S^2 is two-sided, hence orientable – in agreement with our computation with stereographic charts.

Example 14.2.24 (The Möbius Band is Not Two-Sided)

An explicit embedding of the Möbius band in $\mathbb{R}^3$ is

$$\sigma(t, \theta) = \left((1 - t \sin \frac{\theta}{2}) \cos \theta, (1 - t \sin \frac{\theta}{2}) \sin \theta, t \cos \frac{\theta}{2} \right),$$

where $t \in (-1/2, 1/2)$ and θ ranges over $(0, 2\pi)$ or $(-\pi, \pi)$ for the two charts. Geometrically we take a unit interval centred on each point of the unit circle, and let it rotate by half a turn as θ goes around the circle once. A direct computation along the central circle $t = 0$ gives

$$\sigma_t \times \sigma_\theta = \left(-\cos \theta \cos \frac{\theta}{2}, -\sin \theta \cos \frac{\theta}{2}, -\sin \frac{\theta}{2} \right),$$

which is already a unit vector. As $\theta \rightarrow 0^+$ this tends to $(-1, 0, 0)$, while as $\theta \rightarrow 2\pi^-$ it tends to $(1, 0, 0)$ – the normal comes back *flipped* after a loop around the band. So there is no continuous global choice of unit normal, and the Möbius band is not two-sided (hence not orientable).

Remark. There is no sensible classification of all smooth surfaces – already the surfaces $\mathbb{R}^2 \setminus Z$ for closed sets Z form an uncountable zoo. But for *compact* smooth surfaces the situation is remarkably clean: a compact smooth surface is determined up to diffeomorphism by its orientability and its Euler characteristic. This classification is stated here for culture; it will be proved in the Part II course *Algebraic Topology*.

§14.3 The First Fundamental Form

Up until now everything has been topology in disguise – we have said when surfaces are the same as topological or smooth objects, but we have not *measured* anything. In this section we start doing geometry properly: we will measure lengths of curves on a surface, angles between curves, and areas of regions. All of this information is captured by a single gadget called the first fundamental form.

§14.3.1 Isometries of Euclidean Space

It is worth first pausing to understand distance-preserving maps of flat space itself, since these are the ‘symmetries’ against which all our later notions are calibrated.

Definition 14.3.1 (Isometry)

A map $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$ is an **isometry** if it preserves distances, that is

$$\|f(x) - f(y)\| = \|x - y\| \quad \text{for all } x, y \in \mathbb{R}^n.$$

The isometries of $\mathbb{R}^n$ form a group $\text{Isom}(\mathbb{R}^n)$ under composition.

Obvious examples are translations $x \mapsto x + b$, and the linear maps preserving the inner product – the **orthogonal group**

$$\text{O}(n) = \{A \in \text{GL}(n, \mathbb{R}) \mid A^T A = I\}.$$

It turns out these examples generate everything.

Theorem 14.3.2

Every isometry of $\mathbb{R}^n$ has the form $f(x) = Ax + b$ for some $A \in \text{O}(n)$ and $b \in \mathbb{R}^n$.

Proof. Let $b = f(0)$, and set $g(x) = f(x) - b$, an isometry fixing the origin. Since g fixes 0 and preserves distances, it preserves norms, and then by the polarisation identity

$$\langle x, y \rangle = \frac{1}{2} (\|x\|^2 + \|y\|^2 - \|x - y\|^2)$$

it preserves inner products: $\langle g(x), g(y) \rangle = \langle x, y \rangle$ for all x, y . In particular, if $e_1, \dots, e_n$ is the standard orthonormal basis then $g(e_1), \dots, g(e_n)$ is again orthonormal, and for any x ,

$$\left\langle g(x) - \sum_i \langle x, e_i \rangle g(e_i), g(e_j) \right\rangle = \langle x, e_j \rangle - \langle x, e_j \rangle = 0$$

for each j . As the $g(e_i)$ form a basis, the vector on the left is orthogonal to everything, so is zero, i.e.

$$g(x) = \sum_i \langle x, e_i \rangle g(e_i).$$

So g is linear, and being a linear map preserving the inner product, its matrix A satisfies $A^T A = I$, that is $A \in \text{O}(n)$. $\square$

Recall that $\det A = \pm 1$ for $A \in \text{O}(n)$. Isometries with $\det A = 1$ are **orientation-preserving** (or *rigid motions*); those with $\det A = -1$ are orientation-reversing. The simplest orientation-reversing isometries are **reflections**: given an affine hyperplane $H = \{x \mid \langle x, u \rangle = c\}$ with $\|u\| = 1$, the reflection in H is

$$R_H(x) = x - 2(\langle x, u \rangle - c)u,$$

which fixes H pointwise and swaps the two sides. Remarkably, these building blocks suffice.

Theorem 14.3.3 (Reflections Generate)

Every isometry of $\mathbb{R}^n$ is a composite of at most $n+1$ reflections in affine hyperplanes.

Proof. First observe that if an isometry f fixes points $p_0, \dots, p_k$, then it fixes every point of their affine span: indeed a point x is determined by its distances to $p_0, \dots, p_k$ together with the affine subspace it lies in, and one can check directly that f fixes the affine span setwise and preserves those distances. In particular an isometry fixing $n+1$ affinely independent points (whose span is all of $\mathbb{R}^n$) is the identity.

Now take any isometry f , and choose affinely independent points $p_0, \dots, p_n$. We correct f one point at a time. If $f(p_0) \neq p_0$, let R_1 be the reflection in the perpendicular bisector hyperplane of p_0 and $f(p_0)$, so $R_1 f$ fixes p_0 . Inductively, suppose $g = R_k \cdots R_1 f$ fixes $p_0, \dots, p_{k-1}$. If $g(p_k) \neq p_k$, let R_{k+1} be the reflection in the perpendicular bisector of p_k and $g(p_k)$; since

$$\|p_i - p_k\| = \|g(p_i) - g(p_k)\| = \|p_i - g(p_k)\| \quad \text{for } i < k,$$

the points $p_0, \dots, p_{k-1}$ lie on this bisector, so are still fixed by $R_{k+1}g$, which now also fixes p_k . After at most $n+1$ steps we obtain a composite of reflections and f which fixes all of $p_0, \dots, p_n$, hence equals the identity. Rearranging, f is a composite of at most $n+1$ reflections. $\square$

In low dimensions we can be completely explicit. In $\mathbb{R}^2$, an isometry is a composite of at most 3 reflections, and working through the cases gives the classical classification: every isometry of the plane is one of

- (i) the identity;
- (ii) a *translation* $x \mapsto x + b$;
- (iii) a *rotation* about some point c ;
- (iv) a *reflection* in a line ℓ ;
- (v) a *glide reflection* – a reflection in a line ℓ followed by a translation along ℓ .

The first three are orientation-preserving (composites of two reflections), the last two orientation-reversing (one or three reflections).

The moral for the rest of the course is this: the plane $\mathbb{R}^2$ has a very large group of isometries – enough to take any point to any other point, and any direction at a point to any other direction at any other point. We will meet exactly two other surfaces with this much symmetry: the round sphere, and the hyperbolic plane.

§14.3.2 Lengths of Curves

Let $\gamma : (a, b) \rightarrow \mathbb{R}^3$ be a smooth curve. We define its **length** to be

$$L(\gamma) = \int_a^b \|\gamma'(t)\| \, dt,$$

whenever this integral is finite. The length does not depend on the parametrisation of the curve: if $s : (A, B) \rightarrow (a, b)$ is monotonic increasing and smooth, and $\tau = \gamma \circ s$, then by the chain rule and the substitution rule

$$L(\tau) = \int_A^B \|\gamma'(s(t))\| |s'(t)| \, dt = \int_a^b \|\gamma'(t')\| \, dt' = L(\gamma).$$

Lemma 14.3.4

If $\gamma : (a, b) \rightarrow \mathbb{R}^3$ is continuously differentiable with $\gamma'(t) \neq 0$ everywhere, then γ can be reparametrised by **arc length**, so that $\|\gamma'\| \equiv 1$.

Proof. Fix $t_0 \in (a, b)$ and let $s(t) = \int_{t_0}^t \|\gamma'(w)\| dw$. Then s is continuously differentiable with $s'(t) = \|\gamma'(t)\| > 0$, so s is a monotonic bijection onto its image with differentiable inverse. Setting $\tau = \gamma \circ s^{-1}$, the chain rule gives $\|\tau'\| = \|\gamma'\|/s' = 1$. $\square$

§14.3.3 The First Fundamental Form

Now let Σ be a smooth surface in $\mathbb{R}^3$, and $\sigma : V \rightarrow U \subseteq \Sigma$ an allowable parametrisation. If γ is a smooth curve with image in U , we can write $\gamma(t) = \sigma(u(t), v(t))$ for smooth functions $(u, v) : (a, b) \rightarrow V$, and then

$$\gamma'(t) = \sigma_u u'(t) + \sigma_v v'(t).$$

Taking the squared norm,

$$\|\gamma'(t)\|^2 = E u'(t)^2 + 2F u'(t)v'(t) + G v'(t)^2,$$

where

$$E = \langle \sigma_u, \sigma_u \rangle, \quad F = \langle \sigma_u, \sigma_v \rangle, \quad G = \langle \sigma_v, \sigma_v \rangle$$

are smooth functions on V depending only on σ , not on the curve.

Definition 14.3.5 (First Fundamental Form)

The **first fundamental form** of Σ in the allowable parametrisation σ is the expression

$$E du^2 + 2F du dv + G dv^2,$$

with E, F, G as above. The notation records the fact that if $\gamma(t) = \sigma(u(t), v(t))$ then

$$L(\gamma) = \int_a^b \sqrt{E(u')^2 + 2F u' v' + G(v')^2} dt.$$

Remark. There is a cleaner way to think about this. The Euclidean inner product of $\mathbb{R}^3$ restricts to an inner product on the subspace $T_p \Sigma$, and *that* restriction is the real object of study: a symmetric positive definite bilinear form on tangent planes, varying smoothly with p . The functions E, F, G are just its matrix

$$\begin{pmatrix} E & F \\ F & G \end{pmatrix}$$

in the basis $\{\sigma_u, \sigma_v\}$ of $T_p \Sigma$ supplied by a parametrisation. Indeed, since the columns of $D\sigma$ are σ_u and σ_v , we can write the matrix of the first fundamental form compactly as $(D\sigma)^T(D\sigma)$.

Let's compute some examples.

Example 14.3.6 (The Plane)

The plane $\mathbb{R}_{xy}^2 \subseteq \mathbb{R}^3$ has parametrisation $\sigma(u, v) = (u, v, 0)$, giving $\sigma_u = e_1$, $\sigma_v = e_2$ and first fundamental form

$$du^2 + dv^2.$$

We could instead use polar coordinates $\sigma(r, \theta) = (r \cos \theta, r \sin \theta, 0)$ on the plane minus a half-line, giving $\sigma_r = (\cos \theta, \sin \theta, 0)$ and $\sigma_\theta = (-r \sin \theta, r \cos \theta, 0)$, so the first fundamental form is

$$dr^2 + r^2 d\theta^2.$$

Note the same surface can have quite different-looking fundamental forms in different parametrisations.

Example 14.3.7 (The Sphere)

The sphere of radius a has an allowable parametrisation

$$\sigma(u, v) = (a \cos u \cos v, a \cos u \sin v, a \sin u), \quad u \in \left(-\frac{\pi}{2}, \frac{\pi}{2}\right), \quad v \in (0, 2\pi),$$

covering the complement of a half great circle (u is latitude and v longitude). Here

$$\sigma_u = (-a \sin u \cos v, -a \sin u \sin v, a \cos u), \quad \sigma_v = (-a \cos u \sin v, a \cos u \cos v, 0),$$

so $E = a^2$, $F = 0$, $G = a^2 \cos^2 u$, and the first fundamental form is

$$a^2 du^2 + a^2 \cos^2 u dv^2.$$

Example 14.3.8 (Surfaces of Revolution)

For the surface of revolution of $\eta(t) = (f(t), 0, g(t))$ about the z -axis, with parametrisation $\sigma(u, v) = (f(u) \cos v, f(u) \sin v, g(u))$, we compute

$$\sigma_u = (f' \cos v, f' \sin v, g'), \quad \sigma_v = (-f \sin v, f \cos v, 0),$$

giving first fundamental form

$$((f')^2 + (g')^2) du^2 + f^2 dv^2.$$

If the profile curve η is parametrised by arc length, this simplifies to $du^2 + f^2 dv^2$.

§14.3.4 Isometric Surfaces

The first fundamental form is exactly the data needed to measure lengths, so it is the right thing to preserve if we want maps of surfaces that preserve geometry.

Definition 14.3.9 (Isometric Surfaces)

Smooth surfaces Σ, Σ' in $\mathbb{R}^3$ are **isometric** if there is a diffeomorphism $f : \Sigma \rightarrow \Sigma'$ which preserves lengths of curves: for every smooth curve γ on Σ , $L(f \circ \gamma) = L(\gamma)$. Such an f is an **isometry**.

Example 14.3.10

If $f(x) = Ax + b$ is a global isometry of $\mathbb{R}^3$ (with $A \in O(3)$), then for any smooth surface Σ , the surfaces Σ and $f(\Sigma)$ are isometric – rigid motions preserve the lengths of all curves in $\mathbb{R}^3$. But note the definition asks for much less: f need only be defined on Σ , and isometric surfaces certainly need not be related by a rigid motion of the ambient space, as we will see with the cone below.

Definition 14.3.11 (Locally Isometric)

Σ and Σ' are **locally isometric near $p \in \Sigma$ and $q \in \Sigma'$** if there are open neighbourhoods $U \ni p$, $U' \ni q$ which are isometric. We say Σ and Σ' are locally isometric if each point of either surface has a neighbourhood isometric to an open set of the other.

The first fundamental form detects local isometry completely.

Lemma 14.3.12

Smooth surfaces $\Sigma, \Sigma' \subseteq \mathbb{R}^3$ are locally isometric near $p \in \Sigma$ and $q \in \Sigma'$ if and only if there are allowable parametrisations $\sigma : V \rightarrow U \subseteq \Sigma$ and $\sigma' : V \rightarrow U' \subseteq \Sigma'$, with the *same* domain V , near p and q respectively, whose first fundamental forms are equal as functions on V .

Proof. ($\Leftarrow$) If such parametrisations exist, then $f = \sigma' \circ \sigma^{-1} : U \rightarrow U'$ is a diffeomorphism, and given a curve $\gamma = \sigma(u(t), v(t))$ in U , the image curve is $f \circ \gamma = \sigma'(u(t), v(t))$. The two length integrals are computed from the respective first fundamental forms with the identical functions $(u(t), v(t))$, so they agree. Hence f is an isometry.

($\Rightarrow$) Suppose $f : U \rightarrow U'$ is an isometry with $f(p) = q$, and let $\sigma : V \rightarrow U$ be an allowable parametrisation near p ; then $\sigma' = f \circ \sigma$ is an allowable parametrisation of U' near q with the same domain. We must show lengths of curves determine the first fundamental form – then, since σ and σ' assign equal lengths to corresponding curves, their fundamental forms must agree. Without loss of generality let $V = B(0, \delta)$ and $\sigma(0) = p$. For $\epsilon < \delta$, consider the curves

$$\gamma_\epsilon(t) = \sigma(t, 0), \quad t \in [0, \epsilon].$$

Then

$$L(\gamma_\epsilon) = \int_0^\epsilon \sqrt{E(t, 0)} \, dt \implies \left. \frac{d}{d\epsilon} \right|_{\epsilon=0} L(\gamma_\epsilon) = \sqrt{E(0, 0)},$$

so lengths of curves near p determine E at p (and similarly at every point of V). Using instead $t \mapsto \sigma(0, t)$ determines G , and $t \mapsto \sigma(t, t)$ determines $E + 2F + G$, hence F . So the first fundamental form is determined by lengths, as required. $\square$

Example 14.3.13 (The Cone)

Consider the cone with angle $\arctan(a)$ to the vertical (minus its apex and a ruling

line), parametrised for $u > 0, v \in (0, 2\pi)$ by

$$\sigma(u, v) = (au \cos v, au \sin v, u),$$

with first fundamental form

$$(1 + a^2) du^2 + a^2 u^2 dv^2.$$

Intuitively, we can cut the cone along a ruling and flatten it onto the plane – rolling a paper cone flat – to obtain a plane sector of radius $\sqrt{1 + a^2} u$ and total angle $2\pi a/\sqrt{1 + a^2}$. Concretely, the map into the plane

$$\sigma'(u, v) = \left(\sqrt{1 + a^2} u \cos \left(\frac{av}{\sqrt{1 + a^2}} \right), \sqrt{1 + a^2} u \sin \left(\frac{av}{\sqrt{1 + a^2}} \right), 0 \right)$$

with the same domain has first fundamental form

$$(1 + a^2) du^2 + a^2 u^2 dv^2$$

as well. So by Lemma 14.3.12 the cone is *locally isometric to the plane* – despite looking curved, it is flat from the point of view of any measurements made along the surface. The cone and the plane are not *globally* isometric, since they are not even homeomorphic.

Finally, let's record how the first fundamental form transforms when we change parametrisation.

Lemma 14.3.14

Suppose $\sigma : V \rightarrow U$ and $\sigma' : V' \rightarrow U$ are allowable parametrisations of the same open set $U \subseteq \Sigma$, related by the transition map $\varphi = (\sigma')^{-1} \circ \sigma : V \rightarrow V'$. Then their first fundamental forms are related by

$$\begin{pmatrix} E & F \\ F & G \end{pmatrix} = (D\varphi)^T \begin{pmatrix} E' & F' \\ F' & G' \end{pmatrix} (D\varphi).$$

Proof. Since the matrix of the first fundamental form is $(D\sigma)^T(D\sigma)$ and $\sigma = \sigma' \circ \varphi$, the chain rule $D\sigma = (D\sigma')(D\varphi)$ gives

$$(D\sigma)^T(D\sigma) = (D\varphi)^T(D\sigma')^T(D\sigma')(D\varphi),$$

which is the claim. □

§14.3.5 Angles and Conformality

For vectors $v, w \in \mathbb{R}^3$ we have $\langle v, w \rangle = \|v\| \|w\| \cos \theta$, so the angle between them is determined by inner products. If $v, w \in T_p \Sigma$ are tangent vectors, say $v = D\sigma|_0(\hat{v})$ and $w = D\sigma|_0(\hat{w})$, then writing $I(\cdot, \cdot)$ for the first fundamental form as a bilinear form,

$$\cos \theta = \frac{I(\hat{v}, \hat{w})}{\sqrt{I(\hat{v}, \hat{v})} \sqrt{I(\hat{w}, \hat{w})}}.$$

So the first fundamental form measures angles as well as lengths. In particular, if two curves $\gamma(t) = \sigma(u(t), v(t))$ and $\tilde{\gamma}(t) = \sigma(\tilde{u}(t), \tilde{v}(t))$ meet at p , the angle θ at which they

meet satisfies

$$\cos \theta = \frac{E\dot{u}\dot{u} + F(\dot{u}\dot{v} + \dot{v}\dot{u}) + G\dot{v}\dot{v}}{\sqrt{E\dot{u}^2 + 2F\dot{u}\dot{v} + G\dot{v}^2}\sqrt{E\dot{u}^2 + 2F\dot{u}\dot{v} + G\dot{v}^2}}.$$

Definition 14.3.15 (Conformal)

An allowable parametrisation $\sigma : V \rightarrow U$ is **conformal** if it preserves angles: whenever two curves in V meet at some angle, their images under σ meet at the same angle.

Lemma 14.3.16

σ is conformal if and only if $E = G$ and $F = 0$.

Proof. Suppose σ is conformal. The curves $t \mapsto (t, 0)$ and $t \mapsto (0, t)$ meet at angle $\pi/2$ in V , so their images meet at angle $\pi/2$; by the angle formula this gives $F = 0$. Likewise the curves $t \mapsto (t, t)$ and $t \mapsto (t, -t)$ meet at right angles, and the angle formula (using $F = 0$) gives $E - G = 0$.

Conversely if $E = G$ and $F = 0$, then the first fundamental form is $\rho(du^2 + dv^2)$ where $\rho = E > 0$. So at each point it is a pointwise rescaling of the Euclidean inner product, and rescaling an inner product does not change the angles it defines. Hence σ preserves angles. $\square$

Remark. Conformal parametrisations are historically important in cartography – a conformal map of the Earth renders compass bearings faithfully, even though (as we will see) no map can render distances faithfully. The existence of conformal charts on any surface is a hard theorem, closely tied to the theory of *Riemann surfaces*, where surfaces are modelled on $\mathbb{C}$ rather than $\mathbb{R}^2$.

§14.3.6 Area

Recall that the parallelogram spanned by $v, w \in \mathbb{R}^3$ has area

$$\|v \times w\| = \sqrt{\|v\|^2\|w\|^2 - \langle v, w \rangle^2}.$$

Applying this to the ‘infinitesimal parallelogram’ spanned by σ_u and σ_v , whose sides span the image of a small coordinate square under σ , we find its area is

$$\|\sigma_u \times \sigma_v\| = \sqrt{EG - F^2}.$$

This motivates the following definition.

Definition 14.3.17 (Area)

Let $\sigma : V \rightarrow U \subseteq \Sigma$ be an allowable parametrisation. The **area** of U is

$$\text{area}(U) = \int_V \sqrt{EG - F^2} \, du \, dv.$$

Remark. This is independent of the parametrisation. If $\tilde{\sigma} : \tilde{V} \rightarrow U$ is another allowable parametrisation, with transition map $\varphi : \tilde{V} \rightarrow V$, then from the transformation law for the first fundamental form,

$$\sqrt{\tilde{E}\tilde{G} - \tilde{F}^2} = |\det D\varphi| \sqrt{EG - F^2},$$

and the change of variables formula for double integrals gives

$$\int_{\tilde{V}} \sqrt{\tilde{E}\tilde{G} - \tilde{F}^2} \, du \, dv = \int_V \sqrt{EG - F^2} \, du \, dv.$$

For an open set (or a compact surface) not contained in a single chart, we compute the area by breaking the set into finitely many pieces each lying in a chart, and adding up.

Example 14.3.18 (Graphs Stretch Area)

Let Σ be the graph of a smooth function $f : \mathbb{R}^2 \rightarrow \mathbb{R}$, with its global parametrisation $\sigma(u, v) = (u, v, f(u, v))$. Then $\sigma_u = (1, 0, f_u)$ and $\sigma_v = (0, 1, f_v)$, so

$$\sqrt{EG - F^2} = \sqrt{1 + f_u^2 + f_v^2}.$$

If U_R is the part of the graph over the disc $B(0, R)$, then

$$\text{area}(U_R) = \int_{B(0, R)} \sqrt{1 + f_u^2 + f_v^2} \, du \, dv \geq \pi R^2,$$

with equality if and only if $f_u \equiv f_v \equiv 0$ on the disc, i.e. the graph is horizontal. In other words – projecting a graph to the plane always shrinks area, unless the graph was flat to begin with.

Example 14.3.19 (Archimedes)

Let S^2 be the unit sphere, enclosed in the cylinder $\{x^2 + y^2 = 1\}$ of unit radius, and consider the radial projection taking a point of the sphere (other than the poles) horizontally outward to the cylinder. A pleasant computation (on the example sheets) shows this map is *area-preserving*: whatever area a region gains by being pushed outwards horizontally, it loses by being compressed vertically. This is Archimedes' theorem, and gives $\text{area}(S^2) = 4\pi$ immediately – the cylinder unrolls to a $2\pi \times 2$ rectangle. It also underlies the Lambert equal-area projection used in cartography.

§14.4 The Second Fundamental Form and Gaussian Curvature

The first fundamental form records the *intrinsic* geometry of a surface – everything a small ant living on the surface could measure. We now introduce a second quadratic form which records how the surface *bends* inside $\mathbb{R}^3$, and from it we will extract the single most important function in this course: the Gaussian curvature.

§14.4.1 The Second Fundamental Form

Let $\sigma : V \rightarrow U \subseteq \Sigma$ be an allowable parametrisation. By Taylor's theorem, for small (h, ℓ) ,

$$\sigma(u + h, v + \ell) = \sigma(u, v) + h \sigma_u + \ell \sigma_v$$

$$+ \frac{1}{2} (h^2 \sigma_{uu} + 2h\ell \sigma_{uv} + \ell^2 \sigma_{vv}) + O(h^3, \ell^3).$$

Write $p = \sigma(u, v)$ and let n be the unit normal at p . The first order terms lie in $T_p \Sigma$, so the perpendicular distance from $\sigma(u + h, v + \ell)$ to the affine tangent plane $p + T_p \Sigma$ is

$$\langle \sigma(u + h, v + \ell) - \sigma(u, v), n \rangle = \frac{1}{2} (Lh^2 + 2Mh\ell + N\ell^2) + O(h^3, \ell^3),$$

where we define

$$L = \langle n, \sigma_{uu} \rangle, \quad M = \langle n, \sigma_{uv} \rangle, \quad N = \langle n, \sigma_{vv} \rangle.$$

So the following quadratic form measures, to leading order, how the surface pulls away from its tangent plane.

Definition 14.4.1 (Second Fundamental Form)

The **second fundamental form** of Σ in the allowable parametrisation σ is the quadratic form

$$L du^2 + 2M du dv + N dv^2, \quad \text{where } n = \frac{\sigma_u \times \sigma_v}{\|\sigma_u \times \sigma_v\|},$$

with L, M, N as above, thought of as the matrix $\begin{pmatrix} L & M \\ M & N \end{pmatrix}$ with respect to the basis $\{\sigma_u, \sigma_v\}$ of $T_p \Sigma$.

Note that unlike the first fundamental form, which is always positive definite, the second fundamental form can be degenerate, indefinite, or zero. Indeed, vanishing identically means exactly what you would guess.

Lemma 14.4.2

Let V be connected and $\sigma : V \rightarrow U \subseteq \Sigma$ an allowable parametrisation whose second fundamental form vanishes identically. Then U is contained in an affine plane.

Proof. Differentiating the identities $\langle n, \sigma_u \rangle = 0 = \langle n, \sigma_v \rangle$ with respect to u and v gives

$$\begin{aligned} L &= \langle n, \sigma_{uu} \rangle = -\langle n_u, \sigma_u \rangle, & M &= \langle n, \sigma_{uv} \rangle = -\langle n_v, \sigma_u \rangle = -\langle n_u, \sigma_v \rangle, \\ N &= \langle n, \sigma_{vv} \rangle = -\langle n_v, \sigma_v \rangle. \end{aligned}$$

If $L = M = N \equiv 0$, then n_u is orthogonal to σ_u and σ_v ; but also $\langle n, n \rangle = 1$ gives $\langle n_u, n \rangle = 0$. Since $\{\sigma_u, \sigma_v, n\}$ is a basis of $\mathbb{R}^3$, we get $n_u \equiv 0$, and similarly $n_v \equiv 0$. As V is connected, n is a constant vector, and then

$$\frac{\partial}{\partial u} \langle \sigma, n \rangle = \langle \sigma_u, n \rangle = 0, \quad \frac{\partial}{\partial v} \langle \sigma, n \rangle = 0,$$

so $\langle \sigma, n \rangle$ is constant – which says exactly that $U = \sigma(V)$ lies in a plane normal to n . $\square$

The identities in the proof above deserve to be displayed on their own: the second fundamental form can be written as

$$\begin{pmatrix} L & M \\ M & N \end{pmatrix} = - \begin{pmatrix} \langle n_u, \sigma_u \rangle & \langle n_u, \sigma_v \rangle \\ \langle n_v, \sigma_u \rangle & \langle n_v, \sigma_v \rangle \end{pmatrix} = -(Dn)^T (D\sigma),$$

in perfect analogy with $(D\sigma)^T(D\sigma)$ for the first fundamental form. From this one can also derive the transformation rule under a transition map φ :

$$\begin{pmatrix} \tilde{L} & \tilde{M} \\ \tilde{M} & \tilde{N} \end{pmatrix} = \pm (D\varphi)^T \begin{pmatrix} L & M \\ M & N \end{pmatrix} (D\varphi),$$

where the sign is $+$ if φ is orientation-preserving (so the two parametrisations induce the same normal) and $-$ otherwise.

Example 14.4.3 (The Cylinder)

Consider the cylinder of radius a , parametrised by $\sigma(u, v) = (a \cos u, a \sin u, v)$. Then $\sigma_{uv} = \sigma_{vu} = 0$, so $M = N = 0$, while $\sigma_{uu} = (-a \cos u, -a \sin u, 0)$ and $n = (\cos u, \sin u, 0)$ (the outward normal), giving $L = -a$. So the second fundamental form is

$$-a \, du^2.$$

The cylinder bends in one direction and is straight in the other – exactly what the degenerate matrix $\begin{pmatrix} -a & 0 \\ 0 & 0 \end{pmatrix}$ records.

§14.4.2 The Gauss Map

The appearance of Dn above suggests that we study the normal vector as a map in its own right.

Definition 14.4.4 (Gauss Map)

Let Σ be a smooth oriented surface in $\mathbb{R}^3$. The **Gauss map** is

$$n : \Sigma \rightarrow S^2, \quad p \mapsto n(p),$$

sending each point to its (positively oriented) unit normal, viewed as a point of the unit sphere.

Lemma 14.4.5

The Gauss map is smooth.

Proof. Smoothness is a local property, so we can check it in an allowable parametrisation σ compatible with the orientation, where

$$n \circ \sigma = \frac{\sigma_u \times \sigma_v}{\|\sigma_u \times \sigma_v\|}.$$

The numerator is smooth and the denominator is smooth and non-vanishing (since

σ is allowable), so $n \circ \sigma$ is smooth, which is what smoothness of n means. $\square$

Remark. If $\Sigma = f^{-1}(0)$ is cut out by $f : \mathbb{R}^3 \rightarrow \mathbb{R}$ with non-vanishing derivative along Σ , the Gauss map is simply

$$n(p) = \frac{\nabla f}{\|\nabla f\|}.$$

The key observation about the Gauss map is that its derivative at p is an endomorphism of the tangent plane. Indeed, the tangent plane to S^2 at $n(p)$ is $(n(p))^\perp = T_p\Sigma$ – the two planes are orthogonal to the same vector! So the derivative of the Gauss map is a linear map

$$Dn|_p : T_p\Sigma \rightarrow T_{n(p)}S^2 = T_p\Sigma.$$

Concretely, if $v = \gamma'(0)$ for a curve γ on Σ through p , then $Dn|_p(v) = (n \circ \gamma)'(0)$.

We can now give the slick, parametrisation-free description of both fundamental forms. For an oriented smooth surface Σ in $\mathbb{R}^3$ and $p \in \Sigma$:

- (i) The *first* fundamental form is the symmetric bilinear form on $T_p\Sigma$ obtained by restricting the Euclidean inner product:

$$I_p(v, w) = \langle v, w \rangle.$$

- (ii) The *second* fundamental form is the symmetric bilinear form

$$II_p(v, w) = I_p(-Dn|_p(v), w).$$

In an allowable (correctly oriented) parametrisation these have matrices $\begin{pmatrix} E & F \\ F & G \end{pmatrix}$ and $\begin{pmatrix} L & M \\ M & N \end{pmatrix}$ in the basis $\{\sigma_u, \sigma_v\}$, recovering our earlier definitions – this is exactly the identity $-(Dn)^T(D\sigma) = \begin{pmatrix} L & M \\ M & N \end{pmatrix}$ from before. The forms themselves do not depend on σ .

Lemma 14.4.6

The derivative of the Gauss map is self-adjoint with respect to the first fundamental form:

$$I_p(Dn|_p(v), w) = I_p(v, Dn|_p(w)) \quad \text{for all } v, w \in T_p\Sigma.$$

Proof. In a parametrisation, both fundamental forms are represented by *symmetric* matrices ($F = F$ trivially, and $M = \langle n, \sigma_{uv} \rangle = \langle n, \sigma_{vu} \rangle$ by symmetry of mixed partials). Hence

$$I_p(Dn(v), w) = -II_p(v, w) = -II_p(w, v) = I_p(Dn(w), v) = I_p(v, Dn(w)). \quad \square$$

Remark. A theorem worth knowing (though beyond this course) is the *fundamental theorem of surfaces in $\mathbb{R}^3$* : a smooth oriented connected surface in $\mathbb{R}^3$ is determined, up to rigid motion, by its two fundamental forms. So I and II really are a complete set of invariants for local surface theory.

§14.4.3 Gaussian Curvature

Definition 14.4.7 (Gaussian Curvature)

The **Gaussian curvature** of a smooth surface Σ in $\mathbb{R}^3$ is the function

$$\kappa : \Sigma \rightarrow \mathbb{R}, \quad \kappa(p) = \det(Dn|_p).$$

Remark. This is well-defined even when Σ is not orientable: locally there are two choices of normal, differing by a sign, but in two dimensions $\det(-A) = \det(A)$, so the determinant is unaffected.

Let's express κ in terms of the fundamental forms. Fix a parametrisation, and let $A = \begin{pmatrix} E & F \\ F & G \end{pmatrix}$, $B = \begin{pmatrix} L & M \\ M & N \end{pmatrix}$, and let S be the matrix of $Dn|_p$ in the basis $\{\sigma_u, \sigma_v\}$. The relation $\Pi_p(v, w) = \mathbb{I}_p(-Dn(v), w)$ reads $B = -S^T A$, so $S = -(A^{-1}B)^T$ and

$$\kappa = \det S = \frac{\det B}{\det A} = \frac{LN - M^2}{EG - F^2}.$$

Under a transition map φ , A and B transform by $(D\varphi)^T(\cdot)(D\varphi)$ up to the same sign, so this ratio is genuinely independent of the parametrisation.

Example 14.4.8 (The Cylinder is Flat)

For the cylinder, the image of the Gauss map lies in the equator of S^2 : the normal $(\cos u, \sin u, 0)$ is always horizontal. So for any curve γ on the cylinder, $n \circ \gamma$ stays in a fixed circle, and $Dn|_p$ has image of dimension at most 1. Hence $\kappa \equiv 0$. Alternatively, $LN - M^2 = (-a)(0) - 0 = 0$. A surface with $\kappa \equiv 0$ is called **flat**.

Example 14.4.9 (Graphs, and the Sphere)

If Σ is the graph of a smooth function f , a computation from the example sheets gives

$$\kappa = \frac{f_{uu}f_{vv} - f_{uv}^2}{(1 + f_u^2 + f_v^2)^2}.$$

For instance, $f(u, v) = \sqrt{r^2 - u^2 - v^2}$ describes a piece of the sphere of radius r near its north pole, and at the origin $f_u = f_v = 0$, $f_{uu} = f_{vv} = -1/r$, $f_{uv} = 0$, giving

$$\kappa(0, 0, r) = \frac{1}{r^2}.$$

Since $O(3)$ acts transitively on the sphere by rigid motions, which preserve both fundamental forms, $\kappa \equiv 1/r^2$ on the whole sphere of radius r . Notice that a big sphere is gently curved and a small sphere is sharply curved, and that a dilation by a scales κ by $1/a^2$.

Example 14.4.10 (The Paraboloid)

Let $\Sigma = \{z = x^2 + y^2\}$. By the graph formula, at the origin $\kappa = 4 > 0$, and

everywhere

$$\kappa = \frac{4}{(1 + 4x^2 + 4y^2)^2} > 0.$$

One can also check that (for the inward orientation) the image of the Gauss map is precisely the open northern hemisphere: Σ is rotationally symmetric, the Gauss map commutes with rotations about the z -axis, and along $\{y = 0\}$ we have $n(x, 0, x^2) = (-2x, 0, 1)/\sqrt{1 + 4x^2}$, which sweeps out an open arc from pole towards (but never reaching) the equator.

§14.4.4 Elliptic, Hyperbolic and Parabolic Points

Definition 14.4.11

A point p of a smooth surface $\Sigma \subseteq \mathbb{R}^3$ is **elliptic** if $\kappa(p) > 0$, **hyperbolic** if $\kappa(p) < 0$, and **parabolic** if $\kappa(p) = 0$.

The sign of the curvature has a directly visible meaning.

Lemma 14.4.12

Near an elliptic point p , the surface lies entirely on one side of the affine tangent plane $p + T_p\Sigma$. Near a hyperbolic point, the surface meets both sides of the tangent plane in every neighbourhood of p .

Proof. Since the first fundamental form is positive definite, $EG - F^2 > 0$, and the sign of κ is the sign of $LN - M^2 = \det \Pi_p$. Recall the Taylor computation: for $w = h\sigma_u + \ell\sigma_v \in T_p\Sigma$, the signed distance from $\sigma(h, \ell)$ to the affine tangent plane is

$$\frac{1}{2} \Pi_p(w, w) + O(h^3, \ell^3).$$

If p is elliptic, Π_p has two eigenvalues of the same sign, so it is positive or negative definite; on the unit circle of directions w the form is bounded away from 0, so for small (h, ℓ) the quadratic term dominates the error and the signed distance has constant sign. If p is hyperbolic, Π_p has eigenvalues of opposite signs, so along the two eigendirections the signed distance takes opposite signs arbitrarily close to p . $\square$

Remark. At parabolic points nothing can be concluded. The cylinder has $\kappa \equiv 0$ and lies on one side of each tangent plane. On the other hand the *monkey saddle* $\sigma(u, v) = (u, v, u^3 - 3v^2u)$ has a parabolic point at the origin, but crosses its tangent plane there (it has three ‘valleys’ – two for the legs and one for the tail).

Proposition 14.4.13

Every compact smooth surface in $\mathbb{R}^3$ has an elliptic point.

Proof. Being compact, Σ is closed and bounded, so is contained in some closed ball; let R be the smallest radius such that $\Sigma \subseteq \overline{B(0, R)}$ (after translating so that the minimal enclosing ball is centred at the origin). Then Σ touches the sphere $S^2(R)$ at

some point, and applying a rotation we may assume $p = (0, 0, R) \in \Sigma$. The tangent planes of Σ and $S^2(R)$ at p agree (both are characterised by minimality/tangency; more carefully, if they differed then points of Σ near p would leave the ball). So near p we can write Σ as a graph $\{(u, v, f(u, v))\}$ with

$$f(u, v) \leq \sqrt{R^2 - u^2 - v^2},$$

expressing that Σ stays inside the ball, with equality at $(0, 0)$. Since $(0, 0)$ is thus a maximum of $f(u, v) - \sqrt{R^2 - u^2 - v^2}$, second-order Taylor expansion of both sides gives, for small (u, v) ,

$$\frac{1}{2} (f_{uu}u^2 + 2f_{uv}uv + f_{vv}v^2) \leq -\frac{1}{2R}(u^2 + v^2) + O((u^2 + v^2)^{3/2}).$$

So the Hessian of f at 0 is negative definite, and by the graph formula of Example 14.4.9 (using $f_u = f_v = 0$ at the origin),

$$\kappa(p) = f_{uu}f_{vv} - f_{uv}^2 \geq \frac{1}{R^2} > 0. \quad \square$$

This innocuous-looking proposition has a striking consequence: the flat torus $\mathbb{R}^2/\mathbb{Z}^2$, which we will construct properly in Section 14.6, admits *no* isometric embedding as a smooth surface in $\mathbb{R}^3$, since any compact surface in $\mathbb{R}^3$ has a point of positive curvature.

Here is one more interpretation of κ : it is the infinitesimal amount by which the Gauss map distorts area.

Theorem 14.4.14

Let $p \in \Sigma$ with $\kappa(p) \neq 0$, and let (A_i) be a sequence of open neighbourhoods of p which shrink to p , in the sense that for every $\epsilon > 0$ we have $A_i \subseteq B(p, \epsilon)$ for all large i . Then

$$|\kappa(p)| = \lim_{i \rightarrow \infty} \frac{\text{area}_{S^2}(n(A_i))}{\text{area}_{\Sigma}(A_i)}.$$

Proof. Fix an allowable parametrisation σ near p and let $V_i = \sigma^{-1}(A_i)$, so $\bigcap_i V_i = \{0\}$. First,

$$\text{area}_{\Sigma}(A_i) = \int_{V_i} \|\sigma_u \times \sigma_v\| \, du \, dv.$$

Next, by the chain rule, $Dn|_{\sigma(u,v)}(\sigma_u) = (n \circ \sigma)_u$ and similarly for v ; since $\kappa(p) \neq 0$, the map $n \circ \sigma$ has derivative of rank 2 at 0, so (by the inverse function theorem, shrinking V) it is an allowable parametrisation of a neighbourhood of $n(p)$ in S^2 . Hence for large i ,

$$\begin{aligned} \text{area}_{S^2}(n(A_i)) &= \int_{V_i} \|n_u \times n_v\| \, du \, dv = \int_{V_i} |\det Dn| \|\sigma_u \times \sigma_v\| \, du \, dv \\ &= \int_{V_i} |\kappa| \|\sigma_u \times \sigma_v\| \, du \, dv, \end{aligned}$$

using $n_u \times n_v = Dn(\sigma_u) \times Dn(\sigma_v) = \det(Dn) \sigma_u \times \sigma_v$. Finally, κ is continuous, so

given $\epsilon > 0$, for all large i we have $|\kappa| \in (|\kappa(p)| - \epsilon, |\kappa(p)| + \epsilon)$ on V_i , and hence

$$|\kappa(p)| - \epsilon \leq \frac{\text{area}_{S^2}(n(A_i))}{\text{area}_{\Sigma}(A_i)} \leq |\kappa(p)| + \epsilon.$$

Letting $i \rightarrow \infty$ and then $\epsilon \rightarrow 0$ gives the result. $\square$

§14.4.5 The Theorema Egregium

We defined κ using the Gauss map – that is, using the way Σ sits inside $\mathbb{R}^3$. The astonishing discovery of Gauss is that κ doesn't actually depend on the embedding at all.

Theorem 14.4.15 (Theorema Egregium)

The Gaussian curvature is invariant under isometries: if $f : \Sigma_1 \rightarrow \Sigma_2$ is an isometry of smooth surfaces in $\mathbb{R}^3$, then

$$\kappa_{\Sigma_2}(f(p)) = \kappa_{\Sigma_1}(p) \quad \text{for all } p \in \Sigma_1.$$

In other words, the Gaussian curvature is determined by the first fundamental form alone.

The 'remarkable theorem' is remarkable because κ was defined through the second fundamental form, which is definitely *not* an isometry invariant: the plane and the cylinder are locally isometric (unroll the cylinder!) but have different second fundamental forms. Somehow the particular combination $(LN - M^2)/(EG - F^2)$ only depends on E, F, G .

One can prove this by brute force – differentiate everything in sight and grind until κ is expressed in terms of E, F, G and their derivatives – but that proof teaches you nothing. We will instead take a more geometric route: in the next section we will find, on any surface, special parametrisations ('geodesic normal coordinates') in which the first fundamental form looks like

$$du^2 + G(u, v) dv^2,$$

and in such coordinates one can show (example sheet) that

$$\kappa = -\frac{(\sqrt{G})_{uu}}{\sqrt{G}}.$$

Since geodesics – and hence these coordinates – will be defined using lengths of curves only, this formula exhibits κ as an invariant of the first fundamental form, proving the Theorema Egregium.

An immediate and famous consequence: there is no map of the Earth (or any part of it) which preserves distances to scale, since the sphere has $\kappa = 1/r^2 > 0$ while the plane has $\kappa \equiv 0$. Every atlas of the world necessarily distorts.

§14.5 Geodesics

On the plane, the shortest path between two points is a straight line. What is the analogue of a straight line on a curved surface? The right notion turns out to be that of

a *geodesic*, which we will define variationally: a geodesic is a critical point of an energy functional. This section develops the theory and computes geodesics on our favourite examples.

§14.5.1 The Energy Functional

Let Σ be a smooth surface in $\mathbb{R}^3$ and $\gamma : [a, b] \rightarrow \Sigma$ a smooth curve. Alongside the length $L(\gamma) = \int_a^b \|\gamma'\| dt$ we define the **energy**

$$E(\gamma) = \int_a^b \|\gamma'(t)\|^2 dt.$$

Energy is slightly less geometric than length (it is not invariant under reparametrisation), but it is analytically much better behaved – no square roots – and we will see that its critical points are exactly the constant-speed shortest paths.

Definition 14.5.1 (Variation)

A **one-parameter variation with fixed endpoints** of γ is a smooth map

$$\Gamma : (-\epsilon, \epsilon) \times [a, b] \rightarrow \Sigma, \quad \gamma_s(t) = \Gamma(s, t),$$

such that $\gamma_0 = \gamma$, and $\gamma_s(a) = \gamma(a)$, $\gamma_s(b) = \gamma(b)$ for all s .

Definition 14.5.2 (Geodesic)

A smooth curve $\gamma : [a, b] \rightarrow \Sigma$ is a **geodesic** if for every one-parameter variation (γ_s) of γ with fixed endpoints,

$$\left. \frac{d}{ds} \right|_{s=0} E(\gamma_s) = 0.$$

That is, γ is a critical point of the energy functional on paths from $\gamma(a)$ to $\gamma(b)$.

§14.5.2 The Geodesic Equations

Let's turn the variational condition into differential equations. Suppose γ has image in the image of an allowable parametrisation $\sigma : V \rightarrow U$ with first fundamental form $E du^2 + 2F du dv + G dv^2$ (context will always distinguish the function E from the energy). For small s write $\gamma_s(t) = \sigma(u(s, t), v(s, t))$ and let

$$R = E\dot{u}^2 + 2F\dot{u}\dot{v} + G\dot{v}^2, \quad E(\gamma_s) = \int_a^b R dt,$$

where dots denote t -derivatives. Differentiating under the integral,

$$\begin{aligned} \frac{\partial R}{\partial s} &= (E_u \dot{u}^2 + 2F_u \dot{u}\dot{v} + G_u \dot{v}^2) \frac{\partial u}{\partial s} + (E_v \dot{u}^2 + 2F_v \dot{u}\dot{v} + G_v \dot{v}^2) \frac{\partial v}{\partial s} \\ &\quad + 2(E\dot{u} + F\dot{v}) \frac{\partial \dot{u}}{\partial s} + 2(F\dot{u} + G\dot{v}) \frac{\partial \dot{v}}{\partial s}. \end{aligned}$$

Integrating the last two terms by parts in t – the boundary terms vanish since $\partial u/\partial s = \partial v/\partial s = 0$ at $t = a, b$ (fixed endpoints!) – we obtain

$$\left. \frac{d}{ds} \right|_{s=0} E(\gamma_s) = \int_a^b \left(A \frac{\partial u}{\partial s} + B \frac{\partial v}{\partial s} \right) dt,$$

where

$$\begin{aligned} A &= E_u \dot{u}^2 + 2F_u \dot{u}\dot{v} + G_u \dot{v}^2 - 2 \frac{d}{dt} (E\dot{u} + F\dot{v}), \\ B &= E_v \dot{u}^2 + 2F_v \dot{u}\dot{v} + G_v \dot{v}^2 - 2 \frac{d}{dt} (F\dot{u} + G\dot{v}). \end{aligned}$$

Since $\partial u/\partial s$ and $\partial v/\partial s$ can be arbitrary smooth functions vanishing at the endpoints, the integral vanishes for every variation exactly when $A \equiv B \equiv 0$.

Corollary 14.5.3 (Geodesic Equations)

A smooth curve $\gamma(t) = \sigma(u(t), v(t))$ is a geodesic if and only if

$$\begin{aligned} \frac{d}{dt} (E\dot{u} + F\dot{v}) &= \frac{1}{2} (E_u \dot{u}^2 + 2F_u \dot{u}\dot{v} + G_u \dot{v}^2), \\ \frac{d}{dt} (F\dot{u} + G\dot{v}) &= \frac{1}{2} (E_v \dot{u}^2 + 2F_v \dot{u}\dot{v} + G_v \dot{v}^2). \end{aligned}$$

Remark. Being a geodesic looks like a global condition (it quantifies over all variations) but is actually local: any subarc of a geodesic is a geodesic, since a variation of the subarc extends by the constant variation, and conversely the equations above are differential equations, checked pointwise. This is important – it means we may verify the geodesic condition chart by chart.

What is the relationship between minimising energy and minimising length? The Cauchy–Schwarz inequality applied to $f = \|\gamma'\|$ and $g = 1$ gives

$$L(\gamma)^2 = \left(\int_a^b \|\gamma'\| \cdot 1 \, dt \right)^2 \leq (b-a) \int_a^b \|\gamma'\|^2 \, dt = (b-a)E(\gamma),$$

with equality if and only if $\|\gamma'\|$ is constant, i.e. γ is parametrised proportionally to arc length. From this we can deduce:

Corollary 14.5.4

If γ has constant speed and locally minimises length, then γ is a geodesic. Conversely, a curve which globally minimises energy among paths with the given endpoints also globally minimises length, and has constant speed.

We stress that geodesics need not globally minimise length – an arc of a great circle going the ‘long way round’ the sphere between two points is still a geodesic, as we are about to see, but is certainly not shortest. Geodesics are only *critical points* of the length/energy functionals: straightest, not necessarily shortest.

§14.5.3 Geodesics on the Plane and the Sphere

Example 14.5.5 (The Plane)

For $\sigma(u, v) = (u, v, 0)$ we have $E = G = 1$, $F = 0$, and all derivatives of E, F, G vanish. The geodesic equations reduce to

$$\ddot{u} = 0, \quad \ddot{v} = 0,$$

so $u(t) = \alpha t + \beta$ and $v(t) = \gamma t + \delta$: geodesics in the plane are straight lines traversed at constant speed, as they should be.

Example 14.5.6 (The Sphere)

Consider the unit sphere with the latitude–longitude parametrisation of Example 14.3.7, with first fundamental form $du^2 + \cos^2 u \, dv^2$, so $E = 1$, $F = 0$, $G = \cos^2 u$. The geodesic equations become

$$\ddot{u} + \sin u \cos u \dot{v}^2 = 0, \quad \frac{d}{dt} (\cos^2 u \dot{v}) = 0.$$

Geodesics have constant speed, and rescaling time we may assume unit speed:

$$\dot{u}^2 + \cos^2 u \dot{v}^2 = 1.$$

The second geodesic equation gives $\dot{v} = C / \cos^2 u$ for a constant C , and substituting into the unit speed condition,

$$\dot{u}^2 = 1 - \frac{C^2}{\cos^2 u} = \frac{\cos^2 u - C^2}{\cos^2 u}.$$

Assuming we are not on a parallel, we can divide to obtain

$$\frac{dv}{du} = \frac{\dot{v}}{\dot{u}} = \frac{C}{\cos u \sqrt{\cos^2 u - C^2}} = \frac{C \sec^2 u}{\sqrt{1 - C^2 \sec^2 u} \sqrt{1 - C^2} / \sqrt{1 - C^2}},$$

and the substitution $w = C \tan u / \sqrt{1 - C^2}$ turns the integral for v into $\int dw / \sqrt{1 - w^2}$, so

$$v = \arcsin \left(\frac{C \tan u}{\sqrt{1 - C^2}} \right) + \delta, \quad \text{i.e.} \quad \sin(v - \delta) = \lambda \tan u$$

for constants λ, δ . Expanding $\sin(v - \delta)$ and multiplying through by $\cos u$,

$$\underbrace{(\cos u \sin v)}_y \cos \delta - \underbrace{(\cos u \cos v)}_x \sin \delta - \lambda \underbrace{\sin u}_z = 0.$$

This is a linear equation in (x, y, z) – so the geodesic lies on a plane through the origin, and hence on a **great circle**, the intersection of such a plane with the sphere.

Conversely all constant-speed parametrisations of arcs of great circles are geodesics – this will drop out of the symmetry argument below with no computation at all.

Example 14.5.7 (The Torus of Revolution)

Take the torus obtained by revolving the circle of radius 1 centred at $(a, 0, 0)$ (with $a > 1$) in the xz -plane about the z -axis:

$$\sigma(u, v) = ((a + \cos u) \cos v, (a + \cos u) \sin v, \sin u),$$

with first fundamental form $du^2 + (a + \cos u)^2 dv^2$. Formally this is the sphere computation with $\cos u$ replaced by $a + \cos u$, and the same manipulations give

$$\frac{dv}{du} = \frac{C}{(a + \cos u) \sqrt{(a + \cos u)^2 - C^2}}.$$

But this integral cannot be evaluated in elementary functions – it is an *elliptic integral*, and the study of such integrals is precisely where elliptic functions historically came from. The moral: even on very symmetric surfaces, geodesics can be genuinely transcendental objects.

§14.5.4 A Second Characterisation of Geodesics

In the plane, straight lines are not just shortest – they are *straightest*: their tangent vector never turns. On a surface in $\mathbb{R}^3$, a curve's tangent vector may be forced to turn simply because the surface is curved, but a geodesic should turn no more than the surface forces it to. This is captured by the following characterisation.

Proposition 14.5.8

Let Σ be a smooth surface in $\mathbb{R}^3$. A smooth curve $\gamma : [a, b] \rightarrow \Sigma$ is a geodesic if and only if $\ddot{\gamma}(t)$ is normal to Σ (that is, orthogonal to $T_{\gamma(t)}\Sigma$) for every t .

Remark. Before the proof, note a pleasant consequence: if $\ddot{\gamma} \perp T_{\gamma}\Sigma$ then

$$\frac{d}{dt} \langle \dot{\gamma}, \dot{\gamma} \rangle = 2 \langle \ddot{\gamma}, \dot{\gamma} \rangle = 0,$$

since $\dot{\gamma}$ is tangent. So geodesics are automatically parametrised at constant speed.

Proof. Both conditions are local, so we may work in an allowable parametrisation and write $\gamma(t) = \sigma(u(t), v(t))$, with $\dot{\gamma} = \sigma_u \dot{u} + \sigma_v \dot{v}$. Now $\ddot{\gamma}$ is normal to Σ if and

only if it is orthogonal to both σ_u and σ_v . Let's expand the first condition:

$$0 = \left\langle \frac{d}{dt}(\sigma_u \dot{u} + \sigma_v \dot{v}), \sigma_u \right\rangle = \frac{d}{dt} \langle \sigma_u \dot{u} + \sigma_v \dot{v}, \sigma_u \rangle - \left\langle \sigma_u \dot{u} + \sigma_v \dot{v}, \frac{d}{dt} \sigma_u \right\rangle.$$

The first term is $\frac{d}{dt}(E\dot{u} + F\dot{v})$. For the second, $\frac{d}{dt}\sigma_u = \sigma_{uu}\dot{u} + \sigma_{uv}\dot{v}$, so it expands as

$$\dot{u}^2 \langle \sigma_u, \sigma_{uu} \rangle + \dot{u}\dot{v} (\langle \sigma_u, \sigma_{uv} \rangle + \langle \sigma_v, \sigma_{uu} \rangle) + \dot{v}^2 \langle \sigma_v, \sigma_{uv} \rangle.$$

Differentiating $E = \langle \sigma_u, \sigma_u \rangle$, $F = \langle \sigma_u, \sigma_v \rangle$ and $G = \langle \sigma_v, \sigma_v \rangle$ with respect to u gives

$$E_u = 2\langle \sigma_u, \sigma_{uu} \rangle, \quad F_u = \langle \sigma_u, \sigma_{uv} \rangle + \langle \sigma_v, \sigma_{uu} \rangle, \quad G_u = 2\langle \sigma_v, \sigma_{uv} \rangle,$$

so the condition $\langle \ddot{\gamma}, \sigma_u \rangle = 0$ becomes precisely the first geodesic equation

$$\frac{d}{dt}(E\dot{u} + F\dot{v}) = \frac{1}{2} (E_u \dot{u}^2 + 2F_u \dot{u}\dot{v} + G_u \dot{v}^2),$$

and symmetrically $\langle \ddot{\gamma}, \sigma_v \rangle = 0$ is the second geodesic equation. $\square$

§14.5.5 Planes of Symmetry

Here is a beautifully economical way to find geodesics.

Proposition 14.5.9

Let Σ be a smooth surface in $\mathbb{R}^3$ and $\Pi \subseteq \mathbb{R}^3$ a plane such that Σ is setwise preserved by reflection in Π , and $C = \Pi \cap \Sigma$ is a smooth embedded curve. Then C , parametrised at constant speed, is a geodesic.

Proof. Let $p \in C$ and let R denote reflection in Π . Since R preserves Σ and fixes p , its derivative (which is R itself, suitably translated) preserves $T_p\Sigma$ by Lemma 14.2.22. The tangent plane therefore splits into the (± 1) -eigenspaces of the reflection restricted to it; since $T_p\Sigma \not\subseteq \Pi$ would force... let us argue directly: R restricted to $T_p\Sigma$ is a linear isometry of order 2, so $T_p\Sigma$ has an orthogonal basis of eigenvectors with eigenvalues ± 1 . The $+1$ -eigenspace is $T_p\Sigma \cap \Pi$, which is the tangent line to C ; it is one-dimensional (as C is an embedded curve), so the -1 -eigenspace is also one-dimensional. Now the normal line $\mathbb{R}n_p = (T_p\Sigma)^\perp$ is preserved by R ; if R acted by -1 on it, then R would act by -1 on a two-dimensional subspace spanned by n_p and the -1 -eigenvector, and by $+1$ on the tangent line to C – but a reflection acts by -1 only on the one-dimensional $\Pi^\perp$. So $Rn_p = n_p$, that is $n_p \in \Pi$.

Now parametrise C near p at constant speed by $\gamma(t)$. Since γ lies in the plane Π , both $\dot{\gamma}$ and $\ddot{\gamma}$ lie in (the direction space of) Π . Constant speed gives $\langle \dot{\gamma}, \ddot{\gamma} \rangle = 0$, so within the plane Π , $\ddot{\gamma}$ is orthogonal to the tangent line of C . But Π 's direction space is spanned by the tangent line of C together with n_p (both lie in Π , and they are orthogonal). Hence $\ddot{\gamma} \in \mathbb{R}n_p$, i.e. $\ddot{\gamma}$ is normal to Σ , and γ is a geodesic by Proposition 14.5.8. $\square$

Example 14.5.10

Any great circle on S^2 is the intersection of the sphere with a plane through the

origin, which is a plane of reflective symmetry of the sphere. So all great circles, parametrised at constant speed, are geodesics – no computation needed. Together with the computation of Example 14.5.6 (and uniqueness of geodesics, coming shortly), the geodesics of the sphere are *precisely* the constant-speed arcs of great circles.

§14.5.6 Spherical Triangles

Since great circles are the ‘straight lines’ of the sphere, it is natural to do some classical geometry with them – this will also give us a first taste of the Gauss–Bonnet phenomenon. Note the sharp contrast with the plane: any two distinct great circles meet (in two antipodal points), so *there are no parallel lines in spherical geometry*.

Definition 14.5.11 (Spherical Triangle)

A **spherical triangle** on S^2 is a region bounded by three arcs of great circles, each of length less than π , meeting pairwise in three vertices. The **angle** at a vertex is the angle between the tangent vectors of the two arcs meeting there.

Theorem 14.5.12 (Gauss–Bonnet for Spherical Triangles)

Let T be a spherical triangle on the unit sphere with internal angles α, β, γ . Then

$$\text{area}(T) = \alpha + \beta + \gamma - \pi.$$

In particular the angles of a spherical triangle always sum to *more* than π .

Proof. The key player is the *lune*: the region between two great semicircles meeting at a pair of antipodal points with angle θ . Since the area of a lune is proportional to its angle and the lune of angle π is a hemisphere (area 2π), a lune of angle θ has area 2θ .

Now let T have vertices A, B, C . Each pair of the three great circles through the sides of T divides the sphere; consider the three lunes with angles α, β, γ containing T , together with their antipodal images. These six lunes cover the whole sphere; moreover every point of the sphere outside $T \cup (-T)$ is covered exactly once, while the points of T are covered by three lunes and points of the antipodal triangle $-T$ by the three antipodal lunes. Adding up areas,

$$2(2\alpha) + 2(2\beta) + 2(2\gamma) = \text{area}(S^2) + 4 \text{area}(T) = 4\pi + 4 \text{area}(T),$$

using $\text{area}(-T) = \text{area}(T)$. Rearranging gives $\text{area}(T) = \alpha + \beta + \gamma - \pi$. $\square$

This is a first instance of curvature controlling angle sums: on the unit sphere $\kappa \equiv 1$,

and the theorem says

$$\int_T \kappa \, dA = \text{area}(T) = (\alpha + \beta + \gamma) - \pi,$$

the *angle excess* of the triangle. We will later prove the same statement for geodesic triangles on an arbitrary surface – the local Gauss–Bonnet theorem – and the hyperbolic plane will exhibit the opposite behaviour, with angle sums falling short of π .

§14.5.7 Surfaces of Revolution and Clairaut's Relation

Let Σ be the surface of revolution of the curve $\eta(u) = (f(u), 0, g(u))$, with $f > 0$, which we may as well parametrise by arc length so the first fundamental form is $du^2 + f(u)^2 dv^2$ (Example 14.3.8).

Definition 14.5.13 (Parallels and Meridians)

The circles obtained by rotating a fixed point of η about the axis are called **parallels**; the copies of η obtained by rotating through a fixed angle are called **meridians**.

Every plane containing the axis of revolution is a plane of reflective symmetry of Σ , so by Proposition 14.5.9:

Corollary 14.5.14

All meridians of a surface of revolution are geodesics.

Parallels, on the other hand, are usually *not* geodesics – think of a circle of latitude on the sphere near the north pole, which is visibly not straight.

Lemma 14.5.15

The parallel $u = u_0$, parametrised at constant speed, is a geodesic if and only if $f'(u_0) = 0$, i.e. the parallel sits at a critical radius.

Proof. With $E = 1$, $F = 0$, $G = f^2$, the geodesic equations read

$$\ddot{u} = f f' \dot{v}^2, \quad \frac{d}{dt} (f^2 \dot{v}) = 0.$$

On the parallel $u \equiv u_0$ with constant speed, $\dot{v}$ is a non-zero constant, so the second equation holds automatically and the first reduces to $0 = f(u_0) f'(u_0) \dot{v}^2$. Since $f > 0$ and $\dot{v} \neq 0$, this holds precisely when $f'(u_0) = 0$. $\square$

For general geodesics on a surface of revolution there is a striking conservation law. Let

γ be a unit speed curve on Σ , let $\rho = f(u)$ be the radius of the parallel through a point, and let θ be the angle at which γ crosses that parallel.

Proposition 14.5.16 (Clairaut's Relation)

If γ is a geodesic, then $\rho \cos \theta$ is constant along γ .

Proof. Write $\gamma(t) = \sigma(u(t), v(t))$, so $\dot{\gamma} = \sigma_u \dot{u} + \sigma_v \dot{v}$, and the tangent to the parallel is σ_v , of length $\|\sigma_v\| = \sqrt{G} = f = \rho$. By the angle formula from the first fundamental form ($F = 0$),

$$\cos \theta = \frac{\langle \sigma_v, \sigma_u \dot{u} + \sigma_v \dot{v} \rangle}{\|\sigma_v\| \|\dot{\gamma}\|} = \frac{G \dot{v}}{\rho} = \rho \dot{v},$$

using $\|\dot{\gamma}\| = 1$. So $\rho \cos \theta = \rho^2 \dot{v} = f^2 \dot{v}$, and the second geodesic equation says precisely that this is constant. $\square$

Example 14.5.17 (Geodesics Trapped Between Parallels)

Consider an ellipsoid of revolution, and a geodesic γ which crosses some parallel of radius ρ_0 at angle θ_0 , and is not a meridian, so $c = \rho_0 \cos \theta_0 > 0$. Along γ we always have $\rho \cos \theta = c$, and since $|\cos \theta| \leq 1$ this forces $\rho \geq c$: the geodesic can never enter the polar caps where the parallels are narrower than c . Such a geodesic is ‘trapped’ in the band between two parallels of radius c , bouncing between them indefinitely. In particular, any geodesic through a pole must have $c = 0$, i.e. must be a meridian.

§14.5.8 Local Existence of Geodesics

Solving the geodesic equations globally is generally hopeless (we already met elliptic integrals on the torus), but locally the general theory of differential equations does everything for us. Recall *Picard's theorem* from Analysis and Topology: an ODE $\dot{x} = h(t, x)$ with h continuous and Lipschitz in x has a unique local solution through each initial condition, and if h is smooth, the solution is smooth and depends smoothly on the initial conditions.

The geodesic equations can be put in this form. Writing them as

$$\begin{pmatrix} E & F \\ F & G \end{pmatrix} \begin{pmatrix} \ddot{u} \\ \ddot{v} \end{pmatrix} = R(u, v, \dot{u}, \dot{v})$$

with R built smoothly from E, F, G and their derivatives, we can invert the (positive definite, hence invertible) matrix – and matrix inversion is smooth – to get

$$\ddot{u} = A(u, v, \dot{u}, \dot{v}), \quad \ddot{v} = B(u, v, \dot{u}, \dot{v})$$

with A, B smooth. Introducing $p = \dot{u}$, $q = \dot{v}$ converts this to a first-order system in (u, v, p, q) to which Picard's theorem applies.

Corollary 14.5.18

Let Σ be a smooth surface in $\mathbb{R}^3$, $p \in \Sigma$ and $0 \neq v \in T_p \Sigma$. Then there is some $\epsilon > 0$ and a geodesic $\gamma : [0, \epsilon) \rightarrow \Sigma$ with

$$\gamma(0) = p, \quad \dot{\gamma}(0) = v,$$

and γ is unique and depends smoothly on (p, v) .

This local existence gives us the promised ‘best possible’ parametrisations. Fix $p \in \Sigma$ and a unit speed geodesic arc $\gamma(v)$ through $p = \gamma(0)$. For each small v , let γ_v be the unit speed geodesic through $\gamma(v)$ orthogonal to γ , and define

$$\sigma(u, v) = \gamma_v(u).$$

Lemma 14.5.19

For sufficiently small $\epsilon, \delta > 0$, the map $\sigma : (u, v) \mapsto \gamma_v(u)$ on $(-\epsilon, \epsilon) \times (-\delta, \delta)$ is an allowable parametrisation of an open set in Σ .

Proof. Smoothness of σ is the smooth dependence on initial conditions in Picard’s theorem. At the origin, $\sigma_u = \dot{\gamma}_0(0)$ and $\sigma_v = \dot{\gamma}(0)$ are orthogonal unit vectors by construction, so $D\sigma$ has rank 2 at the origin, and by continuity in a neighbourhood; shrinking further makes σ injective. So σ is allowable. $\square$

Corollary 14.5.20 (Geodesic Normal Coordinates)

Every smooth surface in $\mathbb{R}^3$ admits, near each point, an allowable parametrisation with first fundamental form

$$du^2 + G(u, v) dv^2, \quad \text{with} \quad G(0, v) = 1, \quad G_u(0, v) = 0.$$

Proof. Take $\sigma(u, v) = \gamma_v(u)$ as above. For fixed v_0 , the curve $u \mapsto \sigma(u, v_0)$ is a unit speed geodesic, so $E = \|\sigma_u\|^2 = 1$ everywhere, and in particular $E_v = 0$. Substituting the curve $u(t) = t, v(t) = v_0$ (so $\dot{u} = 1, \dot{v} = 0$) into the second geodesic equation,

$$\frac{d}{dt}(F\dot{u} + G\dot{v}) = \frac{1}{2}(E_v\dot{u}^2 + 2F_v\dot{u}\dot{v} + G_v\dot{v}^2) \implies \frac{d}{dt}F = 0 \implies F_u = 0,$$

so F is independent of u . At $u = 0$ we have $F = \langle \dot{\gamma}_v(0), \dot{\gamma}(v) \rangle = 0$ by the orthogonality in the construction; hence $F \equiv 0$. Next, $\sigma_v(0, v) = \dot{\gamma}(v)$ has unit length, so $G(0, v) = 1$. Finally $u = 0$ gives the unit speed geodesic γ itself (with $\dot{u} = 0, \dot{v} = 1$), and the first geodesic equation applied to it gives

$$\frac{d}{dt}(E\dot{u} + F\dot{v}) = \frac{1}{2}(E_u\dot{u}^2 + 2F_u\dot{u}\dot{v} + G_u\dot{v}^2) \implies 0 = \frac{1}{2}G_u(0, v). \quad \square$$

In geodesic normal coordinates one shows (on the example sheets, by direct computation with the formula $\kappa = (LN - M^2)/(EG - F^2)$ and repeated differentiation of the relations among σ_u, σ_v, n) that

$$\kappa = -\frac{(\sqrt{G})_{uu}}{\sqrt{G}}.$$

Since geodesics, and hence these coordinates, are defined purely in terms of lengths of curves, this expresses κ in terms of the first fundamental form alone – completing the proof of the Theorema Egregium (Theorem 14.4.15), as promised.

§14.5.9 Surfaces of Constant Curvature

The formula $\kappa = -(\sqrt{G})_{uu}/\sqrt{G}$ lets us completely determine the local geometry of surfaces of constant curvature. Note first that under a dilation $x \mapsto ax$ of $\mathbb{R}^3$, the functions E, F, G scale by a^2 while L, M, N scale by a , so κ scales by $1/a^2$; thus it suffices to understand $\kappa \equiv 0, \pm 1$.

Proposition 14.5.21

Let Σ be a smooth surface in $\mathbb{R}^3$.

- (i) If $\kappa \equiv 0$, then Σ is locally isometric to the plane $(\mathbb{R}^2, du^2 + dv^2)$.
- (ii) If $\kappa \equiv 1$, then Σ is locally isometric to the unit sphere $(S^2, du^2 + \cos^2 u dv^2)$.

Proof. Take geodesic normal coordinates about a point, so that the first fundamental form is $du^2 + G dv^2$ with $G(0, v) = 1$, $G_u(0, v) = 0$, and

$$(\sqrt{G})_{uu} + \kappa\sqrt{G} = 0.$$

If $\kappa \equiv 0$: then $\sqrt{G} = A(v)u + B(v)$, and the boundary conditions force $A \equiv 0$, $B \equiv 1$, so $G \equiv 1$ and the first fundamental form is $du^2 + dv^2$ – that of the plane. By Lemma 14.3.12, Σ is locally isometric to the plane.

If $\kappa \equiv 1$: then $\sqrt{G} = A(v)\sin u + B(v)\cos u$, and the boundary conditions force $A \equiv 0$, $B \equiv 1$, giving first fundamental form $du^2 + \cos^2 u dv^2$ – that of the unit sphere in latitude–longitude coordinates (Example 14.3.7). $\square$

What about $\kappa \equiv -1$? The same argument gives $\sqrt{G} = \cosh u$, so the first fundamental form is

$$du^2 + \cosh^2 u dv^2.$$

There is a surface of revolution with this geometry: the **pseudosphere** (or tractoid), obtained by revolving the *tractrix* – the curve traced by a weight dragged on the end of a taut string whose other end moves along a line – about its asymptotic axis.

But the pseudosphere is geometrically unsatisfying: it has an edge (the rim), and geodesics run off it in finite time. A theorem of Hilbert says this is unavoidable – *no* complete surface of constant curvature -1 embeds smoothly in $\mathbb{R}^3$. If we want a good home for constant negative curvature, we must leave $\mathbb{R}^3$ behind and work with *abstract* Riemannian metrics. That is the subject of the next section, and the resulting geometry – hyperbolic geometry – will occupy us for most of the rest of the course.

Before moving on, we record a change of variables we will meet again: substituting $V = e^v \tanh u$, $W = e^v \operatorname{sech} u$ transforms $du^2 + \cosh^2 u dv^2$ into
