$$\frac{dV^2 + dW^2}{W^2},$$

which is the ‘standard’ form of the hyperbolic metric on a half-plane.

§14.6 Abstract Riemannian Metrics

The first fundamental form of a surface in $\mathbb{R}^3$ was induced from the ambient Euclidean inner product. But nothing stops us writing down expressions like $E du^2 + 2F du dv + G dv^2$ on an abstract smooth surface directly, without any embedding – and the Theorema Egregium tells us that curvature will still make sense. This idea unlocks geometries, like the hyperbolic plane, which genuinely do not exist inside $\mathbb{R}^3$.

§14.6.1 Riemannian Metrics

Definition 14.6.1 (Riemannian Metric on an Open Set)

Let $V \subseteq \mathbb{R}^2$ be open. A **Riemannian metric** on V is a smooth map from V to the positive definite symmetric bilinear forms on $\mathbb{R}^2$,

$$x \mapsto \begin{pmatrix} E(x) & F(x) \\ F(x) & G(x) \end{pmatrix}, \quad \text{with } E > 0, \ G > 0, \ EG - F^2 > 0,$$

where $E, F, G : V \rightarrow \mathbb{R}$ are smooth. We write it as $E du^2 + 2F du dv + G dv^2$.

Given such a metric, we measure exactly as before: a tangent vector w at $x \in V$ has length $\|w\|^2 = w^T \begin{pmatrix} E & F \\ F & G \end{pmatrix} w$, and a smooth curve $\gamma(t) = (u(t), v(t))$ in V has length

$$L(\gamma) = \int_a^b (E\dot{u}^2 + 2F\dot{u}\dot{v} + G\dot{v}^2)^{1/2} dt.$$

Angles and areas are defined by the same formulae as for surfaces in $\mathbb{R}^3$; and geodesics are again critical points of the energy, characterised by the same geodesic equations (our derivation only ever used E, F, G).

To put a metric on an abstract surface, we put compatible metrics on all its charts.

Definition 14.6.2 (Riemannian Metric on an Abstract Surface)

Let Σ be an abstract smooth surface with atlas $\{(U_i, \phi_i)\}$, $\phi_i : U_i \rightarrow V_i \subseteq \mathbb{R}^2$. A **Riemannian metric** g on Σ is a choice of Riemannian metric on each V_i such that the transition maps are isometries: writing f for the transition map between charts i and j ,

$$(Df)^T \begin{pmatrix} E_j & F_j \\ F_j & G_j \end{pmatrix} (Df) = \begin{pmatrix} E_i & F_i \\ F_i & G_i \end{pmatrix}$$

wherever this makes sense.

The compatibility condition is precisely the transformation law that first fundamental forms of surfaces in $\mathbb{R}^3$ obey under transition maps – so a smooth surface in $\mathbb{R}^3$ with its first fundamental form is an example. The point is that there are now many more examples.

Example 14.6.3 (The Flat Torus)

Recall the torus $T^2 = \mathbb{R}^2/\mathbb{Z}^2$, which has an atlas of charts inverse to $q|_D$ for small

discs $D \subseteq \mathbb{R}^2$, whose transition maps are restrictions of translations of $\mathbb{R}^2$. Equip every chart with the Euclidean metric $du^2 + dv^2$. If f is a translation then $Df = I$, so the compatibility condition

$$(Df)^T I (Df) = I$$

holds trivially, and we obtain a global Riemannian metric on T^2 : the **flat torus**. Every point has a chart which is an isometry onto a Euclidean disc, so this metric has $\kappa \equiv 0$.

Contrast this with the torus of revolution in $\mathbb{R}^3$: by Proposition 14.4.13, any compact surface in $\mathbb{R}^3$ has an elliptic point, so *no* embedding of the torus in $\mathbb{R}^3$ can induce the flat metric. The flat torus is a genuinely abstract object.

Example 14.6.4 ($\mathbb{RP}^2$ and the Klein Bottle)

The real projective plane $\mathbb{RP}^2 = S^2 / \pm 1$ has an atlas of charts lifted from charts of S^2 on open sets contained in hemispheres, with transition maps locally equal to the identity or the antipodal map. The antipodal map is an isometry of the round sphere, so the round metric descends to a Riemannian metric on $\mathbb{RP}^2$ of constant curvature $+1$.

Similarly, the Klein bottle (the square with one pair of sides glued directly and the other with a flip) has an atlas whose transition maps are translations and translations composed with a reflection – all Euclidean isometries – so it inherits a flat Riemannian metric. Neither $\mathbb{RP}^2$ nor the Klein bottle embeds in $\mathbb{R}^3$ at all, so abstract metrics are the only ones available.

Definition 14.6.5 (Isometry of Riemannian Surfaces)

Let (Σ_1, g_1) and (Σ_2, g_2) be abstract smooth surfaces with Riemannian metrics. A diffeomorphism $f : \Sigma_1 \rightarrow \Sigma_2$ is an **isometry** if it preserves the lengths of all curves.

Example 14.6.6 (Pullback Metrics)

If (Σ_2, g_2) is given and $f : \Sigma_1 \rightarrow \Sigma_2$ is any diffeomorphism of smooth surfaces, there is a unique metric on Σ_1 making f an isometry: define the inner product of two tangent vectors to be the g_2 -inner product of their images under Df . This is the **pullback metric** f^*g_2 .

§14.6.2 The Length Metric

A Riemannian metric on Σ measures lengths of curves; from this we get a candidate distance function between points, in the usual ‘infimum over paths’ way.

Definition 14.6.7 (Length Metric)

Let (Σ, g) be a connected abstract smooth surface with a Riemannian metric. For

$p, q \in \Sigma$ define

$$d_g(p, q) = \inf\{L(\gamma) \mid \gamma \text{ a piecewise smooth path from } p \text{ to } q\}.$$

We should check this is an honest metric – the worry being that two distinct points might be joined by paths of arbitrarily small length.

Proposition 14.6.8

d_g is a metric on Σ , and it induces the original topology of Σ .

Proof. First, d_g is well-defined and finite: a connected surface is path-connected, and given a continuous path from p to q we can cover its (compact) image by finitely many charts $U_1, \dots, U_N$ and pick intermediate points $p = x_0, x_1 \in U_1 \cap U_2, \dots, x_N = q$; within each chart, the straight line segment between the images of consecutive points gives a smooth path, and concatenating produces a piecewise smooth path from p to q . Symmetry of d_g follows by reversing paths, and the triangle inequality by concatenating them.

The only issue is showing $d_g(p, q) = 0 \implies p = q$; equivalently, that distinct points are a positive distance apart. Let $p \neq q$, fix a chart (U, ϕ) at p with $\phi(p) = 0$ and $\phi(U) = B(0, 1)$, and choose $\epsilon \in (0, 1)$ small enough that $q \notin \phi^{-1}(\overline{B(0, \epsilon)})$. Any path γ from p to q must cross the circle $\phi^{-1}(\{|z| = \epsilon\})$, so it suffices to bound below the length of the part of γ inside $\phi^{-1}(\overline{B(0, \epsilon)})$.

On the compact set $\overline{B(0, \epsilon)}$, the metric $\begin{pmatrix} E & F \\ F & G \end{pmatrix}$ is a continuous family of positive definite forms, so there is $\delta > 0$ such that

$$\begin{pmatrix} E - \delta & F \\ F & G - \delta \end{pmatrix}$$

is still positive semi-definite everywhere on $\overline{B(0, \epsilon)}$ – for instance because the smallest eigenvalue of the metric is a continuous positive function on a compact set, hence bounded below by some $\delta > 0$. Then for any tangent vector w at a point of $\overline{B(0, \epsilon)}$,

$$\|w\|_g^2 \geq \delta \|w\|_{\text{Euc}}^2,$$

so g -lengths of curves inside the ball dominate $\sqrt{\delta}$ times their Euclidean lengths. The part of $\phi \circ \gamma$ from 0 to the circle of radius ϵ has Euclidean length at least ϵ , whence

$$d_g(p, q) \geq \sqrt{\delta} \epsilon > 0.$$

Finally, the two-sided comparison between g and (a scaled) Euclidean metric on compact sets, argued exactly as above, shows that small d_g -balls contain and are contained in small chart-balls, so d_g induces the given topology. $\square$

We now have all the language we need. The plane $\mathbb{R}^2$ with its flat metric and the sphere S^2 with its round metric are homogeneous, highly symmetric geometries of curvature 0 and +1. The missing member of the family – constant curvature -1 – is the subject of the next section.

§14.7 Hyperbolic Geometry

We now construct the hyperbolic plane: the homogeneous geometry of constant curvature -1 . Historically this was the geometry that resolved the two-thousand-year controversy over Euclid's parallel postulate – in the hyperbolic plane, through any point not on a line ℓ there are *infinitely many* lines not meeting ℓ . We will build it concretely, as a disc (or half-plane) with a rescaled Euclidean metric, and its symmetries will come from the Möbius group.

§14.7.1 The Hyperbolic Disc

Definition 14.7.1 (Hyperbolic Disc)

Let $D = \{z \in \mathbb{C} \mid |z| < 1\}$ be the open unit disc. The **hyperbolic metric** on D is the Riemannian metric

$$g_{\text{hyp}} = \frac{4(du^2 + dv^2)}{(1 - u^2 - v^2)^2} = \frac{4|dz|^2}{(1 - |z|^2)^2}.$$

The disc D with this metric is the **disc model** of the hyperbolic plane.

Since $E = G$ and $F = 0$, the hyperbolic metric is a *conformal* rescaling of the Euclidean metric – hyperbolic angles are Euclidean angles. But lengths are distorted, and dramatically so near the boundary: a smooth curve $\gamma : [0, 1] \rightarrow D$ has hyperbolic length

$$L_{\text{hyp}}(\gamma) = \int_0^1 \frac{2|\dot{\gamma}(t)|}{1 - |\gamma(t)|^2} dt,$$

and the factor $2/(1 - |z|^2)$ blows up as $|z| \rightarrow 1$. The boundary circle is ‘infinitely far away’ – as we will verify shortly – and it is *not* part of the hyperbolic plane.

The flat plane and the round sphere both have very large isometry groups. The same is true here, and the isometries come from a group we know well from IA Groups: the Möbius group

$$\text{Möb} = \left\{ z \mapsto \frac{az + b}{cz + d} \mid \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \text{GL}(2, \mathbb{C}) \right\}$$

acting on $\mathbb{C} \cup \{\infty\}$.

Lemma 14.7.2

The subgroup of Möbius maps preserving the disc, $\text{Möb}(D) = \{T \in \text{Möb} \mid T(D) = D\}$, is

$$\text{Möb}(D) = \left\{ z \mapsto e^{i\theta} \frac{z - a}{1 - \bar{a}z} \mid a \in D, \theta \in \mathbb{R} \right\}.$$

Proof. First we check the given maps preserve D . For $|a| < 1$,

$$\begin{aligned} \left| \frac{z - a}{1 - \bar{a}z} \right| = 1 &\iff (z - a)(\bar{z} - \bar{a}) = (1 - \bar{a}z)(1 - a\bar{z}) \\ &\iff |z|^2 - a\bar{z} - \bar{a}z + |a|^2 = 1 - \bar{a}z - a\bar{z} + |a|^2|z|^2 \\ &\iff (|z|^2 - 1)(1 - |a|^2) = 0 \iff |z| = 1. \end{aligned}$$

So the map preserves the unit circle; being a homeomorphism of $\mathbb{C} \cup \{\infty\}$, it maps D to either the inside or the outside, and since $a \mapsto 0 \in D$, it preserves D . The rotation factor $e^{i\theta}$ clearly preserves D too.

Conversely, suppose $T \in \text{Möb}$ preserves D , and let $a = T^{-1}(0) \in D$. Then composing T with the inverse of $z \mapsto (z - a)/(1 - \bar{a}z)$, we get a Möbius map preserving D and fixing 0; it also preserves the unit circle, and one checks (using preservation of inverse points, or a direct computation) that a Möbius map fixing 0 and preserving the unit circle is a rotation $z \mapsto e^{i\theta}z$. So T has the stated form. $\square$

Lemma 14.7.3

$\text{Möb}(D)$ acts on (D, g_{hyp}) by isometries.

Proof. The group $\text{Möb}(D)$ is generated by rotations $z \mapsto e^{i\theta}z$ and the maps $T_a : z \mapsto \frac{z-a}{1-\bar{a}z}$. Rotations are Euclidean isometries fixing $|z|$, so preserve g_{hyp} , which only depends on $|z|$ and $|dz|$. For T_a , write $w = \frac{z-a}{1-\bar{a}z}$. Differentiating,

$$dw = \left(\frac{1}{1-\bar{a}z} + \frac{(z-a)\bar{a}}{(1-\bar{a}z)^2} \right) dz = \frac{1-|a|^2}{(1-\bar{a}z)^2} dz.$$

Also

$$1-|w|^2 = \frac{|1-\bar{a}z|^2 - |z-a|^2}{|1-\bar{a}z|^2} = \frac{(1-|a|^2)(1-|z|^2)}{|1-\bar{a}z|^2},$$

where the numerator is the same computation as in Lemma 14.7.2. Dividing,

$$\frac{|dw|}{1-|w|^2} = \frac{(1-|a|^2)|dz|}{|1-\bar{a}z|^2} \cdot \frac{|1-\bar{a}z|^2}{(1-|a|^2)(1-|z|^2)} = \frac{|dz|}{1-|z|^2}.$$

So T_a preserves the expression $2|dz|/(1-|z|^2)$, i.e. pulls back g_{hyp} to itself. Hence every element of $\text{Möb}(D)$ is an isometry. $\square$

Note that $\text{Möb}(D)$ acts *transitively* on D (the map T_a sends a to 0), so the hyperbolic plane looks the same at every point – just like the flat plane and the round sphere.

Now we can find the geodesics.

Proposition 14.7.4

In (D, g_{hyp}) :

- (i) any two points are joined by a unique geodesic, up to reparametrisation;
- (ii) the geodesics are the diameters of D and the arcs of circles meeting the boundary circle ∂D at right angles.

The complete geodesics (defined on all of $\mathbb{R}$) are called **hyperbolic lines**.

Proof. Consider first two points on the real diameter, say 0 and $a \in (0, 1)$. Let $\gamma(t) = (u(t), v(t))$ be any smooth path from 0 to a in D . Then

$$L_{\text{hyp}}(\gamma) = \int_0^1 \frac{2\sqrt{\dot{u}^2 + \dot{v}^2}}{1 - u^2 - v^2} dt \geq \int_0^1 \frac{2|\dot{u}|}{1 - u^2} dt \geq \int_0^1 \frac{2\dot{u}}{1 - u^2} dt = 2 \operatorname{artanh} a,$$

where the first inequality is an equality if and only if $\dot{v} \equiv 0$ and $v \equiv 0$ (dropping $\dot{v}^2$ and enlarging the denominator), and the second iff u is monotonic. So the straight segment $[0, a]$, monotonically parametrised, is the unique shortest path, of hyperbolic length $2 \operatorname{artanh} a$; being length-minimising with constant speed (after reparametrising) it is a geodesic, and any geodesic between the two points must equal it.

Now let $p, q \in D$ be arbitrary. Using the transitive isometric action of $\operatorname{Möb}(D)$, choose $T \in \operatorname{Möb}(D)$ with $T(p) = 0$, and then a rotation moves $T(q)$ to some $a \in (0, 1)$. Since isometries carry geodesics to geodesics, p and q are joined by a unique geodesic: the preimage of the segment $[0, a]$. Finally, Möbius maps send circles-and-lines to circles-and-lines and preserve angles, and diameters are exactly the circles-and-lines through 0 meeting ∂D at right angles; so the geodesics through arbitrary points are exactly diameters and circular arcs orthogonal to ∂D . $\square$

Corollary 14.7.5

The hyperbolic distance on D is

$$d_{\text{hyp}}(p, q) = 2 \operatorname{artanh} \left| \frac{p - q}{1 - \bar{p}q} \right|.$$

Proof. The map $z \mapsto \frac{z-p}{1-\bar{p}z}$ is an isometry taking p to 0 and q to $\frac{q-p}{1-\bar{p}q}$, and a rotation about 0 takes this to the positive real point $a = \left| \frac{q-p}{1-\bar{p}q} \right|$, at distance $2 \operatorname{artanh} a$ from 0. $\square$

Notice that $d_{\text{hyp}}(0, a) = 2 \operatorname{artanh} a \rightarrow \infty$ as $a \rightarrow 1$: the boundary really is infinitely far away, so the hyperbolic plane is ‘complete’ in a way the pseudosphere was not.

Remark. A pleasant uniqueness statement: up to a constant scale, g_{hyp} is the *only* Riemannian metric on D invariant under $\operatorname{Möb}(D)$ for which the diameters are length-minimising – essentially because invariance forces the distance function $p(a) = d(0, a)$ to satisfy the functional equation $p(b) - p(a) = p\left(\frac{b-a}{1-\bar{a}b}\right)$, whose differentiable solutions are multiples of artanh . The factor 4 in the metric is chosen precisely so that the curvature is -1 , as we will see.

§14.7.2 The Upper Half-Plane

There is a second standard model of the same geometry, often more convenient for computation.

Definition 14.7.6 (Upper Half-Plane)

The **hyperbolic upper half-plane** is

$$\mathfrak{h} = \{z \in \mathbb{C} \mid \operatorname{Im} z > 0\}, \quad \text{with the metric} \quad g_{\text{hyp}} = \frac{dx^2 + dy^2}{y^2} = \frac{|dz|^2}{(\operatorname{Im} z)^2}.$$

Lemma 14.7.7

(D, g_{hyp}) and $(\mathfrak{h}, g_{\text{hyp}})$ are isometric.

Proof. Consider the mutually inverse Möbius maps

$$T : \mathfrak{h} \rightarrow D, \quad T(w) = \frac{w - i}{w + i}, \quad T^{-1}(z) = i \frac{1 + z}{1 - z}.$$

(T sends $\mathbb{R} \cup \{\infty\}$ to the unit circle and $i \mapsto 0$, so maps $\mathfrak{h}$ onto D .) We compute

$$T'(w) = \frac{2i}{(w + i)^2},$$

and, with $z = T(w)$,

$$1 - |z|^2 = \frac{|w + i|^2 - |w - i|^2}{|w + i|^2} = \frac{4 \operatorname{Im} w}{|w + i|^2}.$$

Hence

$$\frac{2|dz|}{1 - |z|^2} = \frac{2|T'(w)| |dw|}{1 - |T(w)|^2} = \frac{4|dw|}{|w + i|^2} \cdot \frac{|w + i|^2}{4 \operatorname{Im} w} = \frac{|dw|}{\operatorname{Im} w}.$$

So T pulls the disc metric back to the half-plane metric, i.e. T is an isometry. $\square$

Corollary 14.7.8

Any two points of $\mathfrak{h}$ are joined by a unique geodesic, and the hyperbolic lines in $\mathfrak{h}$ are the vertical half-lines and the semicircles centred on the real axis.

Proof. The isometry $T^{-1} : D \rightarrow \mathfrak{h}$ is a Möbius map, so takes circles-and-lines to circles-and-lines, preserves angles, and takes ∂D to $\mathbb{R} \cup \{\infty\}$. So the images of the hyperbolic lines of D (circles-and-lines orthogonal to ∂D) are precisely the circles-and-lines orthogonal to the real axis: vertical lines and semicircles centred on $\mathbb{R}$. $\square$

In the half-plane model the orientation-preserving symmetries take a particularly clean form: one can check that the Möbius maps preserving $\mathfrak{h}$ are exactly those with *real* coefficients and positive determinant,

$$\text{Möb}(\mathfrak{h}) = \left\{ z \mapsto \frac{az+b}{cz+d} \mid a, b, c, d \in \mathbb{R}, ad - bc > 0 \right\} \cong \text{PSL}(2, \mathbb{R}),$$

where $\text{PSL}(2, \mathbb{R}) = \text{SL}(2, \mathbb{R})/\{\pm I\}$, since scaling the matrix doesn't change the map. For example $z \mapsto z + b$ ($b \in \mathbb{R}$) and $z \mapsto \lambda z$ ($\lambda > 0$) are hyperbolic isometries – the second showing that all vertical lines are ‘translates’ of one another.

Remark (The Hyperboloid Model). There is a third model worth knowing about, which makes the analogy with the sphere vivid. Consider $\mathbb{R}^3$ with the *Lorentzian* inner product $\langle x, y \rangle_L = x_1y_1 + x_2y_2 - x_3y_3$, and the upper sheet of the hyperboloid

$$\{x \in \mathbb{R}^3 \mid \langle x, x \rangle_L = -1, x_3 > 0\},$$

which is the ‘sphere of radius $\sqrt{-1}$ ’ for this inner product. The restriction of $\langle \cdot, \cdot \rangle_L$ to its tangent planes is positive definite, and gives a metric of constant curvature -1 isometric to (D, g_{hyp}) – indeed, radial projection from $(0, 0, -1)$ maps the hyperboloid onto the disc $D \times \{0\}$ and carries this metric to g_{hyp} , in perfect analogy with stereographic projection of the sphere. The isometry group becomes the group $\text{O}^+(2, 1)$ of Lorentz transformations preserving the sheet, mirroring $\text{O}(3)$ acting on S^2 .

§14.7.3 Isometries of the Hyperbolic Plane

We have exhibited many isometries of $\mathbb{H}$ (we write $\mathbb{H}$ for the hyperbolic plane in either model). Are there others? Certainly one: complex conjugation $z \mapsto \bar{z}$ on D visibly preserves g_{hyp} but is orientation-reversing. It is the hyperbolic analogue of a reflection, and generalises as follows.

Definition 14.7.9 (Inversion)

Let $\Gamma \subseteq \mathbb{C} \cup \{\infty\}$ be a circle or line. Points z, z' are **inverse with respect to Γ** if every circle-or-line through z orthogonal to Γ also passes through z' . Given z , the inverse point exists and is unique, and the map $J_\Gamma : z \mapsto z'$ is called **inversion** in Γ .

To see existence and uniqueness: for $\Gamma = \mathbb{R} \cup \{\infty\}$, the circles through z orthogonal to $\mathbb{R}$ are precisely those centred on $\mathbb{R}$, and they all pass through $\bar{z}$ and through no other common point; so $J_{\mathbb{R} \cup \{\infty\}}(z) = \bar{z}$. For general Γ , choose $T \in \text{Möb}$ with $T(\mathbb{R} \cup \{\infty\}) = \Gamma$; since Möbius maps preserve circles and angles, they preserve the inversion relation, so

$$J_\Gamma = T \circ (z \mapsto \bar{z}) \circ T^{-1}.$$

Inversion in a straight line is ordinary reflection; inversion in the unit circle is $z \mapsto 1/\bar{z}$. Inversions fix Γ pointwise and swap its two sides, and the composite of two inversions is a Möbius map (conjugating twice removes the conjugations: if $T(z) = \frac{az+b}{cz+d}$, then $z \mapsto \overline{T(\bar{z})} = \frac{\bar{a}z+\bar{b}}{\bar{c}z+\bar{d}}$ is again Möbius).

Theorem 14.7.10

The isometry group of the hyperbolic plane is generated by inversions in hyperbolic

lines; the orientation-preserving isometries are exactly $\text{Möb}(\mathbb{H})$.

Proof. We work in the disc model. First, inversions in hyperbolic lines are isometries: inversion in the diameter $\mathbb{R} \cap D$ is $z \mapsto \bar{z}$, which preserves g_{hyp} ; and a general hyperbolic line is the image of $\mathbb{R} \cap D$ under some $T \in \text{Möb}(D)$, so inversion in it is $T \circ (z \mapsto \bar{z}) \circ T^{-1}$, a composite of isometries.

Now let α be any isometry of (D, g_{hyp}) . Choose $T \in \text{Möb}(D)$ with $T(\alpha(0)) = 0$, so $T \circ \alpha$ is an isometry fixing 0. An isometry fixing 0 permutes the geodesics through 0, i.e. the diameters, and preserves angles up to sign; composing with a rotation R we may assume $R \circ T \circ \alpha$ fixes 0 and maps the positive real radius $D \cap \mathbb{R}_+$ to itself (using that isometries preserve $d_{\text{hyp}}(0, \cdot)$, which is a strictly increasing function of $|z|$, so points of $D \cap \mathbb{R}_+$ go to points at the same radius). Composing if necessary with conjugation $C : z \mapsto \bar{z}$, we get an isometry β fixing 0, fixing $D \cap \mathbb{R}_+$ pointwise (again since distances from 0 are preserved), and preserving the upper half of the disc. We claim $\beta = \text{Id}$: any point $w \in D$ is determined by its distances to three non-collinear points of $D \cap \mathbb{R}$ together with the side of $\mathbb{R}$ it lies on – distances to two points of the fixed diameter determine w up to reflection. So $\alpha = (C) \circ (R \circ T)^{-1}$ or $(R \circ T)^{-1}$, a composite of Möbius maps in $\text{Möb}(D)$ and possibly one conjugation. Since elements of $\text{Möb}(D)$ are themselves composites of (two or four) inversions – this is an exercise on the example sheets, mirroring the Euclidean fact that rotations and translations are composites of two reflections – the full isometry group is generated by inversions. And an orientation-preserving isometry must involve an even number of inversions, hence lies in $\text{Möb}(D)$. $\square$

It is worth recording the trichotomy of non-identity orientation-preserving isometries, in analogy with rotations and translations of the Euclidean plane. Any $\alpha \in \text{Möb}(\mathbb{H})$, $\alpha \neq \text{Id}$, extends to the closed disc (or closed half-plane) and has a fixed point there, and is exactly one of:

- (i) **elliptic**: α fixes a point $p \in \mathbb{H}$. Conjugating so $p = 0 \in D$, α is a rotation $z \mapsto e^{i\theta}z$ – hyperbolic rotations about p .
- (ii) **parabolic**: α fixes exactly one point of the boundary $\partial\mathbb{H}$ and none of $\mathbb{H}$. Conjugating so the fixed point is $\infty \in \partial\mathbb{H}$, α is $z \mapsto z + b$.
- (iii) **hyperbolic**: α fixes exactly two points of $\partial\mathbb{H}$. It then preserves the hyperbolic line joining them (its *axis*) and translates along it; conjugating so the fixed points are $0, \infty \in \partial\mathbb{H}$, α is $z \mapsto \lambda z$ with $\lambda > 0$.

There is a corresponding trichotomy for pairs of hyperbolic lines ℓ, ℓ' : they are **intersecting** if they meet in $\mathbb{H}$; **parallel** if they meet only ‘at infinity’, i.e. their closures share a boundary point; and **ultraparallel** if their closures are disjoint. Given a hyperbolic line ℓ and $p \notin \ell$, there are exactly two lines through p parallel to ℓ (one for each end of ℓ), and a continuum of lines through p ultraparallel to ℓ – so the parallel postulate fails as extravagantly as possible.

§14.7.4 Hyperbolic Triangles

Definition 14.7.11 (Hyperbolic Triangle)

A **hyperbolic triangle** is a region of $\mathbb{H}$ bounded by three hyperbolic line segments,

meeting pairwise in three vertices. We allow vertices to lie on the boundary $\partial\mathbb{H}$ (where the two sides meet at angle 0); such vertices are called **ideal**, and a triangle with all three vertices ideal is an **ideal triangle**.

We adopt the classical labelling: side lengths A, B, C , with opposite angles α, β, γ at vertices a, b, c . Since the hyperbolic metric is conformal, hyperbolic angles are just Euclidean angles in either model. Here is a hyperbolic triangle in the disc model – note how the sides bow inwards, pinching the angles:

As the picture suggests, the angles of a hyperbolic triangle sum to *less* than π ; we will prove this precisely with the area formula below. First, the hyperbolic law of cosines, which controls the metric side of the story.

Proposition 14.7.12 (Hyperbolic Cosine Rule)

For a hyperbolic triangle with the labelling above,

$$\cosh C = \cosh A \cosh B - \sinh A \sinh B \cos \gamma.$$

Proof. Applying an isometry, we may place the vertex c at 0 in the disc model and the vertex b on the positive real axis; then the sides through c are Euclidean radii, meeting at (Euclidean, hence hyperbolic) angle γ at the origin. From $d_{\text{hyp}}(0, z) = 2 \operatorname{artanh} |z|$, the vertices are

$$b = \tanh \frac{A}{2} \in \mathbb{R}_+, \quad a = e^{i\gamma} \tanh \frac{B}{2},$$

(the side ca has length B since it is opposite b , and so on), and the distance formula gives

$$\tanh \frac{C}{2} = \left| \frac{a - b}{1 - \bar{a}b} \right|.$$

Now use the identities, for $t = \tanh \frac{\lambda}{2}$,

$$\cosh \lambda = \frac{1 + t^2}{1 - t^2}, \quad \sinh \lambda = \frac{2t}{1 - t^2}.$$

So

$$\cosh C = \frac{|1 - \bar{a}b|^2 + |a - b|^2}{|1 - \bar{a}b|^2 - |a - b|^2}.$$

Expanding the numerator and denominator,

$$|1 - \bar{a}b|^2 \pm |a - b|^2 = 1 - \bar{a}b - a\bar{b} + |a|^2|b|^2 \pm (|a|^2 - \bar{a}b - a\bar{b} + |b|^2)$$

$$= \begin{cases} (1 + |a|^2)(1 + |b|^2) - 2(\bar{a}b + a\bar{b}) & (+) \\ (1 - |a|^2)(1 - |b|^2) & (-) \end{cases}$$

Since $b \in \mathbb{R}$ and $\bar{a}b + a\bar{b} = 2b \operatorname{Re} a = 2|a|b \cos \gamma$, we get

$$\begin{aligned} \cosh C &= \frac{(1 + |a|^2)(1 + |b|^2)}{(1 - |a|^2)(1 - |b|^2)} - \frac{2|a|}{1 - |a|^2} \cdot \frac{2b}{1 - |b|^2} \cos \gamma \\ &= \cosh A \cosh B - \sinh A \sinh B \cos \gamma, \end{aligned}$$

reading off the hyperbolic functions of A and B via the identities above (note $|b| = \tanh \frac{A}{2}$, $|a| = \tanh \frac{B}{2}$). $\square$

Remark. For small A, B, C , using $\cosh \lambda \approx 1 + \frac{\lambda^2}{2}$ and $\sinh \lambda \approx \lambda$ and keeping second order terms, the formula degenerates to

$$C^2 \approx A^2 + B^2 - 2AB \cos \gamma,$$

the Euclidean cosine rule – at small scales, hyperbolic geometry looks Euclidean, as it must since any Riemannian metric is approximately flat at small scales. Also, since $\cos \gamma \geq -1$,

$$\cosh C \leq \cosh A \cosh B + \sinh A \sinh B = \cosh(A + B),$$

and $\cosh$ is increasing on $\mathbb{R}_{\geq 0}$, so $C \leq A + B$: the triangle inequality, with a sharper quantitative form.

§14.7.5 The Area of a Hyperbolic Triangle

We now come to the hyperbolic counterpart of the spherical triangle theorem (Theorem 14.5.12) – the Gauss–Bonnet theorem for hyperbolic triangles.

Theorem 14.7.13 (Gauss–Bonnet for Hyperbolic Triangles)

Let $T \subseteq \mathbb{H}$ be a hyperbolic triangle with internal angles α, β, γ (with angle 0 at any ideal vertex). Then

$$\operatorname{area}_{\text{hyp}}(T) = \pi - \alpha - \beta - \gamma.$$

In particular the angle sum of a hyperbolic triangle is always strictly less than π , and no triangle has area exceeding π .

Proof. Step 1: ideal triangles. $\operatorname{Möb}(\mathbb{H})$ (together with an inversion if needed) acts transitively on triples of distinct boundary points, so all ideal triangles are isometric and we may compute with the ideal triangle in $\mathfrak{h}$ with vertices $-1, 1, \infty$ – the region above the unit semicircle between the vertical lines $x = \pm 1$:

The hyperbolic area element is $\sqrt{EG - F^2} \, dx \, dy = \frac{1}{y^2} \, dx \, dy$, so

$$\text{area}(T) = \int_{-1}^1 \int_{\sqrt{1-x^2}}^{\infty} \frac{dy}{y^2} \, dx = \int_{-1}^1 \frac{dx}{\sqrt{1-x^2}} = \pi = \pi - 0 - 0 - 0,$$

as claimed for ideal triangles.

Step 2: triangles with two ideal vertices. Let $A(\alpha)$ denote the area of a triangle with angles $\alpha, 0, 0$; this is well defined, as such triangles are determined up to isometry by α (put the vertex at $0 \in D$ with one side along $\mathbb{R}_+$; the ideal vertices are then determined). Sliding the finite vertex continuously shows A is continuous, and A is decreasing in α since a triangle of larger angle sits inside one of smaller angle with the same ideal vertices. Now consider the configuration of a triangle with angle $\alpha + \beta$ split by a hyperbolic line into triangles of angles α and β , with all other vertices ideal: comparing areas of the four triangles formed by the lines in that figure yields the identity

$$A(\alpha) + A(\beta) = \pi + A(\alpha + \beta).$$

(One can see this cleanly in $\mathfrak{h}$: the triangle $\{-1, 1, \infty\}$ is divided by the vertical line through a point $e^{i\theta}$ of the unit semicircle into two triangles with two ideal vertices each.) Setting $F(\alpha) = \pi - A(\alpha)$, this reads $F(\alpha) + F(\beta) = F(\alpha + \beta)$; F is continuous and monotonic, so $F(\alpha) = \lambda\alpha$ for some constant $\lambda > 0$. Finally the two triangles with angles α and $\pi - \alpha$ obtained by cutting a ‘bigon’ with both vertices ideal along a line satisfy $A(\alpha) + A(\pi - \alpha) = \pi$; substituting gives $\lambda = 1$. So

$$A(\alpha) = \pi - \alpha.$$

Step 3: one ideal vertex. Next consider a triangle T_1 with one ideal vertex w and finite vertices a, b with angles α, β . Extend the side from a through b to an ideal point u . The triangle auw has two ideal vertices and angle α at a , so has area $A(\alpha) = \pi - \alpha$, and it decomposes as T_1 together with the triangle buw , which has two ideal vertices and angle $\pi - \beta$ at b . Hence

$$\pi - \alpha = \text{area}(T_1) + A(\pi - \beta) = \text{area}(T_1) + \beta \implies \text{area}(T_1) = \pi - \alpha - \beta.$$

Step 4: general triangles. Finally let T have finite vertices a, b, c with angles α, β, γ . Extend the side from a through b to an ideal point u , and consider the triangle auc : it has one ideal vertex, angle α at a , and angle $\gamma + \delta$ at c , where δ is the angle of the triangle buc at c . By Step 3,

$$\text{area}(auc) = \pi - \alpha - (\gamma + \delta),$$

while the triangle buc has one ideal vertex, angle $\pi - \beta$ at b and angle δ at c , so

$$\text{area}(buc) = \pi - (\pi - \beta) - \delta = \beta - \delta.$$

Since auc decomposes as $T \cup buc$,

$$\text{area}(T) = (\pi - \alpha - \gamma - \delta) - (\beta - \delta) = \pi - \alpha - \beta - \gamma. \quad \square$$

Corollary 14.7.14 (Hyperbolic Polygons)

A **geodesic n -gon** in $\mathbb{H}$ – a disc bounded by n hyperbolic segments – with internal angles $\alpha_1, \dots, \alpha_n$ has area

$$(n-2)\pi - \sum_{i=1}^n \alpha_i.$$

Proof. Cut the polygon into $n-2$ triangles by geodesic diagonals (possible since any two points of $\mathbb{H}$ are joined by a unique geodesic) and sum the triangle formula. $\square$

Compare our three geometries: a triangle with angles α, β, γ has

$$\text{area} = (\alpha + \beta + \gamma) - \pi \text{ on } S^2, \quad \alpha + \beta + \gamma = \pi \text{ on } \mathbb{R}^2, \quad \text{area} = \pi - (\alpha + \beta + \gamma) \text{ on } \mathbb{H},$$

which is exactly the statement $\int_T \kappa \, dA = (\alpha + \beta + \gamma) - \pi$ with $\kappa \equiv 1, 0, -1$ respectively. In particular the hyperbolic plane has constant curvature -1 , as promised (and this can be checked directly: the half-plane metric is $\frac{1}{y^2}(dx^2 + dy^2)$, and the formula for the curvature of a conformal metric gives $\kappa \equiv -1$).

§14.7.6 Hyperbolic Surfaces

We built a flat metric on the torus by gluing the sides of a Euclidean square. The same idea, run in the hyperbolic plane, produces metrics of constant curvature -1 on all surfaces of genus at least 2 – so every compact orientable surface carries one of our three geometries: S^2 carries spherical geometry, T^2 flat geometry, and everything else hyperbolic geometry.

Recall that the surface Σ_g of genus g is obtained from a $4g$ -gon by gluing its edges in the pattern $a_1 b_1 a_1^{-1} b_1^{-1} \cdots a_g b_g a_g^{-1} b_g^{-1}$; for $g = 2$:

(Each label is traversed once in each direction; all eight vertices are identified to a single point of Σ_2 .)

To copy the flat torus construction we need the polygon to be a *hyperbolic* polygon, and for a smooth structure at the glued vertex we need the interior angles to add up to exactly 2π .

Lemma 14.7.15

For each $g \geq 2$ there is a regular hyperbolic $4g$ -gon with all internal angles equal to $\frac{2\pi}{4g} = \frac{\pi}{2g}$.

Proof. Place the vertices at the points $r\omega^k$, $k = 0, \dots, 4g - 1$, in the disc model, where $\omega = e^{2\pi i/4g}$ and $r \in (0, 1)$, joined by hyperbolic segments; by symmetry this is a regular hyperbolic $4g$ -gon with some internal angle $\beta(r)$. As $r \rightarrow 1$ the polygon converges to the *ideal* regular $4g$ -gon, with all angles 0; as $r \rightarrow 0$, small hyperbolic polygons are nearly Euclidean, so $\beta(r)$ tends to the Euclidean regular $4g$ -gon angle $\frac{(4g-2)\pi}{4g}$. The angle $\beta(r)$ varies continuously, so by the intermediate value theorem it takes the value $\frac{\pi}{2g}$ for some r , since

$$0 < \frac{\pi}{2g} < \frac{(4g-2)\pi}{4g} \iff 2 < 4g - 2,$$

which holds exactly when $g \geq 2$ (this is where genus ≥ 2 is needed – for the torus, $g = 1$, the required angle $\pi/2$ is not available for hyperbolic squares, whose angles are strictly less than $\pi/2$... consistent with the torus being flat rather than hyperbolic). $\square$

Theorem 14.7.16

For every $g \geq 2$, the compact orientable surface Σ_g of genus g admits a Riemannian metric locally isometric to $\mathbb{H}$; in particular it has constant curvature $\kappa \equiv -1$.

Proof (sketch). Take the regular hyperbolic $4g$ -gon P of Lemma 14.7.15 with angles $\frac{\pi}{2g}$, with edges labelled and oriented in the pattern $a_1 b_1 a_1^{-1} b_1^{-1} \dots$. For each pair of edges to be glued there is a hyperbolic isometry carrying one to the other, respecting the orientations and exchanging the sides of the edges (isometries act transitively on ‘flags’ – a point on an oriented line together with a choice of side). Now define $\Sigma_g = P / \sim$ as a topological surface (as in Section 1), and give it charts as follows:

- (i) at the image of an interior point of P , take a small hyperbolic disc inside P , included into $\mathbb{H}$;
- (ii) at the image of an edge point, combine a half-disc at the point with the half-disc at the paired point, transported by the gluing isometry; the two half-discs assemble to an honest disc in $\mathbb{H}$;
- (iii) at the single vertex of Σ_g : the $4g$ corners of P have angles summing to $4g \cdot \frac{\pi}{2g} = 2\pi$, so transporting them by gluing isometries, they fit together exactly around a point of $\mathbb{H}$, forming a disc.

All transition maps between these charts are restrictions of hyperbolic isometries, which are smooth and preserve g_{hyp} . So the locally-defined hyperbolic metrics agree on overlaps and define a Riemannian metric on Σ_g , locally isometric to $\mathbb{H}$ by construction. $\square$

Remark. The quotient description of the flat torus as $\mathbb{R}^2/\mathbb{Z}^2$ has a hyperbolic analogue: the side-pairing isometries generate a subgroup $\Gamma \leq \text{Möb}(\mathbb{H})$, and $\Sigma_g = \mathbb{H}/\Gamma$. This point of view is developed properly in Part II *Algebraic Topology*. There is also a more flexible cut-and-paste construction, assembling Σ_g from $2g - 2$ hyperbolic ‘pairs of pants’ – three-holed spheres with geodesic boundary, themselves glued from two right-angled hyperbolic hexagons – which exhibits many essentially different hyperbolic metrics on the same surface. The space of such metrics, the *moduli space*, is among the most-studied

objects in geometry.

§14.8 The Gauss–Bonnet Theorem

We have now seen the same phenomenon three times: on the sphere, the plane and the hyperbolic plane, the failure of a triangle's angles to sum to π is exactly the integral of the curvature over the triangle. This is no coincidence, and its vast generalisation – the Gauss–Bonnet theorem – is the crowning result of the course: it says that curvature, a purely local quantity, integrates up to a purely *topological* one.

Throughout this section, curvature on an abstract surface with a Riemannian metric means the expression from the Theorema Egregium discussion: in geodesic normal coordinates ($E = 1$, $F = 0$),

$$\kappa = -\frac{(\sqrt{G})_{uu}}{\sqrt{G}},$$

which makes sense for any Riemannian metric, embedded or not, and agrees with $\det(Dn)$ for surfaces in $\mathbb{R}^3$. (Geodesic normal coordinates exist in the abstract setting by the same Picard argument as before – the geodesic equations never mentioned the embedding.)

§14.8.1 The Local Gauss–Bonnet Theorem

Definition 14.8.1 (Geodesic Polygon)

A **geodesic n -gon** on a surface Σ with a Riemannian metric is an open region $R \subseteq \Sigma$ homeomorphic to a disc, whose boundary is a piecewise smooth closed curve made up of n geodesic arcs, meeting at n vertices with internal angles $\alpha_1, \dots, \alpha_n \in (0, 2\pi)$.

Theorem 14.8.2 (Local Gauss–Bonnet Theorem)

Let Σ be an abstract smooth surface with Riemannian metric g , and let $R \subseteq \Sigma$ be a geodesic n -gon with internal angles $\alpha_1, \dots, \alpha_n$. Then

$$\int_R \kappa \, dA = \sum_{i=1}^n \alpha_i - (n-2)\pi.$$

For $n = 3$ this is exactly ‘ $\int_T \kappa \, dA$ equals the angle excess’, generalising Theorems 14.5.12 and 14.7.13 simultaneously. It is essential that R is a disc: the theorem fails for regions with holes (as we will see below, this failure is precisely what makes the global theorem interesting).

We will not give a complete proof, but the mechanism deserves to be seen, because it is exactly Green's theorem from Vector Calculus. This discussion is non-examinable. Suppose for simplicity that R lies in the image of a single parametrisation in geodesic normal coordinates, so $E = 1$, $F = 0$, and let

$$e = \sigma_u, \quad f = \frac{\sigma_v}{\sqrt{G}}$$

be the resulting orthonormal frame of the tangent planes. Parametrise ∂R by arc length and consider

$$I = \int_{\partial R} \langle e, \dot{f} \rangle dt.$$

On one hand, writing $\dot{f} = f_u \dot{u} + f_v \dot{v}$ and setting $P = \langle e, f_u \rangle$, $Q = \langle e, f_v \rangle$, Green's theorem gives

$$I = \int_{\partial R} P du + Q dv = \int_R (Q_u - P_v) du dv,$$

and a direct computation using the orthonormality relations shows

$$Q_u - P_v = \langle e_u, f_v \rangle - \langle e_v, f_u \rangle = -(\sqrt{G})_{uu} = \kappa \sqrt{G},$$

where $\sqrt{G} = \sqrt{EG - F^2}$ is exactly the area element – so $I = \int_R \kappa dA$. On the other hand, let $\theta(t)$ be the angle from e to the tangent $\dot{\gamma}$ of the boundary, so $\dot{\gamma} = \cos \theta e + \sin \theta f$. Along a geodesic arc, differentiating and using $\langle \ddot{\gamma}, -\sin \theta e + \cos \theta f \rangle = 0$ (the acceleration has no tangential component) together with orthonormality yields

$$\dot{\theta} = \langle e, \dot{f} \rangle.$$

So I also computes the total rotation of the boundary direction relative to the frame, which for a piecewise-geodesic boundary of a disc is 2π minus the sum of the exterior angles:

$$I = 2\pi - \sum_{i=1}^n (\pi - \alpha_i) = \sum_i \alpha_i - (n-2)\pi.$$

Equating the two computations of I gives the theorem.

§14.8.2 The Global Gauss–Bonnet Theorem

Theorem 14.8.3 (Global Gauss–Bonnet Theorem)

Let Σ be a compact abstract smooth surface with Riemannian metric g . Then

$$\int_{\Sigma} \kappa dA = 2\pi \chi(\Sigma),$$

where $\chi(\Sigma)$ is the Euler characteristic.

Pause on what this says. The left-hand side depends on the metric – deform the surface, and κ changes pointwise, drastically. The right-hand side is a topological invariant, a difference of counts of vertices, edges and faces. The theorem says all the local changes in curvature miraculously cancel: *total* curvature cannot be changed by any deformation whatsoever. For instance, however you dent a sphere, extra negative curvature in the dent is exactly balanced by positive curvature around its rim.

The global theorem follows from the local one, given one plausible (but nontrivial) fact whose proof, via the exponential map, belongs to Part II:

Lemma 14.8.4

A compact surface with a Riemannian metric admits subdivisions all of whose faces are geodesic polygons.

Proof of Theorem 14.8.3. Take such a subdivision, with V vertices, E edges and F faces. Summing the local Gauss–Bonnet theorem over all faces,

$$\int_{\Sigma} \kappa \, dA = \sum_{\text{faces } P} \int_P \kappa \, dA = \sum_{\text{faces } P} \left(\sum_{\text{angles of } P} \alpha - (n_P - 2)\pi \right),$$

where n_P is the number of edges of the face P . Now:

- (i) The angles around each vertex sum to 2π , so summing all angles over all faces gives $2\pi V$.
- (ii) Each edge is an edge of exactly two faces, so $\sum_P n_P = 2E$.
- (iii) $\sum_P 2\pi = 2\pi F$.

Putting these together,

$$\int_{\Sigma} \kappa \, dA = 2\pi V - 2\pi E + 2\pi F = 2\pi \chi(\Sigma). \quad \square$$

Remark. Note the pleasing corollary in the other direction: since $\int_{\Sigma} \kappa \, dA$ manifestly does not depend on any choice of subdivision, the Gauss–Bonnet theorem re-proves that the Euler characteristic is independent of the subdivision – for surfaces admitting a Riemannian metric, which is all of them.

Let’s sanity-check the theorem against everything we have built.

Example 14.8.5 (The Sphere)

The round sphere of radius r has $\kappa \equiv 1/r^2$ and area $4\pi r^2$, so

$$\int_{S^2} \kappa \, dA = \frac{4\pi r^2}{r^2} = 4\pi = 2\pi \cdot 2 = 2\pi \chi(S^2).$$

Note that Gauss–Bonnet forbids a metric of $\kappa \leq 0$ on the sphere: any compact surface with non-positive curvature has $\chi \leq 0$.

Example 14.8.6 (The Flat Torus)

The flat torus of Example 14.6.3 has $\kappa \equiv 0$, so $\int \kappa \, dA = 0 = 2\pi \chi(T^2)$ – consistent with $\chi(T^2) = 0$. Conversely, Gauss–Bonnet shows any metric on T^2 must have total curvature zero; combined with Proposition 14.4.13, this gives another proof that a torus embedded in $\mathbb{R}^3$ must have regions of both positive and negative curvature.

Example 14.8.7 (Hyperbolic Surfaces)

The hyperbolic surface Σ_g ($g \geq 2$) built from the regular $4g$ -gon with angles $\frac{\pi}{2g}$ has

$\kappa \equiv -1$, and its total area is the area of the polygon,

$$\text{area}(\Sigma_g) = (4g - 2)\pi - 4g \cdot \frac{\pi}{2g} = (4g - 4)\pi,$$

by the hyperbolic polygon area formula. So

$$\int_{\Sigma_g} \kappa \, dA = -(4g - 4)\pi = 2\pi(2 - 2g) = 2\pi\chi(\Sigma_g),$$

in perfect agreement. In fact Gauss–Bonnet shows that *every* metric of curvature -1 on Σ_g has the same total area $(4g - 4)\pi$ – a first hint of the rigidity of hyperbolic geometry.

Example 14.8.8 (Closed Geodesics Bounding Discs)

Let Σ be a surface with $\kappa \equiv 0$ (say the flat torus) and suppose γ is a closed geodesic bounding a smooth disc R . Marking two points of γ as vertices makes R a geodesic 2-gon with both internal angles equal to π , and the local Gauss–Bonnet theorem would give

$$0 = \int_R \kappa \, dA = (\pi + \pi) - (2 - 2)\pi = 2\pi,$$

a contradiction. So on a flat surface, no closed geodesic bounds a disc – every closed geodesic on the flat torus must wrap around the torus. Contrast the sphere, where great circles bound hemispheres: there positive curvature supplies the missing 2π .

§14.8.3 Flat Metrics on the Torus

We close with a brief look at a question the course has equipped us to pose: *how many* geometries can a given surface carry? Take the simplest interesting case, flat metrics on T^2 .

The construction of Example 14.6.3 works for any parallelogram, not just the unit square: if $Q \subseteq \mathbb{R}^2$ is the parallelogram spanned by linearly independent v_1, v_2 , then $T^2 = \mathbb{R}^2 / (\mathbb{Z}v_1 \oplus \mathbb{Z}v_2)$ inherits a flat metric g_Q , of total area equal to the Euclidean area of Q . Different parallelograms can give genuinely different geometries:

Lemma 14.8.9

The flat tori built from $Q = [0, 1]^2$ and $\hat{Q} = [0, 10] \times [0, \frac{1}{10}]$ have equal area but are not isometric.

Proof. Geodesics on a flat torus are exactly the images of straight lines in $\mathbb{R}^2$ (the charts are local isometries with $\mathbb{R}^2$, and Picard uniqueness means there are no others). A line through a lift $\hat{p}$ of p descends to a *closed* geodesic exactly when it passes through another lift of p , i.e. has rational slope with respect to the lattice. The shortest closed geodesic therefore has length equal to the shortest nonzero lattice vector: 1 for $\mathbb{Z}^2$, but $\frac{1}{10}$ for $10\mathbb{Z} \oplus \frac{1}{10}\mathbb{Z}$. Isometries preserve the set of lengths of closed geodesics, so the tori are not isometric. $\square$

To organise all flat tori, normalise: rotating, reflecting and dilating Q (which changes

the metric only by a global isometry and scale), we can take $v_1 = 1 \in \mathbb{C}$ and $v_2 = \tau$ with $\text{Im } \tau > 0$. So the upper half-plane $\mathfrak{h}$ – of all places! – parametrises flat metrics on T^2 up to scale. Two parameters τ, τ' give isometric tori (by an orientation-preserving diffeomorphism) exactly when the lattices agree after rotation, which happens exactly when

$$\tau' = \frac{a\tau + b}{c\tau + d} \quad \text{for some} \quad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \text{SL}(2, \mathbb{Z}),$$

the subgroup $\text{SL}(2, \mathbb{Z}) \leq \text{SL}(2, \mathbb{R})$ acting on $\mathfrak{h}$ by Möbius maps as in the previous section. One obtains:

Theorem 14.8.10

The set of flat metrics on T^2 , up to dilation and orientation-preserving diffeomorphism, is in natural bijection with the quotient $\mathfrak{h}/\text{SL}(2, \mathbb{Z})$.

The quotient $\mathfrak{h}/\text{SL}(2, \mathbb{Z})$ is called the **moduli space** of flat tori, and it is a remarkable object: a question purely about *flat* geometry is answered by a quotient of the *hyperbolic* plane. The analogous moduli spaces of hyperbolic metrics on Σ_g for $g \geq 2$ are central objects of modern geometry.

Where Next

Several Part II courses pick up where these notes leave off. *Algebraic Topology* proves the classification of surfaces and the topological invariance of χ , and constructs $\Sigma_g = \mathbb{H}/\Gamma$ properly. *Differential Geometry* develops the second fundamental form further (the trace of Dn , the mean curvature, governs soap films as the determinant governs Gauss–Bonnet). *Riemann Surfaces* studies surfaces through complex analysis, where $\text{Möb}(D)$ reappears as the automorphism group of the disc. And *General Relativity* takes the idea that geometry is encoded in a metric and its geodesics, and applies it to spacetime itself.

15 Groups, Rings and Modules

In this course we will continue our study of groups, focusing on simple groups, p -groups and p -subgroups along with the Sylow theorems. We will then move on to discuss rings and fields, finishing up by discussing modules where the scalars belong to a ring instead of a field.

This article constitutes my notes for the ‘Groups, Rings and Modules’ course, held in Lent 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§15.1 The Theory of Groups

§15.1.1 Definition of a Group

We will begin by recalling the basic definition of a group.

Definition 15.1.1 (Group)

A **group** is a pair $(G, *)$ consisting of a set G and a binary operation $* : G \times G \rightarrow G$ satisfying the axioms:

- *Identity.* There is an element $e \in G$ such that $e * g = g * e = g$ for all $g \in G$,
- *Inverses.* For every element $g \in G$, there is an element $g^{-1} \in G$ such that $g * g^{-1} = g^{-1} * g = e$.
- *Associativity.* The operation $*$ is associative.

Remark. We will usually either use additive or multiplicative notation for groups, and in these cases we will often write 0 or 1 for the identity respectively.

Definition 15.1.2 (Subgroup)

A subset $H \subseteq G$ is a **subgroup** of G , written $H \leq G$, if it is a group with respect to the operation $*$ defined on $H \times H$.

There is a way to test the conditions needed for a subset to be a subgroup in just a few lines, but it does have limited utility.

Lemma 15.1.3 (Fast Subgroup Checking)

A nonempty subset $H \subseteq G$ is a subgroup if $a, b \in H$ implies $a * b^{-1} \in H$.

Proof Sketch. Check that this implies the definition. □

Example 15.1.4 (Examples of Groups)

The following are all examples of groups.

- (i) The additive groups $(\mathbb{Z}, +) \leq (\mathbb{Q}, +) \leq (\mathbb{R}, +)$.
- (ii) The cyclic group of order n , C_n .
- (iii) The dihedral group D_{2n} of the symmetries of a regular n -gon.
- (iv) The symmetric group S_n and alternating group A_n , where S_n is the group of permutations of $\{1, 2, \dots, n\}$ and $A_n \leq S_n$ is the group of even permutations.
- (v) The quaternion group $Q_8 = \{\pm 1, \pm i, \pm j, \pm k\}$ with $i^2 = j^2 = k^2 = ijk = -1$.
- (vi) The matrix groups over some field F , $\text{GL}_n(F)$ of all $n \times n$ matrices over F with non-zero determinant, and $\text{SL}_n(F) \leq \text{GL}_n(F)$, the subgroup of matrices with determinant 1.

Definition 15.1.5 (Direct Product)

The **direct product** of groups G and H is $G \times H$ with operation $(g_1, h_1) * (g_2, h_2) = (g_1 g_2, h_1 h_2)$.

§15.1.2 Lagrange's Theorem

For a subgroup $H \leq G$, the **left cosets** of H in G are the sets $gH = \{gh \mid h \in H\}$ where $g \in G$. The left cosets partition G , and it is straightforward to show that each has the same cardinality as H . These facts immediately give us *Lagrange's theorem*.

Theorem 15.1.6 (Lagrange's Theorem)

If G is a finite group and $H \leq G$, then

$$|G| = |H| \cdot |G : H|,$$

where $|G : H|$ is the **index** of H in G , the number of left cosets of H in G .

Remark. The proof of Lagrange's theorem is equally valid when using right cosets, and as a consequence there is always the same number of left and right cosets for a given subgroup.

Definition 15.1.7 (Order of an Element)

Let G be a group and $g \in G$. The least n such that $g^n = 1$ is the **order** of g . If no such n exists, we say that g has **infinite order**.

Remark. If g has order d , then the division algorithm implies $g^n = 1 \iff d \mid n$. Also by taking powers we can generate a cyclic subgroup of G with $\{1, g, g^2, \dots, g^{d-1}\} \leq G$, so if G is finite then by Lagrange, $d \mid |G|$.

§15.1.3 Homomorphisms and Isomorphisms

As with many mathematical objects, there are many instances in which we are interested in the structure preserving maps between groups. Such maps are called *homomorphisms*.

Definition 15.1.8 (Homomorphism)

If G and H are groups, a function $\phi : G \rightarrow H$ is a **group homomorphism** if $\phi(g_1g_2) = \phi(g_1)\phi(g_2)$ for all $g_1, g_2 \in G$.

We frequently care about what elements in the group H can be obtained through this map, and also what elements in G just get sent to the identity.

Definition 15.1.9 (Kernel)

The **kernel** of ϕ is $\ker(\phi) = \{g \in G \mid \phi(g) = e\}$.

Definition 15.1.10 (Image)

The **image** of ϕ is $\text{img}(\phi) = \{\phi(g) \mid g \in G\}$.

It is straightforward to see that $\ker(\phi) \leq G$ and $\text{img}(\phi) \leq H$.

When we have a homomorphism that gives a bijection between two groups, the groups must have the same underlying algebraic structure. For this reason, we take this to be a notion of two groups being the same.

Definition 15.1.11 (Isomorphism)

We say that two groups G and H are **isomorphic** written $G \cong H$ if there is an *isomorphism* between them. That is, if there is a bijective homomorphism $\phi : G \rightarrow H$ between the groups.

§15.1.4 Quotient Groups and the Isomorphism Theorems

Quotient groups arise naturally in the study of homomorphisms. When we have two groups G and H , and some homomorphism $\varphi : G \rightarrow H$, we can see that the elements of G mapping to certain elements of H naturally arrange themselves together.

Indeed, if two elements of G map to the same element of H under φ , we would find that the two elements must differ by an element of the kernel of φ . So, going back to how the elements of G arrange themselves, it would seem that they are arranged into cosets of the kernel of φ . It is this observation that leads us to the definition of quotient groups and the isomorphism theorems.

From the discussion above, it is natural to see when we can make the cosets of a given subgroup into another group. It turns out that this only works when we have a specific type of subgroup.

Definition 15.1.12 (Normal Subgroup)

We say that a subgroup N of a group G is **normal** if the left and right cosets coincide, that is, $gN = Ng$ for all $g \in G$. If N is normal in G we write $N \trianglelefteq G$.

Now we can show that the set of cosets of N in G , written G/N , forms a group.

Theorem 15.1.13 (Quotient Groups)

If $N \trianglelefteq G$, then the set of cosets of N in G forms the **quotient group** G/N with the operation of coset multiplication, where $gN \cdot g'N = (gg')N$.

Proof. We first need to check that coset multiplication is well defined. If we had $a_1N = a_2N$ and $b_1N = b_2N$, then $a_1 = a_2n_a$ and $b_1 = b_2n_b$ for some $n_a, n_b \in N$. Then $(a_1b_1)N = (a_2n_ab_2n_b)N = (a_2b_2)N$, since N is normal in G . So our group operation is well defined, and we are just left to check the group axioms.

We have closure since g_1N and g_2N being cosets implies $(g_1g_2)N$ is too. Then we have the identity element N , and inverses with $gN \cdot g^{-1}N = N$. Finally we get associativity inherited from G , thus we do indeed have a group. $\square$

Now we initially tried to motivate thinking about groups of cosets by noticing that elements in the same coset of the kernel of ϕ had the same image. We then used this ‘normal’ property of a subgroup to make this actually work. It turns out that these express the same idea – normal subgroups are *exactly* the kernels of homomorphisms.

Theorem 15.1.14 (Kernels are Normal Subgroups)

If $\phi : G \rightarrow H$ is a homomorphism, then $\ker \phi \trianglelefteq G$.

Proof. We already know that the kernel of a homomorphism is a subgroup, so we just need to check that it is normal. Let $n \in \ker \phi$, and $g \in G$. Then $\phi(gng^{-1}) = \phi(g)\phi(n)\phi(g^{-1}) = \phi(g)\phi(g^{-1}) = e$, thus $gng^{-1} \in \ker \phi$, so $\ker \phi \trianglelefteq G$ as required. $\square$

Theorem 15.1.15 (Normal Subgroups are Kernels)

Given $N \trianglelefteq G$, the map $\pi : G \rightarrow G/N$ with $\pi(g) = gN$ is a surjective homomorphism called the **quotient map**, and $\ker \pi = N$.

Proof. We first check that π is a homomorphism. For $g, h \in G$, we have $\pi(gh) = (gh)N = gN \cdot hN = \pi(g)\pi(h)$ as required. This map is clearly surjective, and also $\pi(g) = gN = N \iff g \in N$, so $\ker \pi = N$, as required. $\square$

Looking back again to our original motivation, we can see that the cosets of the kernel seem to form the group that is the image of the homomorphism. This is the exact idea encompassed in quotient groups, and is formalised in the *first isomorphism theorem*.

Theorem 15.1.16 (First Isomorphism Theorem)

Let $\phi : G \rightarrow H$ be a group homomorphism. Then $\ker(\phi) \trianglelefteq G$, and $G/\ker(\phi) \cong$

$\text{img}(\phi)$.

Proof. Let $K = \ker(\phi)$. We already checked that $K \trianglelefteq G$. Now define $\Phi : G/K \rightarrow \text{img}(\phi)$ by $gK \mapsto \phi(g)$.

We first check Φ is well defined and injective. We have

$$\begin{aligned} g_1K = g_2K &\iff g_2^{-1}g_1 \in K \\ &\iff \phi(g_2^{-1}g_1) = e \\ &\iff \phi(g_2)^{-1}\phi(g_1) = e \\ &\iff \phi(g_1) = \phi(g_2). \end{aligned}$$

Then we check that Φ is a group homomorphism, with

$$\begin{aligned} \Phi(g_1K g_2K) &= \Phi(g_1g_2K) \\ &= \phi(g_1g_2) \\ &= \phi(g_1)\phi(g_2) \\ &= \Phi(g_1K)\Phi(g_2K). \end{aligned}$$

Lastly we check that it is surjective. Let $x \in \text{img}(\phi)$, say $x = \phi(g)$ for some $g \in G$. Then $x = \Phi(gK) \in \text{img}(\Phi)$. $\square$

In a sense, this is the way that you should think about normal subgroups and quotient groups – as the kernels and images of homomorphisms.

Example 15.1.17 (Using the First Isomorphism Theorem)

Let $\phi : \mathbb{C} \rightarrow \mathbb{C}^*$ with $z \mapsto e^z$. As $e^{z+w} = e^z e^w$, this is a group homomorphism from $(\mathbb{C}, +)$ to $(\mathbb{C}^*, \times)$.

We find that $\ker(\phi) = \{z \in \mathbb{C} \mid e^z = 1\} = 2\pi i\mathbb{Z}$, and $\text{img}(\phi) = \mathbb{C}^*$. Thus $\mathbb{C}/2\pi i\mathbb{Z} \cong \mathbb{C}^*$.

With the first isomorphism theorem, it is not enough to know the statement and proof – you have to know when to employ it. For example, if asked to prove $\mathbb{C}/2\pi i\mathbb{Z} \cong \mathbb{C}^*$, you should be able to think of a strategy similar to the one used above.

The first isomorphism theorem is sometimes just called the ‘isomorphism theorem’, and it tends to be more important than the corollaries that we will state.

Corollary 15.1.18 (Second Isomorphism Theorem)

Let $H \leq G$ and $K \trianglelefteq G$. Then $HK = \{hk \mid h \in H, k \in K\} \leq G$ and $H \cap K \trianglelefteq H$, moreover $HK/K \cong H/H \cap K$.

Proof. Let $h_1k_1, h_2k_2 \in HK$. We have

$$\begin{aligned} h_1k_1(h_2k_2)^{-1} &= h_1k_1k_2^{-1}h_2^{-1} \\ &= h_1h_2^{-1}h_2k_1k_2^{-1}h_2^{-1} \\ &= (h_1h_2^{-1})(h_2k_1k_2^{-1}h_2^{-1}) \in HK, \end{aligned}$$

thus $HK \leq G$, as required.

Now let $\phi : H \mapsto G/K$ with $h \mapsto hK$. This is the composite of the inclusion $H \hookrightarrow G$ and the quotient map $G \rightarrow G/K$, thus ϕ is a group homomorphism.

We note $\ker(\phi) = \{h \in H \mid hK = K\} = H \cap K \trianglelefteq H$, and $\text{img}(\phi) = \{hK \mid h \in H\} = HK/K$. Thus by the first isomorphism theorem, $H/H \cap K \cong HK/K$. $\square$

Before we state the third isomorphism theorem, consider the following motivation. Suppose $K \trianglelefteq G$. There is a bijection

$$\{\text{subgroups of } G/K\} \longleftrightarrow \{\text{subgroups of } G \text{ containing } K\},$$

obtained by considering the maps $X \mapsto \{g \in G \mid gK \in X\}$ and $H \mapsto H/K$. This restricts to a bijection between

$$\{\text{normal subgroups of } G/K\} \longleftrightarrow \{\text{normal subgroups of } G \text{ containing } K\}.$$

In pictures, the portion of the subgroup lattice of G sitting above K matches the entire subgroup lattice of G/K .

$$\begin{array}{ccc} G & \longleftrightarrow & G/K \\ | & & | \\ H & \longleftrightarrow & H/K \\ | & & | \\ K & \longleftrightarrow & \{e\} \\ | & & \\ \{e\} & & \end{array}$$

Corollary 15.1.19 (Third Isomorphism Theorem)

Let $K \leq H \leq G$ be normal subgroups of G . Then

$$(G/K)/(H/K) \cong G/H.$$

Proof. Let $\phi : G/K \rightarrow G/H$ with $gK \mapsto gH$. If $g_1K = g_2K$, then $g_2^{-1}g_1 \in K \leq H$, so $g_1H = g_2H$, and thus ϕ is well defined. Also ϕ is a surjective group homomorphism with kernel $\ker(\phi) = H/K$. Then apply the first isomorphism. $\square$

§15.1.5 Simple Groups

If $K \trianglelefteq G$, then studying the groups K and the quotient group G/K gives some information about G . However, this approach is not always available.

Definition 15.1.20 (Simple Group)

A group G is **simple** if $\{e\}$ and G are its only normal subgroups.

Lemma 15.1.21 (Abelian Simple Groups)

An abelian group is simple if and only if it is isomorphic to C_p for some prime p .

Proof. By Lagrange's theorem, a subgroup $H \leq C_p$ has order dividing $|C_p| = p$, which is a prime. Hence H has order 1 or p , and H is either $\{e\}$ or $H = G$.

Now let G be an abelian simple group, and $g \in G$ with $g \neq e$. Note that any subgroup of an abelian group is normal, and thus G must have no subgroups other than G and $\{e\}$. But then G has subgroup $\langle g \rangle = \{\dots, g^{-2}, g^{-1}, e, g, g^2, \dots\}$. Since G is simple, this must be the whole group, that is, G is cyclic.

If G is the infinite cyclic group, then $G \cong (\mathbb{Z}, +)$, which is not simple (as $2\mathbb{Z} \leq \mathbb{Z}$). Thus $G \cong C_n$ for some n . Let g be a generator for C_n . If $m \mid n$, then $\langle g^{n/m} \rangle$ is a subgroup of order m , but G is simple thus $m = 1$ or n , hence n must be prime. $\square$

Lemma 15.1.22 (Composition Series of Finite Groups)

If G is a finite group then G has a composition series $\{e\} = G_0 \triangleleft G_1 \triangleleft G_2 \triangleleft \dots \triangleleft G_{m-1} \triangleleft G_m = G$, with each quotient G_i/G_{i-1} is simple.

[Note that G_i need not be normal in G .]

Proof. We induct on $|G|$. If $|G| = 1$ we are done. If $|G| > 1$, then let G_{m-1} be a normal subgroup of largest possible order (not $|G|$). Then G/G_{m-1} is simple, and by induction on G_{m-1} , we are done. $\square$

§15.2 Group Actions

A useful way to study a group is by studying how it 'acts' on some set. The way we look at this mathematically is through the lens of group actions.

§15.2.1 Definitions

We will begin by looking at groups of permutations of a set.

Definition 15.2.1 ($\text{Sym}(X)$)

For a set X , let $\text{Sym}(X)$ be the group of all bijections $X \rightarrow X$ under composition. We let the identity of this group be id .

Definition 15.2.2 (Permutation Group)

A group G is a **permutation group** (of degree n) if $G \leq \text{Sym}(X)$ (where $|X| = n$).

Example 15.2.3 (Examples of Permutation Groups)

The group $S_n = \text{Sym}(\{1, 2, \dots, n\})$ is a permutation group of degree n , as is the alternating group $A_n \leq S_n$.

The group D_n , the symmetries of a regular n -gon, is a permutation group as it is a subgroup of $\text{Sym}(\{\text{vertices of an } n\text{-gon}\})$.

We can now generalize the notion of a permutation group to the idea mentioned before

– slightly more useful (and general) than a permutation group is the notion of a group *acting* on a set.

Definition 15.2.4 (Group Action)

An action of a group G on a set X is a function $*$: $G \times X \rightarrow X$ satisfying

- (i) $e * x = x$ for all $x \in X$.
- (ii) $(g_1 g_2) * x = g_1 * (g_2 * x)$ for all $g_1, g_2 \in G$ and $x \in X$.

We can also think about group actions in the following way, and switching between the two points of view can be quite helpful.

Proposition 15.2.5

An action of a group G on a set X is equivalent to specifying a group homomorphism $\phi : G \rightarrow \text{Sym}(X)$.

Proof. For each $g \in G$, there is a function $\phi_g : X \rightarrow X$ given by $x \mapsto g * x$. We have $\phi_{g_1 g_2}(x) = (g_1 g_2) * x = g_1 * (g_2 * x) = \phi_{g_1}(\phi_{g_2}(x))$. Thus $\phi_{g_1 g_2} = \phi_{g_1} \circ \phi_{g_2}$.

In particular, $\phi_g \circ \phi_{g^{-1}} = \phi_{g^{-1}} \circ \phi_g = \phi_e = \text{id}$. Thus ϕ_g is a bijection, and $\phi_g \in \text{Sym}(X)$. We define $\phi : G \rightarrow \text{Sym}(X)$ with $g \mapsto \phi_g$. Then this is a group homomorphism by the above.

Conversely, let $\phi : G \rightarrow \text{Sym}(X)$ be a group homomorphism. Then defining $*$: $G \times X \rightarrow X$ with $(g, x) \mapsto \phi(g)(x)$, we have that this is a group action since $e * x = \phi(e)(x) = \text{id}(x) = x$ and $(g_1 g_2) * x = \phi(g_1 g_2)(x) = \phi(g_1)(\phi(g_2)(x)) = g_1 * (g_2 * x)$. $\square$

Definition 15.2.6 (Permutation Representation)

We say $\phi : G \rightarrow \text{Sym}(X)$ is a **permutation representation** of G .

§15.2.2 Orbits and Stabilisers

A useful notion is that of *orbits* and *stabilisers*. Informally, the orbit of an element x in a set S acted on by a group G is all of the elements that can be reached by applying elements of G . The stabiliser of x is the set of elements in G so that when we apply them, we still have the element x .

Definition 15.2.7 (Orbits and Stabilisers)

Let G act on a set X . The **orbit** of an element $x \in X$ is $\text{Orb}_G(x) = \{g * x \mid g \in G\}$, which is a subset of X . The **stabiliser** of $x \in X$ is $\text{Stab}_G(x) = \{g \in G \mid g * x = x\}$, which is a subgroup of G .

The orbits partition the set X . If there is only one orbit then we say that the group action is **transitive**. We recall the Orbit-Stabiliser theorem.

Theorem 15.2.8 (Orbit-Stabiliser Theorem)

There is a bijection between $\text{Orb}_G(x)$ and the set of left cosets of $\text{Stab}_G(x)$ in G . In particular, if G is finite, then

$$|G| = |\text{Orb}_G(x)| \cdot |\text{Stab}_G(x)|.$$

The picture to have in mind is the following: the cosets of $\text{Stab}_G(x)$ partition G , and all of the elements of a given coset $g \text{Stab}_G(x)$ move x to the *same* point $g * x$ of the orbit, with distinct cosets giving distinct points.

Remark. The kernel of ϕ , which can be written as $\ker \phi = \bigcap_{x \in X} \text{Stab}_G(x)$, is called the **kernel of the group action**. Also $\text{Stab}(g * x) = g \text{Stab}(x) g^{-1}$, so if $x, y \in X$ belong to the same orbit then their stabilisers are conjugate subgroups of G .

§15.2.3 Using Group Actions

In many cases, choosing the right group action can help make progress on a problem. With this in mind, it's helpful to have a list of standard group actions that you can apply.

Example 15.2.9 (Examples of Group Actions)

The following are all group actions.

- (i) Let G act on itself by left multiplication, with $g * x = gx$. The kernel of this action is $\{g \in G \mid gx = x\} = \{e\}$, and thus G injects into $\text{Sym}(G)$. This proves Cayley's theorem, that any finite group G is isomorphic to a subgroup of S_n for some n (say $n = |G|$).
- (ii) Let $H \leq G$. Then G acts on the left cosets of H in G by left multiplication. This group action is transitive, with $\text{Stab}_G(xH) = \{g \in G \mid gxH = xH\} = xHx^{-1}$. We have the kernel $\ker(\phi) = \bigcap_{x \in G} xHx^{-1}$, which is the largest normal subgroup of G contained in H .
- (iii) Let G act on itself by conjugation, so $g * x = gxg^{-1}$. Here, the orbits and stabilisers are $\text{Orb}_G(x) = \{gxg^{-1} \mid g \in G\} = \text{ccl}_G(x)$, the **conjugacy class** of x in G . The stabilisers are $\text{Stab}_G(x) = \{g \in G \mid gx = xg\} = C_G(x) \leq G$, the **centraliser** of x . The kernel of this action is the **center**, $Z(G) = \{g \in G \mid gx = xg \forall x \in G\}$.

G also acts by conjugation on any normal subgroup.

- (iv) Let X be the set of all subgroups of G . Then G acts on X by conjugation. That is, $g * H = gHg^{-1} \leq G$. The stabiliser of H is $\{g \in G \mid gHg^{-1} = H\} = N_G(H)$ is the **normaliser** of H in G . This is the largest subgroup of G to contain H as a normal subgroup. In particular $H \trianglelefteq G \iff N_G(H) = G$.

Of this last, the frequently useful actions (that you should readily reach for) are the left

multiplication of cosets, conjugation of elements and subgroups.

To see how we can apply group actions to proving a theorem, consider the following result (and mainly it's proof). Here we will use the action of G on the left cosets of a subgroup H .

Theorem 15.2.10

Let G be a non-abelian simple group, and $H \leq G$ a subgroup of index $n > 1$ in G . Then $n \geq 5$ and G is isomorphic to a subgroup of A_n .

Proof. Let G act on X , the set of left cosets of H in G , by left multiplication, and let $\phi : G \rightarrow \text{Sym}(X)$ be the associated permutation representation. Then $\text{Sym}(X) = S_n$. As G is simple, we know that $\ker \phi = \{e\}$ or G . If $\ker \phi = G$, then $\text{img } \phi = \{e\}$, contradicting that G acts transitively on X (since $n > 1$). Thus $\ker \phi$ is trivial, and $G \cong \text{img } \phi \leq S_n$.

Since $G \leq S_n$ and $A_n \trianglelefteq S_n$, the second isomorphism theorem gives $G \cap A_n \trianglelefteq G$ and $G/G \cap A_n \leq S_n/A_n \cong C_2$. But G is simple so $G \cap A_n = \{e\}$ or G . If $G \cap A_n = \{e\}$, then $G \hookrightarrow C_2$, which contradicts that G is non-abelian. Otherwise, $G \cap A_n = G$, and $G \leq A_n$. Finally if $n \leq 4$, then A_n has no non-abelian simple subgroups (by listing them), so $n \geq 5$. $\square$

Another example, looking at the rotational symmetries of an icosahedron, is given below.

Example 15.2.11 (Rotational Symmetries of an Icosahedron)

Let G be the group of rotations of an icosahedron, as pictured.

In this shape, there is 20 faces, 12 vertices and 30 edges. We want to know the possible orders of elements in this group, and the number of elements of each order.

Order	Number of Elements in G
1	1
2	15
3	20
5	24

This gives us a total of 60 elements. We can verify this with the orbit-stabiliser theorem. For G acting on the vertices, and some vertex v , we have $|G| = |\text{Orb}(v)| \cdot |\text{Stab}(v)| = 12 \cdot 5 = 60$.

To consider the conjugacy classes, we note that two elements are conjugate if they 'look the same up to relabelling the icosahedron'.

The elements of order 2 are all conjugate, as are those by order 3. The elements of order 5 split into two conjugacy classes of equal size (12), as the rotations by $\pm \frac{2\pi}{5}$ are all conjugate and rotations by $\pm \frac{4\pi}{5}$ are all conjugate, but not to each-other.

We can use this to deduce G is simple. If $H \triangleleft G$, then $|H| = 1 + 15a + 20b + 12c$ for $a, b \in \{0, 1\}$ and $c \in \{0, 1, 2\}$, but as $|H| \mid 60$ by Lagrange, we get $|H| = 1$ or 60 . Thus G is simple.

In fact, G is isomorphic to A_5 . We will show that the sets $H \setminus \{1\}$ for $H \leq G$ a subgroup of order 4 partition the 15 elements of order 2 into 5 sets of 3.

1. If $|H| = 4$, then $H \cong C_2 \times C_2$ or $H \cong C_4$. But there is no elements of order 4 in G , so $H \cong C_2 \times C_2$. Note that this has three elements of order 2.
2. If $g \in G$ has order 2, then $g \in C_G(g)$ and $|C_G(g)| = \frac{|G|}{|\text{ccl}_G(g)|} = \frac{60}{15} = 4$.
3. Suppose $e \neq g \in H \cap K$ where H and K are distinct subgroups of order 4. Then $|C_G(g)| \geq |H \cup K|$ since H and K are abelian, and $|H \cup K| > 4$.

This proves the claim. Now let G act on the set X of subgroups of order 4 by conjugation. We obtain a group homomorphism $\phi : G \rightarrow \text{Sym}(X) \cong S_5$. Then G simple implies either $\ker \phi = \{e\}$ or G . If it was G , then we would get that there is a normal subgroup of order 4, which is a contradiction. Thus the kernel is trivial, and $G \hookrightarrow S_5$. Then exactly as before, either $G \hookrightarrow C_2$ or $G \leq A_5$, and thus $|G| = |A_5| = 60$, so $G \cong A_5$.

§15.3 Alternating Groups

We know from the ‘Groups’ course that two permutations in S_n are conjugate if and only if they have the same cycle type.

Example 15.3.1 (Conjugacy Classes in S_5)

In S_5 , we have the following:

Cycle Type	Number of Elements	Sign
1, 1, 1, 1, 1	1	+
2, 1, 1, 1	10	−
2, 2, 1	15	+
3, 1, 1	20	+
3, 2	20	−
4, 1	30	−
5	24	+

Thus we know the sizes of the conjugacy classes in S_5 . The same method works in general for S_n .

We want to think about the conjugacy classes of A_n .

§15.3.1 Conjugacy Classes & Simplicity of A_n

One way to think about conjugacy classes is to say that the group acts on itself by conjugation. Then the conjugacy classes correspond to orbits and centralizers correspond

to stabilisers.

So it's going to be useful to think about the centralisers of elements in A_n . Let $g \in A_n$. Then $C_{A_n}(g) = C_{S_n}(g) \cap A_n$. We have then got two cases.

- If there exists an odd permutation commuting with g , then $|C_{A_n}(g)| = \frac{1}{2}|C_{S_n}(g)|$, and $|\text{ccl}_{A_n}(g)| = |\text{ccl}_{S_n}(g)|$.
- Otherwise, $|C_{A_n}(g)| = |C_{S_n}(g)|$ and $|\text{ccl}_{A_n}(g)| = \frac{1}{2}|\text{ccl}_{S_n}(g)|$.

Example 15.3.2 (Conjugacy Classes in A_5)

We can now investigate the conjugacy classes in A_5 . Note that $(1\ 2)(3\ 4)$ commutes with the odd permutation $(1\ 2)$ and $(1\ 2\ 3)$ commutes with $(4\ 5)$. But if $h \in C_{S_5}(g)$ where $g = (1\ 2\ 3\ 4\ 5)$, then

$$(1\ 2\ 3\ 4\ 5) = h(1\ 2\ 3\ 4\ 5)h^{-1} = (h(1)\ h(2)\ h(3)\ h(4)\ h(5)).$$

Thus $h \in \langle g \rangle$, and $|\text{ccl}_{A_5}(g)| = \frac{1}{2}|\text{ccl}_{S_5}(g)| = 12$. Thus A_5 has conjugacy classes of size 1, 15, 20, 12, 12. By the same argument as before, this implies that A_5 is simple.

Lemma 15.3.3 (Generators of A_n)

A_n is generated by 3-cycles.

Proof. We know that each $\sigma \in A_n$ is the product of an even number of transpositions. So it suffices to write the product of any two transpositions as the product of 3-cycles.

For a, b, c, d distinct, we have $(a\ b)(b\ c) = (a\ b\ c)$, and $(a\ b)(c\ d) = (a\ c\ b)(a\ c\ d)$. $\square$

Lemma 15.3.4 (3-Cycles are Conjugate in A_n)

If $n \geq 5$, then all 3-cycles in A_n are conjugate.

Proof. We claim that every 3-cycle is conjugate to $(1\ 2\ 3)$. Indeed, if $(a\ b\ c)$ is a 3-cycle, then $(a\ b\ c) = \sigma(1\ 2\ 3)\sigma^{-1}$ for some $\sigma \in S_n$. If $\sigma \notin A_n$, then replace σ with $\sigma(4\ 5)$. $\square$

Theorem 15.3.5 (A_n is Simple)

The alternating group A_n is simple for all $n \geq 5$.

Proof. Let $N \trianglelefteq A_n$ be a non-trivial subgroup of A_n . It suffices to show that N contains a 3-cycle.

We take some $\sigma \in N$ with $\sigma \neq e$, and write σ as the product of disjoint cycles.

- *Case 1.* σ contains a cycle of length $r \geq 4$.

Without loss of generality, let $\sigma = (1\ 2\ 3 \cdots r)\tau$. Let $\delta = (1\ 2\ 3)$, then $\delta^{-1}\sigma\delta \in N$, and $\sigma^{-1}\delta^{-1}\sigma\delta \in N$. This can be written $(r \cdots 2\ 1)(1\ 3\ 2)(1\ 2 \cdots r)(1\ 2\ 3) =$

$(2\ 3\ r)$, which is a three cycle. Then N contains a three cycle.

- *Case 2.* σ contains two 3-cycles.

Again, without loss of generality say $\sigma = (1\ 2\ 3)(4\ 5\ 6)\tau$. Then let $\delta = (1\ 2\ 4)$, and $\sigma^{-1}\delta^{-1}\sigma\delta = (1\ 3\ 2)(4\ 6\ 5)(1\ 4\ 2)(1\ 2\ 3)(4\ 6\ 5)(1\ 2\ 3) = (1\ 2\ 4\ 3\ 6)$. Then we can apply case 1, and N contains a three cycle.

- *Case 3.* σ contains two 2-cycles.

Without loss of generality, say $\sigma = (1\ 2)(3\ 4)\tau$. Then let $\delta = (1\ 2\ 3)$. Then $\sigma^{-1}\delta^{-1}\sigma\delta = (1\ 2)(3\ 4)(1\ 3\ 2)(1\ 2)(3\ 4)(1\ 2\ 3) = (1\ 4)(2\ 3)$. Calling this π , and letting $\epsilon = (2\ 3\ 5)$, then $\pi^{-1}\epsilon^{-1}\pi\epsilon = (1\ 4)(2\ 3)(2\ 5\ 3)(1\ 4)(2\ 3)(2\ 3\ 5) = (2\ 5\ 3)$, so N contains a 3-cycle. Note that we use $n \geq 5$ here.

It remains to consider σ where it is a three-cycle. But then N contains a 3-cycle. $\square$

Definition 15.3.6 (Automorphism)

An **automorphism** of a group G is an isomorphism $G \rightarrow G$.

The automorphisms of a group form a subgroup $\text{Aut}(G) \leq \text{Sym}(G)$.

§15.4 p -Groups and p -Subgroups

§15.4.1 Basic Properties of p -Groups

Throughout this section, p will denote a fixed prime number.

Definition 15.4.1 (p -group)

A finite group G is a p -group if $|G| = p^n$ for $n \in \mathbb{N}$ where p is a prime.

We will now state some basic properties of p -groups that will be used in the following sections.

Theorem 15.4.2 (p -groups Have Non-trivial Centers)

If G is a p -group, then $Z(G) \neq \{e\}$.

Proof. For $g \in G$, we have $|\text{ccl}_G(g)| \cdot |C_G(g)| = |G| = p^n$. So each conjugacy class has size that is a power of p . Since G is a union of its conjugacy classes,

$$\begin{aligned} |G| &\equiv \#(\text{conj. classes of size 1}) \pmod{p} \\ \implies 0 &\equiv |Z(G)| \pmod{p}. \end{aligned}$$

In particular, $|Z(G)| > 1$. $\square$

Corollary 15.4.3 (Simple p -groups)

The only simple p -group is C_p .

Proof. Let G be a simple p -group. Since $Z(G) \trianglelefteq G$, we have either $Z(G) = \{e\}$ or $Z(G) = G$. The center cannot be trivial by the previous theorem, thus $Z(G) = G$, so G is abelian, and the only abelian simple groups are C_p for a prime p . $\square$

Corollary 15.4.4

Let G be a p -group of order p^n . Then G has a subgroup of order p^r for all $0 \leq r \leq n$.

Proof. We know that any finite group G has a composition series $\{e\} = G_0 \triangleleft G_1 \triangleleft \cdots \triangleleft G_{m-1} \triangleleft G_m = G$, with each quotient G_i/G_{i-1} simple. Then G is a p -group implies G_i/G_{i-1} is a p -group, and thus $G_i/G_{i-1} \cong C_p$. Then $|G_i| = p^i$ for all $0 \leq i \leq m$, and $m = n$. $\square$

Lemma 15.4.5

For G a group, if $G/Z(G)$ is cyclic, then G is abelian, and $G/Z(G)$ is trivial.

Proof. Let $gZ(G)$ be a generator for $G/Z(G)$. Then each coset is of the form $g^r Z(G)$ for some $r \in \mathbb{Z}$. Thus $G = \{g^r z \mid r \in \mathbb{Z}, z \in Z(G)\}$. Then $(g^{r_1} z_1)(g^{r_2} z_2) = g^{r_1+r_2} z_1 z_2$ since z_1 is in the center. Since z_2 is also in the center, we can also write this as $g^{r_1+r_2} z_2 z_1 = (g^{r_2} z_2)(g^{r_1} z_1)$. Thus G is abelian. $\square$

We can now start to consider what various p -groups actually look like. We know that a group of order p is cyclic, so we will begin with groups of order p^2 .

Corollary 15.4.6 (Groups of Order p^2)

If $|G| = p^2$, then G is abelian.

Proof. The center of G is non-trivial, and by thus by Lagrange, $|Z(G)|$ is either p or p^2 . If the order was p^2 , then we would be done. So consider the case $|Z(G)| = p$. Then $|G/Z(G)|$ must have order p , but then it is cyclic and contradicts our previous lemma. $\square$

We will leave considering groups of order p^3 as an exercise.

§15.4.2 Sylow Theorems

Let G be a finite group, and write $|G| = p^a m$ where p is a prime with $p \nmid m$.

Theorem 15.4.7 (First Sylow Theorem)

The set $\text{Syl}_p(G) = \{P \leq G \mid |P| = p^a\}$ of **Sylow p -subgroups** is non-empty.

Proof. We wish to show that G has a subgroup of order p^a . Let Ω be the set of all

subsets of G of size p^a . We have

$$|\Omega| = \binom{p^a m}{p^a} = \frac{p^a m}{p^a} \cdot \frac{p^a m - 1}{p^a - 1} \cdots \frac{p^a m - p^a + 1}{1}.$$

For $0 \leq k < p^a$, the numbers $p^a m - k$ and $p^a - k$ are divisible by the same power of p . Thus $|\Omega|$ is coprime to p .

Let G act on Ω by left multiplication, where for $g \in G$ and $X \in \Omega$, we put $g * X = \{gx \mid x \in X\} \in \Omega$. For any $X \in \Omega$, we have $|\text{Stab}_G(X)| \cdot |\text{Orb}_G(X)| = |G| = p^a m$. But by the coprimality described above, we can pick X such that $|\text{Orb}_G(X)|$ is coprime to p . Therefore $p^a \mid |\text{Stab}_G(X)|$.

On the other hand, if $g \in G$ and $x \in X$, then $g \in (gx^{-1}) * X$. Therefore $G = \bigcup_{g \in G} g * X$. Thus $|G| \leq |\text{Orb}_G(X)| \cdot |X|$, and thus $|\text{Stab}_G(X)| = \frac{|G|}{|\text{Orb}_G(X)|} \leq |X| = p^a$. So $|\text{Stab}_G(X)| = p^a$, and is thus a Sylow p -subgroup. $\square$

Theorem 15.4.8 (Second Sylow Theorem)

All elements of $\text{Syl}_p(G)$ are conjugate.

Proof. We claim that if $P \in \text{Syl}_p(G)$ and $Q \leq G$ is a p -subgroup then $Q \leq gPg^{-1}$ for some $g \in G$.

Let Q act on the set of left cosets of G by left multiplication, where $q * gP = qgP$. The orbit stabiliser theorem implies each orbit has size dividing $|Q|$, so it is either 1 or a multiple of p .

Since $|G : P| = m$ is coprime to p , there exists an orbit of size 1. Thus there exists $g \in G$ such that $qgP = gP$ for all $q \in Q$, and we get $g^{-1}qg \in P$, so $Q \subseteq gPg^{-1}$. $\square$

Theorem 15.4.9 (Third Sylow Theorem)

The number $n_p = |\text{Syl}_p(G)|$ of Sylow p -subgroups satisfies $n_p \equiv 1 \pmod{p}$, and $n_p \mid |G|$.

Proof. Let G act on $\text{Syl}_p(G)$ by conjugation. The second Sylow theorem implies that this action is transitive. So by the orbit stabiliser theorem, $n_p = |\text{Syl}_p(G)|$ divides $|G|$.

Now let $P \in \text{Syl}_p(G)$. P acts on $\text{Syl}_p(G)$ by conjugation. Then the orbits have size dividing $|P|$, so they are either 1 or a multiple of p .

To show $n_p \equiv 1 \pmod{p}$, it suffices to show that $\{P\}$ is the unique orbit of size 1. If $\{Q\}$ is an orbit of size 1, then P normalizes Q , so $P \leq N_G(Q)$. Now P and Q are Sylow p -subgroups of $N_G(Q)$. Hence by the second Sylow theorem, they are conjugate in $N_G(Q)$, and equal since $Q \trianglelefteq N_G(Q)$. Thus $\{P\}$ is the unique orbit of size 1. $\square$

§15.4.3 Applications of the Sylow Theorems

We will now look at how the Sylow theorems can be used to prove some facts about certain groups.

Corollary 15.4.10

If $n_p = 1$, then the unique Sylow p -subgroup is normal.

Proof. Let $g \in G$ and $P \in \text{Syl}_p(G)$. Then $gPg^{-1} \leq G$ is another Sylow p -subgroup, so we must have $gPg^{-1} = P$, for all $g \in G$. Then $P \trianglelefteq G$. $\square$

Example 15.4.11 (No Simple Groups of Order 1000)

Let $|G| = 1000 = 2^3 \cdot 5^3$. Then $n_5 \equiv 1 \pmod{5}$, and $n_5 \mid 8$. Checking, we find that $n_5 = 1$, and the unique Sylow 5-subgroup is normal. Then G is not simple.

Example 15.4.12 (No Simple Groups of Order 132)

Let $|G| = 132 = 2^2 \cdot 3 \cdot 11$. Then $n_{11} \equiv 1 \pmod{11}$, and $n_{11} \mid 12$. Then $n_{11} = 1$ or 12.

Suppose G was simple. Then $n_{11} \neq 1$, so $n_{11} = 12$. Now $n_3 \equiv 1 \pmod{3}$, and $n_3 \mid 44$, so $n_3 = 1, 4$ or 22. But G is simple, and either $n_3 = 4$ or 22. Supposing $n_3 = 4$, then letting G act on $\text{Syl}_3(G)$ by conjugation, we get a group homomorphism $\phi : G \rightarrow S_4$. Then $\ker(\phi) \trianglelefteq G$ implies $\ker(\phi) = \{e\}$ or G . It cannot be G by the second Sylow theorem, thus ϕ is injective. But then $G \hookrightarrow S_4$, and $132 \leq 24$, which is a contradiction.

Thus $n_3 = 22$, and $n_{11} = 12$. But then counting, G has $22 \cdot (3 - 1) = 44$ elements of order 3, and $12 \cdot (11 - 1) = 120$ elements of order 11. But then $120 + 44 = 164 > 132$, which is a contradiction. Thus there does not exist a simple group of order 132.

§15.5 Some Groups

§15.5.1 Matrix Groups

We are going to finish our study of groups by looking at some matrix groups, along with finite abelian groups.

Let F be a field (for example $\mathbb{C}$ or $\mathbb{Z}/p\mathbb{Z}$). Recall the groups $\text{GL}_n(F)$ of $n \times n$ invertible matrices over F , and $\text{SL}_n(F) = \ker(\text{GL}_n \xrightarrow{\det} F^\times) \trianglelefteq \text{GL}_n(F)$. Also let $Z \trianglelefteq \text{GL}_n(F)$ be the group of scalar matrices (scalar multiples of the identity matrices).

We define the *projective general/special linear groups* as follows.

Definition 15.5.1 (Projective General Linear Group)

The **projective general linear group** $\text{PGL}_n(F)$ is defined to be $\text{GL}_n(F)/Z$.

Definition 15.5.2 (Projective Special Linear Group)

The **projective special linear group** $\mathrm{PSL}_n(F)$ is the group $\mathrm{SL}_n(F)/(Z \cap \mathrm{SL}_n(F))$, which is isomorphic to $Z \cdot \mathrm{SL}_n(F)/Z$, by the second isomorphism theorem.

Example 15.5.3

Let $G = \mathrm{GL}_n(\mathbb{Z}/p\mathbb{Z})$. A list of n vectors in $(\mathbb{Z}/p\mathbb{Z})^n$ are the columns of some $A \in G$ if and only if they are linearly independent. Thus

$$\begin{aligned} |G| &= (p^n - 1)(p^n - p)(p^n - p^2) \cdots (p^n - p^{n-1}) \\ &= p^{1+2+\cdots+(n-1)}(p^n - 1)(p^{n-1} - 1) \cdots (p - 1) \\ &= p^{\binom{n}{2}} \prod_{i=1}^n (p^i - 1). \end{aligned}$$

We see that the Sylow p -subgroups have order $p^{\binom{n}{2}}$. One such is the subgroup of upper triangular matrices with 1's on the diagonal.

$$U = \left\{ \begin{pmatrix} 1 & * & * & \cdots & * \\ 0 & 1 & * & \cdots & * \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{pmatrix} \right\} \leq G.$$

Indeed there are $\binom{n}{2}$ entries $*$, each which can take p values, so the order is $p^{\binom{n}{2}}$.

Just as $\mathrm{PGL}_2(\mathbb{C})$ acts on $\mathbb{C} \cup \{\infty\}$ via Möbius maps, $\mathrm{PGL}_2(\mathbb{Z}/p\mathbb{Z})$ acts on $\mathbb{Z}/p\mathbb{Z} \cup \{\infty\}$. Indeed, $\mathrm{GL}_2(\mathbb{Z}/p\mathbb{Z})$ acts as

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} : z \mapsto \frac{az + b}{cz + d},$$

and since scalar matrices act trivially, this is an action of $\mathrm{PGL}_2(\mathbb{Z}/p\mathbb{Z})$.

Lemma 15.5.4

The permutation representation of $\mathrm{PGL}_2(\mathbb{Z}/p\mathbb{Z}) \rightarrow S_{p+1}$ is injective (and is an isomorphism if $p = 2$ or 3).

Proof. Suppose $\frac{az+b}{cz+d} = z$ for all $z \in \mathbb{Z}/p\mathbb{Z} \cup \{\infty\}$. Putting $z = 0$ shows $b = 0$. Putting $z = \infty$ shows $c = 0$. Putting $z = 1$ shows $a = d$, and thus this is a scalar matrix. $\square$

Lemma 15.5.5

If p is an odd prime, then $|\mathrm{PSL}_2(\mathbb{Z}/p\mathbb{Z})| = \frac{p(p-1)(p+1)}{2}$.

Proof. By the previous example, $|\mathrm{GL}_2(\mathbb{Z}/p\mathbb{Z})| = p(p-1)(p^2-1)$. Then consider the group homomorphism $\mathrm{GL}_2(\mathbb{Z}/p\mathbb{Z}) \xrightarrow{\det} (\mathbb{Z}/p\mathbb{Z})^\times$. This is surjective, since we

have

$$\begin{pmatrix} a & 0 \\ 0 & 1 \end{pmatrix} \mapsto a,$$

so $|\mathrm{SL}_2(\mathbb{Z}/p\mathbb{Z})| = \frac{|\mathrm{GL}_2(\mathbb{Z}/p\mathbb{Z})|}{p-1} = p(p-1)(p+1)$.

Then counting the number of scalar matrices, if

$$\begin{pmatrix} \lambda & 0 \\ 0 & \lambda \end{pmatrix} \in \mathrm{SL}_2(\mathbb{Z}/p\mathbb{Z}),$$

then $\lambda^2 \equiv 1 \pmod{p}$ implies $p \mid (\lambda-1)(\lambda+1)$, so $\lambda \equiv \pm 1 \pmod{p}$. So there is two such scalar matrices, and $|\mathrm{PSL}_2(\mathbb{Z}/p\mathbb{Z})| = \frac{1}{2}|\mathrm{SL}_2(\mathbb{Z}/p\mathbb{Z})| = \frac{p(p-1)(p+1)}{2}$. $\square$

Example 15.5.6

Let $G = \mathrm{PSL}_2(\mathbb{Z}/5\mathbb{Z})$. Then $|G| = 60 = 2^2 \cdot 3 \cdot 5$.

Let G act on $\mathbb{Z}/5\mathbb{Z} \cup \{\infty\}$ via Möbius maps. By our previous lemma, there is an injective group homomorphism $\phi : G \rightarrow \mathrm{Sym}(\{0, 1, \dots, 4, \infty\}) \cong S_6$.

Claim. $\mathrm{img}(\phi) \leq A_6$, that is, $\psi : G \rightarrow S_6 \xrightarrow{\mathrm{sgn}} \{\pm 1\}$ is trivial.

If m is odd, then $\psi(g) = e \iff \psi(g)^m = e \iff \psi(g^m) = e$. So it suffices to consider $g \in G$ with order a power of 2. We showed in the proof of the Sylow theorems that every such element belongs to a Sylow 2-subgroup. So it suffices to check that $\psi(H) = e$, where H is a Sylow 2-subgroup (using that we have any two Sylow 2-subgroups are conjugate, and ψ maps to an abelian group).

We take $H = \left\{ \pm \begin{pmatrix} 2 & 0 \\ 0 & 3 \end{pmatrix}, \pm \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \right\} \leq G$. We compute:

$$\begin{aligned} \phi\left(\begin{pmatrix} 2 & 0 \\ 0 & 3 \end{pmatrix}\right) &= (1\ 4)(2\ 3) \\ \phi\left(\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}\right) &= (0\ \infty)(1\ 4). \end{aligned}$$

These are even permutations, so $\psi(H)$ is trivial, and our claim is true.

§15.5.2 Finite Abelian Groups

Later in this course, we will prove the following theorem.

Theorem 15.5.7 (The Fundamental Theorem of Finite Abelian Groups)

Every finite abelian group is isomorphic to the direct product of cyclic groups.

Remark (Non-Uniqueness). While this is possible, such a decomposition is not unique. For example, you may recall from IA groups that if m and n are coprime, then $C_m \times C_n \cong C_{mn}$.

Lemma 15.5.8

If m and n are coprime, then $C_{mn} = C_m \times C_n$.

Proof. Let g and h be generators of C_m and C_n . Then we have $(g, h) \in C_m \times C_n$, and $(g, h)^r = (g^r, h^r)$. In particular, $(g, h)^r = e$ if and only if $m \mid r$ and $n \mid r$, that is, if $mn \mid r$ since they are coprime. Thus (g, h) has order mn , which is $|C_m \times C_n|$. $\square$

Corollary 15.5.9

Let G be a finite abelian group. Then $G \cong C_{n_1} \times C_{n_2} \times \cdots \times C_{n_k}$ where each n_i is a prime power.

Proof. If $n = p_1^{a_1} \cdots p_r^{a_r}$, with p_i prime, then we can (by the previous lemma) write $C_n \cong C_{p_1^{a_1}} \times \cdots \times C_{p_r^{a_r}}$. Writing each of the cyclic groups in the fundamental theorem of abelian groups then gives the result. $\square$

In fact, we will prove the following refinement of the the fundamental theorem of finite abelian groups.

Theorem 15.5.10

Let G be a finite abelian group. Then

$$G \cong C_{d_1} \times C_{d_2} \times \cdots \times C_{d_t},$$

for some $d_1 \mid d_2 \mid \cdots \mid d_t$.

Remark. The integers $n_1, \dots, n_k$ in the previous corollary and $d_1, \dots, d_t$ in the previous theorem are uniquely determined by G . The proof (which we omit) works by counting the number of elements of each prime power order.

Example 15.5.11 (Abelian Groups of Order 8)

The abelian groups of order 8 are C_8 , $C_2 \times C_4$ and $C_2 \times C_2 \times C_2$.

Example 15.5.12 (Abelian Groups of Order 12)

The abelian groups of order 12 are $C_2 \times C_6 \cong C_2 \times C_2 \times C_3$, $C_4 \times C_3 \cong C_{12}$.

Definition 15.5.13 (Exponent)

The **exponent** of a group G is the least integer $n \geq 1$ such that $g^n = e$ for all $g \in G$. That is, it is the lowest common multiple of all of the orders of elements in G .

Example 15.5.14

A_4 has exponent 6.

Corollary 15.5.15

Every finite abelian group contains an element whose order is the exponent of the group.

Proof. If $G \cong C_{d_1} \times \cdots \times C_{d_t}$ with $d_1 \mid d_2 \mid \cdots \mid d_t$, then every $g \in G$ has order dividing d_t , and if $h \in C_{d_t}$ is a generator, then $(1, 1, 1, \dots, h) \in G$ has order d_t . So G has exponent d_t . $\square$

§15.6 Rings**§15.6.1 Basic Definitions**

We will now move on to another central algebraic object in this course – *rings*. Let's start with a definition.

Definition 15.6.1 (Ring)

A **ring** is a triple $(R, +, \cdot)$ consisting of a set R and two binary operations^a $+, \cdot : R \times R \rightarrow R$, referred to as *addition* and *multiplication*, that satisfy

- $(R, +)$ is an abelian group, with identity 0.
- Multiplication is associative and has an identity 1.
- *Distributivity.* For $x, y, z \in R$, we have $x \cdot (y + z) = x \cdot y + x \cdot z$ and $(x + y) \cdot z = x \cdot z + y \cdot z$.

^aAgain this has an implicit *closure* axiom

Remark (Notation). For $x \in R$, we write $-x$ for its inverse under addition, and we abbreviate $x + (-y) = x - y$.

We note that in the definition we require $(R, +)$ to be an abelian group, but the fact that it is abelian is deducible from the other axioms. This means that if we talk about a ring being commutative, we must be referring to the multiplication.

Definition 15.6.2 (Commutative Ring)

A ring R is **commutative** if $x \cdot y = y \cdot x$ for all $x, y \in R$.

In this course, we will *only consider* commutative rings. So whenever we refer to an arbitrary ring, we will be referring to a commutative ring.¹

We can define subrings in the natural way.

Definition 15.6.3 (Subrings)

A subset $S \subset R$ is a **subring**, written $S \leq R$, if it is a ring under the same operations $+$ and $\cdot$, with the same identity elements 0 and 1.

¹There are some notable non-commutative rings such as ones made up of matrices, but they will not be considered in this course.

Example 15.6.4 (Examples of Rings and Subrings)

The following are examples of rings and subrings.

- (i) We have the subrings $\mathbb{Z} \leq \mathbb{Q} \leq \mathbb{R} \leq \mathbb{C}$, under addition and multiplication as normal.
- (ii) $\mathbb{Z}[i] = \{a + bi \mid a, b \in \mathbb{Z}\}$ is a ring, and $\mathbb{Z}[i] \leq \mathbb{C}$.
- (iii) $\mathbb{Q}[\sqrt{2}] = \{a + b\sqrt{2} \mid a, b \in \mathbb{Q}\} \leq \mathbb{R}$.
- (iv) $\mathbb{Z}\left[\frac{1}{p}\right] = \left\{\frac{m}{p^n} \mid m \in \mathbb{Z}, n \geq 0\right\} \leq \mathbb{Q}$.
- (v) $\mathbb{Z}/n\mathbb{Z}$, the integers modulo n , is a ring of order n .

§15.6.2 Constructing Rings

Similar to the direct product of groups, there is a natural way to combine rings.

Definition 15.6.5 (Product Ring)

If R and S are rings, then their **product ring** $R \times S$ is a ring via $(r_1, s_1) + (r_2, s_2) = (r_1 + r_2, s_1 + s_2)$ and $(r_1, s_1) \cdot (r_2, s_2) = (r_1 \cdot r_2, s_1 \cdot s_2)$.

We have $0_{R \times S} = (0_R, 0_S)$ and $1_{R \times S} = (1_R, 1_S)$.

Remark. Note that $R \times \{0\}$ is *not* a subring of $R \times S$ – this doesn't have the same identity elements.

There are some other interesting ways to construct rings from other rings. First of all, we could consider functions from some set onto R .

Definition 15.6.6

If R is a ring and X is a set, then the set of all functions $X \rightarrow R$ is a ring under pointwise operations, $(f + g)(x) = f(x) + g(x)$, and $(f \cdot g)(x) = f(x) \cdot g(x)$.

Other interesting examples appear as subrings. For example, the continuous functions $\mathbb{R} \rightarrow \mathbb{R}$.

We can also construct the *ring of polynomials*

Definition 15.6.7 (Ring of Polynomials)

Let R be a ring and define S to be the set of all sequences $(a_0, a_1, \dots)$ with $a_i \in R$ with $a_i = 0$ for all $i \geq N$ for some N . Then defining addition and multiplication as

$$\begin{aligned}(a_0, a_1, \dots) + (b_0, b_1, \dots) &= (a_0 + b_0, a_1 + b_1, \dots) \\ (a_0, a_1, \dots) \cdot (b_0, b_1, \dots) &= (c_0, c_1, \dots),\end{aligned}$$

where $c_n = \sum_{i=0}^n a_i b_{n-i}$ gives us $R[X]$, the **ring of polynomials in X with coefficients in R** .

Note that if we define $X = (0, 1, 0, \dots)$, then $X^n = (\underbrace{0, 0, \dots, 0}_{n \text{ times}}, 1, 0, \dots)$, and

$$(a_0, a_1, \dots, a_n, 0, \dots) = a_n X^n + a_{n-1} X^{n-1} + \dots + a_1 X + a_0.$$

This is why this is known as the polynomial ring.

You may wonder why we defined things in this way, and the answer is that we are not thinking about polynomials as functions, but as sequences of coefficients. To see why this matters, consider $R = \mathbb{Z}/p\mathbb{Z}$ with p prime and $f(x) = X^p - X$. Then the function $x \mapsto f(x)$ is identically zero, but the polynomial $X^p - X$ is non-zero.

So we can restate our definition in a clearer and more general way.

Definition 15.6.8 (Ring of Polynomials)

If R is a ring then $R[X_1, \dots, X_n]$ is the *ring of polynomials* in $X_1, \dots, X_n$ with coefficients in R .

Remark. We can define this inductively as $R[X_1, \dots, X_n] = R[X_1, \dots, X_{n-1}][X_n]$ using our careful construction for $R[X]$ above.

Some extensions of this are the following rings.

Definition 15.6.9 (Power Series and Laurent Polynomials)

The **power series ring** is the ring $R[[X]] = \{a_0 + a_1 X + a_2 X^2 + \dots \mid a_i \in R\}$ and the **ring of Laurent polynomials** is $R[X, X^{-1}] = \{\sum_{i \in \mathbb{Z}} a_i X^i \mid a_i \in R, \text{ and only finitely many } a_i \neq 0\}$.

§15.6.3 Units and Fields

We now introduce an important definition. Recall that not every element of a ring necessarily has an inverse under multiplication. When an element *does* have one, we call it a *unit*.

Definition 15.6.10 (Unit)

An element $r \in R$ is a **unit** if it has an inverse under multiplication. That is, if there exists $s \in R$ such that $r \cdot s = 1$.

The units in a ring R form a group $(R^\times, \cdot)$ under multiplication. For example, $\mathbb{Z}^\times = \{\pm 1\}$, and $\mathbb{Q}^\times = \mathbb{Q} \setminus \{0\}$.

When every non-zero element in a ring is a unit, we call that ring a *field*.

Definition 15.6.11 (Field)

A **field** is a ring with $0 \neq 1$ such that every non-zero element is a unit.

Examples of fields are $\mathbb{Q}, \mathbb{R}, \mathbb{C}$ and $\mathbb{Z}/p\mathbb{Z}$ where p is prime.

Remark. Note that we require $0 \neq 1$ in the definition of a field. If we did not have this, then if $0 = 1$, $x = 1 \cdot x = 0 \cdot x = 0$, for all $x \in R$. So if a ring has $0 = 1$, then it is the trivial ring $R = \{0\}$. And we don't want this to be a field.

The notion of a ring allows us to do some interesting things.

Lemma 15.6.12 (Polynomial Division Algorithm)

Let $f, g \in R[X]$. Suppose that the leading coefficient of g is a unit. Then there exists $q, r \in R[X]$ such that $f(X) = q(X)g(X) + r(X)$, where $\deg(r) < \deg(g)$.

Proof. We induct on the degree of f . If the degree is n , then we write $f(X) = a_nX^n + \cdots + a_1X + a_0$ with $a_n \neq 0$, and $g(X) = b_mX^m + \cdots + b_1X + b_0$, where $b_m \in R^\times$.

If $n < m$, put $q = 0$ and $r = f$, and we are done. Otherwise, we put $f_1(X) = f(X) - a_nb_m^{-1}X^{n-m}g(X)$. Then the coefficient of X^n is 0, and $\deg(f_1) < n$, and we apply the induction hypothesis to get $f_1(X) = q_1(X)g(X) + r(X)$, with $\deg(r) < \deg(g)$.

Then $f(X) = (q_1(X) + a_nb_m^{-1}X^{n-m})g(X) + r(X)$. $\square$

Remark. If R is a field, then we only need $g \neq 0$.

§15.6.4 Homomorphisms and Ideals

As with groups, we are interested in the structure preserving maps between rings. Since a ring has two operations, we ask that both are preserved, and (importantly) that the multiplicative identity is sent to the multiplicative identity.

Definition 15.6.13 (Ring Homomorphism)

Let R and S be rings. A function $\phi : R \rightarrow S$ is a **ring homomorphism** if

- (i) $\phi(r_1 + r_2) = \phi(r_1) + \phi(r_2)$ for all $r_1, r_2 \in R$,
- (ii) $\phi(r_1 \cdot r_2) = \phi(r_1) \cdot \phi(r_2)$ for all $r_1, r_2 \in R$,
- (iii) $\phi(1_R) = 1_S$.

A bijective ring homomorphism is a **ring isomorphism**.

Note that $\phi(0_R) = 0_S$ comes for free, since ϕ is in particular a group homomorphism $(R, +) \rightarrow (S, +)$. The same reasoning gives us the following.

Definition 15.6.14 (Kernel)

The **kernel** of a ring homomorphism $\phi : R \rightarrow S$ is $\ker(\phi) = \{r \in R \mid \phi(r) = 0\}$.

Lemma 15.6.15

A ring homomorphism ϕ is injective if and only if $\ker(\phi) = \{0\}$.

Proof. ϕ is, in particular, a homomorphism of additive groups, so this follows from the corresponding result for groups. $\square$

Now here is where the theory of rings begins to diverge slightly from the theory of groups. In group theory, the subsets that could appear as kernels of homomorphisms were the

normal subgroups. Let's think about what the kernel of a ring homomorphism looks like. It is certainly a subgroup under addition, but if $r \in R$ and $x \in \ker(\phi)$ then

$$\phi(rx) = \phi(r)\phi(x) = \phi(r) \cdot 0 = 0,$$

so the kernel 'absorbs' multiplication by arbitrary ring elements – something much stronger than being closed under multiplication. Subsets with this property are called *ideals*.

Definition 15.6.16 (Ideal)

A subset $I \subseteq R$ is an **ideal**, written $I \trianglelefteq R$, if

- (i) I is a subgroup of $(R, +)$,
- (ii) if $r \in R$ and $x \in I$, then $rx \in I$.

We say I is **proper** if $I \neq R$.

By the discussion above, if $\phi : R \rightarrow S$ is a ring homomorphism then $\ker(\phi) \trianglelefteq R$.

Remark. If an ideal I contains a unit u , then it contains $u^{-1}u = 1$, and then it contains $r \cdot 1 = r$ for every $r \in R$. So a proper ideal contains no units. In particular, note that a proper ideal is *not* a subring, since $1 \notin I$.

The most familiar example of an ideal comes from the integers.

Lemma 15.6.17 (Ideals of $\mathbb{Z}$)

The ideals of $\mathbb{Z}$ are exactly $n\mathbb{Z}$ for $n = 0, 1, 2, \dots$

Proof. Each $n\mathbb{Z}$ is easily checked to be an ideal. Conversely, let $I \trianglelefteq \mathbb{Z}$ be a non-zero ideal, and let n be its smallest positive element. Then $n\mathbb{Z} \subseteq I$. If $m \in I$, then writing $m = qn + r$ with $0 \leq r < n$, we get $r = m - qn \in I$, so by minimality $r = 0$ and $m \in n\mathbb{Z}$. Thus $I = n\mathbb{Z}$. $\square$

Since $n\mathbb{Z} \subseteq m\mathbb{Z}$ if and only if $m \mid n$, the ideals of $\mathbb{Z}$ ordered by inclusion form precisely the divisibility lattice, drawn below for the ideals containing $12\mathbb{Z}$.

This example generalises: in any ring we can consider the set of 'multiples' of a fixed collection of elements.

Definition 15.6.18 (Generated Ideals)

For $a \in R$, the **principal ideal** generated by a is $(a) = \{ra \mid r \in R\}$. More

generally, for $a_1, \dots, a_n \in R$ we write

$$(a_1, \dots, a_n) = \{r_1 a_1 + \dots + r_n a_n \mid r_i \in R\},$$

the **ideal generated by** $a_1, \dots, a_n$.

For example, every ideal of $\mathbb{Z}$ is principal by the lemma above. Notice also that $(a) = R$ if and only if a is a unit – a small observation that we will use constantly.

§15.6.5 Quotient Rings

Just as we formed quotient groups from normal subgroups, we can form quotient rings from ideals. The additive structure is exactly the quotient group $(R, +)/(I, +)$, and the ideal property is precisely what makes multiplication of cosets well defined.

Theorem 15.6.19 (Quotient Rings)

Let $I \trianglelefteq R$. Then the set R/I of cosets of I in $(R, +)$ is a ring, the **quotient ring**, with operations

$$\begin{aligned}(r_1 + I) + (r_2 + I) &= (r_1 + r_2) + I, \\ (r_1 + I) \cdot (r_2 + I) &= (r_1 r_2) + I,\end{aligned}$$

and identities $0_{R/I} = 0 + I$ and $1_{R/I} = 1 + I$. Moreover the **quotient map** $\pi : R \rightarrow R/I$ with $r \mapsto r + I$ is a surjective ring homomorphism with kernel I .

Proof. From the theory of groups, addition is well defined and gives an abelian group. For multiplication, suppose $r_1 + I = r'_1 + I$ and $r_2 + I = r'_2 + I$, so $r'_1 = r_1 + a_1$ and $r'_2 = r_2 + a_2$ with $a_1, a_2 \in I$. Then

$$r'_1 r'_2 = r_1 r_2 + \underbrace{a_1 r_2 + r_1 a_2 + a_1 a_2}_{\in I},$$

so $r'_1 r'_2 + I = r_1 r_2 + I$, and multiplication of cosets is well defined. The ring axioms are all inherited directly from R , as is easily checked. The quotient map is then a surjective homomorphism by construction, and $\pi(r) = 0 + I \iff r \in I$. $\square$

So exactly as in the group case, ideals are precisely the kernels of ring homomorphisms. Let's look at some examples of quotient rings.

Example 15.6.20 (Quotients of $\mathbb{Z}$)

The quotient of $\mathbb{Z}$ by the ideal $n\mathbb{Z}$ is the familiar ring $\mathbb{Z}/n\mathbb{Z}$ of integers modulo n .

Example 15.6.21 ($\mathbb{C}[X]/(X)$)

Consider the ideal $(X) \trianglelefteq \mathbb{C}[X]$, the set of polynomials with zero constant term. Given $f(X) = a_n X^n + \dots + a_1 X + a_0$, we have $f + (X) = a_0 + (X)$. So the map $\mathbb{C}[X]/(X) \rightarrow \mathbb{C}$ given by $f + (X) \mapsto f(0)$ is a well defined bijection, and it is easily checked to be a ring homomorphism. Thus $\mathbb{C}[X]/(X) \cong \mathbb{C}$.

Example 15.6.22 ($\mathbb{R}[X]/(X^2 + 1)$)

Consider the ideal $(X^2 + 1) \trianglelefteq \mathbb{R}[X]$. Using the polynomial division algorithm, any $f \in \mathbb{R}[X]$ can be written $f(X) = q(X)(X^2 + 1) + r(X)$ with $\deg r < 2$, so every coset has a representative $a + bX$ with $a, b \in \mathbb{R}$, and it's straightforward to check this representative is unique. The bijection

$$\mathbb{R}[X]/(X^2 + 1) \longrightarrow \mathbb{C}, \quad a + bX + (X^2 + 1) \longmapsto a + bi$$

respects addition, and for multiplication note that $(a + bX)(c + dX) = ac + (ad + bc)X + bdX^2 \equiv (ac - bd) + (ad + bc)X \pmod{X^2 + 1}$, matching $(a + bi)(c + di) = (ac - bd) + (ad + bc)i$. So $\mathbb{R}[X]/(X^2 + 1) \cong \mathbb{C}$ – quotienting by $(X^2 + 1)$ amounts to ‘adjoining a square root of -1 ’.

This last example illustrates an important idea – quotients of polynomial rings let us *build* rings in which some chosen polynomial has a root. We will return to this when we discuss fields and algebraic integers.

§15.6.6 The Isomorphism Theorems for Rings

Each of the isomorphism theorems for groups has an analogue for rings, with normal subgroups replaced by ideals. The proofs consist of applying the group versions to the additive groups, and then checking everything respects multiplication.

Theorem 15.6.23 (First Isomorphism Theorem)

Let $\phi : R \rightarrow S$ be a ring homomorphism. Then $\ker(\phi) \trianglelefteq R$, $\text{img}(\phi) \leq S$ is a subring, and

$$R/\ker(\phi) \cong \text{img}(\phi).$$

Proof. We have already seen $\ker(\phi) \trianglelefteq R$. The image is an additive subgroup, it's closed under multiplication as $\phi(r_1)\phi(r_2) = \phi(r_1r_2)$, and $1_S = \phi(1_R) \in \text{img}(\phi)$, so $\text{img}(\phi)$ is a subring of S .

Now let $K = \ker(\phi)$ and define $\Phi : R/K \rightarrow \text{img}(\phi)$ by $r + K \mapsto \phi(r)$. By the first isomorphism theorem for groups, this is a well defined bijective homomorphism of additive groups. Also

$$\Phi((r_1 + K)(r_2 + K)) = \Phi(r_1r_2 + K) = \phi(r_1r_2) = \phi(r_1)\phi(r_2) = \Phi(r_1 + K)\Phi(r_2 + K),$$

and $\Phi(1 + K) = \phi(1_R) = 1_S$, so Φ is a ring isomorphism. $\square$

Example 15.6.24

Consider the ‘evaluation at i ’ homomorphism $\phi : \mathbb{R}[X] \rightarrow \mathbb{C}$ given by $f \mapsto f(i)$. This is surjective, since $a + bX \mapsto a + bi$. Its kernel consists of real polynomials with i as a root, and dividing any such polynomial by $X^2 + 1$ shows $\ker(\phi) = (X^2 + 1)$. So the first isomorphism theorem gives $\mathbb{R}[X]/(X^2 + 1) \cong \mathbb{C}$ immediately – much more efficiently than our direct verification before.

Theorem 15.6.25 (Second Isomorphism Theorem)

Let $R \leq S$ be a subring and $J \trianglelefteq S$. Then $R \cap J \trianglelefteq R$, the set $R + J = \{r + a \mid r \in R, a \in J\}$ is a subring of S , and

$$R/(R \cap J) \cong (R + J)/J.$$

Proof. Let $\phi : R \rightarrow S/J$ be the composite of the inclusion $R \hookrightarrow S$ and the quotient map $S \rightarrow S/J$, so $\phi(r) = r + J$. This is a ring homomorphism, with

$$\ker(\phi) = \{r \in R \mid r + J = J\} = R \cap J \trianglelefteq R,$$

and $\text{img}(\phi) = \{r + J \mid r \in R\} = (R + J)/J$, which is then a subring of S/J . The result follows by the first isomorphism theorem. (One can also check directly that $R + J$ is a subring of S – it is an additive subgroup containing 1, and $(r_1 + a_1)(r_2 + a_2) = r_1r_2 + (r_1a_2 + r_2a_1 + a_1a_2) \in R + J$.) $\square$

For the third isomorphism theorem, we again start with a correspondence. If $I \trianglelefteq R$, then there is a bijection

$$\{\text{ideals of } R/I\} \longleftrightarrow \{\text{ideals of } R \text{ containing } I\},$$

given by $K \mapsto \{r \in R \mid r + I \in K\}$ and $J \mapsto J/I = \{r + I \mid r \in J\}$.

Theorem 15.6.26 (Third Isomorphism Theorem)

Let $I \subseteq J$ be ideals of R . Then $J/I \trianglelefteq R/I$ and

$$(R/I) / (J/I) \cong R/J.$$

Proof. Consider $\phi : R/I \rightarrow R/J$ with $r + I \mapsto r + J$. This is well defined (as $I \subseteq J$), and is a surjective ring homomorphism with kernel $\{r + I \mid r \in J\} = J/I$. Apply the first isomorphism theorem. $\square$

Let's see a genuinely useful consequence of this machinery.

Example 15.6.27 (The Characteristic of a Ring)

For any ring R , there is exactly one ring homomorphism $\iota : \mathbb{Z} \rightarrow R$. Indeed, we are forced to set $\iota(1) = 1_R$, and then $\iota(n) = 1_R + \cdots + 1_R$ (n times) for $n \geq 0$, and $\iota(-n) = -\iota(n)$; one checks this is a ring homomorphism.

Now $\ker(\iota) \trianglelefteq \mathbb{Z}$, so $\ker(\iota) = n\mathbb{Z}$ for a unique $n \geq 0$, called the **characteristic** of R . By the first isomorphism theorem, every ring contains a copy of $\mathbb{Z}/n\mathbb{Z}$ (interpreting $\mathbb{Z}/0\mathbb{Z}$ as $\mathbb{Z}$).

For example, $\mathbb{Z}$, $\mathbb{Q}$, $\mathbb{R}$ and $\mathbb{C}$ have characteristic 0, while $\mathbb{Z}/p\mathbb{Z}$ and $(\mathbb{Z}/p\mathbb{Z})[X]$ have characteristic p .

§15.6.7 Integral Domains

Many familiar rings have the property that a product of non-zero elements is non-zero. This is such a useful property that rings with it get their own name.

Definition 15.6.28 (Integral Domain)

An **integral domain** is a ring R with $0 \neq 1$ such that for all $a, b \in R$,

$$ab = 0 \implies a = 0 \text{ or } b = 0.$$

A non-zero element $a \in R$ for which there is a non-zero b with $ab = 0$ is called a **zero divisor** – so an integral domain is a non-trivial ring with no zero divisors.

Example 15.6.29 (Examples of Integral Domains)

Every field is an integral domain: if $ab = 0$ and $a \neq 0$, then $b = a^{-1}(ab) = 0$. Also, any subring of an integral domain is an integral domain, so for example $\mathbb{Z} \leq \mathbb{Q}$ and $\mathbb{Z}[i] \leq \mathbb{C}$ are integral domains.

On the other hand, $\mathbb{Z} \times \mathbb{Z}$ is not an integral domain, since $(1, 0) \cdot (0, 1) = (0, 0)$, and $\mathbb{Z}/6\mathbb{Z}$ is not, since $2 \cdot 3 = 0$.

Working in an integral domain makes polynomials behave the way we would like them to.

Lemma 15.6.30

If R is an integral domain, then $R[X]$ is an integral domain, and $\deg(fg) = \deg f + \deg g$ for non-zero $f, g \in R[X]$.

Proof. Let $f, g \neq 0$ have leading coefficients $a_n \neq 0$ and $b_m \neq 0$. The coefficient of X^{n+m} in fg is a_nb_m , which is non-zero since R is an integral domain. So $fg \neq 0$ and $\deg(fg) = n + m$. $\square$

Lemma 15.6.31 (Roots of Polynomials)

Let R be an integral domain and $f \in R[X]$ be non-zero. Then f has at most $\deg(f)$ roots in R .

Proof. We induct on $\deg f$. If $\deg f = 0$ then f is a non-zero constant, with no roots. Now suppose a is a root of f . Dividing by the monic polynomial $X - a$, we can write $f(X) = q(X)(X - a) + r$ with r constant, and evaluating at a shows $r = 0$, so $f = q \cdot (X - a)$ with $\deg q = \deg f - 1$. Any other root $b \neq a$ of f satisfies $q(b)(b - a) = 0$, so $q(b) = 0$ since R is an integral domain. By induction q has at most $\deg q - 1$ roots, so f has at most $\deg f$ roots. $\square$

This innocent-looking fact has a rather striking consequence.

Theorem 15.6.32

Let F be a field. Then any finite subgroup $G \leq (F^\times, \cdot)$ is cyclic.

Proof. G is a finite abelian group. If G is not cyclic, then by the classification of finite abelian groups (using the invariant factor form $G \cong C_{d_1} \times \cdots \times C_{d_t}$ with

$d_1 \mid \cdots \mid d_t$ and $t \geq 2$), G contains a subgroup isomorphic to $C_d \times C_d$ for some $d \geq 2$. But then the polynomial $X^d - 1 \in F[X]$ has at least $d^2 > d$ roots in F , contradicting the previous lemma. $\square$

Corollary 15.6.33

$(\mathbb{Z}/p\mathbb{Z})^\times$ is cyclic for any prime p .

We record one more useful fact about integral domains.

Proposition 15.6.34 (Finite Integral Domains are Fields)

Any finite integral domain is a field.

Proof. Let R be a finite integral domain and $0 \neq a \in R$. Consider the map $\phi : R \rightarrow R$ given by $x \mapsto ax$. If $\phi(x) = \phi(y)$ then $a(x - y) = 0$, so $x = y$, that is, ϕ is injective. Since R is finite, ϕ is a bijection, so there is some $b \in R$ with $ab = 1$. Thus every non-zero element is a unit. $\square$

§15.6.8 The Field of Fractions

The integers are not a field, but they sit naturally inside one – the rationals, whose elements are ratios of integers. This construction works in any integral domain.

Theorem 15.6.35 (Field of Fractions)

Let R be an integral domain. Then there is a field F , the **field of fractions** of R , which contains R as a subring and in which every element can be written as ab^{-1} with $a, b \in R$, $b \neq 0$.

Proof. We mimic the construction of $\mathbb{Q}$ from $\mathbb{Z}$. Consider the set $S = \{(a, b) \mid a, b \in R, b \neq 0\}$ of ‘fractions’, with the equivalence relation

$$(a, b) \sim (c, d) \iff ad = bc.$$

This is clearly reflexive and symmetric. For transitivity, if $(a, b) \sim (c, d)$ and $(c, d) \sim (e, f)$, then $adf = bcf = bde$, so $d(af - be) = 0$, and since $d \neq 0$ and R is an integral domain^a, $af = be$.

Write $\frac{a}{b}$ for the equivalence class of (a, b) , and let $F = S/\sim$ with operations

$$\frac{a}{b} + \frac{c}{d} = \frac{ad + bc}{bd}, \quad \frac{a}{b} \cdot \frac{c}{d} = \frac{ac}{bd}.$$

Note $bd \neq 0$, and one checks these operations are well defined and make F a ring, with $0_F = \frac{0}{1}$ and $1_F = \frac{1}{1}$. If $\frac{a}{b} \neq 0_F$ then $a \neq 0$, and $\frac{a}{b} \cdot \frac{b}{a} = 1_F$, so F is a field. Finally, identifying $r \in R$ with $\frac{r}{1} \in F$ embeds R as a subring of F , and $\frac{a}{b} = ab^{-1}$. $\square$

^aThis is where we need R to be an integral domain – without it, transitivity genuinely fails.

Example 15.6.36

The field of fractions of $\mathbb{Z}$ is $\mathbb{Q}$, and the field of fractions of $\mathbb{C}[X]$ is the field $\mathbb{C}(X)$ of **rational functions** $\frac{f(X)}{g(X)}$ with $f, g \in \mathbb{C}[X]$ and $g \neq 0$.

§15.6.9 Maximal and Prime Ideals

We now introduce two special classes of ideals, which correspond exactly to when the quotient ring is a field or an integral domain. First, a small but important observation.

Lemma 15.6.37 (Fields Have No Interesting Ideals)

A non-trivial ring R is a field if and only if its only ideals are $\{0\}$ and R .

Proof. Suppose R is a field and $I \trianglelefteq R$ is non-zero. Then I contains a non-zero element, which is a unit, so $I = R$.

Conversely, suppose the only ideals are $\{0\}$ and R , and let $0 \neq x \in R$. Then $(x) \neq \{0\}$, so $(x) = R$. In particular $1 \in (x)$, meaning $xy = 1$ for some y , so x is a unit. $\square$

Definition 15.6.38 (Maximal Ideal)

An ideal $I \trianglelefteq R$ is **maximal** if $I \neq R$ and the only ideals containing I are I and R .

Proposition 15.6.39

Let $I \trianglelefteq R$. Then I is maximal if and only if R/I is a field.

Proof. R/I is a field if and only if its only ideals are $\{0\} = I/I$ and R/I . By the correspondence between ideals of R/I and ideals of R containing I , this happens if and only if the only ideals of R containing I are I and R , that is, if and only if I is maximal. $\square$

Definition 15.6.40 (Prime Ideal)

An ideal $I \trianglelefteq R$ is **prime** if $I \neq R$ and whenever $ab \in I$, either $a \in I$ or $b \in I$.

Example 15.6.41 (Prime Ideals of $\mathbb{Z}$)

The ideal $n\mathbb{Z} \trianglelefteq \mathbb{Z}$ is prime if and only if $n = 0$ or n is a prime number. Indeed, for $n = p$ prime this is the classical fact that $p \mid ab$ implies $p \mid a$ or $p \mid b$, and (0) is prime since $\mathbb{Z}$ is an integral domain. Conversely if $n = uv$ with $u, v > 1$ then $uv \in n\mathbb{Z}$ but $u, v \notin n\mathbb{Z}$.

Proposition 15.6.42

Let $I \trianglelefteq R$. Then I is prime if and only if R/I is an integral domain.

Proof. Unwinding definitions: R/I is an integral domain if and only if $(a+I)(b+I) = 0 + I$ implies $a + I = 0 + I$ or $b + I = 0 + I$; that is, if and only if $ab \in I$ implies $a \in I$ or $b \in I$. (And $I \neq R$ corresponds to $0 \neq 1$ in R/I .) $\square$

Corollary 15.6.43

Every maximal ideal is prime.

Proof. If I is maximal then R/I is a field, hence an integral domain, hence I is prime. $\square$

The converse fails: $(0) \leq \mathbb{Z}$ is prime but not maximal. As an application of this circle of ideas, note that if R is an integral domain of characteristic n , then $\mathbb{Z}/n\mathbb{Z}$ embeds in R , so $\mathbb{Z}/n\mathbb{Z}$ is an integral domain, and thus n is 0 or prime. So *the characteristic of an integral domain (in particular, of any field) is either 0 or a prime number.*

§15.7 Factorisation in Integral Domains

We now begin the study of factorisation, which will occupy us for some time. The story we are trying to generalise is the fundamental theorem of arithmetic: every integer factors into primes, essentially uniquely. It turns out that in a general integral domain this can fail in interesting ways, and understanding when it holds leads to a hierarchy of classes of rings.

Throughout this section, R is an integral domain.

§15.7.1 Prime and Irreducible Elements

We first need the right vocabulary for talking about divisibility.

Definition 15.7.1 (Divisibility & Associates)

For $a, b \in R$, we say a **divides** b , written $a \mid b$, if $b = ac$ for some $c \in R$. Equivalently, $(b) \subseteq (a)$.

Elements a, b are **associates** if $a = bu$ for a unit u . Equivalently, $(a) = (b)$.

Associate elements are ‘the same up to units’ – for factorisation purposes they are interchangeable, just as $6 = 2 \cdot 3 = (-2)(-3)$ in $\mathbb{Z}$.

Definition 15.7.2 (Irreducible & Prime Elements)

Let $r \in R$ be non-zero and not a unit. Then:

- (i) r is **irreducible** if $r = ab$ implies a or b is a unit;
- (ii) r is **prime** if $r \mid ab$ implies $r \mid a$ or $r \mid b$.

In $\mathbb{Z}$ these two notions coincide (both giving the usual prime numbers, up to sign), but in general they do not, and the distinction is the crux of this whole section. Note that

both notions depend on the ambient ring: 2 is prime in $\mathbb{Z}$ but a unit in $\mathbb{Q}$, and $2X$ is irreducible in $\mathbb{Q}[X]$ but not in $\mathbb{Z}[X]$ (where 2 is not a unit).

Let us relate these notions to ideals.

Lemma 15.7.3

$(r) \trianglelefteq R$ is a prime ideal if and only if $r = 0$ or r is prime.

Proof. Suppose (r) is prime and $r \neq 0$. Since prime ideals are proper, r is not a unit. If $r \mid ab$ then $ab \in (r)$, so $a \in (r)$ or $b \in (r)$, that is, $r \mid a$ or $r \mid b$. So r is prime.

Conversely, $(0) = \{0\}$ is prime as R is an integral domain. If r is prime then $(r) \neq R$, and $ab \in (r)$ means $r \mid ab$, so $r \mid a$ or $r \mid b$, giving $a \in (r)$ or $b \in (r)$. $\square$

Lemma 15.7.4 (Primes are Irreducible)

If $r \in R$ is prime, then r is irreducible.

Proof. Suppose $r = ab$. Then certainly $r \mid ab$, so without loss of generality $r \mid a$, say $a = rc$. Then $r = rc b$, so $r(1 - cb) = 0$, and since $r \neq 0$ and R is an integral domain, $cb = 1$. So b is a unit. $\square$

The converse is *false* in general, and it's worth seeing this fail concretely.

Example 15.7.5 (An Irreducible That Isn't Prime)

Consider the ring

$$R = \mathbb{Z}[\sqrt{-5}] = \{a + b\sqrt{-5} \mid a, b \in \mathbb{Z}\} \leq \mathbb{C},$$

an integral domain (being a subring of $\mathbb{C}$). Define the **norm** $N : R \rightarrow \mathbb{Z}_{\geq 0}$ by $N(a + b\sqrt{-5}) = a^2 + 5b^2$, which is multiplicative: $N(zw) = N(z)N(w)$.

First, the units of R are ± 1 : if $rs = 1$ then $N(r)N(s) = 1$, so $N(r) = 1$, forcing $r = \pm 1$.

Next, 2 is irreducible in R : if $2 = rs$ with neither a unit, then $N(r)N(s) = 4$ with $N(r), N(s) > 1$, so $N(r) = 2$ – but $a^2 + 5b^2 = 2$ has no integer solutions. Similarly 3, $1 + \sqrt{-5}$ and $1 - \sqrt{-5}$ are irreducible (there are no elements of norm 3 either).

Now observe

$$2 \cdot 3 = 6 = (1 + \sqrt{-5})(1 - \sqrt{-5}).$$

So $2 \mid (1 + \sqrt{-5})(1 - \sqrt{-5})$, but 2 divides neither factor (taking norms: $N(2) = 4 \nmid 6 = N(1 \pm \sqrt{-5})$). Hence 2 is irreducible but *not prime*.

Notice what we have really found: two genuinely different factorisations of 6 into irreducibles, not related by reordering and units. Unique factorisation fails in $\mathbb{Z}[\sqrt{-5}]$.

§15.7.2 Principal Ideal Domains

Definition 15.7.6 (Principal Ideal Domain)

An integral domain R is a **principal ideal domain** (PID) if every ideal of R is principal, that is, of the form (a) for some $a \in R$.

We have already shown that $\mathbb{Z}$ is a PID. In a PID, the pathology of the previous example cannot occur.

Proposition 15.7.7 (Irreducible $\iff$ Prime in a PID)

Let R be a principal ideal domain. Then every irreducible element of R is prime.

Proof. Let r be irreducible and suppose $r \mid ab$ but $r \nmid a$; we must show $r \mid b$. Since R is a PID, $(a, r) = (d)$ for some $d \in R$. Then $d \mid r$, say $r = cd$. As r is irreducible, c or d is a unit.

If c were a unit, then $(r) = (d) = (a, r) \ni a$, so $r \mid a$, a contradiction. So d is a unit, and $(a, r) = R$. In particular $1 = sa + tr$ for some $s, t \in R$. Multiplying by b ,

$$b = sab + trb,$$

and r divides both terms on the right ($r \mid ab$ for the first). Hence $r \mid b$. $\square$

Lemma 15.7.8 (Irreducibles Generate Maximal Ideals in a PID)

Let R be a PID and $r \in R$ be non-zero. Then r is irreducible if and only if (r) is maximal.

Proof. Suppose r is irreducible, so $(r) \neq R$. If $(r) \subseteq J \subseteq R$, then $J = (a)$ for some a (as R is a PID), and $r = ab$ for some b . Since r is irreducible, either a is a unit, giving $J = R$, or b is a unit, making a and r associates, giving $J = (r)$. So (r) is maximal.

Conversely if (r) is maximal then r is not a unit, and if $r = ab$ then $(r) \subseteq (a) \subseteq R$, so $(a) = (r)$ (making b a unit) or $(a) = R$ (making a a unit). So r is irreducible. (This direction holds in any integral domain.) $\square$

Combining our results: in a PID, for non-zero r ,

$$(r) \text{ maximal} \iff r \text{ irreducible} \iff r \text{ prime} \iff (r) \text{ prime}.$$

So in a PID, the non-zero prime ideals are exactly the maximal ideals.

§15.7.3 Euclidean Domains

How do we actually *prove* that a ring is a PID? For $\mathbb{Z}$, the key was the division algorithm. Abstracting this gives the following definition.

Definition 15.7.9 (Euclidean Domain)

An integral domain R is a **Euclidean domain** (ED) if there is a function $\phi : R \setminus \{0\} \rightarrow \mathbb{Z}_{\geq 0}$, called a **Euclidean function**, such that

- (i) if $a \mid b$ (with $a, b \neq 0$) then $\phi(a) \leq \phi(b)$,
- (ii) if $a, b \in R$ with $b \neq 0$, then there are $q, r \in R$ with

$$a = bq + r, \quad \text{and either } r = 0 \text{ or } \phi(r) < \phi(b).$$

Example 15.7.10

$\mathbb{Z}$ is a Euclidean domain with $\phi(n) = |n|$, and for a field F , the polynomial ring $F[X]$ is a Euclidean domain with $\phi(f) = \deg f$ – property (ii) is exactly the polynomial division algorithm, which applies since every non-zero element of F is a unit.

Proposition 15.7.11 (ED implies PID)

Every Euclidean domain is a principal ideal domain.

Proof. Let R have Euclidean function ϕ , and let $I \trianglelefteq R$ be a non-zero ideal. Choose $b \in I \setminus \{0\}$ with $\phi(b)$ minimal. Certainly $(b) \subseteq I$. Now take any $a \in I$, and write $a = bq + r$ with $r = 0$ or $\phi(r) < \phi(b)$. But $r = a - bq \in I$, so by minimality of $\phi(b)$ we must have $r = 0$. Hence $a \in (b)$, and $I = (b)$. $\square$

Remark. Only property (ii) was used here. The reason for including property (i) is that it lets us identify the units: they are exactly the non-zero elements with $\phi(u) = \phi(1)$, which is often handy in computations.

The most important new example is the ring of *Gaussian integers*.

Lemma 15.7.12 ($\mathbb{Z}[i]$ is a Euclidean Domain)

The ring $\mathbb{Z}[i] = \{a + bi \mid a, b \in \mathbb{Z}\}$ is a Euclidean domain with Euclidean function $N(a + bi) = a^2 + b^2$.

Proof. The norm is multiplicative, $N(zw) = N(z)N(w)$, which gives property (i) at once. For property (ii), let $z, w \in \mathbb{Z}[i]$ with $w \neq 0$, and consider the complex number $\frac{z}{w} \in \mathbb{C}$. The elements of $\mathbb{Z}[i]$ form a unit square lattice in $\mathbb{C}$, so there is some $q \in \mathbb{Z}[i]$ with $\left| \frac{z}{w} - q \right| < 1$ (any point of $\mathbb{C}$ has distance at most $\frac{\sqrt{2}}{2} < 1$ from the nearest lattice point).

Now set $r = z - wq \in \mathbb{Z}[i]$. Then $z = wq + r$, and if $r \neq 0$,

$$N(r) = |z - wq|^2 = |w|^2 \left| \frac{z}{w} - q \right|^2 < |w|^2 = N(w),$$

as required. □

So $\mathbb{Z}[i]$ is a PID, and $F[X]$ is a PID for any field F . We will use both facts extensively. Here are two quick illustrations of the power of the $F[X]$ case.

Example 15.7.13 (The Minimal Polynomial)

Let A be an $n \times n$ matrix over a field F , and let

$$I = \{f \in F[X] \mid f(A) = 0\}.$$

Then I is an ideal of $F[X]$ (differences and multiples of polynomials vanishing at A vanish at A). Since $F[X]$ is a PID, $I = (f)$ for a single polynomial f , which we may scale to be monic – this is precisely the *minimal polynomial* of A , and we get for free that it divides every polynomial killing A .

Example 15.7.14 (A Field of Order 8)

Let $\mathbb{F}_2 = \mathbb{Z}/2\mathbb{Z}$ and $f(X) = X^3 + X + 1 \in \mathbb{F}_2[X]$. If f factored non-trivially, it would have a linear factor and hence a root in $\mathbb{F}_2$, but $f(0) = f(1) = 1$. So f is irreducible, and since $\mathbb{F}_2[X]$ is a PID, the ideal (f) is maximal. Therefore

$$\mathbb{F}_2[X]/(X^3 + X + 1)$$

is a field. By the division algorithm each coset has a unique representative $aX^2 + bX + c$ with $a, b, c \in \mathbb{F}_2$, so this is a field with exactly 8 elements. This construction of finite fields is taken much further in Galois theory.

Not every PID-related fact extends to all polynomial rings, however.

Example 15.7.15 ($\mathbb{Z}[X]$ is Not a PID)

Consider the ideal $I = (2, X) \leq \mathbb{Z}[X]$, which consists of the polynomials with even constant term. Suppose $I = (f)$. Since $2 \in I$, we have $2 = fg$ for some g , so comparing degrees f is a constant, and $f = \pm 1$ or ± 2 . If $f = \pm 1$ then $I = \mathbb{Z}[X]$, but $1 \notin I$. If $f = \pm 2$ then $X \notin (f)$, but $X \in I$. Either way we have a contradiction, so I is not principal.

§15.7.4 Unique Factorisation Domains

We can now formalise ‘factorisation works like in $\mathbb{Z}$ ’.

Definition 15.7.16 (Unique Factorisation Domain)

An integral domain R is a **unique factorisation domain** (UFD) if

- (i) every non-zero, non-unit element is a product of irreducibles, and
- (ii) if $p_1 \cdots p_m = q_1 \cdots q_n$ with all p_i, q_j irreducible, then $m = n$ and, after reordering, p_i and q_i are associates for each i .

The uniqueness half turns out to be equivalent to the prime/irreducible distinction collapsing.

Proposition 15.7.17

Let R be an integral domain in which every non-zero, non-unit element is a product of irreducibles. Then R is a UFD if and only if every irreducible element of R is prime.

Proof. ($\Rightarrow$) Let p be irreducible with $p \mid ab$, say $ab = pc$. Writing a, b, c as products of irreducibles (or units), uniqueness of the factorisation of ab forces p to be an associate of one of the irreducible factors of a or of b ; hence $p \mid a$ or $p \mid b$.

($\Leftarrow$) Suppose every irreducible is prime, and $p_1 \cdots p_m = q_1 \cdots q_n$ with all factors irreducible, where without loss of generality $m \leq n$. Since p_1 is prime and divides $q_1 \cdots q_n$, it divides some q_i ; reorder so $p_1 \mid q_1$. Then $q_1 = p_1 u$, and u must be a unit as q_1 is irreducible and p_1 is not a unit. So p_1, q_1 are associates. Cancelling p_1 (valid in an integral domain) gives $p_2 \cdots p_m = u q_2 \cdots q_n$, and absorbing u into q_2 we may induct. If $m < n$ we would eventually find that a product of irreducibles equals a unit, which is impossible, so $m = n$ and all pairs are associates. $\square$

To show that PIDs are UFDs, the harder part is existence of factorisations, and for that we need a finiteness condition on chains of ideals – one which will reappear later when we study Noetherian rings.

Definition 15.7.18 (Ascending Chain Condition)

A ring R satisfies the **ascending chain condition** (ACC) if every increasing chain of ideals $I_1 \subseteq I_2 \subseteq I_3 \subseteq \cdots$ is eventually constant, that is, there is some N with $I_n = I_{n+1}$ for all $n \geq N$. Rings satisfying the ACC are called **Noetherian**.

Lemma 15.7.19 (PIDs Satisfy the ACC)

Every principal ideal domain satisfies the ascending chain condition.

Proof. Given a chain $I_1 \subseteq I_2 \subseteq \cdots$, the union $I = \bigcup_{i \geq 1} I_i$ is an ideal (a union of a chain of ideals is an ideal). Since R is a PID, $I = (a)$ for some a , and $a \in I_N$ for some N . Then for all $n \geq N$,

$$(a) \subseteq I_N \subseteq I_n \subseteq I = (a),$$

so all inclusions are equalities. $\square$

Theorem 15.7.20 (PID implies UFD)

Every principal ideal domain is a unique factorisation domain.

Proof. We first show every non-zero, non-unit x is a product of irreducibles. Suppose not. Then in particular x is not itself irreducible, so $x = x_1 y_1$ with neither factor a unit, and at least one of them – say x_1 – is not a product of irreducibles. Note $(x) \subset (x_1)$, and this inclusion is strict since y_1 is not a unit. Repeating with x_1 in

place of x , we build a strictly increasing chain

$$(x) \subset (x_1) \subset (x_2) \subset \cdots,$$

contradicting the ascending chain condition. So factorisations exist.

For uniqueness, by the previous proposition it suffices that every irreducible is prime – which we proved for PIDs earlier. $\square$

§15.7.5 The Hierarchy of Integral Domains

Assembling everything so far, we have a chain of implications

$$\text{ED} \implies \text{PID} \implies \text{UFD} \implies \text{ID},$$

and each implication is strict. The picture to have in mind is the following, with a witness sitting in each gap.

Example 15.7.21 (Separating Examples)

Let's justify the diagram.

- (i) $\mathbb{Z}$, $F[X]$ and $\mathbb{Z}[i]$ are Euclidean domains, as we have seen.
- (ii) $\mathbb{Z}\left[\frac{1+\sqrt{-19}}{2}\right]$ is a PID but not a Euclidean domain. (Both facts require some work, and are beyond this course – this example is treated in Part II Number Fields.)
- (iii) $\mathbb{Z}[X]$ is a UFD (as we will prove in the next section) but not a PID, since the ideal $(2, X)$ is not principal.
- (iv) $\mathbb{Z}[\sqrt{-5}]$ is an integral domain but not a UFD, since 6 factors into irreducibles in two genuinely different ways.

And of course $\mathbb{Z}/4\mathbb{Z}$ fails even to be an integral domain, as $2 \cdot 2 = 0$.

§15.7.6 Greatest Common Divisors

One pleasant consequence of unique factorisation is a good theory of greatest common divisors.

Definition 15.7.22 (GCD and LCM)

Let $a_1, \dots, a_n \in R$. An element $d \in R$ is a **greatest common divisor** of $a_1, \dots, a_n$ if $d \mid a_i$ for all i , and any d' with $d' \mid a_i$ for all i satisfies $d' \mid d$.

Similarly, m is a **least common multiple** if $a_i \mid m$ for all i , and every common multiple m' satisfies $m \mid m'$.

Greatest common divisors need not exist in a general integral domain, but when they do they are unique up to associates – so we allow ourselves to speak of ‘the’ gcd.

Proposition 15.7.23 (GCDs Exist in UFDs)

If R is a UFD, then greatest common divisors and least common multiples always exist.

Proof. Write each $a_i = u_i \prod_j p_j^{n_{ij}}$, where the p_j are pairwise non-associate irreducibles, u_i are units, and $n_{ij} \geq 0$. We claim

$$d = \prod_j p_j^{m_j}, \quad \text{where } m_j = \min_i n_{ij},$$

is a greatest common divisor. Certainly d divides each a_i . If $d' \mid a_i$ for all i , then writing d' as a product of irreducibles, uniqueness of factorisation shows that (up to associates) $d' = w \prod_j p_j^{t_j}$ with $t_j \leq n_{ij}$ for every i , so $t_j \leq m_j$ and $d' \mid d$. The lcm is analogous, taking $\max_i n_{ij}$ instead. $\square$

§15.8 Factorisation in Polynomial Rings

The goal of this section is the following theorem, together with some practical tools it generates for showing that specific polynomials are irreducible.

Theorem 15.8.1 (Polynomial Rings over UFDs)

If R is a unique factorisation domain, then $R[X]$ is a unique factorisation domain.

Note that this is exactly the sort of statement our hierarchy cannot give us directly: $\mathbb{Z}$ is a PID but $\mathbb{Z}[X]$ is not, so we cannot pass through principal ideals. Instead we will compare $R[X]$ with $F[X]$, where F is the field of fractions of R . Since $F[X]$ is a Euclidean domain, it is a UFD, and the strategy is to transfer factorisations back and forth between $R[X]$ and $F[X]$.

Throughout this section, R is a UFD with field of fractions F , so $R[X] \leq F[X]$.

§15.8.1 Content and Gauss’s Lemma

The bookkeeping device that makes the comparison work is the *content* of a polynomial.

Definition 15.8.2 (Content & Primitive Polynomials)

The **content** of $f = a_0 + a_1X + \cdots + a_nX^n \in R[X]$ is

$$c(f) = \gcd(a_0, a_1, \dots, a_n),$$

which is well defined up to associates (using that R is a UFD). We say f is **primitive** if $c(f)$ is a unit.

Any $f \in R[X]$ can be written $f = c(f)f_0$ with f_0 primitive – just pull out the gcd of the coefficients. The key technical fact is that primitivity is preserved by products.

Lemma 15.8.3 (Products of Primitive Polynomials)

If $f, g \in R[X]$ are primitive, then so is fg . Moreover, for any $f, g \in R[X]$, the elements $c(fg)$ and $c(f)c(g)$ are associates.

Proof. Let $f = \sum_i a_i X^i$ and $g = \sum_i b_i X^i$ be primitive, and suppose fg is not, so some irreducible (hence prime) $p \in R$ divides $c(fg)$. Since f and g are primitive, p does not divide all the a_i , nor all the b_i . Let k and ℓ be minimal with $p \nmid a_k$ and $p \nmid b_\ell$. The coefficient of $X^{k+\ell}$ in fg is

$$\sum_{i+j=k+\ell} a_i b_j = \underbrace{(\cdots + a_{k-1} b_{\ell+1})}_{\text{divisible by } p} + a_k b_\ell + \underbrace{(a_{k+1} b_{\ell-1} + \cdots)}_{\text{divisible by } p},$$

where the flanking terms are divisible by p by minimality of k and ℓ . Since p divides the whole coefficient, $p \mid a_k b_\ell$, so $p \mid a_k$ or $p \mid b_\ell$ as p is prime – a contradiction.

For the second part, write $f = c(f)f_0$ and $g = c(g)g_0$ with f_0, g_0 primitive. Then $fg = c(f)c(g)f_0g_0$ with f_0g_0 primitive, so taking contents gives $c(fg) = c(f)c(g)$ up to a unit. $\square$

Corollary 15.8.4

If $p \in R$ is prime in R , then p is prime as an element of $R[X]$.

Proof. Note $R[X]^\times = R^\times$ (degrees add in an integral domain), so p is a non-zero non-unit in $R[X]$. For $f \in R[X]$, we have $p \mid f$ in $R[X]$ if and only if $p \mid c(f)$ in R . So if $p \mid gh$, then $p \mid c(gh) = c(g)c(h)$ (up to units), hence $p \mid c(g)$ or $p \mid c(h)$, that is, $p \mid g$ or $p \mid h$ in $R[X]$. $\square$

The next lemma is the bridge between divisibility in $F[X]$ and in $R[X]$.

Lemma 15.8.5 (Descending Divisibility)

Let $f, g \in R[X]$ with g primitive. If $g \mid f$ in $F[X]$, then $g \mid f$ in $R[X]$.

Proof. Write $f = gh$ with $h \in F[X]$. Clearing denominators, there is a non-zero $a \in R$ with $ah \in R[X]$, and we can write $ah = c(ah)h_0$ with $h_0 \in R[X]$ primitive. Then

$$af = g \cdot ah = c(ah)gh_0,$$

and taking contents: $a \cdot c(f) = c(ah) \cdot c(gh_0) = c(ah)$ up to units, since gh_0 is a product of primitive polynomials, hence primitive. In particular $a \mid c(ah)$, so $h = \frac{c(ah)}{a}h_0 \in R[X]$, and $g \mid f$ in $R[X]$. $\square$

We can now prove the classical result relating irreducibility over R and over the field of fractions.

Lemma 15.8.6 (Gauss's Lemma)

Let $f \in R[X]$ be primitive. Then f is irreducible in $R[X]$ if and only if f is irreducible in $F[X]$.

Proof. ($\Rightarrow$) Since f is irreducible and primitive, $\deg f > 0$, so f is not a unit in $F[X]$. Suppose for contradiction that $f = gh$ with $g, h \in F[X]$ of positive degree. We claim we can arrange for g to lie in $R[X]$ and be primitive. Indeed, choose $b \in R$ non-zero with $bg \in R[X]$, and write $bg = c(bg)g_0$ with g_0 primitive; then setting $\lambda = c(bg)b^{-1} \in F^\times$, we have $g = \lambda g_0$, and replacing (g, h) with $(g_0, \lambda h)$ keeps $f = g_0(\lambda h)$. So assume $g \in R[X]$ is primitive. Then $g \mid f$ in $F[X]$, so by the previous lemma $g \mid f$ in $R[X]$, say $f = gh'$ with $h' \in R[X]$, where $\deg g, \deg h' > 0$. This contradicts irreducibility of f in $R[X]$.

($\Leftarrow$) If $f = gh$ in $R[X]$ with g, h non-units, then since f is primitive neither factor can be constant, so both have positive degree and this also factors f non-trivially in $F[X]$. $\square$

Lemma 15.8.7

Let $g \in R[X]$ be primitive. If g is prime in $F[X]$, then g is prime in $R[X]$.

Proof. g is not a unit in $R[X]$ (it has positive degree, as primitive constants are units). If $g \mid f_1f_2$ with $f_i \in R[X]$, then in $F[X]$ we get $g \mid f_1$ or $g \mid f_2$, and descending divisibility brings this back to $R[X]$. $\square$

With these tools, the main theorem falls out.

Proof that polynomial rings over UFDs are UFDs. Existence. Let $f \in R[X]$ be a non-zero non-unit, and write $f = c(f)f_0$ with f_0 primitive. Since R is a UFD, $c(f)$ factors into irreducibles of R , which remain irreducible in $R[X]$. For f_0 : if it is not irreducible, then $f_0 = gh$ with g, h non-units, and since f_0 is primitive both g and h have positive degree (and are primitive). By induction on degree, f_0 is a product of irreducibles.

Uniqueness. It suffices to show every irreducible $f \in R[X]$ is prime. Since f is irreducible, it is either a constant or primitive. If f is a constant, it is irreducible in R , hence prime in R (R being a UFD), hence prime in $R[X]$ by our corollary. If f is primitive, then by Gauss's lemma f is irreducible in $F[X]$; since $F[X]$ is a UFD, f is prime in $F[X]$, and by the previous lemma f is prime in $R[X]$. $\square$

Example 15.8.8

$\mathbb{Z}[X]$ is a UFD, even though it is not a PID. Iterating the theorem, $R[X_1, \dots, X_n] = R[X_1] \cdots [X_n]$ is a UFD whenever R is – for instance $\mathbb{Z}[X_1, \dots, X_n]$ and $F[X_1, \dots, X_n]$ for a field F .

§15.8.2 Eisenstein's Criterion

Gauss's lemma reduces irreducibility over $\mathbb{Q}$ to irreducibility over $\mathbb{Z}$, where we have more structure to exploit. The following criterion is the classic way to do so.

Theorem 15.8.9 (Eisenstein's Criterion)

Let R be a UFD and let $f(X) = a_n X^n + \cdots + a_1 X + a_0 \in R[X]$ be primitive with $\deg f = n \geq 1$. Suppose there is an irreducible $p \in R$ such that

- (i) $p \nmid a_n$,
- (ii) $p \mid a_i$ for all $i < n$,
- (iii) $p^2 \nmid a_0$.

Then f is irreducible in $R[X]$ (and hence in $F[X]$, by Gauss's lemma).

Proof. Suppose $f = gh$ with g, h non-units. Since f is primitive, g and h have positive degrees k and ℓ , with $k + \ell = n$. Write $g = \sum_{i=0}^k r_i X^i$ and $h = \sum_{i=0}^{\ell} s_i X^i$.

Since $p \nmid a_n = r_k s_\ell$, we have $p \nmid r_k$ and $p \nmid s_\ell$. Since $p \mid a_0 = r_0 s_0$ but $p^2 \nmid a_0$, exactly one of r_0, s_0 is divisible by p – without loss of generality $p \mid r_0$ and $p \nmid s_0$.

Let $j \leq k$ be minimal with $p \nmid r_j$ (this exists as $p \nmid r_k$), so $j \geq 1$. Consider

$$a_j = r_0 s_j + r_1 s_{j-1} + \cdots + r_{j-1} s_1 + r_j s_0.$$

We have $j \leq k < n$, so $p \mid a_j$, and p divides each of the first j terms by minimality of j . Hence $p \mid r_j s_0$, but $p \nmid r_j$ and $p \nmid s_0$ – a contradiction, as p is prime (R is a UFD). $\square$

Example 15.8.10

For a prime $p \in \mathbb{Z}$, the polynomial $X^n - p$ satisfies Eisenstein's criterion at p , so it is irreducible in $\mathbb{Z}[X]$, hence in $\mathbb{Q}[X]$. In particular $\sqrt[n]{p}$ is irrational for $n \geq 2$, and $\mathbb{Q}[X]/(X^n - p)$ is a field.

Sometimes the criterion doesn't apply directly, but does after a change of variable.

Example 15.8.11 (Cyclotomic Polynomials of Prime Order)

Let p be prime and consider

$$f(X) = X^{p-1} + X^{p-2} + \cdots + X + 1 = \frac{X^p - 1}{X - 1} \in \mathbb{Z}[X].$$

Eisenstein does not apply to f directly (all the coefficients are 1). But substituting

$$X = Y + 1,$$

$$f(Y + 1) = \frac{(Y + 1)^p - 1}{Y} = Y^{p-1} + \binom{p}{1}Y^{p-2} + \cdots + \binom{p}{p-2}Y + \binom{p}{p-1}.$$

Now $p \mid \binom{p}{i}$ for $1 \leq i \leq p-1$, and $\binom{p}{p-1} = p$ is not divisible by p^2 , so Eisenstein applies at p and $f(Y + 1)$ is irreducible. Since $X \mapsto Y + 1$ is an isomorphism $\mathbb{Z}[X] \rightarrow \mathbb{Z}[Y]$, the polynomial $f(X)$ is irreducible in $\mathbb{Z}[X]$, and thus in $\mathbb{Q}[X]$.

Example 15.8.12 (When Eisenstein Fails, Try Roots)

Consider $f(X) = X^3 + 2X + 5 \in \mathbb{Z}[X]$. No prime works for Eisenstein, but if f factored in $\mathbb{Z}[X]$, then (being cubic) it would have a linear factor $X + a$ with $a \mid 5$, so an integer root among $\pm 1, \pm 5$. Checking, none of these are roots, so f is irreducible in $\mathbb{Z}[X]$, and by Gauss's lemma also in $\mathbb{Q}[X]$. Hence $\mathbb{Q}[X]/(f)$ is a field.

§15.9 The Gaussian Integers

The ring $\mathbb{Z}[i] = \{a + bi \mid a, b \in \mathbb{Z}\}$ deserves a section of its own – it is a Euclidean domain (with the norm $N(a + bi) = a^2 + b^2$ as Euclidean function), hence a PID and a UFD, and this structure turns out to encode genuinely arithmetic information about $\mathbb{Z}$: which integers are sums of two squares.

Since N is multiplicative and $N(z) = 1 \iff z \in \{\pm 1, \pm i\}$, the units of $\mathbb{Z}[i]$ are exactly $\pm 1, \pm i$. Also note the handy fact that if $N(z)$ is prime in $\mathbb{Z}$, then z is irreducible in $\mathbb{Z}[i]$, since any factorisation splits the norm.

Example 15.9.1

The prime 2 is *not* irreducible in $\mathbb{Z}[i]$: we have $2 = (1 + i)(1 - i)$, and neither factor is a unit ($N(1 \pm i) = 2$). Similarly $5 = (2 + i)(2 - i)$ is not irreducible. But 3 *is* irreducible: $N(3) = 9$, so a non-trivial factorisation $3 = zw$ would need $N(z) = 3$, and $a^2 + b^2 = 3$ has no integer solutions. The same argument shows 7 is irreducible.

There is a clear pattern here, and pinning it down is the main theorem of this section.

Proposition 15.9.2

Let $p \in \mathbb{Z}$ be a prime number. The following are equivalent:

- (i) p is not prime in $\mathbb{Z}[i]$;
- (ii) $p = a^2 + b^2$ for some $a, b \in \mathbb{Z}$;
- (iii) $p = 2$ or $p \equiv 1 \pmod{4}$.

Proof. (i) $\Rightarrow$ (ii): Since $\mathbb{Z}[i]$ is a UFD, ‘not prime’ means ‘not irreducible’, so $p = zw$ with z, w non-units. Then $p^2 = N(p) = N(z)N(w)$ with $N(z), N(w) > 1$, forcing $N(z) = p$. Writing $z = a + bi$ gives $p = a^2 + b^2$.

(ii) $\Rightarrow$ (iii): The squares modulo 4 are 0 and 1, so $a^2 + b^2 \not\equiv 3 \pmod{4}$. Since p is

prime, either $p = 2$ or p is odd with $p \equiv 1 \pmod{4}$.

(iii) $\Rightarrow$ (i): We know $2 = (1+i)(1-i)$ is not prime, so suppose $p \equiv 1 \pmod{4}$. The group $(\mathbb{Z}/p\mathbb{Z})^\times$ is cyclic of order $p-1$, and $4 \mid p-1$, so there is an element x of order 4. Then x^2 has order 2, and the only element of order 2 in the cyclic group is -1 , so $x^2 \equiv -1 \pmod{p}$. Hence

$$p \mid x^2 + 1 = (x+i)(x-i) \quad \text{in } \mathbb{Z}[i].$$

But $p \nmid x \pm i$, since $\frac{x}{p} \pm \frac{1}{p}i \notin \mathbb{Z}[i]$. So p is not prime in $\mathbb{Z}[i]$. $\square$

It is worth pausing here: the statement ‘every prime $p \equiv 1 \pmod{4}$ is a sum of two squares’ is a theorem of Fermat, and makes no mention of complex numbers at all – yet the natural proof goes through the arithmetic of $\mathbb{Z}[i]$. Fermat’s original approach was his method of *descent*: from any solution of $a^2 + b^2 \equiv 0 \pmod{p}$ he constructed a smaller multiple of p expressible as a sum of two squares, descending until reaching p itself. The Euclidean algorithm in $\mathbb{Z}[i]$ is doing exactly this descent for us, packaged as the statement that $\mathbb{Z}[i]$ is a PID.

We can now describe all the primes of $\mathbb{Z}[i]$.

Theorem 15.9.3 (Primes in $\mathbb{Z}[i]$)

Up to associates, the primes of $\mathbb{Z}[i]$ are:

- (i) elements $a + bi$ with $N(a + bi) = a^2 + b^2 = p$ a prime number with $p = 2$ or $p \equiv 1 \pmod{4}$;
- (ii) prime numbers $p \in \mathbb{Z}$ with $p \equiv 3 \pmod{4}$.

Proof. Elements of type (i) are irreducible since their norm is prime, and elements of type (ii) are prime by the previous proposition. Conversely, let z be prime in $\mathbb{Z}[i]$, and note $\bar{z}$ is then also prime, with

$$N(z) = z\bar{z}$$

a factorisation into primes. Pick a prime number $p \in \mathbb{Z}$ dividing $N(z) \in \mathbb{Z}$.

If $p \equiv 3 \pmod{4}$, then p is prime in $\mathbb{Z}[i]$ and divides $z\bar{z}$, so $p \mid z$ or $p \mid \bar{z}$; in either case z is an associate of p (a prime dividing a prime), which is type (ii).

Otherwise $p = 2$ or $p \equiv 1 \pmod{4}$, so $p = a^2 + b^2 = (a + bi)(a - bi)$ with both factors of norm p , hence prime. Then $(a + bi)(a - bi) \mid z\bar{z}$, and unique factorisation in $\mathbb{Z}[i]$ shows z is an associate of $a + bi$ or $a - bi$, which is type (i). $\square$

Corollary 15.9.4 (Sums of Two Squares)

A positive integer n is a sum of two squares if and only if every prime $p \equiv 3 \pmod{4}$ appears in the factorisation of n to an even power.

Proof. Note that n is a sum of two squares if and only if $n = N(z)$ for some $z \in \mathbb{Z}[i]$. Factoring z into primes of $\mathbb{Z}[i]$ and taking norms, n is a product of norms of primes

in $\mathbb{Z}[i]$, which by the classification are the primes $p \not\equiv 3 \pmod{4}$ and the *squares* p^2 of primes $p \equiv 3 \pmod{4}$. The stated condition describes exactly the integers expressible as products of such numbers. Conversely if the condition holds, writing each $p \not\equiv 3 \pmod{4}$ as a norm and each p^{2k} as $N(p^k)$, multiplicativity of N expresses n as a norm. $\square$

Example 15.9.5 (Writing 65 as a Sum of Two Squares)

We have $65 = 5 \cdot 13$, and both primes are $1 \pmod{4}$, so 65 should be a sum of two squares. Factoring in $\mathbb{Z}[i]$:

$$5 = (2 + i)(2 - i), \quad 13 = (2 + 3i)(2 - 3i).$$

Grouping the four prime factors into conjugate pairs,

$$65 = N((2 + i)(2 + 3i)) = N(1 + 8i) = 1^2 + 8^2,$$

but the alternative grouping gives

$$65 = N((2 + i)(2 - 3i)) = N(7 - 4i) = 7^2 + 4^2.$$

So $65 = 1 + 64 = 49 + 16$ – and the two essentially different representations come precisely from the two ways of grouping the Gaussian primes.

§15.10 Algebraic Integers

We now apply our factorisation theory to a class of complex numbers of central importance in number theory.

Definition 15.10.1 (Algebraic Numbers and Algebraic Integers)

A number $\alpha \in \mathbb{C}$ is **algebraic** if it is a root of some non-zero polynomial in $\mathbb{Q}[X]$, and α is an **algebraic integer** if it is a root of some *monic* polynomial in $\mathbb{Z}[X]$.

For example, $\sqrt{2}$, i , and $\frac{-1+\sqrt{-3}}{2}$ (a root of $X^2 + X + 1$) are algebraic integers, while $\frac{1}{2}$ is algebraic but – as we shall see – not an algebraic integer.

For a subring $R \leq S$ and $\alpha \in S$, we write $R[\alpha]$ for the smallest subring of S containing both R and α . Concretely, $R[\alpha] = \text{img}(\phi)$, where $\phi : R[X] \rightarrow S$ is the **evaluation homomorphism** $g(X) \mapsto g(\alpha)$. This notation is consistent with our earlier usage of $\mathbb{Z}[i]$ and $\mathbb{Z}[\sqrt{-5}]$.

Definition 15.10.2 (Minimal Polynomial)

Let α be an algebraic number, and consider the evaluation homomorphism $\phi : \mathbb{Q}[X] \rightarrow \mathbb{C}$, $g \mapsto g(\alpha)$. Since $\mathbb{Q}[X]$ is a PID, $\ker(\phi) = (f)$ for some f , which is non-zero as α is algebraic, and which we scale to be monic. This f is the **minimal polynomial** of α .

Proposition 15.10.3

The minimal polynomial f of an algebraic number α is irreducible in $\mathbb{Q}[X]$, and $\mathbb{Q}[\alpha] \cong \mathbb{Q}[X]/(f)$ is a field.

Proof. By the first isomorphism theorem, $\mathbb{Q}[X]/(f) \cong \mathbb{Q}[\alpha] \leq \mathbb{C}$. A subring of a field is an integral domain, so (f) is a prime ideal, and hence f is prime, so irreducible. But then (f) is a *maximal* ideal ($\mathbb{Q}[X]$ is a PID), so $\mathbb{Q}[X]/(f) \cong \mathbb{Q}[\alpha]$ is a field. $\square$

The corresponding statement over $\mathbb{Z}$ requires more care, because $\mathbb{Z}[X]$ is not a PID – and this is exactly where Gauss’s lemma earns its keep.

Proposition 15.10.4

Let α be an algebraic *integer* with minimal polynomial $f \in \mathbb{Q}[X]$. Then $f \in \mathbb{Z}[X]$, and $\ker(\theta) = (f)$, where $\theta : \mathbb{Z}[X] \rightarrow \mathbb{C}$ is the evaluation homomorphism at α .

Proof. Choose $\lambda \in \mathbb{Q}^\times$ so that $\lambda f \in \mathbb{Z}[X]$ is primitive (clear denominators, then divide by the content). Then $\lambda f(\alpha) = 0$, so $\lambda f \in \ker(\theta)$.

We claim $\ker(\theta) = (\lambda f)$. Indeed, let $g \in \ker(\theta) \subseteq \mathbb{Z}[X]$. Then $g(\alpha) = 0$, so $f \mid g$ in $\mathbb{Q}[X]$, and hence $\lambda f \mid g$ in $\mathbb{Q}[X]$. Since λf is primitive, descending divisibility gives $\lambda f \mid g$ in $\mathbb{Z}[X]$, proving the claim.

Now, since α is an algebraic integer, there is a *monic* $g \in \mathbb{Z}[X]$ with $g(\alpha) = 0$, so $\lambda f \mid g$ in $\mathbb{Z}[X]$. Comparing leading coefficients, the leading coefficient of λf divides 1, so it is ± 1 ; and as f is monic, $\lambda = \pm 1$. Hence $f = \pm \lambda f \in \mathbb{Z}[X]$ and $\ker(\theta) = (f)$. $\square$

Applying the first isomorphism theorem to θ gives presentations of our favourite rings:

$$\mathbb{Z}[X]/(X^2+1) \cong \mathbb{Z}[i], \quad \mathbb{Z}[X]/(X^2-2) \cong \mathbb{Z}[\sqrt{2}], \quad \mathbb{Z}[X]/(X^2+X+1) \cong \mathbb{Z}\left[\frac{-1+\sqrt{-3}}{2}\right],$$

and $\mathbb{Z}[X]/(X^n - p) \cong \mathbb{Z}[\sqrt[n]{p}]$ for a prime p .

Corollary 15.10.5 (Rational Algebraic Integers)

If $\alpha \in \mathbb{Q}$ is an algebraic integer, then $\alpha \in \mathbb{Z}$.

Proof. If $\alpha \neq 0$ is rational, its minimal polynomial is $X - \alpha$, which by the previous proposition lies in $\mathbb{Z}[X]$. Hence $\alpha \in \mathbb{Z}$. (And $0 \in \mathbb{Z}$ trivially.) $\square$

This innocuous corollary is a genuinely useful tool – for instance, it is the cleanest way to see that $\frac{1}{2}$ is not an algebraic integer, and it underlies many irrationality proofs.

§15.11 Noetherian Rings

We finish our study of rings by returning to the ascending chain condition, which we met while proving that PIDs are UFDs. It defines a class of rings large enough to contain almost everything we care about, but restrictive enough to do serious work.

Definition 15.11.1 (Noetherian Ring)

A ring R is **Noetherian** if every ascending chain of ideals $I_1 \subseteq I_2 \subseteq \cdots$ is eventually constant: there is N such that $I_n = I_{n+1}$ for all $n \geq N$.

There is an equivalent characterisation which is often easier to verify and to use.

Lemma 15.11.2 (Noetherian $\iff$ Finitely Generated Ideals)

A ring R is Noetherian if and only if every ideal of R is finitely generated.

Proof. ($\Leftarrow$) Let $I_1 \subseteq I_2 \subseteq \cdots$ be a chain and $I = \bigcup_i I_i$, an ideal. By assumption $I = (a_1, \dots, a_k)$, and each a_j lies in some I_{n_j} ; taking $N = \max_j n_j$, all the generators lie in I_N , so for $n \geq N$,

$$I = (a_1, \dots, a_k) \subseteq I_N \subseteq I_n \subseteq I,$$

and the chain is constant from I_N onwards.

($\Rightarrow$) Suppose some ideal J is not finitely generated. Pick $a_1 \in J$; then $(a_1) \neq J$, so pick $a_2 \in J \setminus (a_1)$, and inductively $a_{n+1} \in J \setminus (a_1, \dots, a_n)$ – possible since $(a_1, \dots, a_n)$ is finitely generated but J is not. This produces a strictly increasing chain $(a_1) \subset (a_1, a_2) \subset \cdots$, contradicting the ACC. $\square$

In particular every PID is Noetherian – each ideal is generated by a single element. Fields are Noetherian for the same reason. The fundamental theorem about Noetherian rings is that the property passes to polynomial rings.

Theorem 15.11.3 (Hilbert Basis Theorem)

If R is Noetherian, then $R[X]$ is Noetherian.

Proof. Suppose for contradiction that $J \trianglelefteq R[X]$ is not finitely generated. Let $f_1 \in J$ have minimal degree; given $f_1, \dots, f_n$, let $f_{n+1} \in J \setminus (f_1, \dots, f_n)$ have minimal degree – such an element exists as J is not finitely generated. Note the degrees $\deg f_1 \leq \deg f_2 \leq \cdots$ are non-decreasing by construction.

Let $a_i \in R$ be the leading coefficient of f_i . In R we have the chain of ideals

$$(a_1) \subseteq (a_1, a_2) \subseteq (a_1, a_2, a_3) \subseteq \cdots,$$

which since R is Noetherian is eventually constant – so there is m with $a_{m+1} \in (a_1, \dots, a_m)$, say $a_{m+1} = \sum_{i=1}^m \lambda_i a_i$ with $\lambda_i \in R$. Now consider

$$g(X) = \sum_{i=1}^m \lambda_i X^{\deg f_{m+1} - \deg f_i} f_i \in (f_1, \dots, f_m),$$

which is engineered to have the same degree and the same leading coefficient as f_{m+1} . Then $f_{m+1} - g \in J$ with $\deg(f_{m+1} - g) < \deg f_{m+1}$, so by minimality of $\deg f_{m+1}$ we must have $f_{m+1} - g \in (f_1, \dots, f_m)$. But then $f_{m+1} = (f_{m+1} - g) + g \in (f_1, \dots, f_m)$, contradicting our choice of f_{m+1} . $\square$

Corollary 15.11.4

$\mathbb{Z}[X_1, \dots, X_n]$ and $F[X_1, \dots, X_n]$ (for a field F) are Noetherian.

Lemma 15.11.5 (Quotients of Noetherian Rings)

If R is Noetherian and $I \trianglelefteq R$, then R/I is Noetherian.

Proof. A chain of ideals $J'_1 \subseteq J'_2 \subseteq \dots$ in R/I corresponds, via the ideal correspondence, to a chain $J_1 \subseteq J_2 \subseteq \dots$ of ideals of R containing I , with $J'_i = J_i/I$. The latter chain stabilises since R is Noetherian, so the former does too. $\square$

So, for example, *any finitely generated ring* – any quotient of some $\mathbb{Z}[X_1, \dots, X_n]$ – is Noetherian. Let's see why one might care.

Example 15.11.6 (Algebraic Varieties)

Let $R = \mathbb{C}[X_1, \dots, X_n]$, and let $\mathcal{F} \subseteq R$ be any (possibly infinite) set of polynomials, with solution set

$$V = \{(a_1, \dots, a_n) \in \mathbb{C}^n \mid f(a_1, \dots, a_n) = 0 \text{ for all } f \in \mathcal{F}\},$$

an **algebraic variety**. Let $I \trianglelefteq R$ be the ideal generated by $\mathcal{F}$. Since R is Noetherian, $I = (g_1, \dots, g_r)$ is finitely generated, and V is exactly the common zero set of $g_1, \dots, g_r$. So *every* system of polynomial equations, however large, is equivalent to a finite system.

Example 15.11.7 (Non-Noetherian Rings)

The ring $\mathbb{Z}[X_1, X_2, \dots]$ of polynomials in countably many variables is not Noetherian: the chain $(X_1) \subset (X_1, X_2) \subset (X_1, X_2, X_3) \subset \dots$ never stabilises. Note that this ring is an integral domain, and in fact a UFD – so ‘UFD’ does not imply ‘Noetherian’.

More surprisingly, a subring of a Noetherian ring need not be Noetherian. Take

$$R = \{f \in \mathbb{Q}[X] \mid f(0) \in \mathbb{Z}\} \leq \mathbb{Q}[X].$$

Then $(X) \subset (\frac{X}{2}) \subset (\frac{X}{4}) \subset \dots$ is a strictly increasing chain in R (each inclusion is strict because 2 is not a unit in R), even though $\mathbb{Q}[X]$ itself is a Euclidean domain.

§15.12 Modules

We now come to the final act of the course. A *module* is what you get when you take the definition of a vector space and allow the scalars to come from a ring rather than a field. This modest-sounding change has dramatic consequences – most of the comfortable facts of linear algebra (every vector space has a basis, spanning sets contain bases, and so on) fail for general modules – but for modules over sufficiently nice rings we will prove a powerful structure theorem, and from it deduce, in one stroke, the classification of finite abelian groups *and* the theory of canonical forms of matrices (including Jordan normal

form).

§15.12.1 Definitions and Examples

Definition 15.12.1 (Module)

Let R be a ring. An R -module is a triple $(M, +, \cdot)$ consisting of a set M , an operation $+: M \times M \rightarrow M$, and a scalar multiplication $\cdot: R \times M \rightarrow M$, such that

- (i) $(M, +)$ is an abelian group with identity $0 = 0_M$,
- (ii) $(r_1 + r_2) \cdot m = r_1 \cdot m + r_2 \cdot m$,
- (iii) $r \cdot (m_1 + m_2) = r \cdot m_1 + r \cdot m_2$,
- (iv) $r_1 \cdot (r_2 \cdot m) = (r_1 r_2) \cdot m$,
- (v) $1_R \cdot m = m$,

for all $r, r_1, r_2 \in R$ and $m, m_1, m_2 \in M$.

These are exactly the vector space axioms, with the field replaced by a ring. The real content of the definition is in the examples.

Example 15.12.2 (Examples of Modules)

The following are all modules.

- (i) If $R = F$ is a field, an F -module is precisely a vector space over F .
- (ii) A $\mathbb{Z}$ -module is precisely an abelian group. Indeed, given an abelian group A , the only possible $\mathbb{Z}$ -action is

$$n \cdot a = \begin{cases} a + \cdots + a & (n \text{ times, if } n > 0), \\ 0 & (n = 0), \\ -(a + \cdots + a) & (|n| \text{ times, if } n < 0), \end{cases}$$

and this does define a module structure. So the theory of $\mathbb{Z}$ -modules *is* the theory of abelian groups.

- (iii) Let F be a field, V a vector space over F , and $\alpha: V \rightarrow V$ a linear map. Then V becomes an $F[X]$ -module, denoted V_α , via

$$f(X) \cdot v = f(\alpha)(v).$$

Note that the module structure remembers α , not just V – different choices of α give genuinely different $F[X]$ -modules on the same underlying space. This example will drive everything we do with canonical forms.

- (iv) Any ring R is an R -module over itself, and more generally R^n is an R -module with coordinatewise operations.
- (v) An ideal $I \trianglelefteq R$ is an R -module, as is the quotient ring R/I , with $r \cdot (s + I) = rs + I$.

- (vi) If $\phi : R \rightarrow S$ is a ring homomorphism, then any S -module M becomes an R -module via $r \cdot m = \phi(r) \cdot m$. In particular, a module over a ring is a module over any subring.

Definition 15.12.3 (Submodule)

Let M be an R -module. A subset $N \subseteq M$ is an **R -submodule**, written $N \leq M$, if N is a subgroup of $(M, +)$ and $rn \in N$ for all $r \in R, n \in N$.

Example 15.12.4

Viewing R as an R -module over itself, the submodules of R are exactly the ideals of R . If $R = F$ is a field, submodules are exactly vector subspaces.

It is worth noticing what has happened here: subrings and ideals, which looked like two different generalisations of ‘subgroup’, are unified by the module point of view – and it is the ideal, not the subring, that is the module-theoretic notion.

Definition 15.12.5 (Quotient Module)

Let $N \leq M$ be R -modules. The **quotient module** M/N is the quotient abelian group with scalar multiplication $r \cdot (m + N) = rm + N$.

This is well defined precisely because N is closed under scalar multiplication – note that, unlike for groups and rings, *every* submodule can be quotiented by; there is no analogue of normality to worry about.

§15.12.2 Homomorphisms and the Isomorphism Theorems

Definition 15.12.6 (Module Homomorphism)

Let M, N be R -modules. A function $f : M \rightarrow N$ is an **R -module homomorphism** if

$$f(m_1 + m_2) = f(m_1) + f(m_2), \quad \text{and} \quad f(r \cdot m) = r \cdot f(m),$$

for all $m, m_1, m_2 \in M$ and $r \in R$. A bijective module homomorphism is an **isomorphism**.

When R is a field, module homomorphisms are exactly linear maps. As always, we have kernels and images, and a family of isomorphism theorems, whose proofs at this point are routine: apply the group-theoretic versions to $(M, +)$, and check that all the maps involved respect scalar multiplication.

Theorem 15.12.7 (First Isomorphism Theorem)

Let $f : M \rightarrow N$ be an R -module homomorphism. Then

$$\ker(f) = \{m \in M \mid f(m) = 0\} \leq M, \quad \text{img}(f) = \{f(m) \mid m \in M\} \leq N,$$

and $M/\ker(f) \cong \text{img}(f)$, via the map $m + \ker(f) \mapsto f(m)$.

$$\begin{array}{ccc}
 M & \xrightarrow{f} & \text{img}(f) \\
 \pi \downarrow & \nearrow \cong & \\
 M/\ker(f) & &
 \end{array}$$

Theorem 15.12.8 (Second Isomorphism Theorem)

Let $A, B \leq M$ be R -submodules. Then $A + B = \{a + b \mid a \in A, b \in B\}$ and $A \cap B$ are submodules of M , and

$$A/(A \cap B) \cong (A + B)/B.$$

Theorem 15.12.9 (Third Isomorphism Theorem)

Let $N \leq L \leq M$ be R -submodules. Then $L/N \leq M/N$, and

$$(M/N)/(L/N) \cong M/L.$$

There is also the familiar correspondence: submodules of M/N biject with submodules of M containing N .

Remark. Since vector spaces are modules, these specialise to facts from linear algebra – for instance, applying the first isomorphism theorem to a linear map $f : V \rightarrow W$ between finite dimensional spaces and taking dimensions gives

$$\dim V - \dim \ker(f) = \dim \text{img}(f),$$

the rank-nullity theorem.

§15.12.3 Finitely Generated Modules

We need a notion of ‘finite dimensional’ for modules.

Definition 15.12.10 (Generation)

For $m \in M$, write $Rm = \{rm \mid r \in R\} \leq M$, the submodule **generated by** m . An R -module M is **finitely generated** if

$$M = Rm_1 + Rm_2 + \cdots + Rm_n$$

for some $m_1, \dots, m_n \in M$, that is, every element of M is an R -linear combination $r_1m_1 + \cdots + r_nm_n$.

The following reformulation is simple but surprisingly useful – it will be the opening move in the proof of the structure theorem.

Lemma 15.12.11

An R -module M is finitely generated if and only if there is a surjective R -module homomorphism $f : R^n \rightarrow M$ for some n .

Proof. If $M = Rm_1 + \cdots + Rm_n$, define $f : R^n \rightarrow M$ by $f(r_1, \dots, r_n) = r_1m_1 + \cdots + r_nm_n$. This is an R -module homomorphism, and it is surjective by assumption.

Conversely, given such an f , let $e_i \in R^n$ be the standard ‘basis’ element with 1 in position i , and put $m_i = f(e_i)$. Any $m \in M$ equals $f(r_1, \dots, r_n) = r_1m_1 + \cdots + r_nm_n$ for some r_i , so the m_i generate M . $\square$

Corollary 15.12.12

Any quotient of a finitely generated module is finitely generated.

Proof. If $f : R^n \rightarrow M$ is surjective and $N \leq M$, then composing with the quotient map gives a surjection $R^n \rightarrow M/N$. $\square$

Example 15.12.13 (Submodules Need Not Be Finitely Generated)

In contrast with vector spaces (where subspaces of finite dimensional spaces are finite dimensional), a submodule of a finitely generated module can fail to be finitely generated. Take a non-Noetherian ring R with an ideal I that is not finitely generated – say $R = \mathbb{Z}[X_1, X_2, \dots]$ and $I = (X_1, X_2, \dots)$. Then R is generated as an R -module by the single element 1, while its submodule I is not finitely generated.

If R is Noetherian, this cannot happen: submodules of finitely generated R -modules are finitely generated.

§15.12.4 Torsion and Direct Sums

Definition 15.12.14 (Torsion)

Let M be an R -module. An element $m \in M$ is a **torsion element** if $rm = 0$ for some $r \neq 0$ in R . We say M is a **torsion module** if every element is torsion, and **torsion-free** if 0 is the only torsion element.

Example 15.12.15

For $\mathbb{Z}$ -modules (abelian groups), the torsion elements are exactly the elements of finite order; so a finite abelian group is a torsion $\mathbb{Z}$ -module, and $\mathbb{Z}^n$ is torsion-free. Any module over a field is torsion-free. The $\mathbb{Z}$ -module $\mathbb{Z} \oplus \mathbb{Z}/2\mathbb{Z}$ is neither torsion nor torsion-free.

Definition 15.12.16 (Direct Sum)

Let $M_1, \dots, M_n$ be R -modules. The **direct sum** $M_1 \oplus \cdots \oplus M_n$ is the set $M_1 \times \cdots \times M_n$ with componentwise addition and scalar multiplication.

For example, $R^n = R \oplus \cdots \oplus R$. We record one convenient compatibility between direct sums and quotients.

Lemma 15.12.17

Let $M = M_1 \oplus \cdots \oplus M_n$ and $N_i \leq M_i$ for each i . Then $N = N_1 \oplus \cdots \oplus N_n \leq M$ and

$$\frac{M_1 \oplus \cdots \oplus M_n}{N_1 \oplus \cdots \oplus N_n} \cong \frac{M_1}{N_1} \oplus \cdots \oplus \frac{M_n}{N_n}.$$

Proof. Apply the first isomorphism theorem to the surjective homomorphism $M \rightarrow \bigoplus_i M_i/N_i$ given by $(m_1, \dots, m_n) \mapsto (m_1 + N_1, \dots, m_n + N_n)$, whose kernel is exactly N . $\square$

§15.12.5 Free Modules

We next isolate the modules that behave like vector spaces.

Definition 15.12.18 (Independence)

Elements $m_1, \dots, m_n \in M$ are **independent** if

$$r_1 m_1 + \cdots + r_n m_n = 0 \implies r_1 = \cdots = r_n = 0.$$

Definition 15.12.19 (Freely Generating Sets & Free Modules)

A subset $S \subseteq M$ **generates M freely** if S generates M , and every function $\psi : S \rightarrow N$ into an R -module N extends to an R -module homomorphism $\theta : M \rightarrow N$. (Such an extension is automatically unique, since S generates M .) A module with a freely generating set is called **free**, and S is a **free basis**.

Proposition 15.12.20

For a finite subset $S = \{m_1, \dots, m_n\} \subseteq M$, the following are equivalent:

- (i) S generates M freely;
- (ii) S generates M and is independent;
- (iii) every element of M is *uniquely* expressible as $r_1 m_1 + \cdots + r_n m_n$;
- (iv) the map $R^n \rightarrow M$, $(r_1, \dots, r_n) \mapsto r_1 m_1 + \cdots + r_n m_n$, is an isomorphism.

Proof. We show (i) $\implies$ (ii); the equivalence of (ii), (iii) and (iv) is exactly as in linear algebra. Suppose S generates M freely but is not independent, say $\sum_i r_i m_i = 0$ with $r_j \neq 0$. Consider the function $\psi : S \rightarrow R$ with $\psi(m_j) = 1$ and $\psi(m_i) = 0$ for $i \neq j$, and extend it to a homomorphism $\theta : M \rightarrow R$. Then

$$0 = \theta(0) = \theta\left(\sum_i r_i m_i\right) = \sum_i r_i \theta(m_i) = r_j \neq 0,$$

a contradiction. For (iii) $\implies$ (i), define $\theta(r_1 m_1 + \cdots + r_n m_n) = \sum r_i \psi(m_i)$; uniqueness of the expression makes this well defined. $\square$

So a finitely generated free module is just (isomorphic to) some R^n . But be warned – the intuition from vector spaces breaks down beyond this.

Example 15.12.21 (Modules Are Not Vector Spaces)

The $\mathbb{Z}$ -module $\mathbb{Z}/2\mathbb{Z}$ is finitely generated, but not free: every element m satisfies $2m = 0$, so no non-empty subset is independent.

More subtly, $\{2, 3\}$ generates $\mathbb{Z}$ as a $\mathbb{Z}$ -module (as $3 - 2 = 1$), but is not independent ($3 \cdot 2 - 2 \cdot 3 = 0$), and *no subset* of $\{2, 3\}$ is a free basis – $\{2\}$ and $\{3\}$ generate proper submodules. So a generating set need not contain a basis, in stark contrast with linear algebra.

One fact from linear algebra does survive, though it now requires genuine proof.

Proposition 15.12.22 (Invariance of Rank)

Let R be a non-trivial ring. If $R^n \cong R^m$ as R -modules, then $n = m$.

Proof. The idea is to reduce to the vector space case by quotienting. For an ideal $I \trianglelefteq R$ and an R -module M , define

$$IM = \{\sum_i a_i m_i \mid a_i \in I, m_i \in M\} \leq M.$$

The quotient M/IM is then naturally an R/I -module, via $(r + I)(m + IM) = rm + IM$ – this is well defined precisely because IM absorbs multiplication by I .

Now let I be a *maximal* ideal of R (one exists, by a Zorn's lemma argument which we will not detail). Applying the above with $M = R^n$, note $IR^n = I^n$ (componentwise), so

$$(R/I)^n \cong R^n/IR^n \cong R^n/IR^n \cong (R/I)^m$$

as R/I -modules. But R/I is a field, so these are vector spaces, and comparing dimensions gives $n = m$. $\square$

§15.12.6 Matrices over Euclidean Domains

We now begin working towards the main structure theorem. The engine of the proof is a normal form for *matrices* over a Euclidean domain, obtained by row and column operations – essentially Gaussian elimination, done without division.

For the rest of this section, R is a Euclidean domain with Euclidean function ϕ , and we consider $m \times n$ matrices A with entries in R .

Definition 15.12.23 (Elementary Operations)

The **elementary row operations** on a matrix over R are:

- (i) add $\lambda \in R$ times row j to row i (where $i \neq j$),
- (ii) swap rows i and j ,
- (iii) multiply row i by a unit $u \in R^\times$.

Elementary column operations are defined analogously. Each is realised by multiplying on the left (respectively right) by an invertible matrix.

Definition 15.12.24 (Equivalence)

Matrices A and B are **equivalent** if one can be obtained from the other by a sequence of elementary row and column operations; equivalently, $B = QAP$ for invertible Q and P .

Notice what is *not* allowed: we cannot divide by non-units. The whole subtlety of the following algorithm is in working around this.

Theorem 15.12.25 (Smith Normal Form)

Any $m \times n$ matrix A over a Euclidean domain R is equivalent to a diagonal matrix

$$\begin{pmatrix} d_1 & & & & \\ & \ddots & & & \\ & & d_t & & \\ & & & 0 & \\ & & & & \ddots \end{pmatrix},$$

with $d_1 \mid d_2 \mid \cdots \mid d_t$. The d_i are called the **invariant factors** of A , and are unique up to associates.

Proof. If $A = 0$ we are done, so assume not, and by swapping rows and columns arrange $a_{11} \neq 0$. The plan is to repeatedly reduce $\phi(a_{11})$ until a_{11} divides everything in sight; since ϕ takes values in $\mathbb{Z}_{\geq 0}$, this cannot go on forever.

Step 1: clear the first row and column. If $a_{11} \nmid a_{1j}$ for some j , write $a_{1j} = qa_{11} + r$ with $\phi(r) < \phi(a_{11})$ (and $r \neq 0$, else $a_{11} \mid a_{1j}$). Subtracting q times column 1 from column j and then swapping those columns puts r in the top-left corner, strictly decreasing $\phi(a_{11})$. Do the same with rows if $a_{11} \nmid a_{i1}$. After finitely many iterations, a_{11} divides every entry of the first row and column, and subtracting suitable multiples of the first row and column makes all those entries zero:

$$A \sim \begin{pmatrix} d & 0 & \cdots & 0 \\ 0 & & & \\ \vdots & & A' & \\ 0 & & & \end{pmatrix}, \quad d = a_{11}.$$

Step 2: make d divide everything. If $d \nmid a_{ij}$ for some entry of A' , add row i to row 1 – now the first row contains an entry not divisible by d , and we return to Step 1, which strictly decreases $\phi(a_{11})$ again. So after finitely many rounds, we reach the displayed form where moreover $d = d_1$ divides every entry of A' .

Step 3: recurse. Apply the algorithm to A' . The operations involved never touch the first row or column, and preserve the property that d_1 divides all entries (each entry of the new matrix is a combination of old ones). Inducting, A is equivalent to $\text{diag}(d_1, \dots, d_t, 0, \dots, 0)$ with $d_1 \mid d_2 \mid \cdots \mid d_t$.

Uniqueness of the d_i is proven below, using the machinery of Fitting ideals. □

Example 15.12.26

Let us put the integer matrix $A = \begin{pmatrix} 2 & -1 \\ 1 & 2 \end{pmatrix}$ into Smith normal form. Working over $\mathbb{Z}$:

$$\begin{pmatrix} 2 & -1 \\ 1 & 2 \end{pmatrix} \xrightarrow{c_1 \mapsto c_1 + c_2} \begin{pmatrix} 1 & -1 \\ 3 & 2 \end{pmatrix} \xrightarrow{c_2 \mapsto c_2 + c_1} \begin{pmatrix} 1 & 0 \\ 3 & 5 \end{pmatrix} \xrightarrow{r_2 \mapsto r_2 - 3r_1} \begin{pmatrix} 1 & 0 \\ 0 & 5 \end{pmatrix},$$

which is in Smith normal form since $1 \mid 5$: the invariant factors are 1, 5.

To prove uniqueness we introduce an invariant of the equivalence class of a matrix.

Definition 15.12.27 (Minors and Fitting Ideals)

A $k \times k$ **minor** of A is the determinant of a $k \times k$ submatrix of A (obtained by deleting all but k rows and k columns). The k -th **Fitting ideal** $\text{Fit}_k(A) \trianglelefteq R$ is the ideal generated by all $k \times k$ minors of A .

Lemma 15.12.28

Equivalent matrices have the same Fitting ideals.

Proof. By symmetry (transposing), it's enough to show row operations preserve Fit_k . Swapping rows and scaling a row by a unit change each minor by at most a unit factor, so preserve the ideal they generate. Consider then the operation adding λ times row j to row i , giving matrix A' , and let C' be a $k \times k$ submatrix of A' with corresponding submatrix C of A . If row i is not involved, $C' = C$. If both rows i and j are involved, then C' is obtained from C by a row operation, so $\det C' = \det C$. If row i is involved but row j is not, expanding the determinant along the modified row gives

$$\det C' = \det C \pm \lambda \det D,$$

where D is a $k \times k$ submatrix of A (using row j instead of row i , with rows reordered). In all cases $\det C' \in \text{Fit}_k(A)$, so $\text{Fit}_k(A') \subseteq \text{Fit}_k(A)$, and since the operation is invertible, equality holds. $\square$

Proof of uniqueness. Suppose the matrix A is equivalent to $\text{diag}(d_1, \dots, d_t, 0, \dots, 0)$ with $d_1 \mid \dots \mid d_t$. A $k \times k$ minor of this diagonal matrix is non-zero only when it uses rows and columns with matching indices, in which case it is a product $d_{i_1} \cdots d_{i_k}$ with $i_1 < \dots < i_k$. Each such product is divisible by $d_1 d_2 \cdots d_k$ (using the divisibility chain), and $d_1 \cdots d_k$ itself is a minor, so

$$\text{Fit}_k(A) = (d_1 d_2 \cdots d_k).$$

Hence the products $d_1 \cdots d_k$ are determined by A up to associates for each k , and dividing successive products recovers each d_i up to associates. $\square$

Remark. Fitting ideals also give a way to *compute* invariant factors without running the algorithm. In the example above, $\text{Fit}_1(A) = (2, -1, 1, 2) = (1)$ gives $d_1 = \pm 1$, and $\text{Fit}_2(A) = (\det A) = (5)$ gives $d_1 d_2 = \pm 5$, so $d_2 = \pm 5$.

§15.12.7 The Structure Theorem

We now harvest the consequences of Smith normal form. The chain of reasoning runs as follows.

We need two preliminary results to make this rigorous. The first says submodules of R^m are manageable, and the second interprets row and column operations module-theoretically.

Lemma 15.12.29 (Submodules of Free Modules)

Let R be a Euclidean domain (or indeed any PID). Then any submodule $N \leq R^m$ is generated by at most m elements.

Proof. We induct on m . Consider the ideal

$$I = \{r \in R \mid (r, r_2, \dots, r_m) \in N \text{ for some } r_2, \dots, r_m \in R\},$$

the set of possible first coordinates of elements of N (an ideal, since N is a submodule). As R is a PID, $I = (a)$ for some a , and we may choose $n_1 = (a, a_2, \dots, a_m) \in N$.

Now take any $x = (r_1, \dots, r_m) \in N$. Then $r_1 = ra$ for some $r \in R$, and

$$x - rn_1 = (0, r_2 - ra_2, \dots, r_m - ra_m) \in N \cap (\{0\} \times R^{m-1}) =: N'.$$

So $N = Rn_1 + N'$, where N' is (identified with) a submodule of R^{m-1} , generated by at most $m-1$ elements $n_2, \dots, n_m$ by induction. Then $n_1, n_2, \dots, n_m$ generate N . $\square$

Theorem 15.12.30

Let R be a Euclidean domain and $N \leq R^m$ a submodule. Then there is a free basis $x_1, \dots, x_m$ of R^m such that N is generated by $d_1x_1, d_2x_2, \dots, d_tx_t$ for some $t \leq m$ and $d_1 \mid d_2 \mid \dots \mid d_t$.

Proof. By the lemma, N is generated by elements $y_1, \dots, y_n \in R^m$ with $n \leq m$. Form the $m \times n$ matrix A whose columns are the y_i , so that N is generated by the columns of A .

Now consider what the elementary operations do to this data. A column operation replaces the generators y_i by a different generating set for the *same* submodule N

(adding a multiple of one generator to another, swapping generators, or scaling by a unit). A row operation corresponds to changing the free basis of R^m : for instance, adding λ times row j to row i amounts to expressing everything in the new basis $e_1, \dots, e_j - \lambda e_i, \dots, e_m$, which is again a free basis.

Putting A into Smith normal form $\text{diag}(d_1, \dots, d_t, 0, \dots)$ therefore produces a free basis $x_1, \dots, x_m$ of R^m (the accumulated row operations) together with generators $d_1 x_1, \dots, d_t x_t$ of N (the non-zero columns). $\square$

Theorem 15.12.31 (Structure Theorem for Finitely Generated Modules over a Euclidean Domain)

Let R be a Euclidean domain and M a finitely generated R -module. Then

$$M \cong R/(d_1) \oplus R/(d_2) \oplus \cdots \oplus R/(d_t) \oplus R^k$$

for some $k \geq 0$ and non-zero $d_1 \mid d_2 \mid \cdots \mid d_t$. The d_i are called the **invariant factors** of M , and (after discarding those d_i which are units, for which $R/(d_i) = 0$) they are unique up to associates.

Proof. Since M is finitely generated, there is a surjective homomorphism $f : R^m \rightarrow M$, and by the first isomorphism theorem $M \cong R^m / \ker(f)$. By the previous theorem, there is a free basis $x_1, \dots, x_m$ of R^m with $\ker(f)$ generated by $d_1 x_1, \dots, d_t x_t$, where $d_1 \mid \cdots \mid d_t$. Using this basis to identify R^m with $R \oplus \cdots \oplus R$,

$$M \cong \frac{R \oplus \cdots \oplus R}{d_1 R \oplus \cdots \oplus d_t R \oplus 0 \oplus \cdots \oplus 0} \cong R/(d_1) \oplus \cdots \oplus R/(d_t) \oplus R^{m-t},$$

using our lemma on quotients of direct sums. We omit the proof of uniqueness (which can be carried out by counting, for each prime $p \in R$ and each j , the ‘sizes’ of the modules $p^j M / p^{j+1} M$). $\square$

Remark. The structure theorem holds more generally over any PID, with essentially the same statement. The proof runs along the same lines, but without a Euclidean function one needs a different induction to establish Smith normal form – one can measure the ‘size’ of a matrix entry by the number of irreducible factors, using unique factorisation.

Some immediate consequences are worth recording.

Corollary 15.12.32

Over a Euclidean domain, any finitely generated torsion-free module is free.

Proof. In the decomposition of the structure theorem, any factor $R/(d_i)$ with d_i a non-zero non-unit contains torsion (the class of 1 is killed by d_i). Torsion-freeness forces all d_i to be units, so $M \cong R^k$. $\square$

Example 15.12.33 (Computing with the Structure Theorem)

Let G be the abelian group generated by elements a and b subject to the relations

$$2a + b = 0, \quad -a + 2b = 0.$$

Formally, $G \cong \mathbb{Z}^2/N$, where $N \leq \mathbb{Z}^2$ is generated by $(2, 1)$ and $(-1, 2)$. These generators are the columns of

$$A = \begin{pmatrix} 2 & -1 \\ 1 & 2 \end{pmatrix},$$

whose Smith normal form we computed: $\text{diag}(1, 5)$. So in a suitable basis of $\mathbb{Z}^2$, N is generated by x_1 and $5x_2$, and

$$G \cong \frac{\mathbb{Z} \oplus \mathbb{Z}}{\mathbb{Z} \oplus 5\mathbb{Z}} \cong \mathbb{Z}/5\mathbb{Z} \cong C_5.$$

§15.12.8 Finitely Generated Abelian Groups

Since abelian groups are exactly $\mathbb{Z}$ -modules and $\mathbb{Z}$ is a Euclidean domain, the structure theorem instantly classifies all finitely generated abelian groups.

Theorem 15.12.34 (Classification of Finitely Generated Abelian Groups)

Let G be a finitely generated abelian group. Then

$$G \cong C_{d_1} \times C_{d_2} \times \cdots \times C_{d_t} \times \mathbb{Z}^r$$

for some $r \geq 0$ and $d_1 \mid d_2 \mid \cdots \mid d_t$.

Proof. This is precisely the structure theorem for $R = \mathbb{Z}$, translated from module notation $(\mathbb{Z}/d\mathbb{Z}, \oplus)$ into group notation $(C_d, \times)$. $\square$

In particular, taking G finite (so $r = 0$), this proves the fundamental theorem of finite abelian groups in its invariant factor form – the statement we promised back when we studied finite abelian groups. The prime power decomposition also generalises. Recall the key lemma was that $C_{mn} \cong C_m \times C_n$ for coprime m, n ; here is the module version.

Lemma 15.12.35 (Chinese Remainder Theorem)

Let R be a PID and $a, b \in R$ with $\gcd(a, b)$ a unit. Then, as R -modules,

$$R/(ab) \cong R/(a) \oplus R/(b).$$

Proof. Since R is a PID, $(a, b) = (d)$ where d is a gcd of a and b , so $(a, b) = R$ and we can write $1 = ra + sb$ for some $r, s \in R$.

Define $\psi : R \rightarrow R/(a) \oplus R/(b)$ by $\psi(x) = (x + (a), x + (b))$, an R -module homomorphism. Note

$$\psi(sb) = (sb + (a), sb + (b)) = (1 - ra + (a), 0 + (b)) = (1 + (a), 0 + (b)),$$

and similarly $\psi(ra) = (0 + (a), 1 + (b))$. Hence $\psi(x \cdot sb + y \cdot ra) = (x + (a), y + (b))$,

so ψ is surjective.

For the kernel: clearly $(ab) \subseteq \ker(\psi)$. Conversely if $x \in \ker(\psi)$ then $a \mid x$ and $b \mid x$, and writing $x = x(ra + sb) = r(ax) + s(bx)$, both terms are divisible by ab (as $b \mid x$ in the first, $a \mid x$ in the second), so $x \in (ab)$. The first isomorphism theorem finishes the proof. $\square$

Theorem 15.12.36 (Primary Decomposition)

Let R be a Euclidean domain and M a finitely generated R -module. Then

$$M \cong R/(p_1^{n_1}) \oplus \cdots \oplus R/(p_k^{n_k}) \oplus R^r$$

where the p_i are primes of R (not necessarily distinct) and $r \geq 0$.

Proof. By the structure theorem, it suffices to decompose each factor $R/(d)$. As R is a UFD, write $d = up_1^{\alpha_1} \cdots p_s^{\alpha_s}$ with u a unit and the p_i pairwise non-associate primes. The prime powers $p_i^{\alpha_i}$ are pairwise coprime, so repeated application of the previous lemma gives

$$R/(d) \cong R/(p_1^{\alpha_1}) \oplus \cdots \oplus R/(p_s^{\alpha_s}).$$

$\square$

For $R = \mathbb{Z}$ this recovers the prime power form of the classification of finite abelian groups: every finite abelian group is a direct product of cyclic groups of prime power order.

§15.12.9 Rational Canonical Form

We now turn to the second great application of the structure theorem: canonical forms for matrices. The bridge is the $F[X]$ -module V_α from the start of this section – a vector space V over a field F together with a linear map $\alpha : V \rightarrow V$, with X acting as α .

Lemma 15.12.37

If V is finite dimensional, then V_α is a finitely generated $F[X]$ -module.

Proof. A basis $v_1, \dots, v_n$ of V as an F -vector space certainly generates V_α over the larger ring $F[X] \supseteq F$. $\square$

Since $F[X]$ is a Euclidean domain, the structure theorem applies to V_α . To interpret the outcome we must understand what the cyclic modules $F[X]/(f)$ look like as ‘vector space plus endomorphism’ data.

Example 15.12.38 (Companion Matrices)

Suppose $V_\alpha \cong F[X]/(f)$ where $f(X) = X^n + a_{n-1}X^{n-1} + \cdots + a_0$ is monic. Then $1, X, X^2, \dots, X^{n-1}$ is an F -vector space basis of $F[X]/(f)$ (by the division algorithm). The action of α is multiplication by X , which sends $X^i \mapsto X^{i+1}$ for $i < n-1$, and

$$X^{n-1} \mapsto X^n = -a_{n-1}X^{n-1} - \cdots - a_1X - a_0.$$

So with respect to this basis, α has matrix

$$C(f) = \begin{pmatrix} 0 & 0 & \cdots & 0 & -a_0 \\ 1 & 0 & \cdots & 0 & -a_1 \\ 0 & 1 & \cdots & 0 & -a_2 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & -a_{n-1} \end{pmatrix},$$

the **companion matrix** of f .

Theorem 15.12.39 (Rational Canonical Form)

Let V be a finite dimensional vector space over a field F , and $\alpha : V \rightarrow V$ a linear map. Then

$$V_\alpha \cong F[X]/(f_1) \oplus F[X]/(f_2) \oplus \cdots \oplus F[X]/(f_t)$$

for monic polynomials $f_1 \mid f_2 \mid \cdots \mid f_t$, and with respect to a suitable basis of V , the map α has block diagonal matrix

$$\begin{pmatrix} C(f_1) & & & \\ & C(f_2) & & \\ & & \ddots & \\ & & & C(f_t) \end{pmatrix}.$$

Proof. V_α is a finitely generated module over the Euclidean domain $F[X]$, so the structure theorem gives

$$V_\alpha \cong F[X]/(f_1) \oplus \cdots \oplus F[X]/(f_t) \oplus F[X]^k$$

with $f_1 \mid \cdots \mid f_t$. Since $F[X]$ is infinite dimensional over F while V is finite dimensional, $k = 0$. Multiplying each f_i by a unit, we may take them monic (and discard unit f_i). Choosing the companion basis in each summand and concatenating gives the block matrix. $\square$

Remark. In matrix language: every square matrix over *any* field is similar to a block diagonal matrix of companion matrices with $f_1 \mid \cdots \mid f_t$. Reading off the diagonal: the *minimal polynomial* of α is f_t (it kills every summand, and nothing smaller kills the last), and the *characteristic polynomial* is $f_1 f_2 \cdots f_t$ (the characteristic polynomial of $C(f)$ is f). In particular the minimal polynomial divides the characteristic polynomial – we have proven the Cayley-Hamilton theorem along the way.

Example 15.12.40 (2×2 Matrices)

Let $\dim V = 2$. Then $\sum_i \deg f_i = 2$, so either $t = 1$ with $\deg f_1 = 2$, or $t = 2$ with both linear. In the second case $f_1 \mid f_2$ forces $f_1 = f_2 = X - \lambda$, so $V_\alpha \cong F[X]/(X - \lambda) \oplus F[X]/(X - \lambda)$ and $\alpha = \lambda \cdot \text{id}$ is scalar.

So: a non-scalar 2×2 matrix satisfies $V_\alpha \cong F[X]/(f)$ with f its characteristic polynomial, and hence *two non-scalar 2×2 matrices are similar if and only if they have the same characteristic polynomial* – both being similar to the same companion

matrix.

Definition 15.12.41 (Annihilator)

The **annihilator** of an R -module M is the ideal

$$\text{Ann}_R(M) = \{r \in R \mid rm = 0 \text{ for all } m \in M\} \trianglelefteq R.$$

Example 15.12.42

For an ideal $I \trianglelefteq R$ we have $\text{Ann}_R(R/I) = I$. For a finite abelian group A viewed as a $\mathbb{Z}$ -module, $\text{Ann}_{\mathbb{Z}}(A) = (e)$ where e is the exponent of A – this finally delivers the proof (promised earlier) that the exponent is realised: in the invariant factor decomposition $A \cong C_{d_1} \times \cdots \times C_{d_t}$, the exponent is d_t , the order of an actual element. And for V_α as above, $\text{Ann}_{F[X]}(V_\alpha) = (f_t)$ is generated by the minimal polynomial of α .

§15.12.10 Jordan Normal Form

Finally we specialise to $F = \mathbb{C}$, where the primes of the polynomial ring are as simple as possible.

Lemma 15.12.43

The irreducibles (equivalently, primes) in $\mathbb{C}[X]$ are exactly the linear polynomials $X - \lambda$ for $\lambda \in \mathbb{C}$, up to associates.

Proof. Linear polynomials are always irreducible. Conversely, by the fundamental theorem of algebra any non-constant $f \in \mathbb{C}[X]$ has a root $\lambda \in \mathbb{C}$, and then $X - \lambda$ divides f (divide and inspect the remainder), so any f of degree ≥ 2 is reducible. $\square$

So over $\mathbb{C}$, the primary decomposition of V_α is a direct sum of modules of the form $\mathbb{C}[X]/((X - \lambda)^n)$. Let's see what such a summand looks like.

Example 15.12.44 (A Single Jordan Block)

Suppose $V_\alpha \cong \mathbb{C}[X]/((X - \lambda)^n)$, and take the $\mathbb{C}$ -vector space basis

$$1, (X - \lambda), (X - \lambda)^2, \dots, (X - \lambda)^{n-1}.$$

The map $\alpha - \lambda \cdot \text{id}$ acts as multiplication by $X - \lambda$, sending each basis vector to the next and the last to $(X - \lambda)^n = 0$. So in this basis $\alpha - \lambda \text{id}$ is the shift matrix, and α has matrix

$$J_n(\lambda) = \begin{pmatrix} \lambda & & & \\ 1 & \lambda & & \\ & \ddots & \ddots & \\ & & 1 & \lambda \end{pmatrix},$$

an $n \times n$ **Jordan block**.^a

^aDepending on the choice of basis ordering, the 1's appear below or above the diagonal – both

conventions are in use.

Theorem 15.12.45 (Jordan Normal Form)

Let V be a finite dimensional vector space over $\mathbb{C}$ and $\alpha : V \rightarrow V$ a linear map. Then

$$V_\alpha \cong \mathbb{C}[X]/((X - \lambda_1)^{n_1}) \oplus \cdots \oplus \mathbb{C}[X]/((X - \lambda_t)^{n_t})$$

with $\lambda_i \in \mathbb{C}$ not necessarily distinct, and with respect to a suitable basis, α has block diagonal matrix

$$\begin{pmatrix} J_{n_1}(\lambda_1) & & \\ & \ddots & \\ & & J_{n_t}(\lambda_t) \end{pmatrix}.$$

The Jordan blocks are unique up to reordering.

Proof. V_α is a finitely generated module over the Euclidean domain $\mathbb{C}[X]$, so the primary decomposition theorem applies; the primes of $\mathbb{C}[X]$ are the $X - \lambda$, and no free summand $\mathbb{C}[X]$ can appear by finite dimensionality. Choosing the basis of the previous example in each summand gives the block matrix. We will not prove uniqueness, but it follows by computing the dimensions of the generalised eigenspaces $\ker((\alpha - \lambda \text{id})^m)$ for each λ and m , which are determined by (and determine) the block sizes. $\square$

Remark (Reading Off Data From the JNF). Every square complex matrix is similar to one in Jordan normal form, and the form contains all similarity-invariant information:

- (i) the eigenvalues of α are the λ_i appearing in blocks;
- (ii) the characteristic polynomial is $\prod_\lambda (X - \lambda)^{a_\lambda}$, where a_λ is the sum of the sizes of the λ -blocks;
- (iii) the minimal polynomial is $\prod_\lambda (X - \lambda)^{c_\lambda}$, where c_λ is the size of the *largest* λ -block;
- (iv) the dimension of the λ -eigenspace is the *number* of λ -blocks.

In particular, α is diagonalisable if and only if all Jordan blocks have size 1, if and only if the minimal polynomial has no repeated roots.

This is a satisfying place to stop and look back. The single idea of doing linear algebra over a ring – keeping track of *which* scalars we are allowed to divide by – has unified the classification of finite abelian groups, the theory of canonical forms, and (through the rings $\mathbb{Z}[i]$ and $F[X]$) a good deal of number theory. Each of these threads is picked up again in Part II, in Number Fields, Galois Theory and Representation Theory.

16 Linear Algebra

Linear algebra is the area of mathematics concerned with *vector spaces* and the *linear maps* between them. On the face of it this sounds like quite a specialised topic, but the truth is quite the opposite – linearity is everywhere. Whether you are solving simultaneous equations, studying differential equations, working in geometry, or doing quantum mechanics, the underlying structure is frequently that of a vector space, and the machinery developed in this course (bases, matrices, determinants, eigenvalues, inner products and more) is the machinery used to understand it.

This article constitutes my notes for the ‘Linear Algebra’ course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered. As a warning, this course has lots of results which involve just checking that a definition holds – such proofs have been intentionally omitted.

§16.1 Vector Spaces

§16.1.1 Vector Spaces and Subspaces

Linear algebra is, somewhat obviously, primarily about studying objects that are *linear* in nature. The objects we really care about are *vector spaces*, settings in which we can add elements and multiply by scalars. We are also going to consider *linear maps*, functions on vector spaces which preserve that linear structure – but more on that later.

Throughout the following discussion (and this course), $\mathbb{F}$ is going to denote an arbitrary field¹

Definition 16.1.1 ($\mathbb{F}$ -Vector Space)

An **$\mathbb{F}$ -vector space** is an abelian group $(V, +)$ together with a function $\mathbb{F} \times V \rightarrow V$, written $(\lambda, v) \mapsto \lambda v$ such that the following axioms hold:

- (i) *Distributivity in V* . $\lambda(v_1 + v_2) = \lambda v_1 + \lambda v_2$,
- (ii) *Distributivity in $\mathbb{F}$* . $(\lambda_1 + \lambda_2)v = \lambda_1 v + \lambda_2 v$,
- (iii) *Associativity*. $\lambda(\mu v) = (\lambda\mu)v$,
- (iv) *Identity*. $1v = v$.

We usually call elements of V **vectors** and elements of $\mathbb{F}$ **scalars**. The identity element in V is usually called the zero vector, and is written 0_V (or just 0 if the context is clear).

If $\mathbb{F}$ is $\mathbb{R}$ or $\mathbb{C}$, we use the terms ‘real vector space’ and ‘complex vector space’, since they’re so common.

¹A field $\mathbb{F}$ is a set $\mathbb{F}$ equipped with two operations $+$ (‘addition’) and $\cdot$ (‘multiplication’). We require $\mathbb{F}$ with addition to form an abelian group, and multiplication must be associative and have an identity element 1 . We also require every element except 0 to have an inverse with respect to multiplication, and multiplication must be distributive over addition.

Informally, you can think of a field as something you can do arithmetic in.

Example 16.1.2 (Examples of Vector Spaces)

- (i) The set of triples

$$\{(x, y, z) \mid x, y, z \in \mathbb{R}\}$$

forms a real vector space called $\mathbb{R}^3$, because you can add any two triples component wise.

- (ii) The set

$$\mathbb{Q}[\sqrt{2}] = \{a + b\sqrt{2} \mid a, b \in \mathbb{Q}\}$$

is a $\mathbb{Q}$ -vector space, where we add elements and scale by rational numbers in the obvious way.

- (iii) The set
- $\mathcal{C}[0, 1]$
- of all continuous functions
- $f : [0, 1] \rightarrow \mathbb{R}$
- forms a real vector space.

As with many new objects, it's helpful to be able to discuss its substructure. In the case of a vector space V , there's a pretty natural notion for what it means for a subset $U \subseteq V$ to still act like a vector space.

Definition 16.1.3 (Subspace)

Let V be a $\mathbb{F}$ -vector space. A subset $U \subseteq V$ is a **subspace** of V if U is also an $\mathbb{F}$ -vector space. If U is a subspace of V , we will write $U \leq V$.

Example 16.1.4 (Examples of Subspaces)

- (i) The set of vectors $\{(x, y, z) \mid x, y, z \in \mathbb{R}, x + y + z = 0\}$ is a subspace of $\mathbb{R}^3$.
- (ii) The set of polynomials with terms of even degree $\{a_0 + a_2x^2 + a_4x^4 + \cdots + a_{2k}x^{2k} \mid a_{2i} \in \mathbb{R}, k \in \mathbb{N}\}$ is a subspace of $\mathbb{R}[X]$, the vector space of polynomials with coefficients in $\mathbb{R}$.

As you would expect, checking that something is a subspace is usually easier than checking all of the axioms for a vector space. In particular, to check that U is a subspace of an $\mathbb{F}$ -vector space V , you can just check that the following hold:

- *Zero vector*². $0_V \in U$,
- *Closure under addition*. $u_1, u_2 \in U$ to imply $u_1 + u_2 \in U$,
- *Closure under scaling*. $\lambda \in \mathbb{F}$ and $u \in U$ to imply $\lambda u \in U$.

There are various ways in which we can manipulate subspaces, for example we can take the intersection of two subspaces, and we will get back another subspace.

Proposition 16.1.5 (Intersecting Subspaces)

Let $U, W \leq V$. Then $U \cap W \leq V$.

²You may wonder why we need to check this when we already check that we are closed under scaling. To see why, notice that we still have to ensure U is non-empty!

Proof. Since U and W are both subspaces of V , we have $0_V \in U \cap W$, and also since they are both closed under addition and scaling, $u_1, u_2 \in U \cap W$ implies that $u_1 + u_2 \in U \cap W$, and $\lambda \in \mathbb{F}$ implies $\lambda u \in U \cap W$. Thus $U \cap W$ is a subspace of V . $\square$

However we can't manipulate subspaces however we want and expect magic. For example, the union of two subspaces is generally *not* a subspace, as it is typically not closed under addition. In fact, the union is only ever a subspace if one of the subspaces is contained in the other.³ You can see what goes wrong already in $\mathbb{R}^2$: if U and W are two distinct lines through the origin, then adding a vector from each takes you off both lines.

We can however try to ‘complete’ the union so that it becomes a subspace.

Definition 16.1.6 (Sum of Subspaces)

Let V be a vector space over $\mathbb{F}$, and let $U, W \leq V$. We define the **sum** of U and W to be the set

$$U + W = \{u + w \mid u \in U, w \in W\}.$$

This definition immediately forces $U + W \leq V$, and indeed it is the minimal such space (in that any subspace of V containing both U and W must also contain $U + W$).

§16.1.2 Quotient Spaces

Since a vector space V forms an abelian group $(V, +)$, we are able to take the quotient by any subspace $U \leq V$.

Definition 16.1.7 (Quotient Space)

Let V an $\mathbb{F}$ -vector space, and let $U \leq V$. The **quotient space** V/U is the abelian group V/U equipped with the scalar multiplication $F \times V/U \rightarrow V/U$ written $(\lambda, v + U) \mapsto \lambda v + U$.

With this definition, we need to check that this scalar multiplication operation is well defined. Indeed, if $v_1 + U = v_2 + U$ then

$$\begin{aligned} v_1 - v_2 &\in U \\ \implies \lambda(v_1 - v_2) &\in U \\ \implies \lambda v_1 + U &= \lambda v_2 + U \in V/U, \end{aligned}$$

so our operation is indeed well defined.

³There are some more exercises of this flavour on the example sheet.

As you would expect, taking a quotient gives you back a vector space.

Proposition 16.1.8 (Quotient Spaces are Vector Spaces)

V/U is an $\mathbb{F}$ -vector space.

Proof Sketch. Check definitions (most properties are inherited from V being a vector space). $\square$

§16.1.3 Basis and Dimension

You are likely informally familiar with the idea of *dimension*, a measure how much freedom exists in a system. Dimensionality is a rather natural concept with respect to vector spaces, but we will need to move through some technicalities to establish the results we want.

To discuss the amount of freedom, we first need a way to quantify what it means for a set of vectors to be independent from one another. This is the idea of *linear independence*.

Definition 16.1.9 (Linear Independence)

We say that $\{v_1, \dots, v_n\} \in V$ are **linearly independent** if

$$\lambda_1 v_1 + \lambda_2 v_2 + \dots + \lambda_n v_n = 0$$

implies that $\lambda_1 = \dots = \lambda_n = 0$.

Remark. For an infinite subset $S \subseteq V$, we say it's linearly independent if every finite subset is linearly independent.

If a set of vectors is *not* linearly independent, then there's some vector in that set that can be written as a linear combination of the others – so it's not independent of them!

The next idea we need to pin down is being able to see if our set of vectors can ‘generate’ the rest of our vector space.

Definition 16.1.10 (Span)

Let V be a vector space over $\mathbb{F}$, and let $S \subset V$. We define the **span** of S , $\langle S \rangle$ to be the set of finite combinations of elements of S .

If $\langle S \rangle = V$, then we say S **spans** or **generates** V .

Remark. By convention, we also take $\langle \emptyset \rangle = \{0\}$. An equivalent definition is that $\langle S \rangle$ is the smallest subspace of V that contains S .

Example 16.1.11 (Quadratic Polynomials)

Let V be the vector space of quadratic polynomials over $\mathbb{R}$,

$$V = \{ax^2 + bx + c \mid a, b, c \in \mathbb{R}\}.$$

Then the subset $S \subseteq V$ with $S = \{1, x, x^2\}$ spans V .

Putting these two concepts together gives us the idea of *bases*, which are sets of linearly independent vectors that span a vector space.

Definition 16.1.12 (Basis)

A subset S of a vector space V is a **basis** if S is a set of linearly independent vectors that span V .

Example 16.1.13 (Basis for $\mathbb{R}^n$)

The **canonical basis** of $\mathbb{R}^n$ is the set of vectors

$$S = \left\{ \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ 1 \\ \vdots \\ 0 \end{pmatrix}, \dots, \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 1 \end{pmatrix} \right\}.$$

Importantly, this is not the *only* basis of $\mathbb{R}^n$, just one that is quite convenient most of the time.

Remark. Note that in the definition of a basis there is no requirement for the set of basis vectors $S \subseteq V$ to be finite – only that any element in V must be representable using finitely many elements of S .

We'd intuitively want to say that the *dimension* of a vector space is the number of elements in its basis. However, we first need to check that this is a well defined notion. We can at this point distinguish between finite and infinite dimensional vector spaces at this point though⁴.

Definition 16.1.14 (Finite & Infinite Dimension)

We say a vector space V is **finite dimensional** if it has a finite basis, and we say it is **infinite dimensional** otherwise.

The next result about bases we will prove is that they induce *unique* representations of elements in the vector space.

Lemma 16.1.15 (Unique Representations with a Basis)

Let V be a vector space over $\mathbb{F}$. Then $S \subseteq V$ is a basis of V if and only if any vector $v \in V$ can be written uniquely as a linear combination of elements $v_1, \dots, v_n \in S$.

Proof. Suppose that S was a basis for V . Then if $v \in V$ can't be written as such a linear combination, then S wouldn't span V , contradicting it being a basis. Also, if v can be written as such a linear combination non-uniquely, then taking

$$v = \lambda_1 v_1 + \dots + \lambda_n v_n = \mu_1 v_1 + \dots + \mu_n v_n.$$

where $\lambda_i \neq \mu_i$ for at least one value of i , we'd have $0 = v - v = (\lambda_1 - \mu_1)v_1 + \dots + (\lambda_n - \mu_n)v_n$, and at least one of these coefficients must be non-zero, contradicting

⁴Can you see why this is well defined already?

S being linearly independent.

Alternatively, if any element in V can be written uniquely, then if $v_1, \dots, v_n \in S$ with $\lambda_1 v_1 + \dots + \lambda_n v_n = 0$ implies that $\lambda_1 = \dots = \lambda_n = 0$, giving that S must be linearly independent. Since S is also spanning by definition, we see that it therefore must be a basis of V . $\square$

With that out of the way, we can prove some results about finite dimensional vector spaces which will help us get towards our definition of dimension.

Lemma 16.1.16 (Spanning Sets Contain a Basis)

Let V be a finite dimensional vector space, and let $S = \{v_1, \dots, v_n\}$ be a set of vectors that spans V . Then there is some subset of S that is a basis of V .

Proof. If $\{v_1, \dots, v_n\}$ is linearly independent, then we are done. If it's not, then (up to reordering) we have $v_n \in \langle \{v_1, \dots, v_{n-1}\} \rangle$. But then $\langle \{v_1, \dots, v_n\} \rangle = \langle \{v_1, \dots, v_{n-1}\} \rangle$, so we can not include v_n in our subset. Not including elements in this way repeatedly, since there is finitely many elements in S , we must eventually get a linearly independent set that still spans V . $\square$

Theorem 16.1.17 (Steinitz Exchange Lemma)

Let V be a finite dimensional vector space. Then if $\{v_1, \dots, v_m\}$ is a set of linearly independent vectors, and $\{w_1, \dots, w_n\}$ spans V , then

- (i) $m \leq n$
- (ii) up to reordering, $\{v_1, \dots, v_m, w_{m+1}, \dots, w_n\}$ spans V .

Proof. We will prove this by induction. Suppose we have replaced $\ell \geq 0$ of the w_i , and that

$$\langle \{v_1, \dots, v_\ell, w_{\ell+1}, \dots, w_n\} \rangle = V.$$

If $m = \ell$, we are done, so assume that $\ell < m$. Then since this set is spanning, we can write $v_{\ell+1} \in V$ as

$$v_{\ell+1} = \alpha_1 v_1 + \dots + \alpha_\ell v_\ell + \beta_{\ell+1} w_{\ell+1} + \dots + \beta_n w_n.$$

Since having $\beta_i = 0$ for all $\ell + 1 \leq i \leq n$ would violate linear independence, we can suppose without loss of generality that $\beta_{\ell+1} \neq 0$. We also note that this implies that $\ell + 1 \leq n$, as otherwise this would not be possible.

Then $w_{\ell+1} \in \langle \{v_1, \dots, v_{\ell+1}, w_{\ell+2}, \dots, w_n\} \rangle$, and this set spans V .

Repeating this process, we will be done after m steps, and we have also shown (at the final step) that $m \leq n$. $\square$

Corollary 16.1.18 (Dimension)

Let V be a finite dimensional vector space over $\mathbb{F}$. Then any two bases of V have the same number of elements, called the **dimension** of V , denoted $\dim V$ or $\dim_{\mathbb{F}} V$.

Proof. Immediate by Steinitz exchange lemma. $\square$

So using Steinitz exchange lemma we have finally been able to pin down exactly what is meant by the dimension of a vector space – it’s the size of it’s basis. This should match up to the intuitive idea of ‘freedom’ that you had at the start of this section. Freedom in a vector space comes from varying coefficients, and in a basis we can both freely vary coefficients and also reach any element in a vector space uniquely, so the number of independent parameters really is the size of the basis.

Steinitz also gives us a few useful results for free.

Corollary 16.1.19

Let V be a vector space over $\mathbb{F}$ with finite dimension $n = \dim V$. Then

- (i) Any independent set of vectors has at most n elements, with equality if and only if it’s a basis.
- (ii) Any spanning set has at least n elements, with equality if and only if it’s a basis.

Proof. Immediate by Steinitz exchange lemma. $\square$

Working with basis and dimension can make the study of vector spaces much easier. For example, Steinitz allows us nicely extend bases. That is,

If we have a vector space V , and a subspace $U \leq V$,
then we can pick a nice basis $\{u_1, \dots, u_\ell\}$ of U , and
extend it to a basis $\{u_1, \dots, u_\ell, u_{\ell+1}, \dots, u_n\}$ of V .

Working with ideas like this can make many results easier to prove, as we will see in the following propositions.

Proposition 16.1.20 (Dimension of the Sum of Subspaces)

Let U, W be subspaces of a vector space V . If U and W are finite dimensional, then so is $U + W$, and $\dim(U + W) = \dim U + \dim W - \dim(U \cap W)$.

Proof. Pick a basis $\{v_1, \dots, v_a\}$ of $U \cap W$, and extend by Steinitz exchange lemma to a basis $\{v_1, \dots, v_a, u_1, \dots, u_b\}$ of U , and to a basis $\{v_1, \dots, v_a, w_1, \dots, w_c\}$ of W .

It suffices to prove that $\{v_1, \dots, v_a, u_1, \dots, u_b, w_1, \dots, w_c\}$ is a basis of $U + W$.

Clearly this set of vectors spans $U + W$, so we just need to check that they are linearly independent. Suppose that

$$\sum_{i=1}^a \alpha_i v_i + \sum_{i=1}^b \beta_i u_i + \sum_{i=1}^c \gamma_i w_i = 0.$$

Rewriting,

$$\sum_{i=1}^a \alpha_i v_i + \sum_{i=1}^b \beta_i u_i = - \sum_{i=1}^c \gamma_i w_i, \quad (\dagger)$$

where the LHS is in U and the RHS is in W . This implies that $\sum_{i=1}^c \gamma_i w_i \in U \cap W$, and can be written as $\sum_{i=1}^c \gamma_i w_i = \sum_{i=1}^a \mu_i v_i$, for some μ_i , and then substituting this back into (†),

$$\sum_{i=1}^a (\alpha_i + \mu_i) v_i + \sum_{i=1}^b \beta_i u_i = 0$$

which forces $\beta_i = 0$. A similar argument also gives $\gamma_i = 0$, which then finally forces $\alpha_i = 0$, since $\{v_1, \dots, v_a\}$ is a basis. $\square$

Proposition 16.1.21 (Dimension of the Quotient Space)

If V is a finite dimensional vector space over $\mathbb{F}$ and $U \leq V$, then U and V/U are also finite dimensional, and $\dim V = \dim U + \dim V/U$.

Proof. Let $\{u_1, \dots, u_\ell\}$ be a basis of U , and extend it via Steinitz exchange lemma to a basis $\{u_1, \dots, u_\ell, w_{\ell+1}, \dots, w_n\}$ of V .

It's easy to see that $\{w_{\ell+1} + U, \dots, w_n + U\}$ is a basis of V/U , as it clearly spans and linear independence is inherited from it being a basis of V . The result then follows. $\square$

§16.1.4 Direct Sums

Previously, we were able to look at the substructure of a vector space by looking at subspaces. Given two subspaces, we were then able to construct their sum, which is the set of all linear combinations of elements in each subspace.

When studying a vector space using its subspaces in this way (considering their sum), it can be useful to impose an *additional* constraint about the way in which the subspaces interact. In particular, it can be useful to impose a uniqueness constraint on the linear combinations that are created.

Definition 16.1.22 (Direct Sum)

Let V be a vector space over $\mathbb{F}$, and let $U, W \leq V$. We say that V is the **direct sum** of U and W , written $V = U \oplus W$ if and only if every element $v \in V$ can be decomposed as

$$v = u + w$$

with $u \in U$ and $w \in W$, with this decomposition being unique.

Of course, we can generalize the notion of a direct sum naturally to the case of multiple subspaces, in the way that you would expect.

Remark (Warning). We say that W is a direct complement of U in V . There is *no uniqueness* of such a complement!

Lemma 16.1.23

Let V be a vector space and let $U, W \leq V$. Then the following are equivalent.

- (i) $V = U \oplus W$

(ii) $V = U + W$ and $U \cap W = \{0\}$

(iii) For any basis B_1 of U and B_2 of W , the union $B = B_1 \cup B_2$ is a basis of V .

Proof. (ii) implies (i). Let $V = U + W$ with $U \cap W = \{0\}$. Then for all $v \in V$, we can write $v = u + w$ with $u \in U$ and $w \in W$. To see that this is unique, suppose that

$$v = u + w = u' + w'.$$

Then $(u - u') = -(w - w')$, and thus they are both in $U \cap W$, but the only element of this is 0, and thus $u = u'$ and $w = w'$, giving us uniqueness.

(i) implies (iii). Let B_1 be a basis of U and B_2 be a basis of W . Then $B = B_1 \cup B_2$ clearly spans V , so we need to check that it's linearly independent. Indeed, if

$$\sum_{u \in B_1} \lambda_u u + \sum_{w \in B_2} \lambda_w w = 0,$$

then $V = U \oplus W$ implies that since this is the sum of an element of U and an element of W , then each is zero, and linear independence follows from B_1, B_2 being sets of linearly independent vectors.

(iii) implies (ii). Clearly we have $V = U + W$, so we just need to check that $U \cap W = \{0\}$. Let $v \in U \cap W$. Then we can write

$$v = \sum_{u \in B_1} \lambda_u u = \sum_{w \in B_2} \lambda_w w \implies \sum_{u \in B_1} \lambda_u u - \sum_{w \in B_2} \lambda_w w = 0,$$

and since $B_1 \cup B_2$ is a basis for V , we must have $\lambda_u, \lambda_w = 0$ for all $u, w \in B_1, B_2$, implying that $v = 0$. $\square$

This result extends as you would expect for the case of direct products using multiple subspaces.

§16.2 Linear Maps

§16.2.1 Linear Maps and Isomorphisms

We are now going to turn our attention to *linear maps*, which are maps that preserve the underlying structure of the vector space that they act on.

Definition 16.2.1 (Linear Map)

Let V, W be vector spaces over $\mathbb{F}$. A map $\alpha : V \rightarrow W$ is a **linear map** if for all $\lambda_1, \lambda_2 \in \mathbb{F}$ and $v_1, v_2 \in V$ we have

$$\alpha(\lambda_1 v_1 + \lambda_2 v_2) = \lambda_1 \alpha(v_1) + \lambda_2 \alpha(v_2).$$

Example 16.2.2 (Examples of Linear Maps)

- (i) Consider the vector space $\mathcal{C}[0, 1]$ of continuous functions $f : [0, 1] \rightarrow \mathbb{R}$. Then for any fixed point $x \in [0, 1]$, the map $\alpha : \mathcal{C}[0, 1] \rightarrow \mathbb{R}$ with $\alpha(f) = f(x)$ is a

linear map.

- (ii) The map $\mathbb{R}^3 \rightarrow \mathbb{R}$ given by $(a, b, c) \mapsto 4a + 2b + c$ is a linear map.
- (iii) The map $\alpha : Q[\sqrt{2}] \rightarrow Q[\sqrt{2}]$ of ‘multiplying by $\sqrt{2}$ ’ is a linear map, with $a + b\sqrt{2} \mapsto 2b + a\sqrt{2}$.

It’s easy to see that the identity map is a linear map, and also that linearity is preserved by composing linear maps.

One nice thing about linear maps is that they interact well with basis, because of linearity. Indeed, specifying a linear map on the basis is sufficient to define that map on all of a vector space.

Lemma 16.2.3 (Extension by Linearity)

Let V and W be vector spaces, and let B be a basis for V . Then if $\alpha_0 : B \rightarrow W$ is *any* map, then there exists a *unique* linear map $\alpha : V \rightarrow W$ extending α_0 , so that for all $v \in B$ we have $\alpha(v) = \alpha_0(v)$.

Proof. For $v \in V$, let $v = \sum_{i=1}^n \lambda_i v_i$. Then necessarily by linearity, we define

$$\alpha(v) = \alpha \left(\sum_{i=1}^n \lambda_i v_i \right) = \sum_{i=1}^n \lambda_i \alpha_0(v_i).$$

By construction this is a linear map and it extends α_0 . □

As with many other areas of pure mathematics, we have a special case for the structure preserving bijections on a given object.

Definition 16.2.4 (Isomorphism)

If V and W are vector spaces over $\mathbb{F}$, the linear map $\alpha : V \rightarrow W$ is an **isomorphism** if it also bijective. We say two vector spaces V and W are **isomorphic**, written $V \cong W$, if there is an isomorphism between them.

Remark. if $\alpha : V \rightarrow W$ is an isomorphism, then the inverse map α^{-1} exists and importantly it’s *also* linear.

Lemma 16.2.5 (Isomorphism is an Equivalence Relation)

$\cong$ is an equivalence relation on the class of all vector spaces over $\mathbb{F}$.

Proof. For reflexivity, we note that the identity map $id : V \rightarrow V$ is an isomorphism. For symmetry, we note that if $\alpha : V \rightarrow W$ is an isomorphism, then $\alpha^{-1} : W \rightarrow V$ is also an isomorphism. Lastly, we get transitivity because if $\alpha : U \rightarrow V$ and $\beta : V \rightarrow W$ are isomorphisms, then $\beta \circ \alpha : U \rightarrow W$ is also an isomorphism. □

From one perspective, isomorphism allows us to know when two objects are really just different representations of the same thing. With this in mind, the following result tells us something interesting (yet unsurprising) about the nature of finite dimensional vector spaces.

Theorem 16.2.6 (Isomorphism for Finite Dimensional Vector Spaces)

If V is an n dimensional vector space over $\mathbb{F}$, then $V \cong \mathbb{F}^n$, the vector space

$$\mathbb{F}^n = \left\{ \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix} \mid x_1, \dots, x_n \in \mathbb{F} \right\},$$

where addition is component-wise.

Proof. Let $B = \{v_1, \dots, v_n\}$ be a basis for V . Then we claim that the map $\alpha : V \rightarrow \mathbb{F}^n$ defined by

$$v = \sum_{i=1}^n \lambda_i v_i \mapsto \begin{pmatrix} \lambda_1 \\ \vdots \\ \lambda_n \end{pmatrix}$$

is an isomorphism. Indeed, it's easy to see that we have linearity inherited from $\mathbb{F}$, and also the map is a bijection, so indeed we do have $V \cong \mathbb{F}^n$. $\square$

In particular, this result tells us that when we choose a basis for a finite dimensional vector space V , it's really the same as picking some isomorphism from V to $\mathbb{F}^n$.

This theorem also directly implies (with isomorphism being an equivalence relation) a criterion for two finite dimensional vector spaces to be isomorphic.

Theorem 16.2.7 (Isomorphism Criterion)

Let V and W be finite dimensional vector spaces over $\mathbb{F}$. Then they are isomorphic if and only if they have the same dimension.

§16.2.2 Images and Kernels

Stepping back from isomorphisms, we need to define some frequently used concepts relating to linear maps.

Definition 16.2.8

Let V, W be vector spaces over F , and let $\alpha : V \rightarrow W$ be a linear map. We define the **kernel** of α as

$$\ker \alpha = \{v \in V \mid \alpha(v) = 0\},$$

and the **image** of α as

$$\text{img } \alpha = \{w \in W \mid w = \alpha(v), v \in V\}.$$

The structure of a linear map carries over to the image and the kernel, and naturally implies that they are both subspaces of their parent vector spaces.

Lemma 16.2.9 (Image and Kernel are Subspaces)

Let $\alpha : V \rightarrow W$ be a linear map. Then $\ker \alpha$ and $\text{img } \alpha$ are subspaces of V and W respectively.

Proof Sketch. Check definitions. $\square$

You may recognize the definitions of the kernel and image from a course in group theory, particularly in relation to the first isomorphism theorem⁵. Indeed, remembering that vector spaces with vector addition are groups, with we can use the kernel and image of a linear map to establish an isomorphism between vector spaces.

Theorem 16.2.10 (First Isomorphism Theorem For Vector Spaces)

Let V and W be $\mathbb{F}$ vector spaces, and let $\alpha : V \rightarrow W$ be a linear map. Then $V/\ker \alpha \cong \text{img } \alpha$.

Proof Sketch. Consider the isomorphism $\bar{\alpha} : V/\ker \alpha \rightarrow \text{img } \alpha$ defined by $\bar{\alpha}(v + \ker \alpha) = \alpha(v)$, and check definitions. $\square$

Now while the kernel and image being subspaces are rather straightforward, slightly more interesting is the *dimension* of these subspaces. This is described by the *rank-nullity theorem*.

Definition 16.2.11 (Rank and Nullity)

Let α be a linear map. Then the **rank** of α , $r(\alpha) = \dim \text{img } \alpha$, is the dimension of the image. The **nullity** of α , $n(\alpha) = \dim \ker \alpha$, is the dimension of the Kernel.

Theorem 16.2.12 (Rank-Nullity Theorem)

Let U and V be vector spaces such that U is finite dimensional. Let $\alpha : U \rightarrow V$ be a linear map. Then

$$\dim U = r(\alpha) + n(\alpha).$$

Proof. We know that $U/\ker \alpha \cong \text{img } \alpha$. Thus $\dim(U/\ker \alpha) = \dim(\text{img } \alpha)$, that is $\dim U - \dim \ker \alpha = \dim \text{img } \alpha$, or $\dim U = r(\alpha) + n(\alpha)$. $\square$

It is worth pausing to picture what this theorem is saying. A linear map $\alpha : U \rightarrow V$ crushes the kernel down to the single point 0, and maps what remains onto the image inside V . The theorem says that the dimensions ‘lost’ and ‘kept’ in this process must account for all of $\dim U$.

This result has an important consequence which is incredibly useful for quickly checking if a map is an isomorphism.

⁵Recall that if G and H are groups, and $\phi : G \rightarrow H$ is a homomorphism, then $G/\ker \phi \cong \text{img } \phi$.

Lemma 16.2.13 (Characterisation of Isomorphism)

Let V and W be vector spaces over $\mathbb{F}$ with *equal finite dimension*. Then the following are equivalent:

- (i) α is injective,
- (ii) α is surjective,
- (iii) α is an isomorphism.

Proof Sketch. Follows directly from the rank-nullity theorem. $\square$

§16.2.3 Matrices

When dealing with vector spaces, it's sometimes convenient to work with vector spaces in the abstract, and other times it's convenient to pick some nice basis which you can easily work with. When dealing with linear maps $\alpha : V \rightarrow W$, it can also be useful to work with bases. The way we do this is by introducing *matrices*.

It's important to say that matrices are not the essence of linear algebra, and in many cases viewing the subject in this way will just give you the impression that linear algebra is an opaque subject. Instead, you should think of matrices as a nice representation of linear maps for which it's easy to perform computations with. With that said, let's talk about linear maps.

In this section, we are going to discuss linear maps between two vector spaces V and W .

Definition 16.2.14 (Space of Linear Maps)

Let V and W be vector spaces over $\mathbb{F}$. We define

$$\mathcal{L}(V, W) = \{\alpha : V \rightarrow W \mid \alpha \text{ is a linear map}\}.$$

Proposition 16.2.15 (Space of Linear Maps is a Vector Space)

$\mathcal{L}(V, W)$ is a vector space over $\mathbb{F}$. Moreover, if V and W are finite dimensional, then

$$\dim \mathcal{L}(V, W) = \dim V \cdot \dim W.$$

Proof Sketch. To see that $\mathcal{L}(V, W)$ is a vector space, one just needs to check definitions. We will leave the proof of the dimension until later. $\square$

Now, given some linear map α , let's think about how we can represent this map with respect to a basis. Suppose that we had a finite dimensional vector space V with basis $\{v_1, \dots, v_m\}$, and a finite dimensional vector space W with basis $\{w_1, \dots, w_n\}$, and suppose that we had some linear map $\alpha : V \rightarrow W$.

Given some $v \in V$, if we wanted to work out $\alpha(v)$, we can write express v in the basis above, with

$$\alpha(v) = \alpha \left(\sum_{i=1}^m \lambda_i v_i \right) = \sum_{i=1}^m \lambda_i \alpha(v_i).$$

So, to compute what $\alpha(v)$ is for any $v \in V$, it suffices to know what $\alpha(v_1), \dots, \alpha(v_m)$ is. To specify what say $\alpha(v_1)$ is, we can use the above basis of W and write

$$\alpha(v_1) = a_{11}w_1 + a_{21}w_2 + \cdots + a_{n1}w_n,$$

for some coefficients a_{i1} . Repeating this for $v_2, \dots, v_n$ then totally specifies the linear map α . These collection of coefficients can be put into a *matrix*, which will then be a representation of α when coupled with the bases $\{v_i\}$ and $\{w_i\}$.

Definition 16.2.16 (Matrix)

An $n \times m$ **matrix** over $\mathbb{F}$ is an array with n rows and m columns, with entries in $\mathbb{F}$:

$$A = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1m} \\ a_{21} & a_{22} & \cdots & a_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nm} \end{pmatrix}.$$

We denote the set of $n \times m$ matrices over $\mathbb{F}$ by $\mathcal{M}_{n,m}(\mathbb{F})$.

Proposition 16.2.17 (Vector Space of Matrices)

$\mathcal{M}_{n,m}(\mathbb{F})$ is an $\mathbb{F}$ -vector space.

Proof Sketch. Taking addition entry-wise we can just check definitions. $\square$

Proposition 16.2.18 (Dimension of $\mathcal{M}_{n,m}(\mathbb{F})$)

$\dim \mathcal{M}_{m,n}(\mathbb{F}) = m \times n$.

Proof. We define the *elementary matrix* $E_{i,j}$ such that every entry is 0 except for the i, j th entry, which is 1. Then the set $\{E_{i,j} \mid 1 \leq i \leq m, 1 \leq j \leq n\}$ is clearly a basis, and has $n \times m$ elements. $\square$

Following on from the discussion above, we can now write down how linear maps can be represented using matrices.

Definition 16.2.19 (Matrix of α in the B, C Basis)

Let $\alpha : V \rightarrow W$ be a linear map, and let $B = \{v_1, \dots, v_m\}$ be a basis of V and $C = \{w_1, \dots, w_n\}$ be a basis of W . Then we define the **matrix of α** to be

$$[\alpha]_{B,C} = \begin{pmatrix} \begin{array}{c} | \\ [\alpha(v_1)]_C \\ | \end{array} & \begin{array}{c} | \\ [\alpha(v_2)]_C \\ | \end{array} & \cdots & \begin{array}{c} | \\ [\alpha(v_m)]_C \\ | \end{array} \end{pmatrix} = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1m} \\ a_{21} & a_{22} & \cdots & a_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nm} \end{pmatrix},$$

where a_{ij} is the coefficient of w_i in $\alpha(v_j)$.

Remark (Notation). We use $[v]_C$ to denote the column vector representing the vector v in the basis C .

Proposition 16.2.20 (Matrix Representation of Linear Maps)

If V and W are vector spaces over $\mathbb{F}$ such that $\dim V = n$ and $\dim W = m$, then $\mathcal{L}(V, W) \cong \mathcal{M}_{m,n}(\mathbb{F})$.

Proof. Fix a basis B, C of V and W respectively. Then consider the linear map $\theta : \mathcal{L}(V, W) \rightarrow \mathcal{M}_{m,n}(\mathbb{F})$ given by $\alpha \mapsto [\alpha]_{B,C}$.

This map is clearly linear, and it's also clearly a bijection thus it's an isomorphism and our result follows. $\square$

Remark. This implies that $\dim \mathcal{L}(V, W) = m \times n$, filling in the gap left in the proposition at the start of this section.

What's nice about matrices is that they make working with linear maps *easy*. It's generally much easier to manipulate arbitrary matrices than it is to arbitrary linear maps (of course, this varies from case to case), and we will see this in the following set of computational results.

You should be familiar from previous courses with the notion of matrix multiplication.

Definition 16.2.21 (Matrix Multiplication)

Let $A = (a_{ij})$ be an $n \times p$ matrix, and $B = (b_{ij})$ be an $p \times m$ matrix. Then their **product** $C = A \cdot B$ is an $n \times m$ matrix $C = (c_{ij})$, with

$$c_{ij} = \sum_{k=1}^p a_{ik} b_{kj}.$$

We can use matrix multiplication in lots of nice ways.

Lemma 16.2.22 (Evaluating Linear Maps)

Let $\alpha : V \rightarrow W$ be a linear map, and let B, C be bases for V and W respectively. Then if $v \in V$, we have

$$[\alpha(v)]_C = [\alpha]_{B,C} \cdot [v]_B.$$

Proof. Let $v \in V$, and let $v = \sum_{j=1}^n \lambda_j v_j$. Then

$$\alpha(v) = \sum_{j=1}^n \lambda_j \alpha(v_j) = \sum_{j=1}^n \lambda_j \sum_{i=1}^m a_{ij} w_i = \sum_{i=1}^m \left(\sum_{j=1}^n a_{ij} \lambda_j \right) w_i,$$

as required. $\square$

Lemma 16.2.23 (Composing Linear Maps)

Let $\alpha : V \rightarrow W$ and $\beta : U \rightarrow V$ be linear maps. Then if A, B, C are bases of U, V and W respectively, we have

$$[\alpha \circ \beta]_{A,C} = [\alpha]_{B,C} \cdot [\beta]_{A,B}.$$

Proof Sketch. Use the definition of matrix multiplication to check that this map corresponds to the correct thing. $\square$

§16.2.4 Change of Basis and Equivalent Matrices

Matrices represent a linear map with respect to a given basis, so a natural question is how do we rewrite a matrix in a different basis? That is, given two vector spaces V, W and a linear map $\alpha : V \rightarrow W$, we want to take the matrix $[\alpha]_{B,C}$ and express it with respect to the basis B', C' .

The way we do this is by introducing a *change of basis* matrix.

Definition 16.2.24 (Change of Basis Matrix)

The **change of basis** matrix from B' to B is the matrix $P = [I]_{B',B}$, where I is the identity map.

Remark. P is an invertible square matrix, and P^{-1} is the change of basis matrix from B to B' .

Given a vector represented in a basis B , the change of basis matrix allows that vector to be expressed in a different basis B' .

Lemma 16.2.25 (Change of Basis for a Vector)

Let B and B' be bases for a vector space V , and let $v \in V$. Then if P is the change of basis matrix from B' to B we have

$$[v]_B = P[v]_{B'}.$$

Proof. We know that $P = [I]_{B',B}$, and so $[v]_B = [I(v)]_B = [I]_{B',B}[v]_{B'} = P[v]_{B'}$. $\square$

Using this idea of change of basis matrices, we can express the matrix of a linear map with respect to another basis. The situation to keep in mind is the following square, where the vertical arrows are the identity map expressed in the relevant bases – the two ways of travelling from the top-left corner to the bottom-right corner must agree.

$$\begin{array}{ccc} V \text{ (basis } B') & \xrightarrow{A' = [\alpha]_{B',C'}} & W \text{ (basis } C') \\ \downarrow P & & \downarrow Q \\ V \text{ (basis } B) & \xrightarrow{A = [\alpha]_{B,C}} & W \text{ (basis } C) \end{array}$$

Proposition 16.2.26 (Change of Basis Formula)

Let $A = [\alpha]_{B,C}$ and $A' = [\alpha]_{B',C'}$, and let P be the change of basis from B' to B and Q be the change of basis matrix from C' to C . Then

$$A' = Q^{-1}AP.$$

Proof. For any $v \in V$ we have, using the change of basis lemma for vectors twice,

$$Q[\alpha(v)]_{C'} = [\alpha(v)]_C = A[v]_B = AP[v]_{B'},$$

and so $[\alpha(v)]_{C'} = Q^{-1}AP[v]_{B'}$. Since the matrix representing α with respect to B' and C' is unique, $A' = Q^{-1}AP$. $\square$

§16.2.5 Equivalent Matrices

A natural notion of equivalence comes from saying two matrices are equivalent if there is some choice of basis for which they represent the same linear map. Using the change of basis formula, we can pin down this notion exactly.

Definition 16.2.27 (Equivalent Matrices)

We say that two matrices $A, A' \in \mathcal{M}_{m,n}(\mathcal{F})$ are **equivalent** if $A' = Q^{-1}AP$ for some invertible matrices $Q \in \mathcal{M}_{m,m}(\mathbb{F})$ and $P \in \mathcal{M}_{n,n}$.

It's easy to check that this definition gives us an equivalence relation, and indeed it turns out that the equivalence classes of matrices are remarkably straightforward.

Proposition 16.2.28 (Natural Basis for Matrices)

Let V, W be vector spaces over $\mathbb{F}$, with $\dim V = n$ and $\dim W = m$. Let $\alpha : V \rightarrow W$ be a linear map. Then there exists a basis B of V and a basis C of W such that

$$[\alpha]_{B,C} = \left(\begin{array}{c|c} I_r & 0 \\ \hline 0 & 0 \end{array} \right),$$

where $r = r(\alpha)$ and I_r is the $r \times r$ identity matrix.

Proof. We first choose a basis $\{v_{r+1}, \dots, v_n\}$ of $\ker \alpha$, and extend it to a basis $B = \{v_1, \dots, v_n\}$ of V . We will first show that $\{\alpha(v_1), \dots, \alpha(v_r)\}$ is a basis of $\text{img } \alpha$.

To see that it's spanning, given $v \in V$ we can write $\alpha(v) = \alpha(\sum_{i=1}^n \lambda_i v_i) = \sum_{i=1}^n \lambda_i \alpha(v_i) = \sum_{i=1}^r \lambda_i \alpha(v_i)$, since $\alpha(v_i) = 0$ for $i > r$.

To see that we have linear independence, suppose that $\sum_{i=1}^r \lambda_i \alpha(v_i) = 0$. Then we have $\alpha(\sum_{i=1}^r \lambda_i v_i) = 0$ implying that $\sum_{i=1}^r \lambda_i v_i \in \ker \alpha$, and since the kernel is spanned by $\{v_{r+1}, \dots, v_n\}$ and $\{v_1, \dots, v_n\}$ is a basis, we must have $\lambda_i = 0$, as required.

We can now extend this basis to a basis $C = \{\alpha(v_1), \dots, \alpha(v_r), w_{r+1}, \dots, w_m\}$ of W . Then we can express α as a matrix in the basis B and C as

$$[\alpha]_{B,C} = \left(\begin{array}{c|ccc|c} | & & & & | \\ \hline [\alpha(v_1)]_C & \cdots & [\alpha(v_r)]_C & [\alpha(v_{r+1})]_C & \cdots & [\alpha(v_n)]_C \\ \hline | & & | & | & & | \end{array} \right)$$

$$= \left(\begin{array}{c|c|c|c|c|c} | & & | & & | & \\ \hline [\alpha(v_1)]_C & \cdots & [\alpha(v_r)]_C & [0]_C & \cdots & [0]_C \\ \hline | & & | & & | & \end{array} \right),$$

and it can easily be seen that this matrix is of the form desired. $\square$

This result gives us a clear criterion for the equivalence of matrices, and also gives us a lovely result which is useful for choosing a basis which works nicely with the matrix representation of a linear map.

Corollary 16.2.29 (Matrix Equivalence Criterion)

Two $m \times n$ matrices are equivalent if the linear maps they represent have the same rank.

The equivalence criterion above is great, but doesn't give us a very easy way to see what the rank of the underlying linear map is, without doing a large amount of work. What we really want is a way to get this rank directly from the matrix. We can do this by considering the *column* and *row rank* of a matrix (which as we will see are really the same notion).

Definition 16.2.30 (Column and Row Rank)

Let $A \in \mathcal{M}_{m,n}(\mathbb{F})$. The **column rank** of A , $r(A)$, is the dimension of the subspace of $\mathbb{F}^m$ spanned by the column vectors of A .

Similarity, the **row rank** is the dimension of the subspace spanned by the row vectors of A (that is, it's the column rank of A^T).

Remark. If α is a linear map, represented by a matrix A with respect to some basis, then $r(A) = r(\alpha)$, so column rank is the same as the rank.

Proposition 16.2.31 (Equivalence from Row Rank)

Two matrices A, A' are equivalent if and only if $r(A) = r(A')$.

Proof. If they are equivalent, then they correspond to the same linear map α , expressed in two different bases. So the column rank is $r(A) = r(A') = r(\alpha)$, and we are done.

If $r(A) = r(A') = r$, then A and A' are both equivalent to

$$\left(\begin{array}{c|c} I_r & 0 \\ \hline 0 & 0 \end{array} \right),$$

and by transitivity of equivalent, we have A and A' equivalent. $\square$

The distinction between column rank and row rank is really non-existent, as the following result shows. This also means that we can refer to the column and row rank as just the 'rank' of the matrix.

Theorem 16.2.32 (Column Rank Equals Row Rank)

$$r(A) = r(A^T)$$

Proof. Let $r = r(A)$. Then we know that we can write

$$Q^{-1}AP = \left(\begin{array}{c|c} I_r & 0 \\ \hline 0 & 0 \end{array} \right),$$

then taking the transpose, we have $(Q^{-1}AP)^T = P^T A^T (Q^{-1})^T = P^T A^T (Q^T)^{-1}$ so $P^T A^T (Q^T)^{-1}$ is

$$\left(\begin{array}{c|c} I_r & 0 \\ \hline 0 & 0 \end{array} \right)^T,$$

which is an $n \times m$ matrix. But then $r = r(A) = r(A^T)$. $\square$

Let's now consider the special case of **endomorphisms**, that is, linear maps $\alpha : V \rightarrow V$.

If B and B' are a basis for V , and P is the change of basis matrix from B' to B , then given α we have $[\alpha]_{B',B'} = P^{-1}[\alpha]_{B,B}P$, which is a special case of the change of basis formula. This idea of writing a matrix using the same basis for the domain and range gives us *similarity*, another notion of matrices being the same.

Definition 16.2.33 (Similar Matrices)

Let A, A' be two $n \times n$ square matrices. We say that A and A' are **similar** or **conjugate** if and only if $A' = P^{-1}AP$ for some invertible $n \times n$ matrix P .

This idea of similarity will be a central concept when we deal with the diagonalization of such matrices later on.

§16.2.6 Elementary Operations and Elementary Matrices

We are going to end this section by looking at the matrix operations that you will have used in previous courses to solve systems of linear equations, and seeing how they fit into the framework we have built up.

Definition 16.2.34 (Elementary Operations)

An **elementary column operation** on a matrix is one of the following:

- (i) swap two columns i and j ,
- (ii) multiply a column i by some $\lambda \in \mathbb{F}$ with $\lambda \neq 0$,
- (iii) add λ times column i to column j , where $i \neq j$.

Elementary row operations are defined analogously, acting on rows.

Each of these operations is invertible, and importantly each of them can be performed by matrix multiplication. That is, for each elementary operation there is a corresponding **elementary matrix**, obtained by performing that operation on the identity matrix.

For example, the elementary matrices

$$S_{ij} = \begin{pmatrix} 1 & & & \\ & 0 & \cdots & 1 \\ & \vdots & \ddots & \vdots \\ & 1 & \cdots & 0 \\ & & & & 1 \end{pmatrix}, \quad M_i(\lambda) = \begin{pmatrix} 1 & & & \\ & \lambda & & \\ & & \ddots & \\ & & & 1 \end{pmatrix}, \quad C_{ij}(\lambda) = I + \lambda E_{ij}$$

correspond to swapping columns i, j , scaling column i by λ , and adding λ times column i to column j respectively (here E_{ij} is the matrix which is zero everywhere except for a 1 in the (i, j) entry).

Lemma 16.2.35 (Elementary Operations as Matrix Multiplication)

Performing an elementary column operation on a matrix A is the same as multiplying A *on the right* by the corresponding elementary matrix. Similarly, performing an elementary row operation is the same as multiplying A *on the left* by the corresponding elementary matrix.

Proof Sketch. Check definitions, using the formula for matrix multiplication. $\square$

These operations give a *constructive* way to see the ‘natural basis for matrices’ proposition from earlier: given any $m \times n$ matrix A , if $A \neq 0$ we can pick some non-zero entry, swap rows and columns to move it to the top-left corner, scale it to be 1, and then use it to clear out the rest of the first row and column. Repeating this on the remaining $(m-1) \times (n-1)$ block, we eventually reach the matrix

$$\left(\begin{array}{c|c} I_r & 0 \\ \hline 0 & 0 \end{array} \right),$$

having multiplied A on the left and right by invertible (elementary) matrices.

In the case of square invertible matrices, we can say a little more.

Proposition 16.2.36 (Invertible Matrices are Products of Elementary Matrices)

Let A be an invertible $n \times n$ matrix. Then A can be reduced to I_n using column operations alone (or row operations alone), and thus A is a product of elementary matrices.

Proof. We induct on the number of rows put into the correct form, supposing that using column operations we have transformed A into a matrix of the shape

$$\left(\begin{array}{c|c} I_k & 0 \\ \hline * & B \end{array} \right).$$

We claim there is some $j > k$ such that the $(k+1, j)$ entry is non-zero. If not, then row $k+1$ of our matrix would be a linear combination of the first k rows, which is impossible as our matrix is a product of A and invertible matrices, hence invertible. Swapping column j with column $k+1$ and scaling so that the $(k+1, k+1)$ entry is 1, we can then clear the rest of row $k+1$ with column operations, extending the identity block to size $k+1$.

Continuing, we obtain elementary matrices with $AE_1E_2\cdots E_m = I_n$. But then $A = E_m^{-1}\cdots E_1^{-1}$, and since the inverse of an elementary matrix is elementary, we are done. $\square$

This gives us a practical algorithm for inverting a matrix: perform column operations on A until you reach the identity, and apply the same operations to I_n as you go – what remains is A^{-1} .

§16.3 Dual Space

§16.3.1 Defining the Dual Space

We are now going to turn our attention to an interesting set of linear maps on a vector space.

Definition 16.3.1 (Dual Space)

Let V be a vector space over a field $\mathbb{F}$. The **dual space** V^* is the set of linear maps from V to $\mathbb{F}$,

$$V^* = \mathcal{L}(V, \mathbb{F}).$$

So how should we understand this space? As usual, things are easier for finite dimensional vector spaces, so we are going to start there. We know from the previous section that *any* linear map is determined by its action on basis vectors. So if we have some finite dimensional vector space V with basis $\{v_1, \dots, v_n\}$ and a linear map $\alpha : V \rightarrow \mathbb{F}$, we just need to know $\alpha(v_1), \dots, \alpha(v_n) \in \mathbb{F}$.

This tells us exactly what the nice way to think about the dual space is – through a basis that just picks out basis vectors so that we can deal with them individually. We call this the *dual basis*.⁶

Definition 16.3.2 (Dual Basis)

Let V be a finite dimensional vector space over $\mathbb{F}$ with a basis $B = \{v_1, \dots, v_n\}$. Then we define the **dual basis** for V^* to be $B^* = \{\varepsilon_1, \dots, \varepsilon_n\}$ where $\varepsilon_j(v_i) = \delta_{ij}$.

In particular, if $v \in V$ can be written as $v = \sum_{i=1}^n \lambda_i v_i$, then $\varepsilon_j(v) = \lambda_j$.

Since this is a basis of V^* , we can immediately see that $\dim V^* = \dim V$. Sometimes it's also convenient to think of V^* as the space of row vectors of length m over $\mathbb{F}$.⁷

§16.3.2 The Annihilator

When we have some subset U of a vector space V , we frequently care about the set of linear maps that are zero on everything in U . This construction ends up giving us a subspace of the dual space V^* .

⁶We just write it as a definition here, but we should really check that it is indeed a basis of the dual, but I think it's relatively clear so this is left to the reader.

⁷There's also a hidden inner product structure here, but we won't dwell on that.

Definition 16.3.3 (Annihilator)

If V is a vector space over $\mathbb{F}$, and $U \subseteq V$, then the **annihilator** of U is the set U^0 of linear maps $V \rightarrow \mathbb{F}$ that are zero on U ,

$$U^0 = \{\alpha \in V^* \mid \alpha(u) = 0 \text{ for all } u \in U\}.$$

Lemma 16.3.4 (Annihilator is a Subspace)

The annihilator is always a subspace of the dual, that is, $U^0 \leq V^*$.

Proof Sketch. Check definitions. □

By thinking about the annihilator, we also get a result that looks a little like rank-nullity.

Lemma 16.3.5 (Rank-Nullity for the Annihilator)

If V is a finite dimensional vector space and $U \leq V$, then $\dim V = \dim U + \dim U^0$.

Proof Sketch. Let $\{v_1, \dots, v_k\}$ be a basis of U , and extend it to a basis $B = \{v_1, \dots, v_n\}$ of V . Then the dual basis is $B' = \{\varepsilon_1, \dots, \varepsilon_n\}$. We then just need to check that $\{\varepsilon_{k+1}, \dots, \varepsilon_n\}$ is a basis of U^0 . □

§16.3.3 The Dual Map

We will now see that thinking about the dual will give us a basis-free interpretation of what corresponds with the transpose of a matrix.

Definition 16.3.6 (Dual Map)

Let V and W be vector spaces, and suppose that $\alpha : V \rightarrow W$ is a linear map. Then we define the **dual map** of α to be the linear map $\alpha^* : W^* \rightarrow V^*$ given by $\varepsilon \mapsto \varepsilon \circ \alpha$.

To see what this is all about, consider the following example.

Example 16.3.7 (Using the Dual Map)

Let V and W be $\mathbb{R}$ vector spaces, and let $B = \{v_1, v_2, v_3\}$ be a basis for V and $C = \{w_1, w_2\}$ be a basis for W .

We define the linear map $\alpha : V \rightarrow W$ by

$$\begin{aligned}\alpha(v_1) &= w_1 + w_2 \\ \alpha(v_2) &= 2w_1 - w_2 \\ \alpha(v_3) &= 6w_1 + 3w_2.\end{aligned}$$

Now we can see what the dual map $\alpha^* : W^* \rightarrow V^*$ looks like. Let $B^* = \{v_1^*, v_2^*, v_3^*\}$ be the corresponding dual basis of V , and let $C^* = \{w_1^*, w_2^*\}$ be the corresponding

dual basis of W . Then for any $v = av_1 + bv_2 + cv_3$ we have

$$\begin{aligned} [\alpha^*(w_1^*)](v) &= w_1^*(\alpha(av_1 + bv_2 + cv_3)) \\ &= w_1^*((a + 2b + 6c)w_1 + (a - b + 3c)w_2) \\ &= a + 2b + 6c, \end{aligned}$$

and in this way, we can really write

$$\alpha^*(w_1^*) = v_1^* + 2v_2^* + 6v_3^*, \quad \text{and} \quad \alpha^*(w_2^*) = v_1^* - v_2^* + 3v_3^*,$$

which totally specifies α^* .

A slightly more interesting way of viewing this example is through the lens of matrices.

Example 16.3.8 (Above with Matrices)

Continuing on from the example above, we can see that in the B, C basis we have

$$[\alpha]_{B,C} = \begin{pmatrix} 1 & 2 & 6 \\ 1 & -1 & 3 \end{pmatrix}.$$

Then α^* in the C^*, B^* basis is given by

$$[\alpha^*]_{C^*,B^*} = \begin{pmatrix} 1 & 1 \\ 2 & -1 \\ 6 & 3 \end{pmatrix}.$$

Of course, in finite dimensions this works in the general case.

Theorem 16.3.9 (Transpose Interpretation of the Dual Map)

Let V and W be finite dimensional vector spaces over $\mathbb{F}$. Let B be a basis for V and C be a basis for W , and let B^*, C^* be the corresponding dual spaces. Then if $\alpha : V \rightarrow W$ is a linear map, we have

$$[\alpha^*]_{C^*,B^*} = [\alpha]_{B,C}^T.$$

Proof. Let $B = \{v_1, \dots, v_n\}$ be a basis for V and $C = \{w_1, \dots, w_m\}$ be a basis for W , and let B^*, C^* be the corresponding dual spaces. Then

$$([\alpha]_{B,C})_{i,j} = ([\alpha(v_i)]_C)_j = ([w_j^* \circ \alpha]_{B^*})_i = ([\alpha^*]_{C^*,B^*})_{j,i},$$

as required. □

This result about viewing the matrix of α^* in terms of the matrix of α hints at a more general perspective where it can be easier to understand one of α and its dual α^* than the other, and indeed many properties of α^* can be derived from α .

For example, the result below is *immensely important*⁸ and is an example of the ‘duality approach’.

⁸But we won’t see in this course why that is.

Proposition 16.3.10 (Properties of the Dual Map)

Let V and W be vector spaces over $\mathbb{F}$, and let $\alpha : V \rightarrow W$ be a linear map. Then

- (i) $\ker \alpha^* = (\operatorname{img} \alpha)^0$, so α^* is injective if and only if α is surjective.
- (ii) $\operatorname{img} \alpha^* \leq (\ker \alpha)^0$, with equality if V and W are finite dimensional (in this case, α^* is surjective if and only if α is injective).

Proof. (i) Let $\varepsilon \in W^*$. Then $\varepsilon \in \ker \alpha^*$ if and only if $\alpha^*(\varepsilon) = 0$, that is, if $\varepsilon(\alpha(v)) = 0$ for all $v \in V$. But this occurs if and only if $\varepsilon \in (\operatorname{img} \alpha)^0$.

(ii) We will first show that $\operatorname{img} \alpha^* \leq (\ker \alpha)^0$. Indeed, let $\varepsilon \in \operatorname{img} \alpha^*$. Then $\varepsilon = \alpha^*(\phi)$ for some $\phi \in W^*$. But then for all $u \in \ker \alpha$ we have $\varepsilon(u) = (\alpha^*(\phi))(u) = \phi(\alpha(u)) = 0$. So then $\varepsilon \in (\ker \alpha)^0$, and thus $\operatorname{img} \alpha^* \leq (\ker \alpha)^0$ as required.

In finite dimensions, we can compute the dimensions of the two spaces. We have

$$\dim \operatorname{img} \alpha^* = r(\alpha^*) = r([\alpha^*]_{C^*, B^*}) = r([\alpha]_{B, C}^T) = r(\alpha).$$

So $\dim \operatorname{img} \alpha^* = r(\alpha)$, and by rank-nullity, this is $\dim V - \dim \ker \alpha = \dim (\ker \alpha)^0$. So $\operatorname{img} \alpha^* \leq (\ker \alpha)^0$ and also $\dim \operatorname{img} \alpha^* = \dim (\ker \alpha)^0$, giving us equality. $\square$

§16.3.4 Double Dual

In general, there is no *obvious* relation between V and V^* , in that all of the relations we discussed in the previous section rely on choosing a basis – and choosing bases is an inherently arbitrary process. However, there *is* a canonical (that is, basis free) relation between V and $(V^*)^*$.

Definition 16.3.11 (Double Dual)

Let V be a vector space over $\mathbb{F}$, and $V^* = \mathcal{L}(V, \mathbb{F})$ be the dual of V . Then we define the **double dual** or **bidual** of V to be

$$V^{**} = \mathcal{L}(V^*, \mathbb{F}) = (V^*)^*.$$

Indeed, there is a *canonical* embedding from V to V^{**} , and there are non-trivial examples⁹ of infinite dimensional spaces where $V \cong V^{**}$.

This canonical embedding is described by ‘evaluating at v ’.

⁹Such as $L^p(\mathbb{R}^d) = \{f : \mathbb{R}^d \rightarrow \mathbb{R} \mid \int_{\mathbb{R}^d} |f(x)|^p dx < \infty\}$.

Theorem 16.3.12 (Canonical Embedding of V into V^{**})

There is a natural injective linear map from V to V^{**} , called the **evaluation map**.

Proof. Let V be an $\mathbb{F}$ vector space, and let $v \in V$. We define the evaluation at v map

$$\hat{v} : V^* \rightarrow \mathbb{F} \quad \text{by} \quad \hat{v}(\varepsilon) = \varepsilon(v).$$

Then $\hat{v}(\varepsilon_1 + \lambda\varepsilon_2) = (\varepsilon_1 + \lambda\varepsilon_2)(v) = \varepsilon_1(v) + \lambda\varepsilon_2(v)$, so $\hat{v} \in V^{**}$.

The proof that this is injective is intentionally omitted. $\square$

Theorem 16.3.13 (Canonical Embedding in Finite Dimensions)

If V is finite dimensional, then the evaluation map is an isomorphism.

Proof. We know that for $v \in V$ we have the evaluation map $\hat{v} \in V^{**}$. It's easy to see that the map $v \mapsto \hat{v}$ is linear in v , so it is left to check that this map is a bijection.

Let $e \in V \setminus \{0\}$. We can extend $\{e\}$ to a basis $B = \{e, e_2, \dots, e_n\}$ of V . Let B^* be the dual basis of V . Then

$$\hat{e}(e^*) = e^*(e) = 1,$$

and in particular, $\hat{e} \neq 0$, so the kernel of the map $v \mapsto \hat{v}$ contains only 0, and thus it is injective^a.

To see that this map is an isomorphism, we just need to compute dimensions. We know that $\dim V = \dim V^* = \dim(V^*)^* = \dim V^{**}$, and this along with injectivity implies that the map $v \mapsto \hat{v}$ is an isomorphism. $\square$

^aThis step of the proof has an analogue in infinite dimensions for a certain kind of vector space (Banach space), but requires the use of non-trivial results (the Hahn-Banach theorem).

This canonical embedding allows us to ‘identify’ V and V^{**} , which in turn can be used to prove various facts about say the annihilator.

Lemma 16.3.14 (Double Annihilator)

Let V be a finite dimensional vector space over $\mathbb{F}$, and $U \leq V$. Then $\hat{U} = U^{00}$, so after identification of V and V^{**} , we have $U = U^{00}$.

Proof. Let us first show that $U \leq U^{00}$. Indeed, let $u \in U$. Then for all $\varepsilon \in U^0$, $\varepsilon(u) = 0$. But then $\varepsilon(u) = \hat{u}(\varepsilon) = 0$, so $\hat{u} \in U^{00}$, and $\hat{U} \leq U^{00}$.

We can then compute dimensions, and $\dim U^{00} = \dim V - \dim U^0 = \dim U$, and since $v \mapsto \hat{v}$ is an isomorphism, $\dim \hat{U} = \dim U$. Thus $\dim \hat{U} = \dim U = \dim U^{00}$, and $\hat{U} = U^{00}$. $\square$

Remark. With the identification of V^{**} and V , for $T \leq V^*$ we can define $T^0 = \{v \in V \mid \alpha(v) = 0, \forall \alpha \in T\}$.

These results give us some unsurprising properties which are useful for doing computations.

Lemma 16.3.15 (Sums and Intersections of Annihilators)

Let V be a finite dimensional vector space over $\mathbb{F}$, and let $U_1, U_2 \leq V$. Then

- (i) $(U_1 + U_2)^0 = U_1^0 \cap U_2^0$;
- (ii) $(U_1 \cap U_2)^0 = U_1^0 + U_2^0$.

Proof. (i) Let $\theta \in V^*$, then $\theta \in (U_1 + U_2)^0$ if and only if $\theta(u_1 + u_2) = 0$ for all $u_1 \in U_1$ and $u_2 \in U_2$. By linearity this is exactly when $\theta(u) = 0$ for $u \in U_1 \cup U_2$, which occurs if and only if $\theta \in U_1^0 \cap U_2^0$.

(ii) Take the annihilator of the result in (i), and use the fact that $U^{00} = U$. $\square$

§16.4 Bilinear Forms**§16.4.1 Introducing Bilinear Forms**

In the previous section we considered linear maps from a vector space to the scalar field that vector space is over. In this section we will look at a related but interesting set of maps which have *two* arguments and are linear in both. Such maps are *bilinear forms*.

Definition 16.4.1 (Bilinear Form)

Let U and V be vector spaces over $\mathbb{F}$. Then $\phi : U \times V \rightarrow \mathbb{F}$ is a **bilinear form** if it is linear in both components.

Example 16.4.2 (Examples of Bilinear Forms)

The following are all bilinear forms.

- (i) A canonical example – the scalar product on $U = V = \mathbb{R}^n$.
- (ii) The map $V \times V^* \rightarrow \mathbb{F}$ given by $(v, \alpha) \mapsto \alpha(v)$.
- (iii) For $U = V = \mathcal{C}([0, 1], \mathbb{R})$ the map $\phi(f, g) = \int_0^1 f(t)g(t) dt$.

There is a standard representation of bilinear forms using matrices.

Definition 16.4.3 (Matrix of a Bilinear Form)

Let $B = \{u_1, \dots, u_n\}$ be a basis of U and $C = \{v_1, \dots, v_m\}$ be a basis of V , and let $\phi : U \times V \rightarrow \mathbb{F}$ be a bilinear form.

We define the **matrix of ϕ** with respect to B and C by

$$([\phi]_{B,C})_{i,j} = \phi(u_i, v_j).$$

Lemma 16.4.4 (Evaluating a Bilinear Form)

Let $\phi : U \times V \rightarrow \mathbb{F}$ be a bilinear form, and let $u \in U$ and $v \in V$. Then if B is a

basis of U and C is a basis of V , we have

$$\phi(u, v) = [u]_B^T [\phi]_{B,C} [v]_C.$$

Proof Sketch. Check definitions. □

Remark. $[\phi]_{B,C}$ is the unique matrix such that this equation holds.

It's sometimes useful to study a bilinear form in just one of its arguments. This can be done by considering the induced maps.

Definition 16.4.5 (Induced Map of a Bilinear Form)

Let $\phi : U \times V \rightarrow \mathbb{F}$ be a bilinear form. Then ϕ determines two linear maps $\phi_L : U \rightarrow V^*$ and $\phi_R : V \rightarrow U^*$, with

$$(\phi_L(u))(v) = \phi(u, v) \quad \text{and} \quad (\phi_R(v))(u) = \phi(u, v).$$

These induced maps are easily obtained from the matrix of the bilinear form.

Lemma 16.4.6 (Matrices of the Induced Maps)

Let $\phi : U \times V \rightarrow \mathbb{F}$ be a bilinear map. Then if $B = \{u_1, \dots, u_n\}$ is a basis of U and $C = \{v_1, \dots, v_m\}$ is a basis of V , then if $A = [\phi]_{B,C}$ we have

$$[\phi_R]_{C,B^*} = A \quad \text{and} \quad [\phi_L]_{B,C^*} = A^T.$$

Proof Sketch. Check definitions. □

Just as with the linear maps that we studied previously, it's possible look at the kernel of a bilinear map by considering the left and right component.

Definition 16.4.7 (Left/Right Kernel)

Let $\phi : U \times V \rightarrow \mathbb{F}$ be a bilinear form. Then the **left kernel** of ϕ is $\ker \phi_L$, and the **right kernel** of ϕ is $\ker \phi_R$.

Definition 16.4.8 (Degeneracy)

We say that a bilinear form ϕ is **non-degenerate** if $\ker \phi_L = \{0\}$ and $\ker \phi_R = \{0\}$. Otherwise, we say that ϕ is **degenerate**.

Lemma 16.4.9 (Matrix Degeneracy Criterion)

Let U and V be finite dimensional vector spaces, and let B be a basis of U and C be a basis of V . Suppose $\phi : U \times V \rightarrow \mathbb{F}$ is a bilinear form with matrix $A = [\phi]_{B,C}$. Then ϕ is non-degenerate if and only if A is invertible.

Proof. We know that ϕ is non-degenerate if and only if $\ker \phi_L = \{0\}$ and $\ker \phi_R = \{0\}$, that is, if and only if $n(A^T) = 0$ and $n(A) = 0$. But then by rank-nullity, we

have this if and only if $r(A^T) = \dim U$ and $r(A) = \dim V$, that is, if and only if A is invertible. $\square$

Corollary 16.4.10

If $\phi : U \times V \rightarrow \mathbb{F}$ is a non-degenerate bilinear form, then $\dim U = \dim V$.

Corollary 16.4.11 (Choosing a Bilinear Form)

When U and V are finite dimensional vector spaces over $\mathbb{F}$, choosing a non-degenerate bilinear form $\phi : U \times V \rightarrow \mathbb{F}$ is equivalent to choosing an isomorphism $\phi_L : U \rightarrow V^*$.

As with matrices for normal linear maps $\alpha : V \rightarrow W$, we can change the basis that the matrix of a bilinear form is represented with.

Proposition 16.4.12 (Change of Basis for Bilinear Forms)

Let U and V be vector spaces over $\mathbb{F}$ and let B, B' be bases for U and C, C' be bases for V . Suppose that P is the change of basis matrix from B' to B and Q is the change of basis matrix from C' to C . Then if $\phi : U \times V \rightarrow \mathbb{F}$ is a bilinear form, then

$$[\phi]_{B',C'} = P^T [\phi]_{B,C} Q.$$

Proof. We have

$$\phi(u, v) = [u]_B^T [\phi]_{B,C} [v]_C = (P[u]_{B'})^T [\phi]_{B,C} (Q[v]_{C'}) = [u]_{B'}^T (P^T [\phi]_{B,C} Q) [v]_{C'},$$

and thus $[\phi]_{B',C'} = P^T [\phi]_{B,C} Q$. $\square$

This change of basis formula also allows us to define the rank of a bilinear map and have that definition be well defined.

Definition 16.4.13 (Rank of a Bilinear Map)

The rank of a bilinear map ϕ , $r(\phi)$, is the rank of any matrix representation of ϕ .

To see that this is well defined, note that $r(P^T A Q) = r(A)$ for any invertible P, Q .

§16.5 The Trace and Determinant

We will now look at the determinant and trace, two quantities you may be familiar with from the study of matrices. In this section, we will consider how these can be interpreted in a basis-free way – that is, how they can be seen as quantities attached to a linear map itself, not just to a particular matrix representation of it.

§16.5.1 The Trace

We begin with the trace, which is by far the simpler of the two.

Definition 16.5.1 (Trace)

Let $A \in \mathcal{M}_{n,n}(\mathbb{F})$ be a square matrix. We define the trace of A by

$$\operatorname{tr} A = \sum_{i=1}^n A_{ii}.$$

In particular, we have

$$\operatorname{tr} \begin{pmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & \ddots & \vdots \\ a_{n1} & \cdots & a_{nn} \end{pmatrix} = a_{11} + \cdots + a_{nn}.$$

Remark. The trace is a linear form $\mathcal{M}_{n,n}(\mathbb{F}) \rightarrow \mathbb{F}$ given by $A \mapsto \operatorname{tr} A$.

The key computational fact about the trace is that it does not notice the order of a product.

Lemma 16.5.2 (Trace of a Product)

For any matrices $A, B \in \mathcal{M}_{n,n}(\mathbb{F})$, we have $\operatorname{tr}(AB) = \operatorname{tr}(BA)$.

Proof. Directly computing, we have

$$\operatorname{tr}(AB) = \sum_{i=1}^n \sum_{j=1}^n a_{ij} b_{ji} = \sum_{j=1}^n \sum_{i=1}^n b_{ji} a_{ij} = \operatorname{tr}(BA). \quad \square$$

Corollary 16.5.3 (Similar Matrices Have Equal Trace)

If A and A' are similar matrices, then $\operatorname{tr} A = \operatorname{tr} A'$.

Proof. If $A' = P^{-1}AP$, then $\operatorname{tr} A' = \operatorname{tr}(P^{-1}(AP)) = \operatorname{tr}((AP)P^{-1}) = \operatorname{tr} A. \quad \square$

This corollary is exactly what we need to make a basis-free definition. Recalling that two matrices represent the same endomorphism (in possibly different bases) precisely when they are similar, the following is well defined.

Definition 16.5.4 (Trace of an Endomorphism)

Let $\alpha : V \rightarrow V$ be an endomorphism of a finite dimensional vector space V . The **trace** of α is $\operatorname{tr} \alpha = \operatorname{tr}[\alpha]_{B,B}$, where B is any basis of V .

As a quick application of thinking this way, the trace interacts with duality in the way you might guess.

Lemma 16.5.5 (Trace of the Dual Map)

Let $\alpha : V \rightarrow V$ be an endomorphism of a finite dimensional vector space. Then $\operatorname{tr} \alpha^* = \operatorname{tr} \alpha$.

Proof. Picking a basis B of V , we have $\operatorname{tr} \alpha^* = \operatorname{tr}[\alpha^*]_{B^*, B^*} = \operatorname{tr}[\alpha]_{B, B}^T = \operatorname{tr}[\alpha]_{B, B} = \operatorname{tr} \alpha$, since transposing a matrix does not change its diagonal. $\square$

§16.5.2 Permutations

The determinant requires a bit more machinery than the trace, and the machinery it requires is that of *permutations*, which we briefly recall from IA Groups.

The **symmetric group** S_n is the group of permutations of $\{1, \dots, n\}$, that is, the group of bijections $\sigma : \{1, \dots, n\} \rightarrow \{1, \dots, n\}$ under composition. A **transposition** $(k \ell)$ is a permutation which swaps k and ℓ and fixes everything else. Every permutation can be written as a product of transpositions, and while such a decomposition is not unique, the *parity* of the number of transpositions used is. This lets us define the **signature** $\varepsilon : S_n \rightarrow \{\pm 1\}$, with $\varepsilon(\sigma) = 1$ if σ is a product of an even number of transpositions and $\varepsilon(\sigma) = -1$ otherwise. Importantly, the signature is a group homomorphism.

§16.5.3 The Determinant

With that, we can write down the (somewhat intimidating looking) definition of the determinant.

Definition 16.5.6 (Determinant)

Let $A \in \mathcal{M}_{n,n}(\mathbb{F})$. The **determinant** of A is

$$\det A = \sum_{\sigma \in S_n} \varepsilon(\sigma) a_{\sigma(1)1} a_{\sigma(2)2} \cdots a_{\sigma(n)n}.$$

Each term in this sum picks exactly one entry from each column of A , with no two entries from the same row, and weights the resulting product by a sign. For small n , this recovers formulas you already know.

Example 16.5.7 (Determinants of Small Matrices)

For $n = 2$, the only permutations are the identity and the transposition $(1 \ 2)$, so

$$\det \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} = a_{11}a_{22} - a_{12}a_{21}.$$

Similarly for $n = 3$, the six permutations of S_3 give the familiar six-term formula.

Directly from the definition we can compute the determinant of triangular matrices.

Lemma 16.5.8 (Determinant of a Triangular Matrix)

If A is an upper (or lower) triangular matrix with diagonal entries $a_{11}, \dots, a_{nn}$, then $\det A = a_{11}a_{22} \cdots a_{nn}$.

Proof. Suppose $a_{ij} = 0$ for $i > j$. For the term corresponding to σ in the sum to be non-zero, we need $\sigma(j) \leq j$ for all j . But then $\sigma(1) = 1$, which forces $\sigma(2) = 2$, and so on – so the only permutation contributing is the identity, and $\det A = a_{11} \cdots a_{nn}$.

The lower triangular case is analogous. $\square$

Lemma 16.5.9 (Determinant of the Transpose)

Let $A \in \mathcal{M}_{n,n}(\mathbb{F})$. Then $\det A^T = \det A$.

Proof. Reindexing the product inside the sum using σ^{-1} , and noting that $\sigma \mapsto \sigma^{-1}$ is a bijection $S_n \rightarrow S_n$ with $\varepsilon(\sigma^{-1}) = \varepsilon(\sigma)$, we get

$$\begin{aligned} \det A &= \sum_{\sigma \in S_n} \varepsilon(\sigma) \prod_{i=1}^n a_{\sigma(i)i} = \sum_{\sigma \in S_n} \varepsilon(\sigma) \prod_{j=1}^n a_{j\sigma^{-1}(j)} \\ &= \sum_{\tau \in S_n} \varepsilon(\tau) \prod_{j=1}^n a_{j\tau(j)} = \det A^T. \square \end{aligned}$$

§16.5.4 Volume Forms

The definition of the determinant above is useful for computing, but it's fair to say it doesn't exactly drip with meaning. The right way to understand the determinant is *geometric*: viewing the columns of A as n vectors in $\mathbb{F}^n$, the determinant is the *signed volume* of the parallelepiped they span.

To make this precise (and to prove the important properties of the determinant cleanly) we isolate the properties that any sensible notion of ‘signed volume’ should satisfy.

Definition 16.5.10 (Volume Form)

A **volume form** d on $\mathbb{F}^n$ is a function $d : \underbrace{\mathbb{F}^n \times \cdots \times \mathbb{F}^n}_{n \text{ times}} \rightarrow \mathbb{F}$ such that:

- (i) d is *multilinear*: for each i and each fixed choice of $v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n$, the map $v \mapsto d(v_1, \dots, v_{i-1}, v, v_{i+1}, \dots, v_n)$ is linear;
- (ii) d is *alternating*: if $v_i = v_j$ for some $i \neq j$, then $d(v_1, \dots, v_n) = 0$.

Both of these are natural if you think of d as measuring volume – scaling one edge of a parallelepiped scales its volume¹⁰, and a ‘parallelepiped’ with two equal edges is squashed flat, so should have zero volume.

¹⁰Additivity in each argument is perhaps slightly less obvious, but can be seen with a ‘shearing’ argument.

Lemma 16.5.11 (Determinant is a Volume Form)

The map $(\mathbb{F}^n)^n \rightarrow \mathbb{F}$ given by $(A^{(1)}, \dots, A^{(n)}) \mapsto \det A$, where A is the matrix with columns $A^{(1)}, \dots, A^{(n)}$, is a volume form.

Proof. For multilinearity, fix $\sigma \in S_n$ and consider the term $\prod_{i=1}^n a_{\sigma(i)i}$. This product contains exactly one entry from each column of A , so it is linear in each column separately. The determinant is a sum of such terms, so is multilinear.

For the alternating property, suppose columns $k \neq \ell$ are equal, and let $\tau = (k \ell)$. Then $a_{ij} = a_{i\tau(j)}$ for all i, j . Splitting $S_n = A_n \cup \tau A_n$ into even permutations and odd permutations, the terms for σ and $\tau\sigma$ have equal products but opposite signs, so cancel in pairs. Hence $\det A = 0$. $\square$

Lemma 16.5.12 (Swapping Entries)

Let d be a volume form. Then swapping two arguments of d changes its sign, that is,

$$d(v_1, \dots, v_i, \dots, v_j, \dots, v_n) = -d(v_1, \dots, v_j, \dots, v_i, \dots, v_n).$$

Proof. Consider d applied with $v_i + v_j$ in both the i th and j th positions. By the alternating property this is zero, and expanding by multilinearity,

$$\begin{aligned} 0 &= \underbrace{d(\dots, v_i, \dots, v_i, \dots)}_{=0} + d(\dots, v_i, \dots, v_j, \dots) \\ &\quad + d(\dots, v_j, \dots, v_i, \dots) + \underbrace{d(\dots, v_j, \dots, v_j, \dots)}_{=0}, \end{aligned}$$

which rearranges to give the result. $\square$

Corollary 16.5.13 (Volume Forms and Permutations)

If d is a volume form and $\sigma \in S_n$, then $d(v_{\sigma(1)}, \dots, v_{\sigma(n)}) = \varepsilon(\sigma) d(v_1, \dots, v_n)$.

Proof. Write σ as a product of transpositions and apply the previous lemma once for each. $\square$

We can now prove the theorem that justifies this whole discussion: up to scaling, the determinant is the *only* volume form on $\mathbb{F}^n$.

Theorem 16.5.14 (Uniqueness of Volume Forms)

Let d be a volume form on $\mathbb{F}^n$, and let A be a matrix with columns $A^{(1)}, \dots, A^{(n)}$. Then

$$d(A^{(1)}, \dots, A^{(n)}) = \det A \cdot d(e_1, \dots, e_n).$$

In particular, the determinant is the unique volume form with $d(e_1, \dots, e_n) = 1$.

Proof. Writing $A^{(1)} = \sum_{i=1}^n a_{i1}e_i$ and using multilinearity in the first argument,

$$d(A^{(1)}, \dots, A^{(n)}) = \sum_{i=1}^n a_{i1} d(e_i, A^{(2)}, \dots, A^{(n)}).$$

Doing the same in every argument, we get

$$d(A^{(1)}, \dots, A^{(n)}) = \sum_{i_1, \dots, i_n} a_{i_1 1} a_{i_2 2} \cdots a_{i_n n} d(e_{i_1}, \dots, e_{i_n}).$$

Since d is alternating, the only non-zero terms are those where $i_1, \dots, i_n$ are distinct – that is, where $i_k = \sigma(k)$ for some permutation $\sigma \in S_n$. Applying the corollary above,

$$d(A^{(1)}, \dots, A^{(n)}) = \sum_{\sigma \in S_n} \varepsilon(\sigma) \prod_{k=1}^n a_{\sigma(k)k} \cdot d(e_1, \dots, e_n) = \det A \cdot d(e_1, \dots, e_n),$$

as required. $\square$

This uniqueness result is more than just aesthetically pleasing – it gives essentially free proofs of facts about the determinant that are painful to obtain from the formula. The prime example is multiplicativity.

Theorem 16.5.15 (Determinant is Multiplicative)

Let $A, B \in \mathcal{M}_{n,n}(\mathbb{F})$. Then $\det(AB) = \det A \det B$.

Proof. Fixing A , define $d_A : (\mathbb{F}^n)^n \rightarrow \mathbb{F}$ by

$$d_A(v_1, \dots, v_n) = \det(Av_1, \dots, Av_n),$$

where the right hand side denotes the determinant of the matrix with the given columns. Since $v \mapsto Av$ is linear and $\det$ is multilinear, d_A is multilinear, and if $v_i = v_j$ then $Av_i = Av_j$, so d_A is alternating. Thus d_A is a volume form, and by uniqueness $d_A = C_A \det$ for the constant

$$C_A = d_A(e_1, \dots, e_n) = \det(Ae_1, \dots, Ae_n) = \det A,$$

since Ae_i is exactly the i th column of A . Applying this with the columns of B ,

$$\det(AB) = d_A(B^{(1)}, \dots, B^{(n)}) = \det A \det B. \quad \square$$

§16.5.5 Singular and Non-Singular Matrices

The determinant gives us a clean test for invertibility.

Definition 16.5.16 (Singular Matrices)

A square matrix A is **singular** if $\det A = 0$, and **non-singular** otherwise.

Theorem 16.5.17 (Determinant Criterion for Invertibility)

Let $A \in \mathcal{M}_{n,n}(\mathbb{F})$. Then the following are equivalent:

- (i) A is invertible,
- (ii) A is non-singular,
- (iii) $r(A) = n$.

Proof. (i) implies (ii). If A is invertible then $\det A \det A^{-1} = \det(AA^{-1}) = \det I = 1$, so $\det A \neq 0$.

(i) is equivalent to (iii). This is the rank-nullity theorem: A is invertible if and only if the linear map it represents is bijective, which happens if and only if it is surjective, that is $r(A) = n$.

(ii) implies (iii). We show the contrapositive. If $r(A) < n$, then the columns $A^{(1)}, \dots, A^{(n)}$ are linearly dependent, so some $A^{(j)} = -\frac{1}{\lambda_j} \sum_{i \neq j} \lambda_i A^{(i)}$ for scalars λ_i with $\lambda_j \neq 0$. Expanding $\det A$ using multilinearity in the j th column expresses it as a sum of determinants of matrices with two equal columns, all of which vanish. So $\det A = 0$. $\square$

§16.5.6 The Determinant of a Linear Map

We can now play the same game that we played with the trace.

Lemma 16.5.18 (Similar Matrices Have Equal Determinant)

If $A' = P^{-1}AP$, then $\det A' = \det A$.

Proof. Using multiplicativity and $\det P^{-1} \det P = 1$, we have

$$\det(P^{-1}AP) = \det P^{-1} \det A \det P = \det A. \quad \square$$

Definition 16.5.19 (Determinant of an Endomorphism)

Let $\alpha : V \rightarrow V$ be an endomorphism of a finite dimensional vector space V . The **determinant** of α is $\det \alpha = \det[\alpha]_{B,B}$, where B is any basis of V .

The properties of the matrix determinant transfer directly: $\det(\text{id}) = 1$, $\det(\alpha\beta) = \det \alpha \det \beta$, and α is invertible if and only if $\det \alpha \neq 0$, in which case $\det \alpha^{-1} = (\det \alpha)^{-1}$.

There is one more computational result that will be repeatedly useful when we study eigenvalues.

Lemma 16.5.20 (Determinant of Block Triangular Matrices)

Let $A \in \mathcal{M}_{k,k}(\mathbb{F})$, $B \in \mathcal{M}_{\ell,\ell}(\mathbb{F})$ and $C \in \mathcal{M}_{k,\ell}(\mathbb{F})$, and consider the block matrix

$$M = \left(\begin{array}{c|c} A & C \\ \hline 0 & B \end{array} \right).$$

Then $\det M = \det A \det B$.

Proof. Let $n = k + \ell$ and write $M = (m_{ij})$. In the sum

$$\det M = \sum_{\sigma \in S_n} \varepsilon(\sigma) \prod_{i=1}^n m_{\sigma(i)i},$$

the term for σ vanishes unless $\sigma(i) \leq k$ for all $i \leq k$ (as the bottom-left block is zero). Such σ decompose uniquely as $\sigma = \sigma_1 \sigma_2$ where σ_1 permutes $\{1, \dots, k\}$ and σ_2 permutes $\{k+1, \dots, n\}$, with $\varepsilon(\sigma) = \varepsilon(\sigma_1)\varepsilon(\sigma_2)$. The sum then factors as

$$\det M = \left(\sum_{\sigma_1} \varepsilon(\sigma_1) \prod_{i=1}^k m_{\sigma_1(i)i} \right) \left(\sum_{\sigma_2} \varepsilon(\sigma_2) \prod_{i=k+1}^n m_{\sigma_2(i)i} \right) = \det A \det B. \quad \square$$

Applying this repeatedly, a block *upper* triangular matrix has determinant equal to the product of the determinants of its diagonal blocks.

§16.5.7 Expanding Determinants and the Adjugate

The formula defining the determinant has $n!$ terms, so is rarely how you want to compute one. A more practical approach reduces an $n \times n$ determinant to a combination of $(n-1) \times (n-1)$ determinants.

Definition 16.5.21 (Minor)

Let $A \in \mathcal{M}_{n,n}(\mathbb{F})$ and $i, j \in \{1, \dots, n\}$. The **minor** $A_{\widehat{i}\widehat{j}} \in \mathcal{M}_{n-1,n-1}(\mathbb{F})$ is the matrix obtained from A by deleting the i th row and j th column.

Lemma 16.5.22 (Row and Column Expansions)

Let $A \in \mathcal{M}_{n,n}(\mathbb{F})$. Then for any fixed column j ,

$$\det A = \sum_{i=1}^n (-1)^{i+j} a_{ij} \det A_{\widehat{i}\widehat{j}},$$

and for any fixed row i , we similarly have $\det A = \sum_{j=1}^n (-1)^{i+j} a_{ij} \det A_{\widehat{i}\widehat{j}}$.

Proof. Write the j th column as $A^{(j)} = \sum_{i=1}^n a_{ij} e_i$. By multilinearity,

$$\det A = \sum_{i=1}^n a_{ij} \det(A^{(1)}, \dots, e_i, \dots, A^{(n)}),$$

with e_i in the j th position. Now move the j th column to the front ($j-1$ adjacent swaps) and the i th row to the top ($i-1$ adjacent swaps), picking up the sign $(-1)^{i+j-2} = (-1)^{i+j}$. The resulting matrix is block triangular with top-left block

(1) and bottom-right block $A_{\widehat{ij}}$, so by the block triangular lemma,

$$\det(A^{(1)}, \dots, e_i, \dots, A^{(n)}) = (-1)^{i+j} \det A_{\widehat{ij}},$$

giving the column expansion. The row expansion follows by transposing. $\square$

Collecting these signed minors into a matrix gives us an explicit (if computationally expensive) formula for the inverse of a matrix.

Definition 16.5.23 (Adjugate)

Let $A \in \mathcal{M}_{n,n}(\mathbb{F})$. The **adjugate** of A is the $n \times n$ matrix $\text{adj } A$ with

$$(\text{adj } A)_{ij} = (-1)^{i+j} \det A_{\widehat{ji}}.$$

Note the transposition of indices – the (i, j) entry of the adjugate involves deleting row j and column i . In the notation of the proof above, $(\text{adj } A)_{ji} = \det(A^{(1)}, \dots, e_i, \dots, A^{(n)})$ with e_i in position j .

Theorem 16.5.24 (Adjugate Formula)

Let $A \in \mathcal{M}_{n,n}(\mathbb{F})$. Then

$$(\text{adj } A)A = (\det A)I.$$

In particular, if A is invertible then

$$A^{-1} = \frac{1}{\det A} \text{adj } A.$$

Proof. On the diagonal, the (j, j) entry of $(\text{adj } A)A$ is

$$\sum_{i=1}^n (\text{adj } A)_{ji} a_{ij} = \sum_{i=1}^n (-1)^{i+j} a_{ij} \det A_{\widehat{ij}} = \det A,$$

by the column expansion. Off the diagonal, for $j \neq k$ the (j, k) entry is

$$\sum_{i=1}^n (\text{adj } A)_{ji} a_{ik} = \sum_{i=1}^n a_{ik} \det(A^{(1)}, \dots, \underbrace{e_i}_{j\text{th}}, \dots, A^{(n)}) = \det(A^{(1)}, \dots, \underbrace{A^{(k)}}_{j\text{th}}, \dots, A^{(n)})$$

after reassembling using multilinearity. But this last determinant has the column $A^{(k)}$ appearing twice (in positions j and k), so vanishes. $\square$

§16.5.8 Cramer's Rule

Finally, the adjugate machinery gives us an algorithm for computing the unique solution to $Ax = b$ without computing A^{-1} .

Proposition 16.5.25 (Cramer's Rule)

Let $A \in \mathcal{M}_{n,n}(\mathbb{F})$ be an invertible matrix, and let $b \in \mathbb{F}^n$. Then the unique solution

to $Ax = b$ is given by

$$x_i = \frac{1}{\det A} \det(A_{ib}),$$

where A_{ib} is the matrix obtained by replacing the i th column of A by b .

Proof. Since A is invertible, there exists a unique $x \in \mathbb{F}^n$ with $Ax = b$. Then computing we have

$$\begin{aligned} \det(A_{ib}) &= \det(A^{(1)}, \dots, A^{(i-1)}, b, A^{(i+1)}, \dots, A^{(n)}) \\ &= \det(A^{(1)}, \dots, A^{(i-1)}, Ax, A^{(i+1)}, \dots, A^{(n)}) \\ &= \det\left(A^{(1)}, \dots, A^{(i-1)}, \sum_{j=1}^n x_j A^{(j)}, A^{(i+1)}, \dots, A^{(n)}\right) \\ &= x_i \det(A^{(1)}, \dots, A^{(i-1)}, A^{(i)}, A^{(i+1)}, \dots, A^{(n)}) \\ &= x_i \det A, \end{aligned}$$

where in the second-to-last step every other term vanishes since it is the determinant of a matrix with a repeated column. $\square$

§16.6 Diagonalization, Eigenvectors and Eigenvalues

§16.6.1 Diagonal and Triangular Matrices

We are now going to take the first steps towards the diagonalisation of endomorphisms. Given a finite dimensional vector space V over $\mathbb{F}$ and some endomorphism $\alpha : V \rightarrow V$, we are going to be guided by the following general problem:

Can we find a basis B of V such that in this basis $[\alpha]_{B,B}$ has a ‘nice’ form?

With this in mind, we will first care about when this ‘nice’ form is a diagonal matrix, or more generally a triangular matrix.

Definition 16.6.1 (Diagonalizable)

Let V be a vector space and let $\alpha : V \rightarrow V$ be a linear map. We say that α is **diagonalizable** if there is a basis B of V such that

$$[\alpha]_{B,B} = \begin{pmatrix} \lambda_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \lambda_n \end{pmatrix}$$

where $\lambda_i \in \mathbb{F}$.

Definition 16.6.2 (Triangular)

Let V be a vector space and let $\alpha : V \rightarrow V$ be a linear map. We say that α is

triangulable if there is a basis B of V such that

$$[\alpha]_{B,B} = \begin{pmatrix} \lambda_1 & \cdots & * \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \lambda_n \end{pmatrix}$$

where $\lambda_i \in \mathbb{F}$.

We will see that when thinking about such matrices, we will frequently turn to the concept of eigenvectors and eigenvalues.

Definition 16.6.3 (Eigenvectors and Eigenvalues)

If V is a vector space over $\mathbb{F}$ and $\alpha : V \rightarrow V$ is a linear map, we say that $\lambda \in \mathbb{F}$ is a **eigenvalue** if there exists some $v \in V \setminus \{0\}$ such that $\alpha(v) = \lambda v$. We say that v is a corresponding **eigenvector**.

Definition 16.6.4 (Eigenspace)

If λ is an eigenvalue of a linear map $\alpha : V \rightarrow V$, we define the corresponding **eigenspace** to be the subspace $V_\lambda = \{v \in V \mid \alpha(v) = \lambda v\}$.

When computing eigenvalues we frequently employ the following lemma.

Lemma 16.6.5 (Computing Eigenvalues)

Let V be a vector space over $\mathbb{F}$, and let $\alpha : V \rightarrow V$ be a linear map. Then $\lambda \in \mathbb{F}$ is an eigenvalue if and only if $\det(\alpha - \lambda \text{id}) = 0$.

Proof. There exists $v \in V \setminus \{0\}$ with $\alpha(v) = \lambda v$ if and only if $\ker(\alpha - \lambda \text{id}) \neq \{0\}$. This occurs if and only if $\alpha - \lambda \text{id}$ is not injective, and since α is an endomorphism, this occurs if and only if $\alpha - \lambda \text{id}$ is not invertible, that is, if $\det(\alpha - \lambda \text{id}) = 0$. $\square$

Applying this lemma gives us a polynomial in λ which one must find the roots of to obtain the eigenvalues of the linear map. We call this polynomial the *characteristic polynomial*.

Definition 16.6.6 (Characteristic Polynomial)

Let $\alpha : V \rightarrow V$ be an endomorphism. Then the **characteristic polynomial**^a of α is $\chi_\alpha(\lambda) = \det(\alpha - \lambda \text{id})$.

^aIt should be checked that this definition is basis free, but this is straightforward.

The heart of the matter is the following criterion of triangulability.

Theorem 16.6.7 (Triangulability Criterion)

Let V be a vector space over $\mathbb{F}$. A linear map $\alpha : V \rightarrow V$ is triangulable if and only

if

$$\chi_\alpha(t) = c \prod_{i=1}^n (t - \lambda_i),$$

for some $c, \lambda_i \in \mathbb{F}$.

Proof. Suppose α was triangulable. Then for some basis B of V we have

$$[\alpha]_{B,B} = \begin{pmatrix} \lambda_1 & \cdots & * \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \lambda_n \end{pmatrix},$$

and so

$$\chi_\alpha(t) = \det \begin{pmatrix} \lambda_1 - t & \cdots & * \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \lambda_n - t \end{pmatrix} = \prod_{i=1}^n (\lambda_i - t),$$

which is of the required form.

Now suppose that this criterion holds. We will prove by induction on $n = \dim V$ that it implies triangulability. For $n = 1$, we are immediately done, so suppose that $n > 1$. Then let λ be a root of $\chi_\alpha(t)$ (which exists by assumption). Then λ is an eigenvalue of α . Let $U = V_\lambda$ be the corresponding eigenspace, and let $\{v_1, \dots, v_k\}$ be a basis of U . We can complete this to a basis $B = \{v_1, \dots, v_n\}$ of V . So then

$$[\alpha]_{B,B} = \left(\begin{array}{c|c} \lambda I & * \\ \hline 0 & C \end{array} \right).$$

Now α induces an endomorphism $\bar{\alpha} : V/U \rightarrow V/U$, and C is the matrix of $\bar{\alpha}$ with respect to the basis $\{v_{k+1} + U, \dots, v_n + U\}$. The characteristic polynomial of $\bar{\alpha}$ divides that of α , so it too is a product of linear factors, and by induction we can write $\bar{\alpha}$ in triangular form by choosing an appropriate basis $\{v'_{k+1} + U, \dots, v'_n + U\}$ of V/U . Taking the basis $B' = \{v_1, \dots, v_k, v'_{k+1}, \dots, v'_n\}$ then gives us $[\alpha]_{B',B'}$ in triangular form. $\square$

Remark. By the fundamental theorem of algebra, if $\mathbb{F} = \mathbb{C}$, then every matrix is triangulable.

§16.6.2 Polynomials

Before we can get a criterion for *diagonalisability*, we need to set up a small dictionary between endomorphisms and polynomials. Let's first recall some basic facts about polynomials over a field $\mathbb{F}$. We write $\mathbb{F}[t]$ for the vector space of polynomials

$$f(t) = a_n t^n + a_{n-1} t^{n-1} + \cdots + a_1 t + a_0$$

with coefficients in $\mathbb{F}$, and $\deg f$ for the degree of f . The facts we will need are the following.

- (i) If λ is a root of f , then $(t - \lambda)$ divides f . This can be seen by writing $f(t) = f(t) - f(\lambda)$ and factoring $(t - \lambda)$ out of each $t^k - \lambda^k$.
- (ii) We say λ is a root of **multiplicity** k if $(t - \lambda)^k$ divides f but $(t - \lambda)^{k+1}$ does not. A non-zero polynomial of degree n has at most n roots counted with multiplicity.

- (iii) Two polynomials of degree less than n agreeing at n distinct points are equal (their difference has too many roots).
- (iv) *The fundamental theorem of algebra*: every non-constant $f \in \mathbb{C}[t]$ has a complex root, and hence factors completely into linear factors.
- (v) Given polynomials $a, b \in \mathbb{F}[t]$ with $b \neq 0$, there are polynomials q, r with $a = qb + r$ and $\deg r < \deg b$ (polynomial division).

The dictionary is then this: given a polynomial $p(t) = a_n t^n + \cdots + a_0$ and an endomorphism α of V , we can form the endomorphism

$$p(\alpha) = a_n \alpha^n + a_{n-1} \alpha^{n-1} + \cdots + a_1 \alpha + a_0 \text{id},$$

where α^k denotes k -fold composition. Similarly for a square matrix A we define $p(A) = a_n A^n + \cdots + a_1 A + a_0 I$. Note that any two polynomials in the same α commute with each other – this simple observation gets used constantly below.

§16.6.3 A Criterion for Diagonalisability

We saw above that triangulability is governed by the characteristic polynomial. Diagonalisability turns out to be governed by polynomials too, in a rather clean way.

Theorem 16.6.8 (Diagonalisability Criterion)

Let V be a finite dimensional vector space over $\mathbb{F}$, and let $\alpha : V \rightarrow V$ be an endomorphism. Then α is diagonalisable if and only if there is a non-zero polynomial p that is a product of *distinct* linear factors such that $p(\alpha) = 0$.

Proof. Suppose first that α is diagonalisable, with distinct eigenvalues $\lambda_1, \dots, \lambda_k$, and set $p(t) = \prod_{i=1}^k (t - \lambda_i)$. If v is a basis vector in the diagonalising basis, then $\alpha(v) = \lambda_i v$ for some i , and since the factors of $p(\alpha)$ commute we can apply $(\alpha - \lambda_i \text{id})$ to v first, giving $p(\alpha)(v) = 0$. Since $p(\alpha)$ kills a basis, $p(\alpha) = 0$.

The converse is the interesting direction. Suppose $p(\alpha) = 0$ where $p(t) = \prod_{i=1}^k (t - \lambda_i)$ with $\lambda_1, \dots, \lambda_k$ distinct, and let $V_{\lambda_i} = \ker(\alpha - \lambda_i \text{id})$. We claim that

$$V = \bigoplus_{i=1}^k V_{\lambda_i},$$

which suffices, since choosing a basis of each eigenspace and taking their union then gives a basis of V consisting of eigenvectors.

To prove the claim, consider the *Lagrange interpolation* polynomials

$$q_j(t) = \prod_{i \neq j} \frac{t - \lambda_i}{\lambda_j - \lambda_i},$$

which are engineered so that $q_j(\lambda_i) = \delta_{ij}$. The sum $q = q_1 + \cdots + q_k$ has degree at most $k - 1$ and takes the value 1 at the k distinct points $\lambda_1, \dots, \lambda_k$, so $q \equiv 1$.

Now define $\pi_j = q_j(\alpha)$. By the above, $\sum_{j=1}^k \pi_j = \text{id}$, so every $v \in V$ decomposes as

$$v = \sum_{j=1}^k \pi_j(v).$$

Moreover each $\pi_j(v)$ lands in the eigenspace V_{λ_j} : up to a scalar, $(\alpha - \lambda_j \text{id}) \circ q_j(\alpha)$ is exactly $p(\alpha) = 0$, so $(\alpha - \lambda_j \text{id})\pi_j(v) = 0$. Hence $V = \sum_j V_{\lambda_j}$.

It remains to check the sum is direct. Note that if $v \in V_{\lambda_j}$, then applying $q_j(\alpha)$ replaces each factor $(\alpha - \lambda_i \text{id})$ acting on v by the scalar $(\lambda_j - \lambda_i)$, so $\pi_j(v) = q_j(\lambda_j)v = v$; and if $v \in V_{\lambda_i}$ with $i \neq j$ then some factor of $q_j(\alpha)$ kills v , so $\pi_j(v) = 0$. So suppose

$$v_1 + v_2 + \cdots + v_k = 0, \quad v_i \in V_{\lambda_i}.$$

Applying π_j to both sides kills every term except the j th, leaving $v_j = 0$. This holds for each j , so the decomposition of 0 is unique and the sum is direct. $\square$

Remark. Along the way we proved something useful in its own right: for *any* endomorphism α , the sum of eigenspaces corresponding to distinct eigenvalues is always direct. Diagonalisability fails only when this direct sum is a proper subspace of V .

This criterion can feel abstract, so let's see it do something impressive with almost no work.

Example 16.6.9 (Matrices of Finite Order)

Let $A \in \mathcal{M}_{n,n}(\mathbb{C})$ with $A^m = I$ for some $m \geq 1$. Then A is diagonalisable, since the polynomial

$$p(t) = t^m - 1 = \prod_{j=1}^m (t - e^{2\pi i j/m})$$

is a product of distinct linear factors and satisfies $p(A) = 0$.

As another application, we can answer the natural question of when two diagonalisable maps can be diagonalised *at the same time*.

Theorem 16.6.10 (Simultaneous Diagonalisation)

Let α, β be diagonalisable endomorphisms of a finite dimensional vector space V . Then α and β are **simultaneously diagonalisable** (there is a single basis B with both $[\alpha]_{B,B}$ and $[\beta]_{B,B}$ diagonal) if and only if $\alpha\beta = \beta\alpha$.

Proof. One direction is immediate: diagonal matrices commute, so if $[\alpha]_{B,B}$ and $[\beta]_{B,B}$ are both diagonal then $\alpha\beta = \beta\alpha$.

Conversely, suppose α and β commute. Since α is diagonalisable, $V = \bigoplus_{i=1}^k V_{\lambda_i}$ where $\lambda_1, \dots, \lambda_k$ are its distinct eigenvalues. The key point is that β preserves each eigenspace of α : for $v \in V_{\lambda_j}$,

$$\alpha(\beta(v)) = \beta(\alpha(v)) = \beta(\lambda_j v) = \lambda_j \beta(v),$$

so $\beta(v) \in V_{\lambda_j}$. Now β is diagonalisable, so some polynomial p with distinct linear

factors has $p(\beta) = 0$, and hence certainly $p(\beta|_{V_{\lambda_j}}) = 0$. So each restriction $\beta|_{V_{\lambda_j}}$ is diagonalisable by our criterion, and we may pick a basis B_j of V_{λ_j} consisting of eigenvectors of β . Since each B_j consists of λ_j -eigenvectors of α as well, the union $B = B_1 \cup \dots \cup B_k$ diagonalises both maps simultaneously. $\square$

§16.6.4 The Minimal Polynomial

The diagonalisability criterion asks whether *some* polynomial with distinct linear factors kills α . It is natural to focus on the smallest polynomial killing α .

Definition 16.6.11 (Minimal Polynomial)

Let α be an endomorphism of a finite dimensional vector space V . The **minimal polynomial** m_α of α is the non-zero monic polynomial of least degree such that $m_\alpha(\alpha) = 0$.

Some polynomial killing α certainly exists: $\dim \mathcal{L}(V, V) = n^2$, so the $n^2 + 1$ endomorphisms $\text{id}, \alpha, \alpha^2, \dots, \alpha^{n^2}$ are linearly dependent, and any dependence gives a polynomial vanishing at α .

Lemma 16.6.12 (Divisibility Property of the Minimal Polynomial)

Let α be an endomorphism of V and $p \in \mathbb{F}[t]$. Then $p(\alpha) = 0$ if and only if m_α divides p . In particular, the minimal polynomial is unique.

Proof. If m_α divides p , say $p = m_\alpha q$, then $p(\alpha) = m_\alpha(\alpha)q(\alpha) = 0$. Conversely, suppose $p(\alpha) = 0$, and divide with remainder: $p = qm_\alpha + r$ with $\deg r < \deg m_\alpha$. Evaluating at α gives $r(\alpha) = 0$, and by minimality of $\deg m_\alpha$ this forces $r \equiv 0$, so m_α divides p .

For uniqueness, two monic minimal polynomials must divide each other and have the same degree, so are equal. $\square$

With this language, our diagonalisability criterion can be restated: α is diagonalisable if and only if m_α is a product of distinct linear factors. (If some product of distinct linear factors kills α , then m_α divides it, so m_α is itself such a product.)

Example 16.6.13 (Telling Matrices Apart)

Consider the matrices

$$A = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad \text{and} \quad B = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}.$$

Both satisfy $p(t) = (t - 1)^2$, i.e. $p(A) = p(B) = 0$, so both minimal polynomials divide $(t - 1)^2$. For A we have $A - I = 0$, so $m_A(t) = t - 1$; but $B - I \neq 0$, so $m_B(t) = (t - 1)^2$. In particular B is *not* diagonalisable, since its minimal polynomial has a repeated root.

§16.6.5 The Cayley-Hamilton Theorem

We now come to one of the most famous theorems of linear algebra, relating the two polynomials we have attached to an endomorphism: *every endomorphism satisfies its own characteristic polynomial*.

Theorem 16.6.14 (Cayley-Hamilton)

Let α be an endomorphism of a finite dimensional vector space V . Then $\chi_\alpha(\alpha) = 0$. Equivalently, m_α divides χ_α .

Before the proof, one warning: it is tempting to argue ‘ $\chi_\alpha(t) = \det(\alpha - t \text{id})$, so $\chi_\alpha(\alpha) = \det(\alpha - \alpha) = 0$ ’. This is nonsense – $\chi_\alpha(\alpha)$ is an *endomorphism*, not a scalar, and substituting a matrix into the determinant formula in this way is not a valid operation.

We will give two proofs: a clean geometric one for $\mathbb{F} = \mathbb{C}$ (which also covers $\mathbb{F} = \mathbb{R}$, viewing a real matrix as a complex one), and an algebraic one that works over any field.

Proof (over $\mathbb{C}$). Since $\mathbb{F} = \mathbb{C}$, we can pick a basis $B = \{v_1, \dots, v_n\}$ in which $A = [\alpha]_{B,B}$ is upper triangular with diagonal entries $a_1, \dots, a_n$, so that

$$\chi_\alpha(t) = \prod_{i=1}^n (a_i - t).$$

Let $U_j = \langle v_1, \dots, v_j \rangle$, so that $U_0 = \{0\} \leq U_1 \leq \dots \leq U_n = V$. Triangularity says exactly that $\alpha(U_j) \leq U_j$, and moreover $(\alpha - a_j \text{id})(U_j) \leq U_{j-1}$, since the j th column of $A - a_j I$ has zero entries from row j downwards.

Now take any $v \in V = U_n$ and feed it through the factors of $\chi_\alpha(\alpha)$ from the right:

$$\chi_\alpha(\alpha)(v) = (\alpha - a_1 \text{id}) \cdots (\alpha - a_{n-1} \text{id}) \underbrace{(\alpha - a_n \text{id})(v)}_{\in U_{n-1}}.$$

Each successive factor pushes the vector down one step in the chain of subspaces, so after all n factors we land in $U_0 = \{0\}$. Hence $\chi_\alpha(\alpha) = 0$. $\square$

Proof (any field). Let A be the matrix of α in some basis, and write

$$\det(tI - A) = (-1)^n \chi_A(t) = t^n + a_{n-1}t^{n-1} + \cdots + a_1t + a_0.$$

Recall the adjugate formula $(\text{adj } B)B = (\det B)I$, and apply it with $B = tI - A$. Every entry of $\text{adj}(tI - A)$ is (up to sign) the determinant of an $(n-1) \times (n-1)$ submatrix of $tI - A$, hence a polynomial in t of degree at most $n-1$. Collecting coefficients, we can write

$$\text{adj}(tI - A) = B_{n-1}t^{n-1} + \cdots + B_1t + B_0$$

for some matrices $B_i \in \mathcal{M}_{n,n}(\mathbb{F})$. The adjugate formula then reads

$$(B_{n-1}t^{n-1} + \cdots + B_0)(tI - A) = (t^n + a_{n-1}t^{n-1} + \cdots + a_0)I,$$

and since this holds for all t (as an identity of polynomials with matrix coefficients),

we may equate the coefficients of each power of t :

$$\begin{aligned} t^n : \quad & B_{n-1} = I \\ t^{n-1} : \quad & B_{n-2} - B_{n-1}A = a_{n-1}I \\ & \vdots \\ t^1 : \quad & B_0 - B_1A = a_1I \\ t^0 : \quad & -B_0A = a_0I. \end{aligned}$$

Multiplying the t^k relation on the right by A^k and summing all of the relations, the left hand side telescopes to zero, leaving

$$0 = A^n + a_{n-1}A^{n-1} + \cdots + a_1A + a_0I = (-1)^n \chi_A(A),$$

as required. $\square$

§16.6.6 Multiplicities of Eigenvalues

We now have three numbers we can attach to each eigenvalue of an endomorphism, and comparing them will give us a rather complete picture of diagonalisability.

Definition 16.6.15 (Algebraic and Geometric Multiplicity)

Let λ be an eigenvalue of an endomorphism α of V . We define:

- (i) the **algebraic multiplicity** a_λ , the multiplicity of λ as a root of χ_α ,
- (ii) the **geometric multiplicity** $g_\lambda = \dim V_\lambda$, the dimension of the corresponding eigenspace,
- (iii) the multiplicity c_λ of λ as a root of the minimal polynomial m_α .

Lemma 16.6.16 (Comparing Multiplicities)

If λ is an eigenvalue of α , then

$$1 \leq g_\lambda \leq a_\lambda \quad \text{and} \quad 1 \leq c_\lambda \leq a_\lambda.$$

Proof. Since λ is an eigenvalue there is a non-zero eigenvector, so $g_\lambda \geq 1$. For $g_\lambda \leq a_\lambda$, pick a basis $\{v_1, \dots, v_{g_\lambda}\}$ of V_λ and extend to a basis B of V . Then

$$[\alpha]_{B,B} = \left(\begin{array}{c|c} \lambda I_{g_\lambda} & * \\ \hline 0 & A_1 \end{array} \right),$$

and expanding using the block triangular lemma, $\chi_\alpha(t) = (\lambda - t)^{g_\lambda} \det(A_1 - tI)$. So $(t - \lambda)^{g_\lambda}$ divides $\chi_\alpha(t)$, that is, $g_\lambda \leq a_\lambda$.

For c_λ : by Cayley-Hamilton, m_α divides χ_α , so $c_\lambda \leq a_\lambda$. And if v is a λ -eigenvector, then $p(\alpha)(v) = p(\lambda)v$ for any polynomial p ; taking $p = m_\alpha$ gives $m_\alpha(\lambda)v = 0$ and so $m_\alpha(\lambda) = 0$, giving $c_\lambda \geq 1$. $\square$

Theorem 16.6.17 (Characterisations of Diagonalisability)

Let α be an endomorphism of a finite dimensional $\mathbb{C}$ -vector space V . Then the following are equivalent:

- (i) α is diagonalisable,
- (ii) $a_\lambda = g_\lambda$ for every eigenvalue λ of α ,
- (iii) $c_\lambda = 1$ for every eigenvalue λ of α .

Proof. Since $\mathbb{F} = \mathbb{C}$, the characteristic polynomial factors completely, so if $\lambda_1, \dots, \lambda_k$ are the distinct eigenvalues then $\sum_{i=1}^k a_{\lambda_i} = \deg \chi_\alpha = n$.

(i) is equivalent to (iii). Over $\mathbb{C}$, m_α factors as $\prod_i (t - \lambda_i)^{c_{\lambda_i}}$, and we know α is diagonalisable if and only if m_α has distinct linear factors, which happens exactly when every $c_{\lambda_i} = 1$.

(i) is equivalent to (ii). We know that the sum of the eigenspaces is always direct, so α is diagonalisable if and only if $\sum_{i=1}^k g_{\lambda_i} = \dim \bigoplus_i V_{\lambda_i}$ equals $n = \sum_{i=1}^k a_{\lambda_i}$. Since $g_{\lambda_i} \leq a_{\lambda_i}$ termwise, the sums are equal if and only if $g_{\lambda_i} = a_{\lambda_i}$ for every i . $\square$

Example 16.6.18 (Using the Minimal Polynomial)

Consider the matrix

$$A = \begin{pmatrix} 1 & 0 & -2 \\ 0 & 1 & 1 \\ 0 & 0 & 2 \end{pmatrix}.$$

Expanding along the bottom row, $\chi_A(t) = (1-t)^2(2-t)$, so the minimal polynomial is $(t-1)(t-2)$ or $(t-1)^2(t-2)$. Multiplying out,

$$(A - I)(A - 2I) = \begin{pmatrix} 0 & 0 & -2 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} -1 & 0 & -2 \\ 0 & -1 & 1 \\ 0 & 0 & 0 \end{pmatrix} = 0,$$

so $m_A(t) = (t-1)(t-2)$, a product of distinct linear factors – hence A is diagonalisable.

§16.7 Jordan Normal Form

Not every endomorphism is diagonalisable, which raises the obvious question: how close can we get? Over $\mathbb{C}$, the answer is ‘remarkably close’, and the precise answer is the *Jordan normal form*. Throughout this section we work over $\mathbb{F} = \mathbb{C}$.

§16.7.1 Jordan Blocks

Definition 16.7.1 (Jordan Block and Jordan Normal Form)

For $\lambda \in \mathbb{C}$, the **Jordan block** of size m is the matrix

$$J_m(\lambda) = \begin{pmatrix} \lambda & 1 & & \\ & \lambda & \ddots & \\ & & \ddots & 1 \\ & & & \lambda \end{pmatrix} \in \mathcal{M}_{m,m}(\mathbb{C}),$$

with λ on the diagonal, 1 just above it, and 0 everywhere else. A matrix is in **Jordan normal form** if it is block diagonal with each block a Jordan block,

$$A = \begin{pmatrix} J_{n_1}(\lambda_1) & & \\ & \ddots & \\ & & J_{n_k}(\lambda_k) \end{pmatrix},$$

where the λ_i need not be distinct.

So a matrix in Jordan normal form is ‘diagonal, plus some pesky 1s’. A diagonal matrix is the special case where every block has size 1. Schematically, the structure looks like this, with each shaded block a single Jordan block:

Note that repeated eigenvalues can appear in several different blocks (here λ_1 owns both a 3×3 and a 2×2 block).

The main theorem, which we will state but not prove¹¹, is that this form can always be reached.

Theorem 16.7.2 (Jordan Normal Form)

Every matrix $A \in \mathcal{M}_{n,n}(\mathbb{C})$ is similar to a matrix in Jordan normal form, which is unique up to reordering the Jordan blocks.

Example 16.7.3 (JNF in Two Dimensions)

Every 2×2 complex matrix is similar to exactly one of

$$\begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix}, \quad \begin{pmatrix} \lambda & 0 \\ 0 & \lambda \end{pmatrix}, \quad \begin{pmatrix} \lambda & 1 \\ 0 & \lambda \end{pmatrix},$$

¹¹The proof is non-examinable, and follows from the structure theory of modules developed in IB Groups, Rings and Modules.

with respective minimal polynomials $(t - \lambda_1)(t - \lambda_2)$, $(t - \lambda)$ and $(t - \lambda)^2$.

§16.7.2 Generalised Eigenspaces

While we won't prove the Jordan normal form theorem in full, we can prove the decomposition of V that underlies it. The idea is to relax the eigenspace condition $(\alpha - \lambda \text{id})(v) = 0$, and instead only require that some *power* of $(\alpha - \lambda \text{id})$ kills v .

Theorem 16.7.4 (Generalised Eigenspace Decomposition)

Let V be a finite dimensional $\mathbb{C}$ -vector space and α an endomorphism of V with minimal polynomial

$$m_\alpha(t) = \prod_{j=1}^k (t - \lambda_j)^{c_j},$$

where the λ_j are distinct. Then

$$V = \bigoplus_{j=1}^k V_j, \quad \text{where } V_j = \ker((\alpha - \lambda_j \text{id})^{c_j})$$

is called the **generalised eigenspace** associated to λ_j .

Proof. The proof mirrors our diagonalisability criterion – we construct explicit projections onto the pieces. Let

$$p_j(t) = \prod_{i \neq j} (t - \lambda_i)^{c_i},$$

so that $p_j(t)(t - \lambda_j)^{c_j} = m_\alpha(t)$. The polynomials $p_1, \dots, p_k$ have no common factor, so by the Euclidean algorithm there are polynomials $q_1, \dots, q_k$ with

$$q_1 p_1 + \dots + q_k p_k = 1.$$

Define $\pi_j = (q_j p_j)(\alpha)$. Then immediately $\sum_j \pi_j = \text{id}$, so every $v \in V$ decomposes as $v = \sum_j \pi_j(v)$; and each piece lies where it should, since

$$(\alpha - \lambda_j \text{id})^{c_j} \pi_j(v) = q_j(\alpha) m_\alpha(\alpha)(v) = 0,$$

so $\pi_j(v) \in V_j$. Hence $V = \sum_j V_j$.

For directness, note that if $i \neq j$ then $p_i p_j$ is divisible by m_α , so $\pi_i \pi_j = 0$. Combining this with $\sum_j \pi_j = \text{id}$ gives $\pi_i = \pi_i \left(\sum_j \pi_j \right) = \pi_i^2$, so each π_i is a projection, and moreover π_i acts as the identity on V_i and as zero on V_j for $j \neq i$.^a Then given any relation $v_1 + \dots + v_k = 0$ with $v_j \in V_j$, applying π_j picks out $v_j = 0$ for each j , so the sum is direct. $\square$

^aTo see π_i acts as the identity on V_i : for $v \in V_i$, all the terms $\pi_j(v)$ with $j \neq i$ lie in V_j , and applying the identity $\text{id} = \sum_j \pi_j$ twice with $\pi_i \pi_j = 0$ collapses everything except $\pi_i(v)$.

Remark. Each V_j is stable under α , and the restriction of $(\alpha - \lambda_j \text{id})$ to V_j is *nilpotent* – its c_j th power is zero. So the Jordan normal form theorem is really a statement about how nilpotent maps can act, and the 1s above the diagonal record that nilpotent action.

It's worth seeing concretely how a single Jordan block acts. Writing $J_m(\lambda) = \lambda I + N$, the basis vectors form a *chain*: N sends each basis vector to the previous one, eventually falling off the end into 0.

$$v_m \xrightarrow{N} v_{m-1} \xrightarrow{N} \cdots \xrightarrow{N} v_2 \xrightarrow{N} v_1 \xrightarrow{N} 0$$

Here $N = J_m(\lambda) - \lambda I$, and N^k shifts the off-diagonal line of 1s one step further from the diagonal each time, so $N^m = 0$ but $N^{m-1} \neq 0$.

This picture lets us read off all three multiplicities of an eigenvalue λ directly from the Jordan normal form:

- a_λ is the *total size* of all blocks with eigenvalue λ (the number of times λ appears on the diagonal),
- g_λ is the *number* of blocks with eigenvalue λ (each block contributes exactly one independent eigenvector – the start of its chain),
- c_λ is the size of the *largest* block with eigenvalue λ (the longest chain takes the most steps to kill).

In particular, knowing $(a_\lambda, g_\lambda, c_\lambda)$ for each eigenvalue determines the Jordan normal form completely for small matrices, which makes computing it quite mechanical.

§16.7.3 Computing the Jordan Normal Form

Example 16.7.5 (Computing a JNF)

Let's find the Jordan normal form of

$$A = \begin{pmatrix} 0 & -1 \\ 1 & 2 \end{pmatrix},$$

along with a basis realising it. The characteristic polynomial is $\chi_A(t) = t(2-t)+1 = (t-1)^2$, so $\lambda = 1$ is the only eigenvalue. Since $A - I \neq 0$, the minimal polynomial is $(t-1)^2$, so $c_1 = 2$ and the JNF has a single 2×2 block:

$$J = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}.$$

To find the basis, we need a chain: a vector v_2 with $(A - I)v_2 = v_1 \neq 0$ and $(A - I)v_1 = 0$. We compute

$$A - I = \begin{pmatrix} -1 & -1 \\ 1 & 1 \end{pmatrix}, \quad \text{so} \quad \ker(A - I) = \left\langle \begin{pmatrix} 1 \\ -1 \end{pmatrix} \right\rangle.$$

Taking $v_1 = (1, -1)^T$, we then solve $(A - I)v_2 = v_1$, which gives (for example) $v_2 = (-1, 0)^T$. In the basis $\{v_1, v_2\}$ the map acts by $v_1 \mapsto v_1$ and $v_2 \mapsto v_1 + v_2$, so with $P = \begin{pmatrix} 1 & -1 \\ -1 & 0 \end{pmatrix}$ we have $A = PJP^{-1}$.

§16.8 Symmetric, Quadratic and Hermitian Forms

We now return to bilinear forms, this time restricting our attention to forms $\phi : V \times V \rightarrow \mathbb{F}$ on a *single* vector space. Just as we asked when an endomorphism can be represented by a diagonal matrix, we will ask when a bilinear form can – and here the answer turns out to be much cleaner.

§16.8.1 Symmetric Bilinear Forms and Congruence

For a bilinear form $\phi : V \times V \rightarrow \mathbb{F}$ and a basis B of V , we write $[\phi]_B = [\phi]_{B,B}$. Specialising our change of basis result for bilinear forms, if B' is another basis and $P = [I]_{B',B}$ is the change of basis matrix, then

$$[\phi]_{B'} = P^T [\phi]_B P.$$

This motivates the following analogue of similarity.

Definition 16.8.1 (Congruent Matrices)

Two square matrices $A, A' \in \mathcal{M}_{n,n}(\mathbb{F})$ are **congruent** if $A' = P^T A P$ for some invertible matrix P .

Congruence is an equivalence relation, and two matrices are congruent exactly when they represent the same bilinear form in different bases. So the question ‘when can ϕ be represented by a diagonal matrix?’ is the question of classifying matrices up to congruence.

There is an immediate necessary condition. If $[\phi]_B = D$ is diagonal in some basis, then for any other basis, $[\phi]_{B'} = P^T D P$ satisfies $([\phi]_{B'})^T = P^T D^T P = [\phi]_{B'}$ – the matrix of ϕ is symmetric in *every* basis. This corresponds to a natural symmetry condition on the form itself.

Definition 16.8.2 (Symmetric Bilinear Form)

A bilinear form $\phi : V \times V \rightarrow \mathbb{F}$ is **symmetric** if $\phi(u, v) = \phi(v, u)$ for all $u, v \in V$.

It’s easy to check that ϕ is symmetric if and only if $[\phi]_B$ is a symmetric matrix for any (equivalently, every) basis B . Remarkably, this necessary condition for diagonalisability turns out to be sufficient, as we will prove shortly.

§16.8.2 Quadratic Forms

Before that, let’s meet the closely-related notion of a *quadratic form*, which is what you get when you feed a bilinear form the same vector twice.

Definition 16.8.3 (Quadratic Form)

A map $Q : V \rightarrow \mathbb{F}$ is a **quadratic form** if there is some bilinear form $\phi : V \times V \rightarrow \mathbb{F}$ with

$$Q(v) = \phi(v, v) \text{ for all } v \in V.$$

In coordinates, if $[\phi]_B = A$ and $x = [v]_B$, then $Q(v) = x^T A x$ is a homogeneous quadratic

polynomial in the coordinates of v – hence the name. Note that

$$x^T A x = \sum_{i,j} a_{ij} x_i x_j = \sum_{i,j} \frac{a_{ij} + a_{ji}}{2} x_i x_j = x^T \left(\frac{A + A^T}{2} \right) x,$$

so we lose nothing by assuming the underlying matrix is symmetric. This observation upgrades to a bijection between quadratic forms and symmetric bilinear forms.

Proposition 16.8.4 (Polarisation Identity)

Let $Q : V \rightarrow \mathbb{F}$ be a quadratic form (where the characteristic of $\mathbb{F}$ is not 2). Then there is a *unique* symmetric bilinear form ϕ with $Q(v) = \phi(v, v)$, given by

$$\phi(u, v) = \frac{1}{2} (Q(u + v) - Q(u) - Q(v)).$$

Proof. For existence, take any bilinear ψ with $Q(v) = \psi(v, v)$ and symmetrise: $\phi(u, v) = \frac{1}{2}(\psi(u, v) + \psi(v, u))$ is symmetric, bilinear, and has $\phi(v, v) = \psi(v, v) = Q(v)$.

For uniqueness, if ϕ is any symmetric bilinear form representing Q , then expanding gives

$$Q(u + v) = \phi(u + v, u + v) = Q(u) + Q(v) + 2\phi(u, v),$$

so ϕ is determined by Q via the stated formula. $\square$

So symmetric bilinear forms and quadratic forms are two views of the same data, and we can pass between them freely.

§16.8.3 Diagonalising Symmetric Bilinear Forms

Theorem 16.8.5 (Diagonalisability of Symmetric Bilinear Forms)

Let $\phi : V \times V \rightarrow \mathbb{F}$ be a symmetric bilinear form on a finite dimensional vector space V . Then there is a basis B of V such that $[\phi]_B$ is diagonal.

Proof. We induct on $n = \dim V$, the case $n \leq 1$ being trivial. If $\phi(v, v) = 0$ for every $v \in V$, then by the polarisation identity $\phi = 0$, which is certainly diagonal. Otherwise, pick e_1 with $\phi(e_1, e_1) \neq 0$, and let

$$U = \{v \in V \mid \phi(e_1, v) = 0\},$$

the kernel of the linear map $v \mapsto \phi(e_1, v)$. This map is a non-zero element of V^* (it doesn't vanish at e_1), so by rank-nullity $\dim U = n - 1$. Moreover $\langle e_1 \rangle \cap U = \{0\}$, since $\lambda e_1 \in U$ forces $\lambda \phi(e_1, e_1) = 0$, so $\lambda = 0$. Counting dimensions, $V = \langle e_1 \rangle \oplus U$.

By induction, the restriction $\phi|_{U \times U}$ is diagonal in some basis $\{e_2, \dots, e_n\}$ of U . Then in the basis $B = \{e_1, e_2, \dots, e_n\}$, using symmetry and $\phi(e_1, e_j) = 0$ for $j \geq 2$, the matrix $[\phi]_B$ is diagonal. $\square$

The proof is really an algorithm, but in practice there's often a faster route: *completing the square*.

Example 16.8.6 (Diagonalising by Completing the Square)

Consider the quadratic form on $\mathbb{R}^3$ given by

$$Q(x_1, x_2, x_3) = x_1^2 + x_2^2 + 2x_3^2 + 2x_1x_2 + 2x_1x_3 - 2x_2x_3,$$

corresponding to the symmetric matrix

$$A = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & 2 \end{pmatrix}$$

(note the off-diagonal entries are *half* the corresponding coefficients, since each cross term appears twice in $x^T Ax$). Gathering every appearance of x_1 into a single square, we compute

$$Q - (x_1 + x_2 + x_3)^2 = x_3^2 - 4x_2x_3,$$

and then completing the square again in x_3 ,

$$\begin{aligned} Q &= (x_1 + x_2 + x_3)^2 + x_3^2 - 4x_2x_3 \\ &= (x_1 + x_2 + x_3)^2 + (x_3 - 2x_2)^2 - 4x_2^2. \end{aligned}$$

So in the new coordinates $x'_1 = x_1 + x_2 + x_3$, $x'_2 = x_3 - 2x_2$, $x'_3 = 2x_2$, we have $Q = x'^2_1 + x'^2_2 - x'^2_3$, and the form is diagonal with diagonal entries 1, 1, -1.

§16.8.4 Sylvester's Law of Inertia

Over $\mathbb{C}$, we can go further than just 'diagonal': dividing each basis vector e_i by a square root of $\phi(e_i, e_i)$, every non-zero diagonal entry can be scaled to 1.

Corollary 16.8.7 (Canonical Form over $\mathbb{C}$)

Let ϕ be a symmetric bilinear form on a finite dimensional $\mathbb{C}$ -vector space V . Then there is a basis B with

$$[\phi]_B = \left(\begin{array}{c|c} I_r & 0 \\ \hline 0 & 0 \end{array} \right),$$

where $r = r(\phi)$. Equivalently, every complex symmetric matrix is congruent to exactly one matrix of this form.

Over $\mathbb{R}$ we cannot take square roots of negative numbers, so the best we can do is scale each non-zero diagonal entry to ± 1 .

Corollary 16.8.8 (Canonical Form over $\mathbb{R}$)

Let ϕ be a symmetric bilinear form on a finite dimensional $\mathbb{R}$ -vector space V . Then there is a basis B with

$$[\phi]_B = \begin{pmatrix} I_p & & \\ & -I_q & \\ & & 0 \end{pmatrix}$$

for some non-negative integers p, q with $p + q = r(\phi)$.

Proof. Diagonalise ϕ , reorder the basis so the positive diagonal entries $a_1, \dots, a_p$ come first, then the negative entries $a_{p+1}, \dots, a_{p+q}$, then the zeros, and replace e_i by $e_i/\sqrt{|a_i|}$ for $i \leq p+q$. $\square$

In terms of the associated quadratic form, this says that after a linear change of coordinates, any real quadratic form looks like

$$Q(x) = x_1^2 + \dots + x_p^2 - x_{p+1}^2 - \dots - x_{p+q}^2,$$

where p directions count positively, q count negatively, and the rest are invisible to Q .

The remarkable fact – *Sylvester’s law of inertia* – is that the numbers p and q do not depend on how you diagonalised.

Theorem 16.8.9 (Sylvester’s Law of Inertia)

Let ϕ be a symmetric bilinear form on a finite dimensional real vector space V . If ϕ is represented by the matrix above with parameters (p, q) in one basis and (p', q') in another, then $p = p'$ and $q = q'$.

Definition 16.8.10 (Signature)

The **signature** of a real symmetric bilinear form ϕ is $s(\phi) = p - q$.

To prove Sylvester’s law, we need a basis-independent characterisation of p , and the right notion is the following.

Definition 16.8.11 (Definiteness)

A symmetric bilinear form ϕ on a real vector space V is:

- (i) **positive definite** if $\phi(v, v) > 0$ for all $v \neq 0$,
- (ii) **positive semi-definite** if $\phi(v, v) \geq 0$ for all $v \in V$,

with **negative (semi-)definite** defined analogously with the inequalities reversed.

Proof of Sylvester’s Law. Suppose $B = \{v_1, \dots, v_n\}$ is a basis in which $[\phi]_B$ has the canonical form with parameters (p, q) . We claim

$$p = \max\{\dim X \mid X \leq V, \phi|_{X \times X} \text{ positive definite}\},$$

which is manifestly basis-independent, so proves that p (and by the same argument

applied to $-\phi$, also q) is well defined.

First, ϕ restricted to $X_0 = \langle v_1, \dots, v_p \rangle$ is positive definite, so the maximum is at least p . Conversely, let $Y = \langle v_{p+1}, \dots, v_n \rangle$, on which ϕ is negative semi-definite, and suppose X' is any subspace on which ϕ is positive definite. Then $X' \cap Y = \{0\}$, since any v in the intersection has $\phi(v, v) > 0$ and $\phi(v, v) \leq 0$ unless $v = 0$. Hence the sum $X' + Y$ is direct, and

$$\dim X' + (n - p) = \dim X' + \dim Y \leq \dim V = n,$$

giving $\dim X' \leq p$ as required. $\square$

Remark. Since $p + q = r(\phi)$ is the rank, and (p, q) determine the canonical form completely, we get a tidy classification: two real symmetric matrices are congruent if and only if they have the same rank and signature.

§16.8.5 Sesquilinear and Hermitian Forms

Over $\mathbb{C}$, symmetric bilinear forms are not quite the right notion for measuring ‘length’. The problem is visible even in one dimension: for the form $\phi(x, y) = xy$ on $\mathbb{C}$, we get $\phi(ix, ix) = -\phi(x, x)$, so no non-zero form of this kind takes only real positive values. The fix is to build in a complex conjugate.

Definition 16.8.12 (Sesquilinear Form)

Let V, W be $\mathbb{C}$ -vector spaces. A map $\phi : V \times W \rightarrow \mathbb{C}$ is **sesquilinear** if it is linear in the first argument and *antilinear* in the second, meaning

$$\phi(v, \lambda_1 w_1 + \lambda_2 w_2) = \overline{\lambda_1} \phi(v, w_1) + \overline{\lambda_2} \phi(v, w_2).$$

The matrix theory carries over with only cosmetic changes: with respect to bases B of V and C of W , we define $([\phi]_{B,C})_{ij} = \phi(v_i, w_j)$ as before, and then

$$\phi(v, w) = [v]_B^T [\phi]_{B,C} \overline{[w]_C}, \quad [\phi]_{B',C'} = P^T [\phi]_{B,C} \overline{Q}$$

for change of basis matrices P, Q .

The analogue of a symmetric form is the following.

Definition 16.8.13 (Hermitian Form)

A sesquilinear form $\phi : V \times V \rightarrow \mathbb{C}$ is **Hermitian** if

$$\phi(u, v) = \overline{\phi(v, u)} \quad \text{for all } u, v \in V.$$

Note that for a Hermitian form, $\phi(v, v) = \overline{\phi(v, v)}$ is always *real* – which is what makes definiteness meaningful over $\mathbb{C}$ – and $\phi(\lambda v, \lambda v) = |\lambda|^2 \phi(v, v)$, so scaling can’t change signs as it did above.

Lemma 16.8.14 (Matrix Criterion for Hermitian Forms)

A sesquilinear form ϕ on V is Hermitian if and only if for any basis B of V ,

$$[\phi]_B = \overline{[\phi]_B}^T =: [\phi]_B^\dagger.$$

Proof. If ϕ is Hermitian, then $a_{ji} = \phi(v_j, v_i) = \overline{\phi(v_i, v_j)} = \overline{a_{ij}}$. Conversely, if $A = A^\dagger$, then expanding $u = \sum_i \lambda_i v_i$ and $v = \sum_j \mu_j v_j$ gives

$$\phi(u, v) = \sum_{i,j} \lambda_i \overline{\mu_j} a_{ij}, \quad \overline{\phi(v, u)} = \overline{\sum_{i,j} \mu_j \overline{\lambda_i} a_{ji}} = \sum_{i,j} \lambda_i \overline{\mu_j} \overline{a_{ji}},$$

and these agree since $\overline{a_{ji}} = a_{ij}$. $\square$

There is also a Hermitian version of polarisation, this time requiring four terms:

$$\phi(u, v) = \frac{1}{4} (Q(u+v) - Q(u-v) + iQ(u+iv) - iQ(u-iv)),$$

where $Q(v) = \phi(v, v)$. So again, a Hermitian form is entirely determined by the real-valued function Q .

Sylvester's law then goes through essentially verbatim.

Theorem 16.8.15 (Sylvester's Law for Hermitian Forms)

Let ϕ be a Hermitian form on a finite dimensional $\mathbb{C}$ -vector space V . Then there is a basis B of V in which

$$[\phi]_B = \begin{pmatrix} I_p & & \\ & -I_q & \\ & & 0 \end{pmatrix},$$

and the integers p and q depend only on ϕ , not on the basis.

Proof Sketch. Existence follows the real symmetric case: if $\phi \neq 0$, polarisation gives some e_1 with $\phi(e_1, e_1) \neq 0$ (a real number), we normalise so that $\phi(v_1, v_1) = \pm 1$, split off $\langle v_1 \rangle^\perp$ using rank-nullity, and induct. Uniqueness follows Sylvester's law: p is again the maximal dimension of a subspace on which ϕ is positive definite, which makes sense as $\phi(v, v)$ is real. $\square$

§16.8.6 Skew-Symmetric Forms

For completeness, let us briefly mention the opposite symmetry class. A bilinear form ϕ on a real vector space is **skew-symmetric** if $\phi(u, v) = -\phi(v, u)$ for all u, v , or equivalently if its matrix satisfies $A = -A^T$ in any basis. Note that any bilinear form decomposes as a sum of a symmetric and a skew-symmetric form, via

$$\phi(u, v) = \underbrace{\frac{\phi(u, v) + \phi(v, u)}{2}}_{\text{symmetric}} + \underbrace{\frac{\phi(u, v) - \phi(v, u)}{2}}_{\text{skew-symmetric}}.$$

Theorem 16.8.16 (Canonical Form for Skew-Symmetric Forms)

Let ϕ be a skew-symmetric bilinear form on a finite dimensional real vector space V . Then there is a basis $B = \{v_1, w_1, \dots, v_m, w_m, v_{2m+1}, \dots, v_n\}$ in which $[\phi]_B$ is block diagonal, beginning with m blocks of the form

$$\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$$

followed by zeros. In particular, a skew-symmetric matrix has even rank.

Proof Sketch. If $\phi \neq 0$, pick v_1, w_1 with $\phi(v_1, w_1) = 1$ (rescaling as needed); skew-symmetry gives $\phi(w_1, v_1) = -1$, and v_1, w_1 are independent since $\phi(v, v) = 0$ for every v . Set $U = \langle v_1, w_1 \rangle$ and let $W = \{v \in V \mid \phi(v_1, v) = \phi(w_1, v) = 0\}$. A dimension count shows $V = U \oplus W$, and we induct on W . $\square$

§16.9 Inner Product Spaces

In this final section we add the last piece of structure to our vector spaces: a notion of *length* and *angle*. All of the geometry that this makes possible comes from a single piece of data – an inner product – and the positive-definite forms of the previous section are exactly what we need. Throughout this section, V is a vector space over $\mathbb{R}$ or $\mathbb{C}$.

§16.9.1 Inner Products

Definition 16.9.1 (Inner Product)

An **inner product** on V is a positive definite symmetric bilinear form (if V is a real vector space) or positive definite Hermitian sesquilinear form (if V is complex). We write $\phi(u, v) = \langle u, v \rangle$, and call V equipped with an inner product an **inner product space**.

Example 16.9.2 (Examples of Inner Products)

- (i) On $\mathbb{R}^n$, the familiar dot product $\langle x, y \rangle = \sum_{i=1}^n x_i y_i$; on $\mathbb{C}^n$, the standard inner product $\langle x, y \rangle = \sum_{i=1}^n x_i \overline{y_i}$.
- (ii) On $\mathcal{C}([0, 1], \mathbb{C})$, the L^2 inner product

$$\langle f, g \rangle = \int_0^1 f(t) \overline{g(t)} \, dt.$$

- (iii) More generally, given a continuous ‘weight’ function $w : [0, 1] \rightarrow \mathbb{R}_{>0}$, we can define $\langle f, g \rangle = \int_0^1 f(t) \overline{g(t)} w(t) \, dt$.

When checking that something is an inner product, linearity and symmetry are usually immediate, and the only real content is positive definiteness – often just the statement that $\langle v, v \rangle = 0$ implies $v = 0$.

Definition 16.9.3 (Norm)

Let V be an inner product space. The **norm** of $v \in V$ is

$$\|v\| = \sqrt{\langle v, v \rangle},$$

which is a non-negative real number, and is zero only for $v = 0$.

The single most useful inequality relating the norm and the inner product is the following.

Theorem 16.9.4 (Cauchy-Schwarz Inequality)

Let V be an inner product space, and $u, v \in V$. Then

$$|\langle u, v \rangle| \leq \|u\| \|v\|.$$

Proof. If $u = 0$ the result is trivial, so assume $u \neq 0$. For any scalar t , positive definiteness gives

$$0 \leq \|tu - v\|^2 = |t|^2 \|u\|^2 - 2 \operatorname{Re}(t \langle u, v \rangle) + \|v\|^2.$$

Choosing $t = \overline{\langle u, v \rangle} / \|u\|^2$ (the choice that makes the bound tightest), the right hand side becomes

$$\frac{|\langle u, v \rangle|^2}{\|u\|^2} - 2 \frac{|\langle u, v \rangle|^2}{\|u\|^2} + \|v\|^2 = \|v\|^2 - \frac{|\langle u, v \rangle|^2}{\|u\|^2} \geq 0,$$

which rearranges to the desired inequality. $\square$

Corollary 16.9.5 (Triangle Inequality)

In an inner product space, $\|u + v\| \leq \|u\| + \|v\|$.

Proof. Expanding and applying Cauchy-Schwarz,

$$\|u + v\|^2 = \|u\|^2 + 2 \operatorname{Re}\langle u, v \rangle + \|v\|^2 \leq \|u\|^2 + 2 \|u\| \|v\| + \|v\|^2 = (\|u\| + \|v\|)^2. \quad \square$$

§16.9.2 Orthogonality**Definition 16.9.6 (Orthogonal and Orthonormal Sets)**

A set $\{e_1, \dots, e_k\}$ of vectors in an inner product space is **orthogonal** if $\langle e_i, e_j \rangle = 0$ for all $i \neq j$, and **orthonormal** if additionally $\|e_i\| = 1$ for each i , so that $\langle e_i, e_j \rangle = \delta_{ij}$.

Orthogonality is a strong condition – strong enough to give linear independence for free, along with an explicit formula for coordinates.

Lemma 16.9.7 (Orthogonality Implies Independence)

Let $\{e_1, \dots, e_k\}$ be orthogonal non-zero vectors. Then they are linearly independent,

and if $v = \sum_{j=1}^k \lambda_j e_j$ then

$$\lambda_j = \frac{\langle v, e_j \rangle}{\|e_j\|^2}.$$

Proof. Taking the inner product of $v = \sum_i \lambda_i e_i$ with e_j , all terms with $i \neq j$ vanish, leaving $\langle v, e_j \rangle = \lambda_j \|e_j\|^2$, which gives the coordinate formula. In particular if $v = 0$ then every $\lambda_j = 0$, which is linear independence. $\square$

For orthonormal *bases* the coordinate formula becomes $\lambda_j = \langle v, e_j \rangle$, and the inner product itself takes a particularly clean coordinate form.

Corollary 16.9.8 (Parseval's Identity)

Let V be a finite dimensional inner product space with orthonormal basis $\{e_1, \dots, e_n\}$. Then for all $u, v \in V$,

$$\langle u, v \rangle = \sum_{i=1}^n \langle u, e_i \rangle \overline{\langle v, e_i \rangle}, \quad \text{and in particular} \quad \|u\|^2 = \sum_{i=1}^n |\langle u, e_i \rangle|^2.$$

Proof. Expand $u = \sum_i \langle u, e_i \rangle e_i$ and $v = \sum_j \langle v, e_j \rangle e_j$ and use sesquilinearity together with $\langle e_i, e_j \rangle = \delta_{ij}$. The second identity is the case $u = v$. $\square$

§16.9.3 The Gram-Schmidt Process

Orthonormal bases are clearly a pleasant thing to have, and happily there is an algorithm that manufactures them from arbitrary bases: the *Gram-Schmidt process*. The idea of each step is simple – subtract off the components of the next vector lying along the directions already constructed, then rescale what's left.

Theorem 16.9.9 (Gram-Schmidt Orthogonalisation)

Let V be an inner product space, and let $v_1, v_2, \dots$ be a (finite or countable) linearly independent family of vectors. Then there is an orthonormal family $e_1, e_2, \dots$ such that for every k ,

$$\langle v_1, \dots, v_k \rangle = \langle e_1, \dots, e_k \rangle.$$

Proof. We construct the e_i inductively. To start, take $e_1 = v_1 / \|v_1\|$. Now suppose

$e_1, \dots, e_k$ have been constructed, orthonormal and spanning $\langle v_1, \dots, v_k \rangle$. Define

$$e'_{k+1} = v_{k+1} - \sum_{i=1}^k \langle v_{k+1}, e_i \rangle e_i.$$

For each $j \leq k$ we then have

$$\langle e'_{k+1}, e_j \rangle = \langle v_{k+1}, e_j \rangle - \langle v_{k+1}, e_j \rangle = 0,$$

so e'_{k+1} is orthogonal to everything so far. It is also non-zero, since otherwise v_{k+1} would lie in $\langle e_1, \dots, e_k \rangle = \langle v_1, \dots, v_k \rangle$, contradicting linear independence. So we can set $e_{k+1} = e'_{k+1} / \|e'_{k+1}\|$, and the spans match up since e_{k+1} is a linear combination of v_{k+1} and $e_1, \dots, e_k$ (and vice versa). $\square$

Corollary 16.9.10 (Orthonormal Bases Exist)

Every finite dimensional inner product space has an orthonormal basis, and any orthonormal set of vectors can be extended to an orthonormal basis.

Proof. Apply Gram-Schmidt to any basis for the first claim. For the second, extend the orthonormal set to any basis and apply Gram-Schmidt – the process leaves the already-orthonormal initial vectors unchanged. $\square$

Interpreting Gram-Schmidt through matrices gives a classical matrix factorisation.

Definition 16.9.11 (Orthogonal and Unitary Matrices)

A matrix $A \in \mathcal{M}_{n,n}(\mathbb{R})$ is **orthogonal** if $A^T A = I$, that is $A^{-1} = A^T$. A matrix $A \in \mathcal{M}_{n,n}(\mathbb{C})$ is **unitary** if $A^\dagger A = I$, that is $A^{-1} = A^\dagger = \overline{A}^T$.

Note that A is orthogonal (or unitary) precisely when its columns form an orthonormal basis of $\mathbb{F}^n$ with the standard inner product.

Proposition 16.9.12 (QR Decomposition)

Every invertible matrix $A \in \mathcal{M}_{n,n}(\mathbb{R})$ (respectively $\mathbb{C}$) can be written as $A = QR$ with Q orthogonal (respectively unitary) and R upper triangular.

Proof Sketch. Apply Gram-Schmidt to the columns $v_1, \dots, v_n$ of A , producing an orthonormal basis $e_1, \dots, e_n$. By construction each v_k is a linear combination of $e_1, \dots, e_k$ only, so the matrix Q with columns e_i satisfies $A = QR$ with R upper triangular. $\square$

§16.9.4 Orthogonal Complements and Projections

Definition 16.9.13 (Orthogonal Complement)

Let V be an inner product space and $W \leq V$. The **orthogonal complement** of W is

$$W^\perp = \{v \in V \mid \langle v, w \rangle = 0 \text{ for all } w \in W\}.$$

Lemma 16.9.14 (Orthogonal Decomposition)

Let V be a finite dimensional inner product space and $W \leq V$. Then $V = W \oplus W^\perp$.

Proof. If $v \in W \cap W^\perp$ then $\|v\|^2 = \langle v, v \rangle = 0$, so the intersection is trivial. For the sum, take an orthonormal basis $\{e_1, \dots, e_k\}$ of W and extend it to an orthonormal basis $\{e_1, \dots, e_n\}$ of V ; then $e_{k+1}, \dots, e_n \in W^\perp$, so $W + W^\perp$ contains a basis of V . $\square$

Compare this with the general situation for direct complements: earlier we emphasised that a subspace has *many* complements, with no way to prefer one. An inner product fixes this – $W^\perp$ is a *canonical* complement.

Whenever $V = U \oplus W$, we can define the **projection** $\pi : V \rightarrow V$ onto W by writing $v = u + w$ uniquely and setting $\pi(v) = w$; this is linear and satisfies $\pi^2 = \pi$. When the decomposition is the orthogonal one, π has a beautiful geometric property: it finds the *closest point* of W .

**Proposition 16.9.15** (Orthogonal Projection is the Closest Point)

Let V be an inner product space and $W \leq V$ a finite dimensional subspace with orthonormal basis $\{e_1, \dots, e_k\}$. Define

$$\pi(v) = \sum_{i=1}^k \langle v, e_i \rangle e_i.$$

Then π is the projection onto W along $W^\perp$, and for every $w \in W$,

$$\|v - \pi(v)\| \leq \|v - w\|,$$

with equality if and only if $w = \pi(v)$. That is, $\pi(v)$ is the unique closest point of W to v .

Proof. Certainly $\pi(v) \in W$. Moreover $v - \pi(v) \in W^\perp$, since for each basis vector e_j ,

$$\langle v - \pi(v), e_j \rangle = \langle v, e_j \rangle - \sum_{i=1}^k \langle v, e_i \rangle \langle e_i, e_j \rangle = \langle v, e_j \rangle - \langle v, e_j \rangle = 0.$$

So $v = (v - \pi(v)) + \pi(v)$ is exactly the decomposition of v with respect to $V = W^\perp \oplus W$, and π is the claimed projection.

For the closest point property, let $w \in W$ and split $v - w$ into orthogonal pieces:

$$\|v - w\|^2 = \left\| \underbrace{(v - \pi(v))}_{\in W^\perp} + \underbrace{(\pi(v) - w)}_{\in W} \right\|^2 = \|v - \pi(v)\|^2 + \|\pi(v) - w\|^2,$$

where the cross terms vanish by orthogonality (this is just Pythagoras). The right hand side is minimised exactly when $\pi(v) = w$. $\square$

§16.9.5 Adjoint Maps

We come now to the inner product space analogue of the dual map.

Theorem 16.9.16 (Existence of the Adjoint)

Let V, W be finite dimensional inner product spaces and let $\alpha : V \rightarrow W$ be a linear map. Then there is a unique linear map $\alpha^* : W \rightarrow V$, the **adjoint** of α , such that

$$\langle \alpha(v), w \rangle = \langle v, \alpha^*(w) \rangle \quad \text{for all } v \in V, w \in W.$$

Moreover, if B and C are *orthonormal* bases of V and W , then

$$[\alpha^*]_{C,B} = [\alpha]_{B,C}^\dagger,$$

the conjugate transpose of the matrix of α .

Proof. Let $B = \{v_1, \dots, v_n\}$, $C = \{w_1, \dots, w_m\}$ be orthonormal bases, and let $A = [\alpha]_{B,C}$. Define α^* to be the linear map with matrix $[\alpha^*]_{C,B} = A^\dagger$. Then for basis vectors, using orthonormality to compute inner products,

$$\langle \alpha(v_i), w_j \rangle = \left\langle \sum_k a_{ki} w_k, w_j \right\rangle = a_{ji}, \quad \langle v_i, \alpha^*(w_j) \rangle = \left\langle v_i, \sum_k \overline{a_{jk}} v_k \right\rangle = \overline{a_{ji}} = a_{ji},$$

and by (sesqui)linearity the two sides agree for all vectors. For uniqueness, if β also satisfies the defining property then $\langle v, (\alpha^* - \beta)(w) \rangle = 0$ for all v , and taking $v = (\alpha^* - \beta)(w)$ shows $(\alpha^* - \beta)(w) = 0$ for every w . $\square$

Remark. We are recycling the notation α^* from dual maps, and this is no accident. The inner product gives an (antilinear) identification $v \mapsto \langle \cdot, v \rangle$ of V with V^* , and under this identification the adjoint *is* the dual map. This is also why the matrix of the adjoint is a (conjugate) transpose, just as the matrix of the dual map was a transpose.

§16.9.6 Self-Adjoint Maps and Isometries

Two classes of endomorphisms of an inner product space deserve special attention – those that equal their own adjoint, and those whose adjoint is their inverse.

Definition 16.9.17 (Self-Adjoint and Isometric Maps)

Let V be a finite dimensional inner product space, and let $\alpha : V \rightarrow V$ be an

endomorphism.

- (i) α is **self-adjoint** if $\alpha^* = \alpha$, that is, $\langle \alpha(v), w \rangle = \langle v, \alpha(w) \rangle$ for all v, w . Over $\mathbb{R}$ such maps are called **symmetric**; over $\mathbb{C}$, **Hermitian**.
- (ii) α is an **isometry** if $\alpha^* = \alpha^{-1}$, or equivalently $\langle \alpha(v), \alpha(w) \rangle = \langle v, w \rangle$ for all v, w . Over $\mathbb{R}$ such maps are called **orthogonal**; over $\mathbb{C}$, **unitary**.

Let's check the claimed equivalence for isometries. If α preserves all inner products, then in particular $\|\alpha(v)\| = \|v\|$, so α is injective, hence invertible; and then

$$\langle v, \alpha^*(w) \rangle = \langle \alpha(v), w \rangle = \langle \alpha(v), \alpha(\alpha^{-1}(w)) \rangle = \langle v, \alpha^{-1}(w) \rangle$$

for all v, w , forcing $\alpha^* = \alpha^{-1}$. The converse is immediate: $\langle \alpha(v), \alpha(w) \rangle = \langle v, \alpha^* \alpha(w) \rangle = \langle v, w \rangle$. In fact, by polarisation, preserving norms alone is enough to make α an isometry.

In matrix terms: with respect to any *orthonormal* basis, self-adjoint maps are represented by symmetric (Hermitian) matrices, and isometries by orthogonal (unitary) matrices. The isometries of V form the **orthogonal group** $O(V)$ (respectively the **unitary group** $U(V)$) under composition.

§16.9.7 The Spectral Theorems

We now arrive at the crowning results of the course, the *spectral theorems*: self-adjoint maps (and over $\mathbb{C}$, isometries) are not just diagonalisable, but diagonalisable in an *orthonormal* basis. First, a lemma that makes everything work.

Lemma 16.9.18 (Eigenvalues of Self-Adjoint Maps)

Let α be a self-adjoint endomorphism of a finite dimensional inner product space V . Then:

- (i) every eigenvalue of α is real,
- (ii) eigenvectors corresponding to distinct eigenvalues are orthogonal.

Proof. (i) Suppose $\alpha(v) = \lambda v$ with $v \neq 0$. Then

$$\lambda \|v\|^2 = \langle \alpha(v), v \rangle = \langle v, \alpha(v) \rangle = \bar{\lambda} \|v\|^2,$$

so $\lambda = \bar{\lambda}$ is real.^a

(ii) If additionally $\alpha(w) = \mu w$ with $\mu \neq \lambda$, then

$$\lambda \langle v, w \rangle = \langle \alpha(v), w \rangle = \langle v, \alpha(w) \rangle = \bar{\mu} \langle v, w \rangle = \mu \langle v, w \rangle,$$

using that μ is real. Since $\lambda \neq \mu$, this forces $\langle v, w \rangle = 0$. □

^aIn the real case this argument should be read as applying to the complexification – concretely, a real symmetric matrix, viewed as a complex matrix, has real eigenvalues. This is exactly what lets the induction in the spectral theorem proceed over $\mathbb{R}$.

Theorem 16.9.19 (Spectral Theorem for Self-Adjoint Maps)

Let V be a finite dimensional (real or complex) inner product space, and let $\alpha : V \rightarrow$

V be self-adjoint. Then V has an orthonormal basis consisting of eigenvectors of α . In particular, α is diagonalisable in an orthonormal basis, and V is the orthogonal direct sum of the eigenspaces of α .

Proof. We induct on $\dim V$, with the case $\dim V = 1$ being trivial. The characteristic polynomial of α has a complex root λ by the fundamental theorem of algebra, and by the lemma λ is real – so in both the real and complex cases, λ is a genuine eigenvalue of α . Pick an eigenvector v_1 , scaled so that $\|v_1\| = 1$, and let $U = \langle v_1 \rangle^\perp$.

The key step is that U is α -stable. Indeed, for $u \in U$,

$$\langle \alpha(u), v_1 \rangle = \langle u, \alpha(v_1) \rangle = \lambda \langle u, v_1 \rangle = 0,$$

so $\alpha(u) \in U$. The restriction $\alpha|_U$ is a self-adjoint endomorphism of the inner product space U with $\dim U = \dim V - 1$, so by induction U has an orthonormal basis of eigenvectors $\{v_2, \dots, v_n\}$. Since $V = \langle v_1 \rangle \oplus U$ orthogonally, $\{v_1, v_2, \dots, v_n\}$ is an orthonormal basis of eigenvectors of V . $\square$

Geometrically, the spectral theorem says a self-adjoint map is just *scaling along some set of perpendicular axes*. Applied to the unit circle in the plane, a symmetric map produces an ellipse whose principal axes are the (orthogonal) eigendirections:

Over $\mathbb{C}$, the same conclusion holds for unitary maps, with almost the same proof.

Lemma 16.9.20 (Eigenvalues of Unitary Maps)

Let α be a unitary endomorphism of a finite dimensional complex inner product space. Then every eigenvalue of α satisfies $|\lambda| = 1$, and eigenvectors corresponding to distinct eigenvalues are orthogonal.

Proof. If $\alpha(v) = \lambda v$ with $v \neq 0$, then $\|v\| = \|\alpha(v)\| = |\lambda| \|v\|$, so $|\lambda| = 1$ (in particular $\lambda \neq 0$). If also $\alpha(w) = \mu w$ with $\mu \neq \lambda$, then

$$\lambda \langle v, w \rangle = \langle \alpha(v), w \rangle = \langle v, \alpha^{-1}(w) \rangle = \left\langle v, \frac{1}{\mu} w \right\rangle = \frac{1}{\mu} \langle v, w \rangle = \mu \langle v, w \rangle,$$

using $\mu \bar{\mu} = 1$, and since $\lambda \neq \mu$ we get $\langle v, w \rangle = 0$. $\square$

Theorem 16.9.21 (Spectral Theorem for Unitary Maps)

Let V be a finite dimensional complex inner product space, and let $\alpha : V \rightarrow V$ be unitary. Then V has an orthonormal basis of eigenvectors of α .

Proof. As before, we induct on the dimension. Pick an eigenvalue λ (which exists as $\mathbb{F} = \mathbb{C}$) with unit eigenvector v_1 , and let $U = \langle v_1 \rangle^\perp$. For $u \in U$,

$$\langle \alpha(u), v_1 \rangle = \langle u, \alpha^{-1}(v_1) \rangle = \langle u, \frac{1}{\lambda} v_1 \rangle = \frac{1}{\lambda} \langle u, v_1 \rangle = 0,$$

so U is α -stable, and $\alpha|_U$ is a unitary endomorphism of U . Induction and the orthogonal decomposition $V = \langle v_1 \rangle \oplus U$ finish the proof as before. $\square$

Remark. The restriction to $\mathbb{C}$ really is needed for isometries: the rotation matrix

$$\begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}$$

is orthogonal, but has eigenvalues $e^{\pm i\theta}$, so is not diagonalisable over $\mathbb{R}$ for general θ – there is simply no real direction that a rotation preserves.

§16.9.8 Applications to Bilinear Forms

The spectral theorem lets us sharpen our earlier results on diagonalising symmetric bilinear forms: not only can we diagonalise, we can do so with an *orthonormal* change of basis.

Corollary 16.9.22 (Orthogonal Diagonalisation of Symmetric Matrices)

Let $A \in \mathcal{M}_{n,n}(\mathbb{R})$ be symmetric (or $A \in \mathcal{M}_{n,n}(\mathbb{C})$ Hermitian). Then there is an orthogonal (respectively unitary) matrix P such that $P^T A P$ (respectively $P^\dagger A P$) is diagonal with real entries.

Proof. View A as a self-adjoint endomorphism of $\mathbb{F}^n$ with the standard inner product. By the spectral theorem there is an orthonormal basis $\{v_1, \dots, v_n\}$ of eigenvectors; let P be the matrix with these as columns. Then P is orthogonal (unitary), and $P^{-1} A P = P^T A P$ (respectively $P^\dagger A P$) is diagonal, with entries the eigenvalues of A , which are real. $\square$

Note the happy coincidence that makes this work: for orthogonal matrices, the change of basis formula for linear maps ($P^{-1} A P$) and for bilinear forms ($P^T A P$) *agree*. So the diagonal entries produced are exactly the eigenvalues of A , and we can read off the signature of a real symmetric form: $s(\phi) = (\text{number of positive eigenvalues}) - (\text{number of negative eigenvalues})$ of any matrix representing ϕ .

We can also now prove a satisfying result about pairs of forms.

Corollary 16.9.23 (Simultaneous Diagonalisation of Forms)

Let V be a finite dimensional real (or complex) vector space, and let ϕ, ψ be symmetric (respectively Hermitian) forms on V with ϕ positive definite. Then there is

a single basis B of V in which $[\phi]_B$ and $[\psi]_B$ are both diagonal.

Proof. Since ϕ is positive definite, it makes V into an inner product space with $\langle u, v \rangle = \phi(u, v)$. By the previous corollary applied in this inner product space, there is a ϕ -orthonormal basis B of V in which $[\psi]_B$ is diagonal. But orthonormality of B with respect to ϕ says precisely that $[\phi]_B = I$, which is certainly diagonal. $\square$

In matrix language: if A, B are real symmetric (or Hermitian) matrices with A positive definite, then there is an invertible Q with $Q^T A Q$ and $Q^T B Q$ both diagonal. This result is the abstract heart of many applications – for instance, finding the normal modes of a mechanical system simultaneously diagonalises the kinetic and potential energy forms.

And with that, we have reached the end of the course. Starting from nothing but the axioms of a vector space, we have built up bases and dimension, classified linear maps up to change of basis, developed determinants, eigenvalues and canonical forms, and finally seen how an inner product turns linear algebra into geometry. These tools appear constantly throughout mathematics – and if the subject appeals to you, the story continues in courses on modules (IB Groups, Rings and Modules) and functional analysis, where infinite dimensional spaces take centre stage.

17 Markov Chains

A stochastic process is said to have the ‘Markov property’ if, conditional on its present value, the future is independent of the past. This is a *restrictive* assumption, but we do end up with a useful model with a rich mathematical theory, which we shall study in this course. Despite the restriction, Markov chains turn out to be everywhere: shuffling cards, random walks, population growth, queues, and the algorithms behind modern statistical sampling are all naturally described by them. The pay-off of the theory is that remarkably detailed questions – will the process return to where it started? how long does it take? what does it look like after a long time? – admit complete and often beautiful answers.

This article constitutes my notes for the ‘Markov Chains’ course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§17.1 The Markov Property

§17.1.1 What is a Markov Chain?

Let S be a countable set (the set of possible ‘states’), and let X_n be a sequence of random variables taking values in S .

Definition 17.1.1 (Markov Chain)

The sequence of random variables X_n is a **Markov chain** if it satisfies the **Markov property**

$$\mathbb{P}(X_{n+1} = x_{n+1} \mid X_n = x_n, \dots, X_0 = x_0) = \mathbb{P}(X_{n+1} = x_{n+1} \mid X_n = x_n).$$

The Markov chain is said to be **homogeneous** if for all $i, j \in S$ the conditional probability $\mathbb{P}(X_{n+1} = j \mid X_n = i)$ is independent of n .

In this course we are only going to study homogeneous Markov chains.

Markov chains are often best described by diagrams¹ which show the probability of moving from one state to another. For example, the Markov chain in the diagram below has three states which we label $\{1, 2, 3\}$, and the probability of moving from state 1 to state 2 is $1/2$, and the probability of moving from state 2 to state 3 is $1/3$, and so on.

¹You might notice that these diagrams are labelled directed graphs, and indeed you will see concepts from graph theory such as connectivity reoccur when we later talk about communicating classes.

In general, to calculate the probabilities associated with a Markov chain, we need to know two quantities.

- *The initial distribution.* We first need to know about the starting state of a Markov chain. This is described by the initial distribution $\lambda = (\lambda_i \mid i \in S)$, where $\lambda_i = \mathbb{P}(X_0 = i)$.
- *The transition probabilities.* We also need to know the probability of moving from a state $i \in S$ to a state $j \in S$. This is typically given by a *transition matrix* $P = (P_{i,j} \mid i, j \in S)$ with $p_{i,j} = \mathbb{P}(X_1 = j \mid X_0 = i)$.

These quantities are of course subject to some constraints, in that we require $\sum_{i \in S} \lambda_i = 1$ and the transition matrix P must be **stochastic**, in that $\sum_{j \in S} P_{i,j} = 1$ for all $i \in S$.

If a Markov chain X_n has initial distribution λ and transition matrix P , we say that it is **Markov**(λ, P).

Once we have these quantities, we can begin to actually establish various properties about the Markov chain, for example the probability that it goes through a given sequence of states.

Theorem 17.1.2 (Probability of a Sequence of States)

The sequence of random variables X_n is Markov(λ, P) if and only if

$$\mathbb{P}(X_0 = i_0, X_1 = i_1, \dots, X_n = i_n) = \lambda_{i_0} P_{i_0, i_1} \cdots P_{i_{n-1}, i_n},$$

for all $n \geq 0$ and $i_0, \dots, i_n \in S$.

Proof. Let A_k denote the event $\{X_k = i_k\}$. First suppose that X_n is Markov(λ, P). We prove the result holds by induction. For $n = 0$ this is true by definition. Then if it holds up to n , we have

$$\begin{aligned} \mathbb{P}(A_0 \cap \cdots \cap A_n) &= \mathbb{P}(A_0 \cap \cdots \cap A_{n-1}) \mathbb{P}(A_n \mid A_0 \cap \cdots \cap A_{n-1}) \\ &= \mathbb{P}(A_0 \cap \cdots \cap A_{n-1}) \mathbb{P}(A_n \mid A_{n-1}) \\ &= (\lambda_{i_0} P_{i_0, i_1} \cdots P_{i_{n-2}, i_{n-1}}) P_{i_{n-1}, i_n}, \end{aligned}$$

which completes our induction.

Conversely, suppose that the result holds. Then with $n = 0$ we get that the initial distribution of X_n is λ . Then

$$\mathbb{P}(A_{n+1} \mid A_0 \cap \cdots \cap A_n) = \frac{\mathbb{P}(A_0 \cap \cdots \cap A_{n+1})}{\mathbb{P}(A_0 \cap \cdots \cap A_n)} = P_{i_n, i_{n+1}}.$$

Since this does not depend on $i_0, \dots, i_{n-1}$, X_n is a homogeneous Markov chain with transition matrix P , as required. $\square$

Before moving on, let's get a feel for what is and isn't a Markov chain.

Example 17.1.3 (Some Markov Chains, and a Non-Example) (i) *An i.i.d. sequence.*

If $X_0, X_1, X_2, \dots$ are independent and identically distributed random variables taking values in S , then X_n is (rather boringly) a Markov chain: conditioning on the past changes nothing at all, and $P_{i,j} = \mathbb{P}(X_1 = j)$ doesn't even depend on i .

- (ii) *A random walk.* Let $\xi_1, \xi_2, \dots$ be i.i.d. integer-valued random variables and set $X_n = X_0 + \xi_1 + \dots + \xi_n$. Then X_n is a Markov chain on $\mathbb{Z}$, since given $X_n = x$, we have $X_{n+1} = x + \xi_{n+1}$, and ξ_{n+1} is independent of everything that came before. Random walks will be recurring characters throughout this course. A typical trajectory of the walk with steps $\xi_i = \pm 1$ looks like the following.

- (iii) *A non-example.* Let X_n be the random walk above with steps ± 1 , and let $M_n = \max_{0 \leq k \leq n} X_k$ be its running maximum. Then M_n is *not* a Markov chain in general: knowing that $M_n = M_{n-1} = m$ tells us the walk is currently strictly below its maximum, while knowing only $M_n = m$ leaves open the possibility $X_n = m$, and these lead to different probabilities that $M_{n+1} = m+1$. The past leaks information about the present position of the underlying walk, which the value of M_n alone doesn't capture.

Example 17.1.4 (Probability of a Path)

Let's also see the previous theorem in action on the three-state chain drawn at the start of this section, with $S = \{1, 2, 3\}$ and initial distribution $\lambda = \delta_1$ (i.e. we start at state 1 with certainty). The probability that the chain follows the path $1 \rightarrow 2 \rightarrow 3 \rightarrow 1$ is

$$\mathbb{P}(X_0 = 1, X_1 = 2, X_2 = 3, X_3 = 1) = \lambda_1 P_{1,2} P_{2,3} P_{3,1} = 1 \cdot \frac{1}{2} \cdot \frac{1}{3} \cdot 1 = \frac{1}{6}.$$

Notice how the answer is just the product of the probabilities written on the arrows of the diagram, along the path taken – this is a perfectly good way to think about the theorem.

§17.1.2 Simple Markov Property

An important aspect of Markov chains is that they are *memoryless*, in the future is independent of the past, conditional on the present. This is encapsulated in the **simple Markov property**.

Theorem 17.1.5 (Simple Markov Property)

Let X_n be a Markov chain. Then conditional on $X_m = i$, the sequence of random variables $(X_{m+n})_{n \geq 0}$ is^a Markov(δ_i, P), and is independent of $X_0, \dots, X_{m-1}$.

^aHere δ_{ij} is 1 if $i = j$ and 0 otherwise.

Proof. Given any event H determined by $X_0, \dots, X_{m-1}$, we want to show that for an event $F = \{X_m = i_m, \dots, X_{m+n} = i_{m+n}\}$ we have

$$\mathbb{P}(H \cap F \mid X_m = i) = \delta_{ii_m} P_{i_m, i_{m+1}} \cdots P_{i_{m+n-1}, i_{m+n}} \mathbb{P}(H \mid X_m = i).$$

Indeed, considering the case of $H = \{X_0 = i_0, \dots, X_m = i_m\}$ we have

$$\begin{aligned} \mathbb{P}(H \cap F \mid X_m = i) &= \frac{\lambda_{i_0} P_{i_0, i_1} \cdots P_{i_{m-1}, i_m} P_{i_m, i_{m+1}} \cdots P_{i_{m+n-1}, i_{m+n}}}{\mathbb{P}(X_m = i)} \\ &= \delta_{ii_m} P_{i_m, i_{m+1}} \cdots P_{i_{m+n-1}, i_{m+n}} \mathbb{P}(H \mid X_m = i), \end{aligned}$$

as required.

Then for a general H , we can write it as the disjoint union $H = \bigcup_{k=1}^{\infty} H_k$, and then the overall result follows by summing the above result for relevant H_k . $\square$

Remark. It is worth internalising what the simple Markov property really says: the chain, observed from time m onwards, is a fresh copy of the Markov chain started from wherever it happened to be at time m – and this fresh copy doesn't care at all about the route taken to get there. For instance, for any states i, j, k ,

$$\mathbb{P}(X_5 = j \mid X_3 = i, X_0 = k) = \mathbb{P}(X_5 = j \mid X_3 = i) = \mathbb{P}(X_2 = j \mid X_0 = i),$$

so conditional probabilities of the future can always be 're-rooted' to time zero. We will use manipulations of this sort constantly, and usually without comment.

§17.1.3 Transition Probabilities

We are now going to address how to find the probability that a Markov chain is in a given state after n steps. The core idea of this section is that we will be able to reduce such questions into questions about the transition matrix that we introduced earlier.

Recall that if X_n is a Markov chain with transition matrix P , then $P_{i,j}$ was the probability of moving from the state i to the state j . We call these the **one-step transition probabilities**. We can generalize this slightly.

Definition 17.1.6 (n -Step Transition Probabilities)

For a Markov chain X_n , the **n -step transition probabilities** are given by

$$p_{i,j}(n) = \mathbb{P}(X_n = j \mid X_0 = i).$$

These n -step transition probabilities naturally form the **n -step transition matrix** $P(n) = (p_{i,j}(n) \mid i, j \in S)$. The nice thing about writing these transition probabilities as a matrix is that they satisfy a lovely set of equations that relate extremely well to matrix algebra.

Theorem 17.1.7 (Chapman-Kolmogorov Equations)

We have that

$$p_{i,j}(n+m) = \sum_{k \in S} p_{i,k}(n)p_{k,j}(m),$$

where $i, j \in S$ and $m, n \geq 0$. In particular, $P(m+n) = P(m)P(n)$.

Proof. Using the partition theorem and simple Markov property,

$$\begin{aligned} p_{i,j}(n+m) &= \mathbb{P}(X_{n+m} = j \mid X_0 = i) \\ &= \sum_{k \in S} \mathbb{P}(X_{m+n} = j \mid X_n = k, X_0 = i) \mathbb{P}(X_n = k \mid X_0 = i) \\ &= \sum_{k \in S} \mathbb{P}(X_{m+n} = j \mid X_n = k) \mathbb{P}(X_n = k \mid X_0 = i) \\ &= \sum_{k \in S} p_{i,k}(n)p_{k,j}(m). \end{aligned}$$

□

So, if we have some n -step transition matrix $P(n)$, the above result shows us that it satisfies $P(n) = P^n$. This reduces our problem to just this:

To compute $p_{i,j}(n)$, we can compute powers of
the transition matrix, and take $(P^n)_{i,j}$.

In general, this makes our problem significantly easier, and if the state space is finite, we can use tools from linear algebra such as diagonalisation.

Example 17.1.8 (Predicting the Weather)

Suppose the weather in Cambridge is sunny, cloudy or rainy, and that tomorrow's weather depends only on today's^a, according to the transition matrix

$$P = \begin{pmatrix} 1/2 & 1/3 & 1/6 \\ 1/4 & 1/2 & 1/4 \\ 1/4 & 1/4 & 1/2 \end{pmatrix},$$

where the states are (sunny, cloudy, rainy) in that order. If it is sunny today, what is the probability that it rains two days from now?

By our discussion above, this is just the matrix entry

$$(P^2)_{1,3} = \sum_{k=1}^3 P_{1,k}P_{k,3} = \frac{1}{2} \cdot \frac{1}{6} + \frac{1}{3} \cdot \frac{1}{4} + \frac{1}{6} \cdot \frac{1}{2} = \frac{1}{12} + \frac{1}{12} + \frac{1}{12} = \frac{1}{4},$$

where the three terms account for the three possible weathers tomorrow. There is nothing special about two days – the probability for any horizon n is read off from P^n , computable by repeated squaring or by diagonalisation as described above.

^aA bold modelling assumption, but this is a mathematics course.

While we are speaking the language of matrices, it is worth recording what happens when

the starting state is itself random. Treating the initial distribution λ as a *row vector*, the distribution of the chain at time n is obtained by simply multiplying by powers of P .

Proposition 17.1.9 (Distribution at Time n)

Let X_n be $\text{Markov}(\lambda, P)$. Then for all $n \geq 0$ and $j \in S$,

$$\mathbb{P}(X_n = j) = (\lambda P^n)_j.$$

Proof. Conditioning on the starting state and using the previous result,

$$\mathbb{P}(X_n = j) = \sum_{i \in S} \mathbb{P}(X_0 = i) \mathbb{P}(X_n = j \mid X_0 = i) = \sum_{i \in S} \lambda_i (P^n)_{i,j} = (\lambda P^n)_j. \quad \square$$

So the entire distributional evolution of a Markov chain is captured by the linear algebra of the pair (λ, P) – a fact we will lean on constantly, and which will become especially interesting when we ask what happens as $n \rightarrow \infty$ later in the course.

Example 17.1.10 (Computing Transition Probabilities)

Let $\alpha, \beta \in (0, 1)$. Consider the Markov chain X_n with states $S = \{1, 2\}$, with transition matrix

$$P = \begin{pmatrix} 1 - \alpha & \alpha \\ \beta & 1 - \beta \end{pmatrix}.$$

A diagram of this Markov chain is shown below.

We want to find the n -step transition probabilities.

Method 1 (Difference Equations). We are first going to find $p_{1,1}(n)$ using a ‘bare-hands’ method. By the Chapman-Kolmogorov equations (that is, conditioning on X_n) we have

$$\begin{aligned} p_{1,1}(n+1) &= p_{1,1}(n)p_{1,1}(1) + p_{1,2}(n)p_{2,1}(1) \\ &= (1 - \alpha)p_{1,1}(n) + \beta p_{1,2}(n) \\ &= (1 - \alpha)p_{1,1}(n) + \beta(1 - p_{1,1}(n)) \\ &= p_{1,1}(n)(1 - \alpha - \beta) + \beta. \end{aligned}$$

This is a recurrence relation which we can then solve using the boundary condition $p_{1,1}(0) = 1$ to get

$$p_{1,1}(n) = \begin{cases} \frac{\beta}{\alpha + \beta} + \frac{\alpha}{\alpha + \beta} \cdot (1 - \alpha - \beta)^n & \text{if } \alpha + \beta > 0, \\ 1 & \text{if } \alpha + \beta = 0. \end{cases}$$

Method 2 (Diagonalisation). An alternative solution uses some tools from matrix algebra. To calculate the n -step transition matrix P^n , we are going to diagonalise P .

The eigenvalues of P are given by the solutions to $\det(P - \mu I) = 0$, which are $\{1, 1 - \alpha - \beta\}$. Thus for some invertible matrix U we have

$$P = U^{-1} \begin{pmatrix} 1 & 0 \\ 0 & 1 - \alpha - \beta \end{pmatrix} U \quad \text{and} \quad P^n = U^{-1} \begin{pmatrix} 1 & 0 \\ 0 & (1 - \alpha - \beta)^n \end{pmatrix} U.$$

Thus $p_{1,1}(n) = A + B(1 - \alpha - \beta)^n$, for constants A and B . We can find these by noting the boundary conditions $p_{1,1}(0) = 1$ and $p_{1,1}(1) = 1 - \alpha$, giving

$$p_{1,1}(n) = \begin{cases} \frac{\beta}{\alpha + \beta} + \frac{\alpha}{\alpha + \beta} \cdot (1 - \alpha - \beta)^n & \text{if } \alpha + \beta > 0, \\ 1 & \text{if } \alpha + \beta = 0. \end{cases}$$

In general, if the state space of a Markov chain is finite with $|S| = k$, then P is a $k \times k$ matrix with eigenvalues $\mu_1, \dots, \mu_k$.

If *all of the eigenvalues are distinct*, then P is diagonalisable, and we can write

$$P = U^{-1} \begin{pmatrix} \mu_1 & \cdots & 0 \\ 0 & \ddots & 0 \\ 0 & \cdots & \mu_k \end{pmatrix} U \quad \text{and} \quad P^n = U^{-1} \begin{pmatrix} \mu_1^n & \cdots & 0 \\ 0 & \ddots & 0 \\ 0 & \cdots & \mu_k^n \end{pmatrix} U,$$

and $p_{i,j} = a_1 \mu_1^n + \cdots + a_k \mu_k^n$, for some constants $a_1, \dots, a_k$, which are determined by the boundary conditions.

If some eigenvalue μ_k is complex, then its conjugate is also an eigenvalue, so if $\mu_k = re^{i\theta}$ we have also the eigenvalue $\overline{\mu_k} = re^{-i\theta}$, and we can write

$$p_{i,j} = a_1 \mu_1^n + \cdots + a_{k-2} \mu_{k-2}^n + a_{k-1} r^n \cos(n\theta) + a_k r^n \sin(n\theta),$$

since $p_{i,j}$ is real and so all of the imaginary parts must cancel out.

If *some eigenvalues repeat*, then the situation is slightly more complicated. If an eigenvalue μ_k has multiplicity m , we can simply replace a_k by a degree m polynomial in n ².

Example 17.1.11 (Transition Matrix with Complex Eigenvalues)

Consider the Markov chain X_n with states $S = \{1, 2, 3\}$ as shown in the diagram below. We want to find the n -step transition probability $p_{i,i}(n)$.

²This comes from considering the Jordan Normal form of the transition matrix.

This Markov chain has the transition matrix

$$P = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 1/2 & 1/2 \\ 1/2 & 0 & 1/2 \end{pmatrix},$$

which has distinct eigenvalues $\{1, i/2, -i/2\}$.

We can rewrite the complex eigenvalues using trigonometric functions as

$$\begin{aligned} \frac{i}{2} &= \cos \frac{\pi}{2} + i \sin \frac{\pi}{2}, \\ -\frac{i}{2} &= \cos \frac{\pi}{2} - i \sin \frac{\pi}{2}. \end{aligned}$$

The general form for $p_{1,1}(n)$ is then given by

$$p_{1,1}(n) = A + B \cdot \left(\frac{1}{2}\right)^n \cos\left(\frac{n\pi}{2}\right) + C \cdot \left(\frac{1}{2}\right)^n \sin\left(\frac{n\pi}{2}\right).$$

The boundary conditions can be computed by hand as $p_{1,1}(0) = 1$, $p_{1,1}(1) = 0$ and $p_{1,1}(2) = 0$. This allows us to solve for A , B and C to get

$$p_{1,1}(n) = \frac{1}{5} + \left(\frac{1}{2}\right)^n \left(\frac{4}{5} \cos\left(\frac{n\pi}{2}\right) - \frac{2}{5} \sin\left(\frac{n\pi}{2}\right) \right).$$

§17.2 Class Structure

§17.2.1 Communicating Classes

In Graph Theory, one can often make a problem easier by looking at the *connected components* of the graph, effectively splitting it up into smaller disconnected chunks which are easier to understand on their own. This has a natural analogue in the study of Markov chains,³ where we consider which states can interact.

Definition 17.2.1 (Communication)

Let X_n be a Markov chain. For $i, j \in S$, we say that i **leads to** j , written $i \rightarrow j$, if $p_{i,j}(n) > 0$ for some $n \geq 0$.

If $i \rightarrow j$ and $j \rightarrow i$, we say that i and j **communicate**, and write $i \leftrightarrow j$.

We can use this idea of communication to break up our state space by noting that communication is an equivalence relation.

Theorem 17.2.2 (Communication is an Equivalence Relation)

The relation $\leftrightarrow$ is an equivalence relation on S .

³Indeed, one can view a Markov chain as a labelled directed graph, and then apply the same connected components argument to obtain the theory shown here.

Proof. For any $i \in S$, $p_{i,i}(0) = 1$ and thus $i \leftrightarrow i$, so the relation is reflexive. The relation is symmetric by definition, so we are just left to check transitivity.

Let $i, j, k \in S$, and suppose that $i \leftrightarrow j$ and $j \leftrightarrow k$. Then there exists $m, n \geq 0$ such that $p_{i,j}(n) > 0$ and $p_{j,k}(m) > 0$. Then by the Chapman-Kolmogorov equations,

$$p_{i,k}(m+n) = \sum_{l \in S} p_{i,l}(m)p_{l,k}(n) \geq p_{i,j}(n)p_{j,k}(m) > 0,$$

so $i \rightarrow k$. By the same argument $k \rightarrow i$, and thus $\leftrightarrow$ is transitive. $\square$

Because communication is an equivalence relation, it partitions the state space.

Definition 17.2.3 (Communicating Classes)

The equivalence classes induced by $\longleftrightarrow$ on S are called **communicating classes**.

Because communication is really a notion about directed graphs (and not *really* about individual probabilities), it's usually relatively easy to identify the communicating classes from the diagram of a Markov chain.

For example, the Markov chain below has its communicating classes coloured (and the transition probabilities are not labelled, as they are not needed to infer the communicating classes, aside from knowing they are non-zero along each edge).

In the Markov chain above, we can see that there are a few different ways that communicating classes can appear.

A communicating class C is **closed** if there is no way to leave it, in that if $i \in C$ and $i \rightarrow j$, then $j \in C$. For example, in the Markov chain above, the communicating class $\{1, 2\}$ is closed.

A state $i \in S$ is **absorbing** if there is no way to leave that state, that is, $\{i\}$ is a communicating class. In the Markov chain above, 4 is absorbing.

If a Markov chain has only one communicating class, we call it **irreducible**, as we cannot split it into smaller parts in this way.

Let's put these definitions to use on a concrete example.

Example 17.2.4 (Finding the Communicating Classes)

Consider the Markov chain on $S = \{1, 2, 3, 4, 5\}$ with transition matrix

$$P = \begin{pmatrix} 1/2 & 1/2 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ 1/3 & 0 & 1/3 & 1/3 & 0 \\ 0 & 0 & 0 & 1/2 & 1/2 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}.$$

Drawing the diagram (which, as we said, is usually the right move) gives the following.

We can now just read off the class structure. States 1 and 2 communicate (each leads to the other in one step), and nothing outside $\{1, 2\}$ can be reached from them, so $\{1, 2\}$ is a *closed* communicating class. Similarly $\{4, 5\}$ is a closed class. State 3 leads to state 2 and state 4, but neither leads back to 3, so $\{3\}$ is a communicating class by itself, and it is *not* closed.

This chain is not irreducible – it has three communicating classes. Intuitively, the chain will linger at 3 for a (geometrically distributed) while, and then fall either left into $\{1, 2\}$ or right into $\{4, 5\}$, where it will remain trapped forever. Computing the probability of each of these outcomes is a matter of *hitting probabilities*, which is exactly the business of the next section.

§17.3 Hitting Times, Stopping Times and Absorption Probabilities

§17.3.1 Hitting Times

When studying Markov chains, a frequently occurring question is ‘*how long does it take to reach a given state $i \in S$?*’, a concept which we formulate as the *hitting time*.

Definition 17.3.1 (Hitting Time)

Let X_n be a Markov chain. The **hitting time** of some subset of states $A \subseteq S$ is the random variable T_A , which is the least n for which $X_n \in A$. In particular,

$$T_A = \inf\{n \geq 0 \mid X_n \in A\},$$

where this may be ∞ if $X_n \notin A$ for all $n \geq 0$.

In this section, we will also look some related quantities, such as the *hitting probability* and *mean hitting time*.

Definition 17.3.2 (Hitting Probability)

Let X_n be a Markov chain, and let $A \subseteq S$ be some subset of states. The **hitting probability** h_i^A of A is the probability that X_n eventually reaches a state in A , given $X_0 = i$. That is,

$$h_i^A = \mathbb{P}(T_A < \infty \mid X_0 = i),$$

where $i \in S$.

Definition 17.3.3 (Mean Hitting Time)

Let X_n be a Markov chain, and let $A \subseteq S$ be some subset of states. The **mean hitting time** k_i^A of A is the expected number of steps taken for X_n to reach a state in A , given $X_0 = i$. That is,

$$k_i^A = \mathbb{E}[T_A \mid X_0 = i],$$

where $i \in S$. We note that this may be ∞ .

So how do we go about calculating these quantities? An intuitive way is to try and consider what happens as we move from one state to another, as we will see in the example below.

Example 17.3.4 (Computing Hitting Probabilities and Mean Hitting Times)

Consider the Markov chain in the diagram below.

Suppose we took $A = \{4\}$ and wanted to find the hitting probability $h_2^A = \mathbb{P}(T_A < \infty \mid X_0 = 2)$. One might intuitively suppose that

$$h_2^A = P_{2,3}h_3^A = \frac{1}{2}h_3^A,$$

$$h_3^A = P_{3,2} \cdot h_2^A + P_{3,4} \cdot h_4^A = \frac{1}{2} \cdot h_2^A + \frac{1}{2}.$$

which when solved gives us $h_2^A = 1/3$.

Alternatively, if we took $B = \{1, 4\}$ and wanted to find the mean hitting time k_2^B , we could again try the intuitive approach of writing

$$k_2^B = 1 + \frac{1}{2}k_3^B,$$

and noting that $k_3^B = k_2^B$ by symmetry, giving $k_2^B = 2$.

In the computations above, we really should check that these are valid methods (though it *really is* quite intuitive).

Theorem 17.3.5 (Computing Hitting Probabilities)

Let $A \subseteq S$. Then the set of hitting probabilities $h^A = (h_i^A \mid i \in S)$ is the minimal^a non-negative solution to the equations

$$h_i^A = \begin{cases} 1 & \text{if } i \in A, \\ \sum_{j \in S} P_{i,j} h_j^A & \text{if } i \notin A. \end{cases}$$

^aMinimal in that if x is another non-negative solution, then $x_i \geq h_i^A$ for all $i \in S$.

Proof. We first check that h_i solves this system. Clearly if $i \in A$, then $h_i^A = 1$, so take $i \in S \setminus A$. Then conditioning on the first step in the chain,

$$\begin{aligned} h_i^A &= \sum_{j \in S} P_{i,j} \mathbb{P}(T_A < \infty \mid X_0 = i, X_1 = j) \\ &= \sum_{j \in S} P_{i,j} h_j^A, \end{aligned}$$

by the simple Markov property. So h_i does indeed solve this system.

We now check minimality. Let $x = (x_i \mid i \in S)$ be another non-negative solution. For $i \in A$, we have $x_i = h_i^A = 1$, so that holds. Then for $i \in S \setminus A$, since x satisfies the system of equations we can write

$$x_i = \sum_{j \in S} P_{i,j} x_j = \sum_{j \in A} P_{i,j} x_j + \sum_{j \in S \setminus A} P_{i,j} x_j. \quad (\dagger)$$

Then with $x_j = 1$ for $j \in A$ and $x \geq 0$, we have

$$x_i \geq \sum_{j \in A} P_{i,j} = \mathbb{P}(X_1 \in A \mid X_0 = i) = \mathbb{P}(T_A < 2 \mid X_0 = i).$$

Similarly, expanding $(\dagger)$, we have

$$\begin{aligned} x_i &= \mathbb{P}(X_1 \in A \mid X_0 = i) + \sum_{j \in S \setminus A} P_{i,j} \left(\sum_{k \in A} P_{j,k} x_k + \sum_{k \in S \setminus A} P_{j,k} x_k \right) \\ &\geq \mathbb{P}(X_1 \in A \mid X_0 = i) + \mathbb{P}(X_1 \notin A, X_2 \in A \mid X_0 = i) \\ &= \mathbb{P}(T_A < 3 \mid X_0 = i). \end{aligned}$$

We can repeat this argument to eventually establish that $x_i \geq \mathbb{P}(T_A < n \mid X_0 = i)$, for all $n \geq 0$. Then as $n \rightarrow \infty$, we have $x_i \geq \mathbb{P}(T_A < \infty \mid X_0 = i)$, as required. $\square$

Let's also settle a question we left dangling at the end of the previous section: for the five-state chain whose classes were $\{1, 2\}$ (closed), $\{3\}$ and $\{4, 5\}$ (closed), where does the chain end up when started from state 3?

Example 17.3.6 (Absorption Probabilities)

Take $A = \{1, 2\}$, and let $h_i = h_i^A$. We have $h_1 = h_2 = 1$, and since states 4 and 5 can never reach A , also $h_4 = h_5 = 0$. From state 3, the chain moves to each of

states 2, 3, 4 with probability $1/3$, so

$$h_3 = \frac{1}{3}h_2 + \frac{1}{3}h_3 + \frac{1}{3}h_4 = \frac{1}{3} + \frac{1}{3}h_3,$$

giving $h_3 = 1/2$. So the chain started from 3 is absorbed into $\{1, 2\}$ or into $\{4, 5\}$ with probability $1/2$ each – which makes sense, as the two escape routes from state 3 are equally likely, and dawdling at 3 doesn't favour either.

This method of computing hitting probabilities is perfectly valid on Markov chains with infinite state spaces.

Example 17.3.7 (Hitting Probabilities on an Infinite State Space)

Consider the Markov chain with states $S = \{0, 1, \dots\}$ such that $P_{0,1} = 1$, and

$$P_{i,i+1} = p, \quad P_{i,i-1} = q \quad \text{for all } i \geq 1,$$

where $p, q \in (0, 1)$ with $p + q = 1$.

Let $h_i = \mathbb{P}(T_0 < \infty \mid X_0 = i)$, and suppose that $p \neq q$. Then we clearly have $h_0 = 1$, and generally we can write down the recurrence

$$h_i = ph_{i+1} + qh_{i-1}.$$

This then implies $p(h_{i+1} - h_i) = q(h_i - h_{i-1})$, so that

$$h_{i+1} - h_i = \left(\frac{q}{p}\right)^i (h_1 - 1).$$

This inspires us to write h_i as a telescoping sum

$$\begin{aligned} h_i &= \sum_{j=1}^i (h_j - h_{j-1}) + 1 \\ &= (h_1 - 1) \sum_{j=1}^i \left(\frac{q}{p}\right)^j + 1, \end{aligned}$$

which gives us our general solution $h_i = a + b(q/p)^i$, which we can then solve.

In the case that $q > p$, then in order for h_i to be the minimal solution, we need to have $a = 1$ and $b = 0$, so $h_i = 1$.

We also need to check that our method for calculating the mean hitting time was valid.

Theorem 17.3.8 (Computing Mean Hitting Times)

Let $A \subseteq S$. Then the set of mean hitting times $k^A = (k_i^A \mid i \in S)$ is the minimal

non-negative solution to the equations

$$k_i^A = \begin{cases} 0 & \text{if } i \in A, \\ 1 + \sum_{j \in S \setminus A} P_{i,j} k_j^A & \text{if } i \notin A. \end{cases}$$

Proof. We first check that k_i solves this system. Clearly if $i \in A$, then $k_i^A = 0$, so take $i \in S \setminus A$. Then conditioning on the first step in the chain,

$$\begin{aligned} k_i^A &= \sum_{j \in S} P_{i,j} \mathbb{E}[T_A \mid X_0 = i, X_1 = j] \\ &= \sum_{j \in S} P_{i,j} (1 + \mathbb{E}[T_A \mid X_0 = j]) \\ &= 1 + \sum_{j \in S} P_{i,j} k_j^A, \end{aligned}$$

which is equivalent to our original sum.

We now show that the solution is minimal. Let $y = (y_i \mid i \in S)$ be another non-negative solution. Then for $i \in A$ we have $y_i = k_i^A = 0$, so consider $i \in S \setminus A$. We can then write

$$\begin{aligned} y_i &= 1 + \sum_{j \in S \setminus A} P_{i,j} y_j \\ &= 1 + \sum_{j \in S \setminus A} P_{i,j} \left(1 + \sum_{k \in S \setminus A} P_{j,k} y_k \right) \\ &\geq \mathbb{P}(T_A \geq 1 \mid X_0 = i) + \mathbb{P}(T_A \geq 2 \mid X_0 = i). \end{aligned}$$

By iterating this, we obtain

$$y_i \geq \sum_{m=1}^n \mathbb{P}(T_A \geq m \mid X_0 = i),$$

and taking the limit as $n \rightarrow \infty$, this gives

$$y_i \geq \sum_{m=1}^{\infty} \mathbb{P}(T_A \geq m \mid X_0 = i) = k_i^A,$$

where we note that for a random variable M taking non-negative integer values we have $\mathbb{E}[M] = \sum_{m=1}^{\infty} \mathbb{P}(M \geq m)$. $\square$

So it does work, how lovely.

§17.3.2 Gambler's Ruin

Let's now put these tools to work on one of the oldest problems in probability. A gambler walks into a casino with $\mathcal{L}i$ in their pocket, and repeatedly plays a game in which they win $\mathcal{L}1$ with probability p and lose $\mathcal{L}1$ with probability $q = 1 - p$. The gambler has no self-control, and will keep playing until they go bankrupt. We'd like to know the

probability that this happens⁴.

We can model this situation with a Markov chain on the states $S = \{0, 1, 2, \dots\}$, where the state tracks the gambler's current fortune. We set

$$P_{i,i+1} = p, \quad P_{i,i-1} = q \quad \text{for all } i \geq 1,$$

and $P_{0,0} = 1$, since a bankrupt gambler can no longer play. A diagram of this chain is shown below.

The probability of ruin starting from a fortune of i is exactly the hitting probability $h_i = h_i^{\{0\}}$, so we can use the machinery of the previous section. We know that $h = (h_i \mid i \in S)$ is the minimal non-negative solution to

$$h_0 = 1, \quad h_i = ph_{i+1} + qh_{i-1} \quad \text{for } i \geq 1.$$

This is a linear difference equation, which we know how to solve. Suppose first that $p \neq q$. Then the general solution is

$$h_i = A + B \left(\frac{q}{p} \right)^i,$$

and the boundary condition $h_0 = 1$ forces $A + B = 1$.

If $p < q$ (the game is stacked against the gambler, as it usually is), then $(q/p)^i \rightarrow \infty$ as $i \rightarrow \infty$, and since $h_i \in [0, 1]$ is a probability we must have $B = 0$. Thus $h_i = 1$ for all i – *the gambler is certain to go bankrupt*.

If instead $p > q$, then substituting $B = 1 - A$ gives

$$h_i = \left(\frac{q}{p} \right)^i + A \left(1 - \left(\frac{q}{p} \right)^i \right),$$

which is a genuine non-negative solution for any $A \geq 0$. Minimality then tells us to take $A = 0$, giving

$$h_i = \left(\frac{q}{p} \right)^i.$$

So with a favourable game the gambler has a positive chance $1 - (q/p)^i$ of playing forever.

We are left with the fair case $p = q = 1/2$. Here the general solution to the difference equation is $h_i = A + Bi$, and for h_i to remain in $[0, 1]$ for all i we need $B = 0$, so $h_0 = 1$ forces $h_i = 1$ for all i . That is, *even in a perfectly fair game, ruin is certain*.

The same circle of ideas handles the case where the gambler resolves to walk away upon reaching some target fortune.

⁴Spoiler: unless the game is rigged in the gambler's favour, it happens with probability 1. The house always wins.

Example 17.3.9 (Gambling Against a Target)

Suppose the game is fair ($p = q = 1/2$), and the gambler starts with $\mathcal{L}i$ but will stop when they reach either $\mathcal{L}0$ or a target of $\mathcal{L}N$, where $0 \leq i \leq N$. Now both 0 and N are absorbing, and the interesting quantities are the ruin probability $h_i = h_i^{\{0\}}$ and the expected duration of the game $k_i = k_i^{\{0,N\}}$.

For the ruin probability, we have the same difference equation $h_i = \frac{1}{2}h_{i-1} + \frac{1}{2}h_{i+1}$ for $0 < i < N$, but now with *two* boundary conditions $h_0 = 1$ and $h_N = 0$, which pin down the solution uniquely (no appeal to minimality needed):

$$h_i = 1 - \frac{i}{N}.$$

Reassuringly, letting $N \rightarrow \infty$ recovers $h_i = 1$, matching the one-sided problem.

For the expected duration, the mean hitting time equations give

$$k_0 = k_N = 0, \quad k_i = 1 + \frac{1}{2}k_{i-1} + \frac{1}{2}k_{i+1} \text{ for } 0 < i < N.$$

The homogeneous solutions are $A + Bi$ as before, and since the inhomogeneous term is a constant, we try a particular solution of the form ci^2 ; substituting in gives $c = -1$. So $k_i = A + Bi - i^2$, and the boundary conditions force $A = 0$ and $B = N$, yielding the rather elegant

$$k_i = i(N - i).$$

So a fair game between a gambler with $\mathcal{L}i$ and an opponent with $\mathcal{L}(N - i)$ lasts $i(N - i)$ rounds on average – and note how the duration blows up quadratically as we let the opponent's wealth grow, consistent with the infinite expected duration we will find for the one-sided game.

Remark. There is something quite striking hiding in the fair case. Ruin occurs with probability 1, but we shall see shortly (using generating functions and the strong Markov property) that the *expected* time until ruin is infinite. Certain events can still take a rather long time to happen.

§17.3.3 Birth-Death Chains

The gambler's ruin chain has the same transition probabilities at every state, which makes the associated difference equation easy to solve. We will now consider a generalisation where the transition probabilities vary from state to state, a model known as a *birth-death chain*. These chains model, for example, the size of a population, where the rates of births and deaths depend on the current population size.

Let $(p_i \mid i \geq 1)$ be a sequence with $p_i \in (0, 1)$, and let $q_i = 1 - p_i$. The **birth-death**

chain is the Markov chain on $S = \{0, 1, 2, \dots\}$ with transition probabilities

$$P_{i,i+1} = p_i, \quad P_{i,i-1} = q_i \quad \text{for } i \geq 1,$$

and $P_{0,0} = 1$ (once the population dies out, it stays extinct).

We would like to compute the probability of extinction $h_i = h_i^{\{0\}}$, starting from a population of size i . As always, h is the minimal non-negative solution to

$$h_0 = 1, \quad h_i = p_i h_{i+1} + q_i h_{i-1} \quad \text{for } i \geq 1.$$

This is *not* a constant-coefficient difference equation, so we need to be slightly cleverer. Using $p_i + q_i = 1$, we can rearrange the relation into

$$p_i(h_{i+1} - h_i) = q_i(h_i - h_{i-1}).$$

So setting $u_i = h_{i-1} - h_i$ (which will turn out to be non-negative), we get $u_{i+1} = (q_i/p_i)u_i$, and iterating this down to u_1 gives

$$u_{i+1} = \left(\frac{q_i}{p_i}\right) \left(\frac{q_{i-1}}{p_{i-1}}\right) \cdots \left(\frac{q_1}{p_1}\right) u_1 = \gamma_i u_1, \quad \text{where } \gamma_i = \prod_{j=1}^i \frac{q_j}{p_j},$$

and we take $\gamma_0 = 1$ for convenience. Summing $u_j = h_{j-1} - h_j$ over $j = 1, \dots, i$ telescopes to give

$$h_i = 1 - u_1(\gamma_0 + \gamma_1 + \cdots + \gamma_{i-1}).$$

All that remains is to identify the constant u_1 , and this is exactly what minimality is for. Everything hinges on whether the sum

$$\mathcal{S} = \sum_{i=0}^{\infty} \gamma_i$$

converges.

If $\mathcal{S} = \infty$, then any $u_1 > 0$ would make h_i negative for large i , so we must have $u_1 = 0$, and $h_i = 1$ for all i – extinction is certain.

If $\mathcal{S} < \infty$, then to minimise h_i we want u_1 as large as possible, subject to $h_i \geq 0$ for all i . Taking $i \rightarrow \infty$, the constraint becomes $1 - u_1 \mathcal{S} \geq 0$, so the minimal solution takes $u_1 = 1/\mathcal{S}$, giving

$$h_i = \frac{\sum_{j=i}^{\infty} \gamma_j}{\sum_{j=0}^{\infty} \gamma_j} < 1.$$

So the population survives forever with positive probability exactly when $\sum \gamma_i$ converges, that is, when the birth rates outweigh the death rates sufficiently strongly.

Example 17.3.10 (A Sanity Check)

Let's check this against the gambler's ruin, where $p_i = p$ and $q_i = q$ are constant. Then $\gamma_i = (q/p)^i$, a geometric series, and $\mathcal{S} = \sum_i (q/p)^i$ converges if and only if $q < p$. If $q \geq p$ then $h_i = 1$, and if $q < p$ then

$$h_i = \frac{\sum_{j=i}^{\infty} (q/p)^j}{\sum_{j=0}^{\infty} (q/p)^j} = \left(\frac{q}{p}\right)^i,$$

in agreement with what we found before. As a more interesting case, if the birth rate decays towards criticality like $p_i = \frac{1}{2} + \frac{c}{i}$ for a constant $c > 0$ (and large i), one can show γ_i behaves like i^{-4c} , so extinction is uncertain if $c > 1/4$ and certain if $c \leq 1/4$ – the boundary between the two behaviours is surprisingly delicate.

§17.3.4 Stopping Times and the Strong Markov Property

We previously proved the *simple Markov property*, that conditional on the value of a Markov chain at a given time m , the future is independent of the past. This property required that we take some fixed time m – but what if m itself is random? It's *not* true in general⁵ that the Markov property still holds for an arbitrary random time, but it is true for certain kinds of times.

Definition 17.3.11 (Stopping Times)

A random time $T : \Omega \rightarrow \{0, 1, \dots\} \cup \{\infty\}$ is a **stopping time** for a Markov chain X_n if for all $n \geq 0$ the event $\{T = n\}$ is given in terms of $X_0, X_1, \dots, X_n$ only.

In particular, random times that ‘look into the future’ are not stopping times. A straightforward example of a stopping time is the hitting time T^A that we defined in the previous section.

Example 17.3.12 (Stopping Times and Non-Stopping Times)

Let X_n track a gambler's fortune, and consider the following rules for when to leave the casino.

- (i) ‘Leave when your fortune first hits £10.’ This is the hitting time $T_{\{10\}}$: the event $\{T_{\{10\}} = n\}$ is exactly $\{X_0 \neq 10, \dots, X_{n-1} \neq 10, X_n = 10\}$, which depends only on $X_0, \dots, X_n$. So this is a stopping time – it is a rule you could actually follow.
- (ii) ‘Leave one round after your fortune first hits £10.’ This is $T_{\{10\}} + 1$, which is also a stopping time, as $\{T_{\{10\}} + 1 = n\}$ depends only on $X_0, \dots, X_{n-1}$.
- (iii) ‘Leave one round *before* your fortune first hits £10.’ This is $T_{\{10\}} - 1$, and it is *not* a stopping time: deciding whether to stop at time n requires knowing X_{n+1} . However appealing this rule sounds, there is no way to implement it.

With stopping times, we can indeed make a statement similar to the Markov property using random times.

⁵For example, let T be the first time that a Markov chain hits some value i . Then if we condition on time $T - 1$, the future is then determined since the next step will be to i ! You will see that this type of event is not allowed in our definition of stopping times.

Theorem 17.3.13 (Strong Markov Property)

Let X_n be a Markov chain with transition matrix P , and let T be a stopping time. Then conditional on $T < \infty$ and $X_T = i$, the sequence of random variables $(X_{T+n})_{n \geq 0}$ is Markov(δ_i, P) and is independent of $X_0, \dots, X_T$.

Proof. Let H be an event given in terms of $X_0, \dots, X_{T-1}$. Then it suffices to show that

$$\begin{aligned} & \mathbb{P}(X_{T+1} = i_1, \dots, X_{T+n} = i_n, H \mid T < \infty, X_T = i) \\ &= \mathbb{P}(X_1 = i_1, \dots, X_n = i_n \mid X_0 = i) \mathbb{P}(H \mid T < \infty, X_T = i). \end{aligned}$$

The event $H \cap \{T = m\}$ is given in terms of $X_1, X_2, \dots, X_m$ only. Furthermore, $X_T = X_m$ when $T = m$. We condition on the event $H \cap \{T = m\} \cap \{X_m = i\}$ and use the simple Markov property at time m to get

$$\begin{aligned} & \mathbb{P}(X_{T+1} = i_1, \dots, X_{T+n} = i_n, H \mid T < \infty, X_T = i) \\ &= \mathbb{P}(X_1 = i_1, \dots, X_n = i_n) \mathbb{P}(H, T = m, X_T = i). \end{aligned}$$

Summing this over $m = 0, 1, \dots$ and dividing by $\mathbb{P}(T < \infty, X_T = i)$ then gives the desired result. $\square$

The strong Markov property is one of those results whose usefulness is best appreciated by watching it in action. Let's return to our friend the gambler, and work out not just *whether* they go bankrupt, but *how long* it takes.

Example 17.3.14 (Duration of the Gambler's Ruin)

Consider again the gambler's ruin chain on $S = \{0, 1, 2, \dots\}$ with $P_{i,i+1} = p$ and $P_{i,i-1} = q = 1 - p$ for $i \geq 1$, and 0 absorbing. Let $H = T_{\{0\}}$ be the time of bankruptcy, and suppose the gambler starts with £1.

We are going to study the probability generating function

$$G(s) = \mathbb{E}[s^H \mid X_0 = 1] = \sum_{n=0}^{\infty} s^n \mathbb{P}(H = n \mid X_0 = 1), \quad \text{for } |s| < 1,$$

where we adopt the convention $s^\infty = 0$ (recall it is possible that $H = \infty$).

Conditioning on the first step, we have

$$G(s) = p\mathbb{E}[s^H \mid X_0 = 1, X_1 = 2] + q\mathbb{E}[s^H \mid X_0 = 1, X_1 = 0].$$

The second term is easy: if $X_1 = 0$ then $H = 1$, so $\mathbb{E}[s^H \mid X_0 = 1, X_1 = 0] = s$. For the first term, starting from 2 the chain must pass through 1 on its way to 0, so we can write $H = 1 + H' + H''$, where H' is the time taken to go from 2 to 1, and H'' is the time taken to go from 1 to 0 after that. The random time at which we first hit 1 is a stopping time, so by the strong Markov property H' and H'' are independent, and each is distributed as H . Hence

$$G(s) = psG(s)^2 + qs. \quad (*)$$

Solving this quadratic in $G(s)$ gives

$$G(s) = \frac{1 \pm \sqrt{1 - 4pqs^2}}{2ps}.$$

We should be a little careful here – a priori the sign might depend on s . But G is a power series and hence continuous on $(0, 1)$, so a single sign must be taken throughout, and since $G(s)$ remains bounded as $s \downarrow 0$ we are forced to take the negative root:

$$G(s) = \frac{1 - \sqrt{1 - 4pqs^2}}{2ps}.$$

This function knows everything about the distribution of H . For example, the ruin probability is

$$\mathbb{P}(H < \infty \mid X_0 = 1) = \lim_{s \uparrow 1} G(s) = \frac{1 - \sqrt{1 - 4pq}}{2p} = \frac{1 - |p - q|}{2p} = \begin{cases} 1 & \text{if } p \leq q, \\ q/p & \text{if } p > q, \end{cases}$$

using $1 - 4pq = (p + q)^2 - 4pq = (p - q)^2$. This agrees (reassuringly!) with our hitting probability computation from before.

We can also extract the mean. If $p \leq q$ then differentiating (*) and rearranging gives

$$G'(s) = \frac{pG(s)^2 + q}{1 - 2psG(s)},$$

and letting $s \uparrow 1$ we obtain

$$\mathbb{E}[H \mid X_0 = 1] = \begin{cases} \frac{1}{q-p} & \text{if } p < q, \\ \infty & \text{if } p = q = \frac{1}{2}. \end{cases}$$

So in a fair game, ruin is certain but takes infinite expected time – exactly the curiosity we promised earlier.

§17.4 Recurrence and Transience

§17.4.1 Recurrent and Transient States

We now consider states that a Markov chain continues to come back to, or only visits finitely many times. It will turn out (perhaps surprisingly) that for each state, one of these two behaviours *must* occur, in quite a strong sense: either the chain returns to the state infinitely often with probability 1, or it returns only finitely many times with probability 1. We give these two behaviours names.

Definition 17.4.1 (Recurrence and Transience)

Let X_n be a Markov chain and let $i \in S$. We say the state i is **recurrent** if

$$\mathbb{P}(X_n = i \text{ for infinitely many } n \mid X_0 = i) = 1,$$

and we say i is **transient** if

$$\mathbb{P}(X_n = i \text{ for infinitely many } n \mid X_0 = i) = 0.$$

A priori, this probability could lie strictly between 0 and 1, in which case a state would be neither recurrent nor transient. The first goal of this section is to rule this out, and to obtain a usable criterion for telling the two cases apart. Doing this will be a lovely application of the strong Markov property.

We will need a little notation for ‘repeated visits’. Define the **first passage time** to a state $i \in S$ as

$$T_i = \inf\{n \geq 1 \mid X_n = i\},$$

which differs from the hitting time in that we do not count the chain as having returned to i at time 0. More generally, we let $T_i^{(0)} = 0$ and inductively define the **r -th passage time** by

$$T_i^{(r+1)} = \inf\{n \geq T_i^{(r)} + 1 \mid X_n = i\},$$

so that $T_i^{(1)} = T_i$. We also define the **return probability**

$$f_i = \mathbb{P}(T_i < \infty \mid X_0 = i),$$

and the total **number of visits**

$$V_i = \sum_{n=0}^{\infty} \mathbb{1}[X_n = i].$$

With this notation, i is recurrent exactly if $\mathbb{P}(V_i = \infty \mid X_0 = i) = 1$, and transient exactly if this probability is 0.

Intuitively, every time the chain returns to i , it ‘starts afresh’ by the strong Markov property, and so has probability f_i of returning again. So the number of returns should behave like a run of independent trials each with success probability f_i . The following lemma makes this precise.

Lemma 17.4.2 (Probability of Repeated Visits)

Let $i \in S$. Then $\mathbb{P}(V_i > r \mid X_0 = i) = f_i^r$, for all $r \in \mathbb{N}$.

Proof. We use induction on r . For $r = 0$ the claim is clear, since if $X_0 = i$ then $V_i \geq 1$. Now note that, given $X_0 = i$, the event $\{V_i > r\}$ is precisely the event $\{T_i^{(r)} < \infty\}$. So suppose the result is true for r . Then

$$\begin{aligned} \mathbb{P}(V_i > r + 1 \mid X_0 = i) &= \mathbb{P}(T_i^{(r+1)} < \infty \mid X_0 = i) \\ &= \mathbb{P}(T_i^{(r+1)} < \infty, T_i^{(r)} < \infty \mid X_0 = i) \\ &= \mathbb{P}(T_i^{(r+1)} < \infty \mid T_i^{(r)} < \infty, X_0 = i) \cdot \mathbb{P}(T_i^{(r)} < \infty \mid X_0 = i) \\ &= \mathbb{P}(T_i^{(r+1)} < \infty \mid T_i^{(r)} < \infty, X_0 = i) \cdot f_i^r. \end{aligned}$$

Now $T_i^{(r)}$ is a stopping time, and on the event $T_i^{(r)} < \infty$ we have $X_{T_i^{(r)}} = i$. So by the strong Markov property, conditional on $T_i^{(r)} < \infty$, the chain $(X_{T_i^{(r)}+n})_{n \geq 0}$ is

Markov(δ_i, P), and hence

$$\mathbb{P}(T_i^{(r+1)} < \infty \mid T_i^{(r)} < \infty, X_0 = i) = \mathbb{P}(T_i < \infty \mid X_0 = i) = f_i,$$

and thus $\mathbb{P}(V_i > r + 1 \mid X_0 = i) = f_i^{r+1}$, completing the induction. $\square$

So given $X_0 = i$, the number of visits V_i is a geometric random variable with parameter $1 - f_i$. In particular, if $f_i = 1$ then $V_i = \infty$ almost surely, and if $f_i < 1$ then V_i is almost surely finite with finite expectation. This immediately gives us the dichotomy we were after.

Theorem 17.4.3 (Recurrence and Transience Criterion)

Let X_n be a Markov chain with transition matrix P , and let $i \in S$. Then we have the following dichotomy:

- (1) If $\mathbb{P}(T_i < \infty \mid X_0 = i) = 1$, then i is recurrent and $\sum_{n=0}^{\infty} p_{i,i}(n)$ is infinite.
- (2) If $\mathbb{P}(T_i < \infty \mid X_0 = i) < 1$, then i is transient and $\sum_{n=0}^{\infty} p_{i,i}(n) < \infty$.

In particular, every state is either recurrent or transient.

Proof. Recall we can write V_i using indicator functions as $V_i = \sum_{n=0}^{\infty} \mathbb{1}[X_n = i]$, and then by linearity of expectation we can write

$$\mathbb{E}[V_i \mid X_0 = i] = \sum_{n=0}^{\infty} \mathbb{P}(X_n = i \mid X_0 = i) = \sum_{n=0}^{\infty} p_{i,i}(n).$$

Part (1). If $f_i = 1$, then for all r we have $\mathbb{P}(V_i > r \mid X_0 = i) = 1$, and thus $\mathbb{P}(V_i = \infty \mid X_0 = i) = 1$, implying that i is recurrent, and $\mathbb{E}[V_i \mid X_0 = i] = \infty$, implying that $\sum_{n=0}^{\infty} p_{i,i}(n) = \infty$.

Part (2). If $f_i < 1$, then by the previous lemma we have $\mathbb{E}[V_i \mid X_0 = i] = \sum_{r=0}^{\infty} \mathbb{P}(V_i > r \mid X_0 = i) = 1/(1 - f_i) < \infty$, implying that $\mathbb{P}(V_i < \infty \mid X_0 = i) = 1$, so i is transient, and $\sum_{n=0}^{\infty} p_{i,i}(n) < \infty$. $\square$

This criterion is genuinely useful – the quantity $\sum_n p_{i,i}(n)$ is frequently something that we can estimate, and we will do exactly this when we study random walks on $\mathbb{Z}^d$ in the next section. But first, let's see how recurrence and transience interact with the class structure that we developed earlier. The headline is that recurrence and transience are *class properties*: within a communicating class, all states behave in the same way.

Theorem 17.4.4 (Recurrence and Transience of Communicating States)

Let x and y be two states that communicate. Then either they are both recurrent or they are both transient.

Proof. Suppose that x is recurrent. We will show that y is also recurrent. Since $x \rightarrow y$, there is some $m, l \in \mathbb{N}$ such that $p_{x,y}(m) > 0$ and $p_{y,x}(l) > 0$. Then we know

that $\sum_{n=0}^{\infty} p_{x,x}(n) = \infty$, and then

$$\begin{aligned} \sum_{n=0}^{\infty} p_{y,y}(n) &\geq \sum_{n=0}^{\infty} p_{y,y}(n+m+l) \\ &\geq \sum_{n=0}^{\infty} p_{y,x}(l) p_{x,x}(n) p_{x,y}(m) \\ &\geq p_{y,x}(l) p_{x,y}(m) \sum_{n=0}^{\infty} p_{x,x}(n) = \infty, \end{aligned}$$

using the Chapman-Kolmogorov equations, and thus y is recurrent by our criterion. The transient case follows since if x was transient but y was recurrent, then swapping the roles of x and y in the above argument would make x recurrent, a contradiction. $\square$

This immediately can be applied to the entire class structure of a Markov chain.

Corollary 17.4.5 (Class Structure of Recurrence and Transience)

Either all of the states in a communicating class are recurrent or they are all transient.

Recurrent communicating classes have a certain flavour to them, which should be intuitive. Really, for a communicating class to be recurrent we have to avoid getting stuck outside of that given communicating class. This forces closure of the communicating class.

Theorem 17.4.6 (Closure of Recurrent Communicating Classes)

If C is a recurrent communicating class, then it must be closed.

Proof. Suppose that C was not closed. Then there exists $x \in C$ and $y \notin C$ such that $x \rightarrow y$. Let m be such that $p_{x,y}(m) > 0$. We first note that $y \not\rightarrow x$, since if we had $y \rightarrow x$ then x and y would communicate, and we would have $y \in C$. So if starting from x we hit y at some point, then we can never visit x again. Thus

$$\mathbb{P}(V_x < \infty \mid X_0 = x) \geq \mathbb{P}(X_m = y \mid X_0 = x) = p_{x,y}(m) > 0,$$

so x is not recurrent, which is a contradiction. $\square$

In the other direction, a closed class need not be recurrent in general (we will meet examples of this when we study random walks), but it *is* when the class is finite. This should feel right – a chain trapped in a finite set of states has to visit some state infinitely often.

Theorem 17.4.7 (Finite Closed Classes are Recurrent)

A finite closed class is recurrent.

Proof. Let C be a finite closed class, and pick any state $x \in C$. Starting from x , the chain remains in C forever (as C is closed), and since C is finite, there must be

some state $y \in C$ that is visited infinitely often with positive probability, that is^a,

$$\mathbb{P}(X_n = y \text{ for infinitely many } n \mid X_0 = x) > 0.$$

Now, for the chain to visit y infinitely often it must visit y at least once, so conditioning on the first visit and applying the strong Markov property,

$$\begin{aligned} 0 &< \mathbb{P}(X_n = y \text{ for infinitely many } n \mid X_0 = x) \\ &= \mathbb{P}(T_y < \infty \mid X_0 = x) \cdot \mathbb{P}(X_n = y \text{ for infinitely many } n \mid X_0 = y). \end{aligned}$$

In particular $\mathbb{P}(X_n = y \text{ for infinitely many } n \mid X_0 = y) > 0$. But by the dichotomy this probability is either 0 or 1, so it equals 1, and y is recurrent. Finally, since $x, y \in C$ they communicate, and recurrence is a class property, so all of C is recurrent. $\square$

^aThis is really the pigeonhole principle: infinitely many time steps must be distributed amongst finitely many states, so if each $y \in C$ was visited infinitely often with probability zero, then with probability one every state would be visited finitely often – which is impossible for a chain that stays in C forever.

Corollary 17.4.8 (Finite Irreducible Chains are Recurrent)

If S is finite and P is irreducible, then every state is recurrent.

Proof. The whole state space is a single communicating class, which is certainly closed, and it is finite. $\square$

So for *finite* chains the story is pleasantly complete: the transient states are precisely those in non-closed classes, and the recurrent states are precisely those in closed classes. Let's see this classification on our worked example from the section on class structure.

Example 17.4.9 (Classifying the States of a Finite Chain)

Recall the five-state chain whose communicating classes we found to be $\{1, 2\}$ (closed), $\{3\}$ (not closed) and $\{4, 5\}$ (closed). By our theorems:

- The classes $\{1, 2\}$ and $\{4, 5\}$ are finite and closed, hence recurrent – once the chain enters one of them, it revisits each of its states infinitely often.
- The class $\{3\}$ is not closed, hence not recurrent, so state 3 is transient. (Of course, we can also see this directly: on each visit to 3, the chain escapes forever with probability $2/3$, so the number of visits is geometric and finite.)

For an *infinite* chain the classification is genuinely more subtle – a closed class can be transient, as the asymmetric random walk on $\mathbb{Z}$ (which is irreducible, so its single class is closed) will shortly demonstrate.

Sometimes we don't need any of this machinery, because the return probability f_i can simply be computed by hand. Here is an infinite chain where that happens.

Example 17.4.10 (The Success-Runs Chain)

Fix $p \in (0, 1)$ and $q = 1 - p$, and consider the chain on $S = \{0, 1, 2, \dots\}$ with

$$P_{i,i+1} = p, \quad P_{i,0} = q \quad \text{for all } i \geq 0.$$

This chain tracks the length of the current run of successes in a sequence of independent trials: each success extends the run, and each failure resets the counter to zero. The chain is irreducible (we can reach i from 0 via i successes, and return in one failure).

Let's compute the return probability of state 0 directly. Starting from 0, the chain fails to return to 0 for n consecutive steps precisely if the first n trials are all successes, so

$$\mathbb{P}(T_0 > n \mid X_0 = 0) = p^n \rightarrow 0,$$

giving $f_0 = \mathbb{P}(T_0 < \infty \mid X_0 = 0) = 1$, so 0 is recurrent – and hence, recurrence being a class property, the whole chain is recurrent. Moreover T_0 is geometrically distributed, with

$$m_0 = \mathbb{E}[T_0 \mid X_0 = 0] = \sum_{n=0}^{\infty} \mathbb{P}(T_0 > n \mid X_0 = 0) = \frac{1}{q} < \infty.$$

So state 0 takes on average $1/q$ steps to revisit, however long the runs of successes may occasionally be. (Once we have developed the theory of invariant distributions, this will tell us instantly that $\pi_0 = q$ – and it's a nice check that solving $\pi = \pi P$ gives the geometric distribution $\pi_i = qp^i$, whose value at 0 is indeed q .)

To close out this discussion, we prove one more result about irreducible, recurrent chains: not only does the chain return to where it started, it visits *every* state with certainty, no matter where it begins.

Theorem 17.4.11 (Recurrent Chains Visit Everything)

Let P be irreducible and recurrent. Then for all $x, y \in S$, $\mathbb{P}(T_y < \infty \mid X_0 = x) = 1$.

Proof. Fix $y \in S$, and let m be such that $p_{y,x}(m) > 0$, which exists by irreducibility. Since y is recurrent, using the simple Markov property at time m ,

$$\begin{aligned} 1 &= \mathbb{P}(X_n = y \text{ for infinitely many } n \mid X_0 = y) \\ &= \sum_{z \in S} \mathbb{P}(X_m = z \mid X_0 = y) \mathbb{P}(X_n = y \text{ for infinitely many } n \geq m \mid X_m = z) \\ &= \sum_{z \in S} p_{y,z}(m) \mathbb{P}(X_n = y \text{ for infinitely many } n \mid X_0 = z). \end{aligned}$$

Now each term $\mathbb{P}(X_n = y \text{ for infinitely many } n \mid X_0 = z) \leq \mathbb{P}(T_y < \infty \mid X_0 = z) \leq 1$, and the weights $p_{y,z}(m)$ sum to 1. So the only way the weighted average above can equal 1 is if

$$\mathbb{P}(T_y < \infty \mid X_0 = z) = 1 \quad \text{whenever } p_{y,z}(m) > 0.$$

In particular, taking $z = x$ (recalling $p_{y,x}(m) > 0$) gives the result. $\square$

Aside: A Generating Function Approach

There is a slick alternative route to the recurrence–transience dichotomy using generating functions, which is worth seeing. Fix a state i , write $f(n) = \mathbb{P}(T_i = n \mid X_0 = i)$ for the distribution of the first return time, and consider the two generating functions

$$F(s) = \sum_{n=1}^{\infty} f(n)s^n, \quad U(s) = \sum_{n=0}^{\infty} p_{i,i}(n)s^n, \quad |s| < 1.$$

Conditioning on the time of the *first* return to i , for $n \geq 1$ we have

$$p_{i,i}(n) = \sum_{k=1}^n f(k) p_{i,i}(n-k),$$

using the strong Markov property at the first return time. But this is precisely a convolution! So multiplying by s^n and summing over $n \geq 1$ (the $n = 0$ term of U being 1),

$$U(s) - 1 = F(s)U(s), \quad \text{that is, } U(s) = \frac{1}{1 - F(s)}.$$

Now we let $s \uparrow 1$. For power series with non-negative coefficients, we have $\lim_{s \uparrow 1} F(s) = \sum_n f(n) = f_i$ and $\lim_{s \uparrow 1} U(s) = \sum_n p_{i,i}(n)$, whether these are finite or infinite (this is *Abel's lemma*, which follows from monotone convergence). Hence

$$\sum_{n=0}^{\infty} p_{i,i}(n) = \frac{1}{1 - f_i},$$

with the convention $1/0 = \infty$. This identity contains the whole dichotomy at a glance: the left hand side is infinite if and only if $f_i = 1$. It also quantifies the relationship rather pleasingly – for a transient state, the expected total number of visits is exactly $1/(1 - f_i)$, the mean of the geometric distribution we found earlier.

§17.4.2 Random Walks on $\mathbb{Z}^d$ and Pólya's Theorem

We now turn our attention to simple random walks in low and high dimensions, and in particular at an interesting result due to Pólya which informally says

A drunk man will find his way home, but a drunk bird may get lost forever.

Let's make this precise. The **simple random walk** on $\mathbb{Z}^d$ is the Markov chain with state space $\mathbb{Z}^d$ and transition probabilities

$$P_{x, x+e_i} = P_{x, x-e_i} = \frac{1}{2d} \quad \text{for } i = 1, \dots, d,$$

where $e_1, \dots, e_d$ are the standard basis vectors. That is, at each step the walker moves to one of its $2d$ neighbouring lattice points, chosen uniformly at random. For $d = 1$, this is a walk on the integers, moving left or right with probability $1/2$ each.

The chain is clearly irreducible, so all states are of the same type – either the walk is recurrent, and returns to its starting point over and over forever, or it is transient, and eventually escapes to infinity for good. Pólya's theorem tells us that which of these occurs depends only on the dimension.

Theorem 17.4.12 (Pólya's Recurrence Theorem)

The simple random walk on $\mathbb{Z}^d$ is recurrent for $d = 1$ and $d = 2$, and transient for $d \geq 3$.

The strategy for the proof is the one suggested by our recurrence and transience criterion: we will estimate the return probabilities $p_{0,0}(n)$, and determine whether $\sum_n p_{0,0}(n)$ converges or diverges. The main analytic input is Stirling's formula, which we will not prove here.

Fact 17.4.13 (Stirling's Formula)

As $n \rightarrow \infty$, we have $n! \sim n^n e^{-n} \sqrt{2\pi n}$, in the sense that the ratio of the two sides tends to 1.

We take the three cases $d = 1, 2, 3$ in turn.

Proof ($d = 1$ is recurrent). First note that the walk can only return to 0 at even times, since the parity of X_n changes at every step. So it suffices to study $p_{0,0}(2n)$.

For the walk to be back at 0 after $2n$ steps, it must have taken exactly n steps up and n steps down. There are $\binom{2n}{n}$ ways to choose which steps are the 'up' steps, and each arrangement occurs with probability $(1/2)^{2n}$. Hence

$$p_{0,0}(2n) = \binom{2n}{n} \left(\frac{1}{2}\right)^{2n} = \frac{(2n)!}{(n!)^2} \cdot \frac{1}{2^{2n}}.$$

Applying Stirling's formula,

$$p_{0,0}(2n) \sim \frac{(2n)^{2n} e^{-2n} \sqrt{4\pi n}}{n^{2n} e^{-2n} (2\pi n)} \cdot \frac{1}{2^{2n}} = \frac{1}{\sqrt{\pi n}}.$$

In particular, there is a constant $A > 0$ and some n_0 such that $p_{0,0}(2n) \geq A/\sqrt{n}$ for all $n \geq n_0$. Thus

$$\sum_{n=0}^{\infty} p_{0,0}(n) \geq \sum_{n \geq n_0} \frac{A}{\sqrt{n}} = \infty,$$

and the walk is recurrent. □

Remark (Asymmetric Walks are Transient). Suppose instead the walk moves up with

probability p and down with probability $q = 1 - p$, where $p \neq q$. The same counting gives

$$p_{0,0}(2n) = \binom{2n}{n} (pq)^n \sim \frac{(4pq)^n}{\sqrt{\pi n}},$$

and since $4pq < 1$ when $p \neq q$ (as $4pq = 1 - (p - q)^2$), the series $\sum_n p_{0,0}(n)$ converges by comparison with a geometric series. So *any* asymmetry makes the walk transient – the symmetric case is quite delicate!

Now let's move up to two dimensions. The key idea here is a rather beautiful trick: if we rotate the lattice by 45° , a simple random walk on $\mathbb{Z}^2$ splits into two *independent* simple random walks on (scaled copies of) $\mathbb{Z}$.

Proof ($d = 2$ is recurrent). Let X_n be the simple random walk on $\mathbb{Z}^2$, and write $X_n = \xi_1 + \cdots + \xi_n$, where the steps ξ_i are independent and uniform on the four unit vectors $\pm(1, 0)$ and $\pm(0, 1)$. We project onto the diagonal lines $y = x$ and $y = -x$, defining

$$X_n^+ = \sum_{i=1}^n \frac{\xi_i^{(1)} + \xi_i^{(2)}}{\sqrt{2}}, \quad X_n^- = \sum_{i=1}^n \frac{\xi_i^{(1)} - \xi_i^{(2)}}{\sqrt{2}},$$

where $\xi_i = (\xi_i^{(1)}, \xi_i^{(2)})$.

We claim that X_n^+ and X_n^- are independent simple random walks on $\frac{1}{\sqrt{2}}\mathbb{Z}$. Indeed, checking each of the four possible values of ξ_i , we see that $(\xi_i^{(1)} + \xi_i^{(2)})/\sqrt{2}$ and $(\xi_i^{(1)} - \xi_i^{(2)})/\sqrt{2}$ each take the values $\pm 1/\sqrt{2}$ with probability $1/2$, and moreover each of the four possible combinations of signs occurs with probability $1/4$ – so the two increments are independent. Since X_n^+ and X_n^- are built from independent increments in this way, they are independent simple random walks, as claimed.

Now, the walk X_n is at the origin if and only if both projections are at 0. So using independence and our one-dimensional estimate,

$$p_{0,0}(2n) = \mathbb{P}(X_{2n}^+ = 0) \mathbb{P}(X_{2n}^- = 0) \sim \frac{1}{\sqrt{\pi n}} \cdot \frac{1}{\sqrt{\pi n}} = \frac{1}{\pi n}.$$

Hence there is $A > 0$ with $p_{0,0}(2n) \geq A/n$ for all sufficiently large n , and $\sum_n p_{0,0}(n)$ diverges by comparison with the harmonic series. So the walk is recurrent. $\square$

Proof ($d = 3$ is transient). Again $p_{0,0}(n) = 0$ for odd n , so we consider $p_{0,0}(2n)$. For the walk to return to the origin after $2n$ steps, it must take i steps in each of

the $+x$ and $-x$ directions, j steps in each of the $\pm y$ directions and k steps in each of the $\pm z$ directions, for some $i + j + k = n$. Counting arrangements,

$$\begin{aligned} p_{0,0}(2n) &= \sum_{\substack{i,j,k \geq 0 \\ i+j+k=n}} \frac{(2n)!}{(i!)^2(j!)^2(k!)^2} \left(\frac{1}{6}\right)^{2n} \\ &= \binom{2n}{n} \left(\frac{1}{2}\right)^{2n} \sum_{\substack{i,j,k \geq 0 \\ i+j+k=n}} \left(\binom{n}{i,j,k} \left(\frac{1}{3}\right)^n \right)^2, \end{aligned}$$

where $\binom{n}{i,j,k} = \frac{n!}{i!j!k!}$ is the multinomial coefficient.

Now, the numbers $\binom{n}{i,j,k} (1/3)^n$ are exactly the probabilities of the possible outcomes when placing n balls into 3 boxes uniformly at random, so they sum to 1. Hence, bounding one factor in each square by the maximum,

$$p_{0,0}(2n) \leq \binom{2n}{n} \left(\frac{1}{2}\right)^{2n} \max_{i+j+k=n} \binom{n}{i,j,k} \left(\frac{1}{3}\right)^n.$$

The multinomial coefficient is maximised when i, j, k are as equal as possible^a, so writing $n = 3m$ we have

$$p_{0,0}(6m) \leq \binom{6m}{3m} \left(\frac{1}{2}\right)^{6m} \binom{3m}{m,m,m} \left(\frac{1}{3}\right)^{3m} \sim \frac{C}{m^{3/2}}$$

for some constant C , applying Stirling's formula to each factorial. In particular, the sum $\sum_m p_{0,0}(6m)$ converges.

We are not quite done, since we have only summed over times divisible by 6. But the walk can always waste time by stepping out and back, so

$$p_{0,0}(6m) \geq \left(\frac{1}{6}\right)^2 p_{0,0}(6m-2) \quad \text{and} \quad p_{0,0}(6m) \geq \left(\frac{1}{6}\right)^4 p_{0,0}(6m-4),$$

which gives $p_{0,0}(6m-2) \leq 36 p_{0,0}(6m)$ and $p_{0,0}(6m-4) \leq 6^4 p_{0,0}(6m)$. Hence

$$\sum_{n=0}^{\infty} p_{0,0}(2n) \leq (1 + 6^2 + 6^4) \sum_{m=0}^{\infty} p_{0,0}(6m) < \infty,$$

and the walk is transient. □

^aIf, say, $i \geq j + 2$, then swapping (i, j) for $(i-1, j+1)$ multiplies the coefficient by $i/(j+1) > 1$.

Remark. For $d > 3$, one can check that the first three coordinates of the simple random walk on $\mathbb{Z}^d$, observed at the times when one of them changes, form a simple random walk on $\mathbb{Z}^3$. If the walk on $\mathbb{Z}^d$ were recurrent, it would return to the origin infinitely often, forcing the embedded walk on $\mathbb{Z}^3$ to do the same – contradicting transience in three dimensions. So the walk is transient for all $d \geq 3$.

So the drunk man on the plane will stagger home eventually, but the drunk bird, with the extra dimension at its disposal, may drift away forever.

§17.5 Invariant Distributions

§17.5.1 What is an Invariant Distribution?

Having spent some time on the question of *whether* a Markov chain comes back, we now turn to the long-run behaviour of the chain: if we let a Markov chain run for a very long time, what does its distribution look like?

Back when we computed n -step transition probabilities for the two-state chain, we found

$$p_{1,1}(n) = \frac{\beta}{\alpha + \beta} + \frac{\alpha}{\alpha + \beta} \cdot (1 - \alpha - \beta)^n,$$

and if $\alpha + \beta < 2$ the second term dies away as $n \rightarrow \infty$, leaving $p_{1,1}(n) \rightarrow \beta/(\alpha + \beta)$. The chain forgets where it started, and settles down to some limiting distribution. We would like to understand this phenomenon in general: when does a Markov chain settle down, and to what?

If the distribution of X_n is to converge to something, a natural first step is to look for distributions that the chain leaves unchanged. Suppose X_0 has distribution π , and we would like X_1 to have distribution π as well. Conditioning on the first state,

$$\mathbb{P}(X_1 = j) = \sum_{i \in S} \mathbb{P}(X_0 = i) \mathbb{P}(X_1 = j \mid X_0 = i) = \sum_{i \in S} \pi_i P_{i,j},$$

so what we require is exactly that $\pi_j = \sum_i \pi_i P_{i,j}$ for all $j \in S$. Viewing π as a row vector, this says precisely $\pi = \pi P$.

Definition 17.5.1 (Invariant Distribution)

A distribution^a π on S is an **invariant distribution** (also called an *equilibrium* or *stationary* distribution) for the transition matrix P if

$$\pi = \pi P.$$

^aThat is, $\pi = (\pi_i \mid i \in S)$ with $\pi_i \geq 0$ and $\sum_i \pi_i = 1$.

In the language of linear algebra, π is a left eigenvector of P with eigenvalue 1, normalised to sum to 1. The name ‘invariant’ is justified by the following observation.

Proposition 17.5.2 (Invariance for All Time)

Let π be an invariant distribution for P , and let X_n be $\text{Markov}(\pi, P)$. Then X_n has distribution π for all $n \geq 0$.

Proof. The distribution of X_n is given by the row vector πP^n , and by induction $\pi P^n = \pi P^{n-1} = \dots = \pi$. $\square$

So a chain started in an invariant distribution is, in a distributional sense, in perfect equilibrium – at every time it looks statistically identical. Let’s compute an example.

Example 17.5.3 (Invariant Distribution of the Two-State Chain)

Consider our two-state chain with transition matrix

$$P = \begin{pmatrix} 1 - \alpha & \alpha \\ \beta & 1 - \beta \end{pmatrix},$$

with $\alpha, \beta \in (0, 1)$. To find an invariant distribution we solve $\pi = \pi P$, that is,

$$\begin{aligned}\pi_1 &= (1 - \alpha)\pi_1 + \beta\pi_2, \\ \pi_2 &= \alpha\pi_1 + (1 - \beta)\pi_2.\end{aligned}$$

Both equations reduce to $\alpha\pi_1 = \beta\pi_2$, and combining this with $\pi_1 + \pi_2 = 1$ we get

$$\pi = \left(\frac{\beta}{\alpha + \beta}, \frac{\alpha}{\alpha + \beta} \right).$$

Notice that this is exactly the limit of $p_{1,1}(n)$ and $p_{2,1}(n)$ that we found by diagonalisation – the limiting distribution of the chain is the invariant distribution. This is not a coincidence, as we will see in the next section.

Example 17.5.4 (Invariant Distribution of a Three-State Chain)

Recall the three-state chain with complex eigenvalues from Section 1, with transition matrix

$$P = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 1/2 & 1/2 \\ 1/2 & 0 & 1/2 \end{pmatrix}.$$

Solving $\pi = \pi P$ coordinate by coordinate:

$$\begin{aligned}\pi_1 &= \frac{1}{2}\pi_3, \\ \pi_2 &= \pi_1 + \frac{1}{2}\pi_2 \implies \pi_2 = 2\pi_1, \\ \pi_3 &= \frac{1}{2}\pi_2 + \frac{1}{2}\pi_3 \implies \pi_3 = \pi_2.\end{aligned}$$

So $\pi \propto (1, 2, 2)$, and normalising gives $\pi = (1/5, 2/5, 2/5)$.

Back in Section 1 we computed, with some effort involving complex eigenvalues,

$$p_{1,1}(n) = \frac{1}{5} + \left(\frac{1}{2}\right)^n \left(\frac{4}{5} \cos\left(\frac{n\pi}{2}\right) - \frac{2}{5} \sin\left(\frac{n\pi}{2}\right) \right) \longrightarrow \frac{1}{5} = \pi_1,$$

so the mysterious constant $1/5$ appearing there was the invariant probability of state 1 all along. The oscillating terms, damped by the factor $(1/2)^n = |\mu|^n$, describe *how* the chain spirals in towards equilibrium.

The relationship between limits and invariant distributions goes both ways, at least when the state space is finite: if the n -step probabilities converge, then whatever they converge to must be invariant.

Theorem 17.5.5 (Limits are Invariant)

Let S be finite, and suppose that for some $i \in S$ we have $p_{i,j}(n) \rightarrow \pi_j$ as $n \rightarrow \infty$, for all $j \in S$. Then $\pi = (\pi_j \mid j \in S)$ is an invariant distribution.

Proof. We first check that π is a distribution. Certainly $\pi_j \geq 0$ for all j , and since S is finite we may interchange the (finite) sum and the limit to get

$$\sum_{j \in S} \pi_j = \sum_{j \in S} \lim_{n \rightarrow \infty} p_{i,j}(n) = \lim_{n \rightarrow \infty} \sum_{j \in S} p_{i,j}(n) = 1.$$

Next we check invariance. Using the Chapman-Kolmogorov equations, and again exchanging the limit with the finite sum,

$$\pi_j = \lim_{n \rightarrow \infty} p_{i,j}(n) = \lim_{n \rightarrow \infty} \sum_{k \in S} p_{i,k}(n-1)P_{k,j} = \sum_{k \in S} \pi_k P_{k,j},$$

so $\pi = \pi P$ as required. $\square$

Remark. Finiteness really is needed here, because exchanging limits with infinite sums is a dangerous business. For example, for the simple random walk on $\mathbb{Z}$ our estimates showed $p_{0,j}(n) \rightarrow 0$ for every j , and the zero vector is certainly not a probability distribution – the mass of the walk ‘escapes to infinity’ in the limit.

This remark shows that invariant distributions need not exist in general. The next portion of this section is devoted to pinning down exactly when they do exist, and when they are unique. The answer will turn out to be a lovely story involving recurrence.

§17.5.2 Existence of Invariant Measures

It will be convenient to temporarily drop the requirement that our distributions sum to 1. We say $\lambda = (\lambda_i \mid i \in S)$ is a **measure** on S if $\lambda_i \geq 0$ for all i , and an **invariant measure** if additionally $\lambda = \lambda P$. If an invariant measure has finite total mass $\sum_i \lambda_i < \infty$, we can normalise it into an invariant distribution.

So where might an invariant measure come from? Here is a probabilistic way to think about it: fix a state k , and consider an ‘excursion’ of the chain from k back to k . If the chain is in equilibrium, then the amount of time it spends in each state i per excursion ought to describe the equilibrium proportions. This motivates the following definition.

Definition 17.5.6 (Expected Time Spent Per Excursion)

Let $k \in S$. For each $i \in S$, define

$$\nu_k(i) = \mathbb{E} \left[\sum_{n=0}^{T_k-1} \mathbb{1}[X_n = i] \mid X_0 = k \right],$$

the expected number of visits to i during an excursion from k , before the chain first returns to k .

Note that $\nu_k(k) = 1$, since the chain starts the excursion at k and doesn’t count its return. The following theorem says that this excursion recipe really does produce an invariant measure, at least when the chain is recurrent (so that excursions actually finish).

Theorem 17.5.7 (Existence of Invariant Measures)

Let P be irreducible and recurrent. Then ν_k is an invariant measure, and moreover

$0 < \nu_k(i) < \infty$ for all $i \in S$.

Proof. Since P is irreducible and recurrent, we know $T_k < \infty$ almost surely, and $X_{T_k} = k$. Because the excursion begins and ends at k , we can shift our time window by one step: counting visits to i at times $0, 1, \dots, T_k - 1$ is the same as counting visits at times $1, 2, \dots, T_k$, since the only disagreement could be at the endpoints, where $X_0 = X_{T_k} = k$ contributes to both counts exactly when $i = k$. Hence, throughout taking probabilities conditional on $X_0 = k$,

$$\begin{aligned} \nu_k(i) &= \mathbb{E} \left[\sum_{n=1}^{T_k} \mathbb{1}[X_n = i] \right] = \mathbb{E} \left[\sum_{n=1}^{\infty} \mathbb{1}[X_n = i, T_k \geq n] \right] \\ &= \sum_{n=1}^{\infty} \mathbb{P}(X_n = i, T_k \geq n) \\ &= \sum_{n=1}^{\infty} \sum_{j \in S} \mathbb{P}(X_n = i \mid X_{n-1} = j, T_k \geq n) \mathbb{P}(X_{n-1} = j, T_k \geq n). \end{aligned}$$

Now here is the key point: the event $\{T_k \geq n\} = \{T_k \leq n-1\}^c$ is determined by $X_0, \dots, X_{n-1}$ only, so by the simple Markov property $\mathbb{P}(X_n = i \mid X_{n-1} = j, T_k \geq n) = P_{j,i}$. Continuing,

$$\begin{aligned} \nu_k(i) &= \sum_{j \in S} P_{j,i} \sum_{n=1}^{\infty} \mathbb{P}(X_{n-1} = j, T_k \geq n) \\ &= \sum_{j \in S} P_{j,i} \mathbb{E} \left[\sum_{n=0}^{T_k-1} \mathbb{1}[X_n = j] \right] = \sum_{j \in S} \nu_k(j) P_{j,i}, \end{aligned}$$

which is exactly the statement $\nu_k = \nu_k P$.

It remains to show that ν_k is finite and positive. Note that invariance gives $\nu_k = \nu_k P^n$ for all n . Given $i \in S$, by irreducibility we can pick n, m with $p_{k,i}(n) > 0$ and $p_{i,k}(m) > 0$. Then

$$\nu_k(i) = \sum_{j \in S} \nu_k(j) p_{j,i}(n) \geq \nu_k(k) p_{k,i}(n) = p_{k,i}(n) > 0,$$

and in the other direction

$$1 = \nu_k(k) = \sum_{j \in S} \nu_k(j) p_{j,k}(m) \geq \nu_k(i) p_{i,k}(m),$$

so $\nu_k(i) \leq 1/p_{i,k}(m) < \infty$. □

§17.5.3 Uniqueness of Invariant Measures

We now know that irreducible recurrent chains have at least one invariant measure. Conveniently, it turns out they have essentially *only* one – every invariant measure is a scalar multiple of ν_k .

Theorem 17.5.8 (Uniqueness of Invariant Measures)

Let P be irreducible, and let λ be an invariant measure with $\lambda_k = 1$. Then $\lambda \geq \nu_k$. If moreover P is recurrent, then $\lambda = \nu_k$.

Proof. For the first part, the idea is to repeatedly expand the invariance equation, each time splitting off the terms that pass through k . Indeed, for any i ,

$$\lambda_i = \sum_{j_1 \in S} \lambda_{j_1} P_{j_1, i} = P_{k, i} + \sum_{j_1 \neq k} \lambda_{j_1} P_{j_1, i},$$

using $\lambda_k = 1$. Substituting the invariance equation into λ_{j_1} again,

$$\lambda_i = P_{k, i} + \sum_{j_1 \neq k} P_{k, j_1} P_{j_1, i} + \sum_{j_1, j_2 \neq k} \lambda_{j_2} P_{j_2, j_1} P_{j_1, i},$$

and continuing in this way, after n expansions we obtain

$$\begin{aligned} \lambda_i &= P_{k, i} + \sum_{j_1 \neq k} P_{k, j_1} P_{j_1, i} + \cdots + \sum_{j_1, \dots, j_{n-1} \neq k} P_{k, j_{n-1}} \cdots P_{j_2, j_1} P_{j_1, i} \\ &\quad + \sum_{j_1, \dots, j_n \neq k} \lambda_{j_n} P_{j_n, j_{n-1}} \cdots P_{j_1, i}. \end{aligned}$$

The final term is non-negative, and the earlier terms have a probabilistic meaning: the m -th term is exactly the probability that the chain started at k is at i at time m without having returned to k in between. That is,

$$\lambda_i \geq \sum_{m=1}^n \mathbb{P}(X_m = i, T_k \geq m \mid X_0 = k),$$

and letting $n \rightarrow \infty$, the right hand side converges^a to $\nu_k(i)$. So $\lambda \geq \nu_k$.

Now suppose P is recurrent, so that ν_k is invariant by the previous theorem. Then $\mu = \lambda - \nu_k$ is also an invariant measure (it's non-negative by the first part), and $\mu_k = 1 - 1 = 0$. Given any $i \in S$, choose n with $p_{i, k}(n) > 0$ by irreducibility. Then

$$0 = \mu_k = \sum_{j \in S} \mu_j p_{j, k}(n) \geq \mu_i p_{i, k}(n),$$

forcing $\mu_i = 0$. Hence $\lambda = \nu_k$. □

^aHere we are using the shifted-window description of $\nu_k(i)$ from the proof of the existence theorem: $\nu_k(i) = \sum_{m \geq 1} \mathbb{P}(X_m = i, T_k \geq m \mid X_0 = k)$.

§17.5.4 Positive Recurrence and Existence of Invariant Distributions

Let's take stock. For an irreducible recurrent chain, we have a family of invariant measures ν_k (one for each $k \in S$), all proportional to one another. To produce an invariant *distribution* we need to normalise, which is possible exactly when ν_k has finite total

mass. And the total mass has a beautiful interpretation:

$$\sum_{i \in S} \nu_k(i) = \mathbb{E} \left[\sum_{n=0}^{T_k-1} \sum_{i \in S} \mathbb{1}[X_n = i] \mid X_0 = k \right] = \mathbb{E} \left[\sum_{n=0}^{T_k-1} 1 \mid X_0 = k \right] = \mathbb{E}[T_k \mid X_0 = k],$$

the expected length of an excursion from k . So everything comes down to whether the *mean return time* is finite. This suggests refining our notion of recurrence.

Definition 17.5.9 (Positive and Null Recurrence)

Let $i \in S$ be a recurrent state, and let $m_i = \mathbb{E}[T_i \mid X_0 = i]$ denote the **mean return time** of i . We say i is **positive recurrent** if $m_i < \infty$, and **null recurrent** if $m_i = \infty$.

Note that a recurrent state has $T_i < \infty$ almost surely, but this does *not* imply that $\mathbb{E}[T_i] < \infty$ – we saw exactly this phenomenon with the gambler’s ruin. The following theorem ties everything in this section together.

Theorem 17.5.10 (Existence and Uniqueness of Invariant Distributions)

Let P be irreducible. Then the following are equivalent:

- (i) every state is positive recurrent;
- (ii) some state is positive recurrent;
- (iii) P has an invariant distribution π .

Moreover, when these hold, the invariant distribution is unique and is given by

$$\pi_i = \frac{1}{m_i} \quad \text{for all } i \in S.$$

Proof. Clearly (i) implies (ii).

(ii) *implies* (iii). Let k be a positive recurrent state. Then k is in particular recurrent, and since recurrence is a class property and P is irreducible, P is recurrent. So by our existence theorem, ν_k is an invariant measure, with total mass $\sum_i \nu_k(i) = m_k < \infty$. Hence

$$\pi_i = \frac{\nu_k(i)}{m_k}$$

defines an invariant distribution.

(iii) *implies* (i). Suppose π is an invariant distribution, and let $k \in S$ be any state; we will show k is positive recurrent. First we claim $\pi_k > 0$: there is certainly some i with $\pi_i > 0$, and choosing n with $p_{i,k}(n) > 0$ by irreducibility, invariance gives

$$\pi_k = \sum_{j \in S} \pi_j p_{j,k}(n) \geq \pi_i p_{i,k}(n) > 0.$$

Before we can apply our uniqueness theorem, we need to know that P is recurrent. Suppose instead that P was transient. Then for all states i, j , we have $\sum_n p_{j,i}(n) < \infty$ and so certainly $p_{j,i}(n) \rightarrow 0$ as $n \rightarrow \infty$. But then, since $\pi_i = \sum_j \pi_j p_{j,i}(n)$ for

every n , and the summands are dominated^a by the summable sequence (π_j) , we may pass to the limit and conclude $\pi_i = 0$ for all i – contradicting $\sum_i \pi_i = 1$. So P is recurrent.

Now define $\lambda_i = \pi_i/\pi_k$. This is an invariant measure with $\lambda_k = 1$, so by the uniqueness theorem, $\lambda = \nu_k$. Hence

$$m_k = \sum_{i \in S} \nu_k(i) = \sum_{i \in S} \frac{\pi_i}{\pi_k} = \frac{1}{\pi_k} < \infty,$$

so k is positive recurrent, establishing (i). This computation also gives the final claim: $\pi_k = 1/m_k$ for every state k , and in particular the invariant distribution is unique, since its values are determined by the mean return times. $\square$

^aWe are using here the discrete version of the dominated convergence theorem: if $|f_n(j)| \leq g(j)$ with $\sum_j g(j) < \infty$ and $f_n(j) \rightarrow f(j)$ pointwise, then $\sum_j f_n(j) \rightarrow \sum_j f(j)$. In our case $\pi_j p_{j,i}(n) \leq \pi_j$, which is summable.

This is a genuinely satisfying result: for irreducible chains, the existence of an invariant distribution is a sharp dividing line, and when it exists, the equilibrium probability of a state is exactly the reciprocal of its mean return time. States that the chain returns to quickly get lots of mass; states it takes ages to revisit get little.

Example 17.5.11 (Mean Return Times of the Two-State Chain)

For the two-state chain, the theorem predicts the mean return time

$$m_1 = \frac{1}{\pi_1} = \frac{\alpha + \beta}{\beta},$$

and this is easy enough to verify by hand – always a healthy exercise. Starting from state 1, either the chain stays put (probability $1 - \alpha$), in which case $T_1 = 1$; or it jumps to state 2 (probability α), where it must wait a $\text{Geometric}(\beta)$ number of steps to jump back, giving $T_1 = 1 + \text{Geometric}(\beta)$ in distribution. Hence

$$m_1 = (1 - \alpha) \cdot 1 + \alpha \left(1 + \frac{1}{\beta}\right) = 1 + \frac{\alpha}{\beta} = \frac{\alpha + \beta}{\beta},$$

exactly as predicted.

Before moving on, let's record one more consequence of the uniqueness theory, which gives the excursion counts ν_k a pleasingly simple form in the positive recurrent case.

Corollary 17.5.12 (Visits Per Excursion)

Let P be irreducible with invariant distribution π . Then for any states $x, y \in S$, the expected number of visits to y during an excursion from x is

$$\nu_x(y) = \frac{\pi_y}{\pi_x}.$$

Proof. By the theorem above, P is positive recurrent, and in particular recurrent, with $\pi_x > 0$ for all x . Now $\lambda_y = \pi_y/\pi_x$ defines an invariant measure with $\lambda_x = 1$, so by the uniqueness of invariant measures, $\lambda = \nu_x$. $\square$

So, for example, between successive rainy days, the expected number of sunny days is simply the ratio of the equilibrium probabilities of sun and rain. Equilibrium ratios really do describe the fine structure of the chain's excursions, not just long-run averages.

Let's see the trichotomy of positive recurrence, null recurrence and transience play out on our favourite examples.

Example 17.5.13 (The Simple Random Walk on $\mathbb{Z}$ is Null Recurrent)

We proved via Pólya's theorem that the simple random walk on $\mathbb{Z}$ is recurrent. Is it positive recurrent? If it were, it would have an invariant distribution π . Solving $\pi = \pi P$ means

$$\pi_i = \frac{1}{2}\pi_{i-1} + \frac{1}{2}\pi_{i+1} \quad \text{for all } i \in \mathbb{Z},$$

and we can spot the invariant measure $\lambda_i = 1$ for all i . By uniqueness of invariant measures (the walk is irreducible and recurrent), *every* invariant measure is a constant multiple of this one – and none of these have finite total mass, so no invariant distribution exists. Hence the walk is null recurrent: it always returns home, but the expected time to do so is infinite.

Remark. One might hope for a converse: does having a 'nice' invariant measure imply recurrence? No – the simple random walk on $\mathbb{Z}^3$ is transient, and yet $\lambda_i = 1$ is a perfectly good invariant measure for it (the transition matrix is doubly stochastic). Existence of invariant *measures* is cheap; it is invariant *distributions* that carry real information.

Example 17.5.14 (A Transient Chain with Many Invariant Measures)

Consider the asymmetric random walk on $\mathbb{Z}$ with $P_{i,i+1} = p$, $P_{i,i-1} = q$, where $p + q = 1$ and $p > q$. This chain is transient. Solving $\lambda = \lambda P$ gives the recurrence $\lambda_i = p\lambda_{i-1} + q\lambda_{i+1}$, with general solution

$$\lambda_i = a + b \left(\frac{p}{q}\right)^i, \quad a, b \geq 0.$$

These are genuinely different invariant measures (not multiples of each other), so the uniqueness theorem really does need recurrence. And again, none of them can be normalised, so there is no invariant distribution – as must be the case, since the chain is not positive recurrent.

Example 17.5.15 (A Positive Recurrent Walk)

Now consider a random walk on $S = \{0, 1, 2, \dots\}$ with a drift towards the origin: let $0 < p < 1/2$, and set

$$P_{i,i+1} = p, \quad P_{i,i-1} = q = 1 - p \quad \text{for } i \geq 1, \quad P_{0,1} = p, \quad P_{0,0} = q.$$

Rather than trying to compute mean return times directly, we look for an invariant distribution. The equations $\pi = \pi P$ read

$$\pi_0 = q\pi_0 + q\pi_1, \quad \pi_i = p\pi_{i-1} + q\pi_{i+1} \quad \text{for } i \geq 1.$$

The first equation gives $\pi_1 = (p/q)\pi_0$, and then induction on the second^a gives

$$\pi_i = \left(\frac{p}{q}\right)^i \pi_0.$$

Since $p < q$, this has finite total mass, and normalising gives the geometric distribution

$$\pi_i = \left(1 - \frac{p}{q}\right) \left(\frac{p}{q}\right)^i.$$

So by our theorem the chain is positive recurrent, with mean return times $m_i = 1/\pi_i$ – and we found this out without ever computing an expectation directly. This is the invariant distribution machinery at its best.

^aSubstituting $\pi_i = (p/q)^i \pi_0$ into the second equation: $p(p/q)^{i-1} + q(p/q)^{i+1} = (p/q)^i(q+p) = (p/q)^i$, as needed.

§17.6 Convergence to Equilibrium

We now come to the central limit-theorem-flavoured result of this course: for a nice enough Markov chain, the distribution of X_n converges to the invariant distribution π , *regardless of the initial distribution*. Run the chain for long enough and it forgets where it started.

Of course, some hypotheses will be needed. We have already seen that we should assume irreducibility and positive recurrence, so that an invariant distribution exists and is unique. But there is one more, sneakier obstruction, which we address first.

§17.6.1 Aperiodicity

Consider the Markov chain that cycles deterministically around three states, as below.

This chain is irreducible and positive recurrent, and its invariant distribution is the uniform one, $\pi = (1/3, 1/3, 1/3)$. But started from state 1, we have $\mathbb{P}(X_n = 1) = 1$ when $3 \mid n$ and $\mathbb{P}(X_n = 1) = 0$ otherwise – the distribution of X_n just cycles, and certainly doesn't converge to π . The chain never forgets its starting point, because its position modulo 3 remembers it forever. To rule out this kind of parity problem, we introduce the notion of periodicity.

Definition 17.6.1 (Period)

For a state $i \in S$, the **period** of i is

$$d_i = \gcd\{n \geq 1 \mid p_{i,i}(n) > 0\}.$$

We say the state i is **aperiodic** if $d_i = 1$.

In the cycle above, each state has period 3. In the simple random walk on $\mathbb{Z}$, each state has period 2 – and indeed we took care to work with $p_{0,0}(2n)$ throughout our analysis of it. More generally, the simple random walk on any *bipartite* graph (one whose vertices can be 2-coloured so that every edge joins different colours) has period 2, since every closed walk has even length: the chain forever alternates between the two colour classes, and its colour at time n remembers the parity of n . On the other hand, note that a single self-loop anywhere in an irreducible chain is enough to give that state period 1 (as $p_{i,i}(1) > 0$), and we shall see shortly that aperiodicity then spreads to every state.

For our purposes, the importance of aperiodicity is the following characterisation.

Lemma 17.6.2 (Aperiodicity Criterion)

A state i is aperiodic if and only if $p_{i,i}(n) > 0$ for all sufficiently large n .

Proof. Let $D = \{n \geq 1 \mid p_{i,i}(n) > 0\}$. One direction is easy: if D contains all sufficiently large integers, then it certainly has greatest common divisor 1 (say, it contains two consecutive integers).

For the other direction, first note that D is closed under addition: if $a, b \in D$ then $p_{i,i}(a+b) \geq p_{i,i}(a)p_{i,i}(b) > 0$ by Chapman-Kolmogorov. Now suppose $\gcd D = 1$. Then there is some finite collection $n_1, \dots, n_r \in D$ with $\gcd\{n_1, \dots, n_r\} = 1$, and so by Bézout's lemma^a there are integers $a_1, \dots, a_r$ with $a_1 n_1 + \dots + a_r n_r = 1$. Collecting the positive and negative terms, we can write $M - N = 1$, where M and N are each non-negative integer combinations of the n_s , and hence (assuming $N \neq 0$; if $N = 0$ then $1 \in D$ and we're immediately done) both M and N lie in D by closure under addition.

So D contains the consecutive integers N and $N+1$. Now take any $n \geq N^2$, and write $n = qN + s$ with $0 \leq s < N$. Then $q \geq N > s$, so

$$n = (q-s)N + s(N+1)$$

expresses n as a non-negative integer combination of N and $N+1$. Hence $n \in D$, and D contains every integer at least N^2 . $\square$

^aStrictly, Bézout's lemma as usually stated handles two integers; the general case follows by induction on r .

Like recurrence and transience, aperiodicity turns out to be a class property, so for irreducible chains we can simply speak of *the chain* being aperiodic.

Lemma 17.6.3 (Aperiodicity is a Class Property)

Suppose P is irreducible and some state i is aperiodic. Then every state is aperiodic.

Proof. Let $j \in S$. By irreducibility there are n, m with $p_{j,i}(n) > 0$ and $p_{i,j}(m) > 0$. Then for any r ,

$$p_{j,j}(n+r+m) \geq p_{j,i}(n) p_{i,i}(r) p_{i,j}(m),$$

and by the previous lemma the middle factor is positive for all sufficiently large r . Hence $p_{j,j}(s) > 0$ for all sufficiently large s , and j is aperiodic. $\square$

§17.6.2 The Convergence Theorem

We can now state and prove the main theorem of this section.

Theorem 17.6.4 (Convergence to Equilibrium)

Let P be irreducible and aperiodic with invariant distribution π , and let X_n be Markov(λ, P) for any initial distribution λ . Then for all $j \in S$,

$$\mathbb{P}(X_n = j) \rightarrow \pi_j \quad \text{as } n \rightarrow \infty.$$

In particular, taking $\lambda = \delta_i$, we have $p_{i,j}(n) \rightarrow \pi_j$ for all $i, j \in S$.

The proof uses a technique known as *coupling*, which is worth dwelling on for a moment, as it's one of the loveliest ideas in probability. We want to compare the chain X_n with a chain in equilibrium. So we simply run a second, independent copy Y_n of the chain, started in the invariant distribution. The trick is then this: we watch the two chains until the (random) moment they happen to collide, and after that moment, we make X ‘copy’ Y . Copying Y doesn't change the distribution of X (by the strong Markov property, both chains restart identically from the collision point), but once they've collided, our chain literally *is* in equilibrium. So all we need is that the collision happens eventually, and this is a recurrence statement, which we have the tools to prove.

Proof. Let Y_n be Markov(π, P), independent of X_n .

Step 1: the product chain. Consider the process $W_n = (X_n, Y_n)$ on the state space $S \times S$. By independence, W_n is a Markov chain with initial distribution $\mu_{(x,y)} = \lambda_x \pi_y$ and transition matrix

$$\tilde{P}_{(x,y),(x',y')} = P_{x,x'} P_{y,y'}.$$

We claim $\tilde{P}$ is irreducible. Given states (x, y) and (x', y') , choose ℓ and m with $p_{x,x'}(\ell) > 0$ and $p_{y,y'}(m) > 0$. For any $r \geq 0$, we have $p_{x,x'}(\ell+r) \geq p_{x,x'}(\ell) p_{x',x'}(r)$, which by aperiodicity is positive for all sufficiently large r ; similarly $p_{y,y'}(m+r) > 0$ for all large r . So for sufficiently large n , both $p_{x,x'}(n)$ and $p_{y,y'}(n)$ are positive^a, and hence $\tilde{P}_{(x,y),(x',y')}(n) = p_{x,x'}(n) p_{y,y'}(n) > 0$.

Moreover, $\tilde{P}$ has an invariant distribution $\tilde{\pi}_{(x,y)} = \pi_x \pi_y$, as is easily checked using invariance of π in each coordinate. So by our existence and uniqueness theorem, the product chain is positive recurrent, and in particular recurrent.

Step 2: the coupling time. Fix any state $a \in S$, and let

$$T = \inf\{n \geq 1 \mid W_n = (a, a)\}$$

be the first time the two chains simultaneously sit at a . Since the product chain

is irreducible and recurrent, our ‘recurrent chains visit everything’ theorem gives $\mathbb{P}(T < \infty) = 1$.

Step 3: the swap. Now define

$$Z_n = \begin{cases} X_n & \text{if } n < T, \\ Y_n & \text{if } n \geq T. \end{cases}$$

We claim that Z_n has the same distribution as X_n , i.e. that Z is $\text{Markov}(\lambda, P)$. To see this, consider the swapped product process

$$W'_n = \begin{cases} (X_n, Y_n) & \text{if } n < T, \\ (Y_n, X_n) & \text{if } n \geq T. \end{cases}$$

The time T is a stopping time for W , and $W_T = (a, a)$. By the strong Markov property, conditional on $T < \infty$, the process $(W_{T+n})_{n \geq 0}$ is $\text{Markov}(\delta_{(a,a)}, \tilde{P})$, independent of $W_0, \dots, W_T$. But both the transition matrix $\tilde{P}$ and the state (a, a) are symmetric under swapping the two coordinates, so the coordinate-swapped process $((Y_{T+n}, X_{T+n}))_{n \geq 0}$ is *also* $\text{Markov}(\delta_{(a,a)}, \tilde{P})$, independent of the same past. Gluing this back onto the pre- T process, we conclude that W' is a Markov chain with the same initial distribution and transition matrix as W . In particular its first coordinate, which is exactly Z , is $\text{Markov}(\lambda, P)$ as claimed.

Step 4: the conclusion. Since $Y_0 \sim \pi$ and π is invariant, $\mathbb{P}(Y_n = j) = \pi_j$ for all n . Now for any $j \in S$,

$$\begin{aligned} |\mathbb{P}(X_n = j) - \pi_j| &= |\mathbb{P}(Z_n = j) - \mathbb{P}(Y_n = j)| \\ &= |\mathbb{P}(X_n = j, n < T) + \mathbb{P}(Y_n = j, n \geq T) \\ &\quad - \mathbb{P}(Y_n = j, n < T) - \mathbb{P}(Y_n = j, n \geq T)| \\ &= |\mathbb{P}(X_n = j, n < T) - \mathbb{P}(Y_n = j, n < T)| \\ &\leq \mathbb{P}(T > n). \end{aligned}$$

Since T is almost surely finite, $\mathbb{P}(T > n) \rightarrow 0$ as $n \rightarrow \infty$, and we are done. $\square$

^aThis is where aperiodicity earns its keep: without it, $p_{x,x'}(n)$ and $p_{y,y'}(n)$ might only be positive on disjoint sets of times (consider the 3-cycle), and the product chain fails to be irreducible.

It is worth appreciating how much of the theory we developed went into this proof: invariant distributions, positive recurrence, the classification of when invariant distributions exist, the strong Markov property, and aperiodicity all played essential roles.

Example 17.6.5 (The Two-State Chain, One Last Time)

The two-state chain with $\alpha, \beta \in (0, 1)$ is irreducible, and aperiodic since $p_{1,1}(1) = 1 - \alpha > 0$. So the convergence theorem applies, and predicts

$$p_{1,1}(n) \rightarrow \pi_1 = \frac{\beta}{\alpha + \beta},$$

which is precisely what our explicit formula $p_{1,1}(n) = \frac{\beta}{\alpha + \beta} + \frac{\alpha}{\alpha + \beta}(1 - \alpha - \beta)^n$ shows, since $|1 - \alpha - \beta| < 1$. It's pleasing to see the general theorem and the bare-hands

computation agree – and of course, the theorem’s real value is for chains where no explicit formula is available.

Example 17.6.6 (Convergence of the Reflected Biased Walk)

Recall the walk on $\{0, 1, 2, \dots\}$ with $P_{i,i+1} = p$ and $P_{i,i-1} = q$ for $i \geq 1$, and $P_{0,1} = p$, $P_{0,0} = q$, where $p < 1/2 < q$. We showed it is positive recurrent with geometric invariant distribution $\pi_i = (1 - p/q)(p/q)^i$. The chain is aperiodic thanks to the lazy loop at 0 ($P_{0,0} = q > 0$), so the convergence theorem applies:

$$\mathbb{P}(X_n = i) \rightarrow \left(1 - \frac{p}{q}\right) \left(\frac{p}{q}\right)^i \quad \text{for every } i,$$

no matter the initial distribution. Computing $p_{i,j}(n)$ explicitly for this chain would be thoroughly unpleasant – yet its limit comes almost for free. Note the contrast with the unreflected walk on $\mathbb{Z}$: one boundary and a drift towards it are enough to change the walk from null recurrent (or transient) to positive recurrent.

Remark (The Lazy Chain Trick). Periodicity, while a genuine obstruction to convergence, is a rather fragile one. Given any irreducible chain P , consider the *lazy chain* $P' = \frac{1}{2}(I + P)$, which at each step flips a fair coin and either stays put or takes a step of P . Then P' is aperiodic (each state has $P'_{i,i} \geq 1/2 > 0$), it is irreducible, and it has exactly the same invariant distributions as P , since $\pi P' = \frac{1}{2}\pi + \frac{1}{2}\pi P = \pi$ if and only if $\pi P = \pi$. So laziness destroys periodicity while preserving equilibrium – a trick worth remembering.

Aside: How Many Shuffles Suffice?

Convergence to equilibrium is not just an abstract limit theorem – it is the mathematics of *shuffling cards*. The arrangements of a deck of 52 cards form a set S of size $52!$, and a shuffling method (repeatedly cutting and riffing, say) defines a Markov chain on S : the next arrangement depends only on the current one and the randomness of the shuffle. Provided the shuffle is ‘random enough’ for the chain to be irreducible and aperiodic, our convergence theorem promises that the distribution of the deck’s arrangement converges to the unique invariant distribution – which, by the symmetry of the situation, is uniform on all $52!$ arrangements⁶. In other words, shuffle for long enough and the deck genuinely becomes perfectly mixed, regardless of how it started.

The really interesting question – *how fast?* – is beyond this course, but has a famously crisp answer: Bayer and Diaconis showed that for riffle shuffles of a 52-card deck, about *seven* shuffles are needed before the distribution is close to uniform, with a sharp ‘cut-off’ from poorly-mixed to well-mixed occurring around that point. The study of such mixing times is a thriving area of modern probability, and it all rests on the framework we have just built.

⁶A little more precisely: each shuffle composes the current arrangement with a random permutation, so the transition matrix satisfies $P_{\sigma,\tau} = P_{\rho\sigma,\rho\tau}$ for any permutation ρ , which forces each column of P to sum to 1 as well as each row. For such *doubly stochastic* matrices, the uniform distribution is invariant, since $\sum_{\sigma} \frac{1}{52!} P_{\sigma,\tau} = \frac{1}{52!}$.

§17.6.3 What Happens Without Positive Recurrence?

If the chain is irreducible but *not* positive recurrent, then there is no invariant distribution to converge to, and indeed the distribution of the chain flattens out entirely.

Theorem 17.6.7 (Null Recurrent and Transient Chains Forget Everything)

Let P be irreducible and aperiodic, and suppose P is not positive recurrent (that is, it is null recurrent or transient). Then for all $x, y \in S$,

$$p_{x,y}(n) \rightarrow 0 \quad \text{as } n \rightarrow \infty.$$

Proof. As in the convergence theorem, form the product chain on $S \times S$ with transition matrix $\tilde{P}_{(x,y),(x',y')} = P_{x,x'}P_{y,y'}$, which is irreducible by aperiodicity (this part of the earlier proof did not use positive recurrence). We consider two cases.

Case 1: $\tilde{P}$ is transient. For a transient chain, the expected total number of visits to any fixed state is finite from any starting point^a. Applying this to the product chain started at (x, x) , looking at visits to (y, y) ,

$$\sum_{n=0}^{\infty} \tilde{p}_{(x,x),(y,y)}(n) = \sum_{n=0}^{\infty} p_{x,y}(n)^2 < \infty,$$

so $p_{x,y}(n)^2 \rightarrow 0$, giving the result.

Case 2: $\tilde{P}$ is recurrent. Note that in this case P itself must be recurrent (if the product chain returns to (y, y) infinitely often, its first coordinate returns to y infinitely often), and hence P is null recurrent, and the invariant measure ν_y (for any fixed $y \in S$) has infinite total mass $\sum_z \nu_y(z) = m_y = \infty$.

Let $M > 0$. Since ν_y has infinite mass but is finite on each state, we can choose a *finite* set $A \subseteq S$ with $\nu_y(A) = \sum_{z \in A} \nu_y(z) > M$. Define a distribution μ by

$$\mu_z = \frac{\nu_y(z)}{\nu_y(A)} \mathbb{1}[z \in A].$$

The point of this construction is the following bound: for any $z \in S$ and $n \geq 0$, since $\mu \leq \nu_y/\nu_y(A)$ entrywise and ν_y is invariant,

$$(\mu P^n)_z \leq \frac{(\nu_y P^n)_z}{\nu_y(A)} = \frac{\nu_y(z)}{\nu_y(A)}.$$

In particular $(\mu P^n)_y \leq \nu_y(y)/\nu_y(A) = 1/\nu_y(A) < 1/M$.

Now we couple. Let (X_n, Y_n) be the product chain with initial distribution $\mu \times \delta_x$, that is, $X_0 \sim \mu$ and $Y_0 = x$ independently. Fix $s \in S$ and let $T = \inf\{n \geq 1 \mid (X_n, Y_n) = (s, s)\}$; since the product chain is irreducible and recurrent, $T < \infty$ almost surely. Defining Z_n to follow X before T and Y afterwards, exactly as in the convergence theorem, Z is Markov(μ, P), so $\mathbb{P}(Z_n = y) = (\mu P^n)_y < 1/M$. Then

$$\begin{aligned} p_{x,y}(n) &= \mathbb{P}(Y_n = y) \leq \mathbb{P}(Y_n = y, n \geq T) + \mathbb{P}(T > n) \\ &= \mathbb{P}(Z_n = y, n \geq T) + \mathbb{P}(T > n) \leq \frac{1}{M} + \mathbb{P}(T > n). \end{aligned}$$

Taking $n \rightarrow \infty$ gives $\limsup_n p_{x,y}(n) \leq 1/M$, and since M was arbitrary, $p_{x,y}(n) \rightarrow 0$. $\square$

^aIndeed, by the strong Markov property, the number of visits to state w' starting from w is bounded by a geometric random variable: $\mathbb{E}[V_{w'} \mid W_0 = w] = \mathbb{P}(T_{w'} < \infty \mid W_0 = w)/(1 - f_{w'}) < \infty$.

Example 17.6.8

For the simple random walk on $\mathbb{Z}$ (null recurrent, though periodic – consider instead its lazy version to meet the aperiodicity hypothesis) we can see this flattening concretely: our Stirling estimate gave

$$p_{0,0}(2n) \sim \frac{1}{\sqrt{\pi n}} \rightarrow 0.$$

The walk keeps coming back to 0 forever, but the *probability* of finding it at 0 (or any fixed state) at a given large time dwindles to nothing, as the walk spreads out over an ever-larger range of $\mathbb{Z}$.

§17.7 The Ergodic Theorem

The convergence theorem tells us about the distribution of the chain at a single large time n . In this section we will prove a different kind of limit theorem, about the behaviour of a single realisation of the chain over time: the *long-run proportion of time* spent in each state. This is the Markov chain analogue of the strong law of large numbers – and indeed the strong law is exactly what we will use to prove it. Let us recall the statement (it is proved in a course on probability theory, and we will treat it as a black box).

Fact 17.7.1 (Strong Law of Large Numbers)

Let $U_1, U_2, \dots$ be independent, identically distributed, non-negative random variables with $\mathbb{E}[U_1] = \mu \leq \infty$. Then

$$\mathbb{P}\left(\frac{U_1 + \dots + U_r}{r} \rightarrow \mu \text{ as } r \rightarrow \infty\right) = 1.$$

This holds also when $\mu = \infty$, in the sense that the averages tend to infinity almost surely.

We will apply this to the durations of the successive excursions of a Markov chain from a state. Since these excursions are independent (thanks to the strong Markov property), the total time taken for r excursions grows like $r \cdot m_i$, and inverting this relationship will give us the proportion of time spent at i . Let's set up notation: define the **number of visits to i before time n** as

$$V_i(n) = \sum_{m=0}^{n-1} \mathbb{1}[X_m = i],$$

so that $V_i(n)/n$ is the proportion of the first n time steps spent at i .

Theorem 17.7.2 (Ergodic Theorem)

Let P be irreducible, and let X_n be $\text{Markov}(\lambda, P)$ for any initial distribution λ . Then

$$\mathbb{P}\left(\frac{V_i(n)}{n} \rightarrow \frac{1}{m_i} \text{ as } n \rightarrow \infty\right) = 1,$$

where $m_i = \mathbb{E}[T_i \mid X_0 = i]$ is the mean return time, and we interpret $1/\infty = 0$. In particular, if P is positive recurrent with invariant distribution π , then the long-run proportion of time spent in each state i is almost surely π_i .

Note the hypotheses: there is no aperiodicity assumption here, and the result holds even in the null recurrent and transient cases. Time averages are more forgiving than distributional limits. To see the contrast at its starkest, consider our deterministic 3-cycle: the distribution of X_n cycles forever and never converges, but the proportion of time spent in each state converges beautifully to $1/3 = 1/m_i$, as each state is visited exactly once every three steps.

Proof. First suppose P is transient. Then the total number of visits $V_i = \lim_n V_i(n)$ is almost surely finite, so

$$\frac{V_i(n)}{n} \leq \frac{V_i}{n} \rightarrow 0,$$

and since transient states have $\mathbb{P}(T_i < \infty \mid X_0 = i) < 1$, certainly $m_i = \infty$ and $1/m_i = 0$, in agreement.

So suppose P is recurrent, and fix the state i . Let $T = T_i$ be the first passage time to i . By our ‘recurrent chains visit everything’ theorem, $T < \infty$ almost surely, and by the strong Markov property the process $(X_{T+n})_{n \geq 0}$ is $\text{Markov}(\delta_i, P)$. Moreover, discarding the initial segment of the chain before time T changes neither the limit of $V_i(n)/n$ (we discard only finitely many steps) nor $1/m_i$. So it suffices to prove the result when $\lambda = \delta_i$, i.e. assuming $X_0 = i$.

Now let $U_r = T_i^{(r)} - T_i^{(r-1)}$ be the length of the r -th excursion from i . By the strong Markov property applied at the stopping times $T_i^{(r-1)}$ (which are finite almost surely, by recurrence), the excursion lengths $U_1, U_2, \dots$ are independent and identically distributed with mean $\mathbb{E}[U_1] = m_i$. Writing $T_i^{(r)} = U_1 + \dots + U_r$, the strong law of large numbers gives

$$\frac{T_i^{(r)}}{r} \rightarrow m_i \quad \text{almost surely}$$

(including in the null recurrent case $m_i = \infty$).

The final step is to relate the passage times back to $V_i(n)$, which we do by a sandwiching argument. Since $X_0 = i$, at time $n - 1$ the chain has made exactly $V_i(n)$ visits to i (counting the one at time 0), so the $(V_i(n) - 1)$ -th return has happened by time $n - 1$, but the $V_i(n)$ -th has not:

$$T_i^{(V_i(n)-1)} \leq n - 1 < T_i^{(V_i(n))}.$$

Dividing through by $V_i(n)$,

$$\frac{T_i^{(V_i(n)-1)}}{V_i(n)-1} \cdot \frac{V_i(n)-1}{V_i(n)} \leq \frac{n}{V_i(n)} \leq \frac{T_i^{(V_i(n))}}{V_i(n)}.$$

By recurrence $V_i(n) \rightarrow \infty$ almost surely, so both the left and right hand sides converge almost surely to m_i (using our strong law statement along the random subsequence $r = V_i(n)$, which is valid since $V_i(n) \rightarrow \infty$). Hence $n/V_i(n) \rightarrow m_i$ almost surely, which is exactly the claim.

Finally, if P is positive recurrent, then $\pi_i = 1/m_i$ by our existence and uniqueness theorem. $\square$

Remark. The ergodic theorem is the theoretical justification for estimating π by *simulation*: run the chain for a long time and record the empirical proportions of time spent in each state. This idea underlies Markov chain Monte Carlo, one of the most widely used computational techniques in modern statistics – there, one cleverly *constructs* a Markov chain whose invariant distribution is a distribution one wishes to sample from. (The construction is usually done via detailed balance, which we discuss next.)

Example 17.7.3 (An Unreliable Printer)

A printer is either working or broken, and its state is inspected each morning. If it is working today, it breaks down overnight with probability α ; if it is broken, an engineer manages to fix it overnight with probability β . This is exactly our two-state chain, with invariant distribution

$$\pi = \left(\frac{\beta}{\alpha + \beta}, \frac{\alpha}{\alpha + \beta} \right)$$

on the states {working, broken}. By the ergodic theorem, the long-run *proportion of days* on which the printer works is, with probability one,

$$\frac{V_{\text{working}}(n)}{n} \rightarrow \frac{\beta}{\alpha + \beta}.$$

Note the subtle upgrade from the convergence theorem: not only is the printer working with probability close to $\beta/(\alpha + \beta)$ on any particular distant day, but the actual observed fraction of good days converges to this value on almost every realisation of history. If, say, each working day generates income c , then the long-run income rate is $c\beta/(\alpha + \beta)$ per day, almost surely – statements of this form are exactly what the ergodic theorem is for.

§17.8 Time Reversal

§17.8.1 Reversing a Markov Chain

Here is a curious question to end the course with: if we film a Markov chain in equilibrium and play the tape backwards, what do we see? The Markov property is symmetric in time to a greater extent than one might expect – conditional on the present, the past and future are independent, and this description doesn't distinguish a direction of time. Indeed, it turns out the reversed film shows another Markov chain, and we can say

exactly which one.

Theorem 17.8.1 (Time Reversal)

Let P be irreducible with invariant distribution π , and let X_n be $\text{Markov}(\pi, P)$. Fix $N \geq 1$, and define $Y_n = X_{N-n}$ for $0 \leq n \leq N$. Then $(Y_n)_{0 \leq n \leq N}$ is $\text{Markov}(\pi, \widehat{P})$, where

$$\widehat{P}_{i,j} = \frac{\pi_j}{\pi_i} P_{j,i}.$$

Moreover $\widehat{P}$ is also irreducible, with invariant distribution π .

The chain $\widehat{P}$ is called the **time reversal** of P . (Note $\pi_i > 0$ for all i by irreducibility and positive recurrence, so there are no division-by-zero worries here.)

Proof. First, $\widehat{P}$ is a genuine (stochastic) transition matrix: its entries are non-negative, and using $\pi = \pi P$,

$$\sum_{j \in S} \widehat{P}_{i,j} = \frac{1}{\pi_i} \sum_{j \in S} \pi_j P_{j,i} = \frac{\pi_i}{\pi_i} = 1.$$

Next we check that Y has the right finite-dimensional distributions. For any states $i_0, \dots, i_N$,

$$\begin{aligned} \mathbb{P}(Y_0 = i_0, \dots, Y_N = i_N) &= \mathbb{P}(X_0 = i_N, X_1 = i_{N-1}, \dots, X_N = i_0) \\ &= \pi_{i_N} P_{i_N, i_{N-1}} \cdots P_{i_1, i_0}. \end{aligned}$$

Now we repeatedly substitute using $\pi_j P_{j,i} = \pi_i \widehat{P}_{i,j}$, moving from left to right: first $\pi_{i_N} P_{i_N, i_{N-1}} = \pi_{i_{N-1}} \widehat{P}_{i_{N-1}, i_N}$, then combining $\pi_{i_{N-1}}$ with the next factor, and so on. After N substitutions we obtain

$$\mathbb{P}(Y_0 = i_0, \dots, Y_N = i_N) = \pi_{i_0} \widehat{P}_{i_0, i_1} \cdots \widehat{P}_{i_{N-1}, i_N},$$

which by our very first theorem (the probability of a sequence of states) says exactly that Y is $\text{Markov}(\pi, \widehat{P})$.

For invariance of π under $\widehat{P}$,

$$\sum_{i \in S} \pi_i \widehat{P}_{i,j} = \sum_{i \in S} \pi_j P_{j,i} = \pi_j.$$

Finally, for irreducibility, let $i, j \in S$. By irreducibility of P there is a path $i = i_0, i_1, \dots, i_k = j$ with $P_{i_0, i_1} P_{i_1, i_2} \cdots P_{i_{k-1}, i_k} > 0$. Then, reversing the path,

$$\widehat{P}_{i_k, i_{k-1}} \cdots \widehat{P}_{i_1, i_0} = \frac{\pi_{i_0}}{\pi_{i_k}} P_{i_0, i_1} \cdots P_{i_{k-1}, i_k} > 0,$$

(the intermediate π factors telescope), so $j \rightarrow i$ in the reversed chain, as required. $\square$

Remark. The hypothesis that the chain starts *in equilibrium* is doing real work here. If X_0 had some other distribution, the reversed process would generally fail to be a homogeneous Markov chain at all – for instance, if $X_0 = i$ is deterministic, then watching

the film backwards, the process is mysteriously compelled to arrive at state i at the final frame, which no homogeneous transition mechanism can arrange. Equilibrium is exactly the condition that makes the chain look statistically the same at every time, so that reversing time doesn't distinguish any particular moment.

Example 17.8.2 (Reversing a Biased Cycle)

Let $n \geq 3$ and consider the walk on $\mathbb{Z}_n$ (the integers modulo n) that steps clockwise with probability $2/3$ and anticlockwise with probability $1/3$. By symmetry, the invariant distribution is uniform, $\pi_i = 1/n$. The time reversal is then

$$\widehat{P}_{i,j} = \frac{\pi_j}{\pi_i} P_{j,i} = P_{j,i},$$

so $\widehat{P}_{i,i-1} = P_{i-1,i} = 2/3$ and $\widehat{P}_{i,i+1} = 1/3$: the reversed chain is the walk biased *anticlockwise* instead. This is exactly what intuition demands – a film of a clockwise-drifting walker, played backwards, shows an anticlockwise-drifting walker. In particular $\widehat{P} \neq P$ here, and the direction of drift is precisely the feature that betrays the direction of time.

§17.8.2 Detailed Balance and Reversibility

The most interesting case of time reversal is when running the film backwards is *undetectable* – when the reversed chain is statistically identical to the original.

Definition 17.8.3 (Reversibility)

Let P be irreducible with invariant distribution π . The chain is **reversible** (in equilibrium) if $\widehat{P} = P$, that is, if

$$\pi_i P_{i,j} = \pi_j P_{j,i} \quad \text{for all } i, j \in S.$$

These equations are called the **detailed balance equations**.

The detailed balance equations have a very physical interpretation. In equilibrium, the quantity $\pi_i P_{i,j}$ is the probability of seeing the chain make the specific transition $i \rightarrow j$ at a given time step – a ‘flow of probability’ from i to j . Invariance ($\pi = \pi P$) says that the total flow into each state balances the total flow out. Detailed balance is a much stronger, local statement: the flow from i to j equals the flow from j to i , *along every edge individually*.

Why do we care? One excellent practical reason:

Lemma 17.8.4 (Detailed Balance Implies Invariance)

Let P be a transition matrix and μ a distribution satisfying the detailed balance equations $\mu_i P_{i,j} = \mu_j P_{j,i}$ for all i, j . Then μ is an invariant distribution for P .

Proof. We simply sum:

$$(\mu P)_j = \sum_{i \in S} \mu_i P_{i,j} = \sum_{i \in S} \mu_j P_{j,i} = \mu_j. \quad \square$$

The detailed balance equations are a system of ‘one equation per pair of states’, each involving only two unknowns, and are usually *far* easier to solve than $\pi = \pi P$. So a sensible strategy when hunting for an invariant distribution is: try detailed balance first. If it has a solution, you’ve found π (and shown the chain is reversible as a bonus). If not, the chain isn’t reversible, and you must go back to $\pi = \pi P$.

Example 17.8.5 (A Chain That is Not Reversible)

Let $n \geq 3$, and consider the random walk on $\mathbb{Z}_n$ (the integers modulo n) which steps clockwise with probability $2/3$ and anticlockwise with probability $1/3$:

$$P_{i,i+1} = \frac{2}{3}, \quad P_{i,i-1} = \frac{1}{3} \quad (\text{indices mod } n).$$

By symmetry we can check that $\pi_i = 1/n$ is invariant: each state receives flow $\frac{1}{n} \cdot \frac{2}{3}$ from its anticlockwise neighbour, and $\frac{1}{n} \cdot \frac{1}{3}$ from its clockwise neighbour, totalling $1/n$. But detailed balance fails:

$$\pi_i P_{i,i+1} = \frac{2}{3n} \neq \frac{1}{3n} = \pi_{i+1} P_{i+1,i}.$$

And this makes perfect sense – in equilibrium there is a net current of probability flowing clockwise around the cycle, and if we watched a film of this chain we could tell whether it was being played backwards, by watching which way the walker predominantly moves.

Example 17.8.6 (A Reversible Chain)

Now cut the cycle open: consider the same walk on $\{0, 1, \dots, n-1\}$, but where the walk cannot wrap around, say

$$P_{i,i+1} = \frac{2}{3} \quad (i < n-1), \quad P_{i,i-1} = \frac{1}{3} \quad (i > 0), \quad P_{0,0} = \frac{1}{3}, \quad P_{n-1,n-1} = \frac{2}{3}.$$

This time there is nowhere for a net current to circulate, and indeed detailed balance succeeds: the equations

$$\pi_i P_{i,i+1} = \pi_{i+1} P_{i+1,i} \implies \pi_{i+1} = 2\pi_i,$$

give $\pi_i = c \cdot 2^i$, and normalising, $\pi_i = 2^i / (2^n - 1)$. So this chain is reversible, with an invariant distribution that piles up geometrically at the right-hand end.

The moral of the pair of examples: reversibility is characteristically obstructed by *cycles*

with a preferred direction. On tree-like or line-like state spaces, where every transition must eventually be retraced, chains tend to be reversible. In fact, for chains on the non-negative integers that only ever step to a neighbour, this is a theorem.

Proposition 17.8.7 (Birth-Death Chains are Reversible)

Let P be an irreducible birth-death chain on $S = \{0, 1, 2, \dots\}$ (or a finite interval of integers), i.e. $P_{i,j} = 0$ whenever $|i - j| > 1$, and suppose P has an invariant distribution π . Then the chain is reversible.

Proof. We must show $\pi_i P_{i,j} = \pi_j P_{j,i}$ for all i, j . This is trivial if $i = j$ or $|i - j| > 1$, so it suffices to show $\pi_i P_{i,i+1} = \pi_{i+1} P_{i+1,i}$ for all i , and we induct on i . Consider the invariance equation at state 0. Since only states 0 and 1 can move to 0,

$$\pi_0 = \pi_0 P_{0,0} + \pi_1 P_{1,0},$$

and $P_{0,0} = 1 - P_{0,1}$, so rearranging gives $\pi_0 P_{0,1} = \pi_1 P_{1,0}$, the base case. For the inductive step, invariance at state $i + 1$ reads

$$\pi_{i+1} = \pi_i P_{i,i+1} + \pi_{i+1} P_{i+1,i+1} + \pi_{i+2} P_{i+2,i+1},$$

and substituting $P_{i+1,i+1} = 1 - P_{i+1,i} - P_{i+1,i+2}$ along with the inductive hypothesis $\pi_i P_{i,i+1} = \pi_{i+1} P_{i+1,i}$, everything cancels down to

$$\pi_{i+1} P_{i+1,i+2} = \pi_{i+2} P_{i+2,i+1},$$

completing the induction. $\square$

So the Ehrenfest urn didn't just *happen* to satisfy detailed balance – any chain with that skeleton must. The probabilistic explanation is the one we gave above: to travel from i to j the chain must cross each intermediate edge, and every crossing of an edge in one direction must (in the long run) be matched by a crossing in the other direction, since the chain cannot go round any other way.

Let's do one more substantial example, which is a classical model from statistical physics.

Example 17.8.8 (The Ehrenfest Urn)

Two chambers are connected by a small hole, and contain N gas molecules between them. At each time step, a molecule is chosen uniformly at random and moves through the hole to the other chamber. Let X_n be the number of molecules in the left chamber, so X_n is a Markov chain on $\{0, 1, \dots, N\}$ with

$$P_{i,i-1} = \frac{i}{N}, \quad P_{i,i+1} = \frac{N-i}{N}.$$

For example, when $N = 3$ the chain looks as follows.

The state space is line-like, so we optimistically try detailed balance:

$$\pi_i P_{i,i+1} = \pi_{i+1} P_{i+1,i} \implies \pi_{i+1} = \pi_i \cdot \frac{N-i}{i+1}.$$

Iterating this down to π_0 gives

$$\pi_i = \pi_0 \cdot \frac{N(N-1) \cdots (N-i+1)}{i!} = \pi_0 \binom{N}{i},$$

and since $\sum_i \binom{N}{i} = 2^N$, normalising gives

$$\pi_i = \binom{N}{i} \frac{1}{2^N}.$$

So in equilibrium, the number of molecules in the left chamber is distributed as $\text{Bin}(N, 1/2)$ – exactly as if each molecule independently tossed a fair coin to choose its chamber. The chain is reversible: watching the molecules shuffle back and forth, we cannot tell which way time is flowing.

The mean return times contain a famous lesson. The mean return time to a half-full chamber is

$$m_{N/2} = \frac{1}{\pi_{N/2}} = \frac{2^N}{\binom{N}{N/2}} \approx \sqrt{\frac{\pi N}{2}},$$

(taking N even, and using Stirling), which is tiny. But the mean return time to the state where the left chamber is *empty* is

$$m_0 = \frac{1}{\pi_0} = 2^N,$$

which for N of the order of Avogadro's number is unimaginably vast. So the chain *is* recurrent – all the air in the room will eventually gather in one half of it! – but the expected time for this is so astronomically long that we will never observe it. This resolves (or at least, quantifies) the apparent conflict between microscopic reversibility and the macroscopic arrow of time.

§17.8.3 Random Walks on Graphs

We finish with a family of Markov chains where detailed balance works beautifully: random walks on graphs. Let $G = (V, E)$ be a finite connected graph. The **simple random walk on G** is the Markov chain with state space V in which, at each step, the walker moves to a uniformly random neighbour of its current vertex. Writing $d(v)$ for the degree of the vertex v , the transition matrix is

$$P_{u,v} = \begin{cases} \frac{1}{d(u)} & \text{if } uv \in E, \\ 0 & \text{otherwise.} \end{cases}$$

Connectedness of G makes the chain irreducible. So, what is the invariant distribution? Following our own advice, we try detailed balance first. For an edge $uv \in E$, the equations read

$$\pi_u \cdot \frac{1}{d(u)} = \pi_v \cdot \frac{1}{d(v)},$$

which says exactly that $\pi_v \propto d(v)$. Since $\sum_v d(v) = 2|E|$ (each edge is counted from both ends), normalising gives the following.

Proposition 17.8.9 (Invariant Distribution for Random Walk on a Graph)

The simple random walk on a finite connected graph $G = (V, E)$ is reversible, with invariant distribution

$$\pi_v = \frac{d(v)}{2|E|}, \quad v \in V.$$

In equilibrium, the walker is found at each vertex with probability proportional to its degree – well-connected vertices are visited more. A special case worth noting: if G is *regular* (all degrees equal), the invariant distribution is uniform. So a random walk on the vertices of a cube, or on a cycle, spends its time equally amongst all vertices in the long run – and, for instance, a walker on the corners of a cube takes on average $m_v = 1/\pi_v = 8$ steps to return to its starting corner.

Let's see the general case on a concrete graph.

Example 17.8.10 (A Walk on a Small Graph)

Consider the simple random walk on the graph below, where each vertex is labelled with its invariant probability $\pi_v = d(v)/2|E|$; here $|E| = 6$, so $2|E| = 12$.

The vertex c , with its four edges, carries the most mass, while the pendant vertex e carries the least. By our earlier theory, we can immediately read off facts that would be quite painful to compute directly: for example the mean return time to e is $m_e = 1/\pi_e = 12$, while the mean return time to c is $m_c = 12/4 = 3$.

Aside: The Random Surfer

A relative of the random walk on a graph powers one of the most consequential algorithms ever deployed: Google's *PageRank*. Imagine a 'random surfer' on the web, who at each step clicks a uniformly random link on their current page – a random walk on the (directed!) graph of the web. The importance of a page is then defined to be its invariant probability π_v : the long-run proportion of time the surfer spends there, which by the ergodic theorem is a genuinely meaningful quantity. A page is important if many important pages link to it, and this apparently circular definition is resolved exactly by the equation $\pi = \pi P$.

Because the web graph is directed, the lovely formula $\pi_v \propto d(v)$ no longer applies (detailed balance fails – links very much have a preferred direction), and the chain is far from irreducible. The fix is a version of the lazy chain trick: with small probability at each step, the surfer teleports to a uniformly random page. This makes the chain

irreducible and aperiodic, so a unique invariant distribution exists and can be found by simply iterating $\lambda \mapsto \lambda P$ – which, by convergence to equilibrium, approaches π from any starting guess.

Example 17.8.11 (The Knight on a Chessboard)

As a parting example: place a knight on the corner square of an otherwise empty chessboard, and let it make uniformly random legal moves. How long, on average, until it first returns to its starting corner?

This looks like a nightmare of a computation, but the theory makes it almost trivial. The knight performs a simple random walk on the graph whose vertices are the 64 squares, with edges given by legal knight moves. This graph is connected, so

$$m_{\text{corner}} = \frac{1}{\pi_{\text{corner}}} = \frac{2|E|}{d(\text{corner})} = \frac{\sum_v d(v)}{d(\text{corner})}.$$

Summing the degrees over the whole board^a gives 336, and a corner square has exactly 2 knight moves, so

$$m_{\text{corner}} = \frac{336}{2} = 168.$$

A lovely answer, obtained with essentially no computation – a fitting note on which to end the course.

^aThe degrees form the pattern: corner squares have 2 moves, squares adjacent to corners have 3 or 4, central squares have 8, and so on; carrying out the count gives $\sum_v d(v) = 336$.

Epilogue: The Big Picture

This is a good point to pause and assemble the whole story in one place. For an *irreducible* Markov chain, everything we have proved organises the possible behaviours into a clean trichotomy.

- *Transient*. The chain visits each state only finitely often, and escapes to infinity: $\mathbb{P}(T_i < \infty \mid X_0 = i) < 1$ and $\sum_n p_{i,i}(n) < \infty$. There is no invariant distribution, and $p_{i,j}(n) \rightarrow 0$. The long-run proportion of time in each state is 0. (Example: the simple random walk on $\mathbb{Z}^3$.)
- *Null recurrent*. The chain returns to each state infinitely often, but with infinite mean return time. Invariant *measures* exist and are unique up to scaling, but have infinite mass, so there is still no invariant *distribution*; again $p_{i,j}(n) \rightarrow 0$ (given aperiodicity) and the long-run proportions are 0. The chain is recurrent but only just. (Example: the simple random walk on $\mathbb{Z}$ or $\mathbb{Z}^2$.)
- *Positive recurrent*. Mean return times are finite, and there is a unique invariant distribution π , given by $\pi_i = 1/m_i$. The long-run proportion of time spent in state i is π_i almost surely (the ergodic theorem, no aperiodicity needed), and if the chain is additionally aperiodic then $\mathbb{P}(X_n = i) \rightarrow \pi_i$ from any initial distribution (convergence to equilibrium). (Examples: every finite irreducible chain, and drifting walks like the reflected biased walk.)

For finite state spaces, only the third behaviour is possible for irreducible chains, which

is why finite chains are so pleasant: an invariant distribution always exists, and irreducibility plus aperiodicity guarantees convergence to it.

Finally, the theory of time reversal gives a practical route to finding π : solve the detailed balance equations if you can (as for birth-death chains, the Ehrenfest urn, and random walks on graphs), and fall back on $\pi = \pi P$ when the chain carries a genuine probability current around a cycle. With these tools, remarkably many questions – mean return times, long-run proportions, limiting probabilities – reduce to a small amount of linear algebra.

Of course, this is only the beginning of the story of Markov processes. Natural next steps include chains that evolve in *continuous* time (the subject of the Part II course ‘Applied Probability’, where the exponential distribution takes centre stage), the quantitative study of *how fast* chains mix (as in the card shuffling aside), and the theory of martingales, which generalises the ‘restart and forget’ philosophy of the strong Markov property into one of the most powerful toolkits in modern probability. The reader is warmly encouraged to keep walking.

18 Methods

A large amount of physics (and indeed applied mathematics as a whole) is governed by a rather small collection of partial differential equations: the wave equation, the diffusion equation and Laplace's equation. The aim of this course is to build up a toolbox of techniques for solving these equations, and equations like them. The tools themselves – Fourier series, Sturm–Liouville theory, Green's functions, Fourier transforms and the method of characteristics – are united by a single underlying idea, that of *linearity*. Almost everything we do will amount to breaking a complicated problem into simple pieces (usually eigenfunctions or point sources), solving each piece, and adding up the results.

This article constitutes my notes for the 'Methods' course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§18.1 Fourier Series

§18.1.1 Periodic Functions

We will begin our study of methods and in particular Fourier series by considering some periodic functions.

Definition 18.1.1 (Periodic)

A function $f(x)$ is **periodic** if $f(x + T) = f(x)$ for all x , where T is the **period**.

Example 18.1.2 (Simple Harmonic Motion)

Many physical objects are described by *simple harmonic motion*, with the position given by

$$y = A \sin \omega t.$$

We call A the **amplitude**, and the period is $T = 2\pi/\omega$. The **frequency** is $1/T$.

Fourier series is all about trying to write periodic functions as particular sums of sines and cosines. Consider the set of functions

$$g_n(x) = \cos \frac{n\pi x}{L}, \quad \text{and} \quad h_n(x) = \sin \frac{n\pi x}{L},$$

where we take $n \in \mathbb{N}$. These functions are periodic with period $2L$.

You may recall the following set of identities:

$$\begin{aligned} \cos A \cos B &= \frac{1}{2} (\cos(A - B) + \cos(A + B)) \\ \sin A \sin B &= \frac{1}{2} (\cos(A - B) - \cos(A + B)) \\ \sin A \cos B &= \frac{1}{2} (\sin(A - B) + \sin(A + B)). \end{aligned}$$

We are going to try and define an inner product on this domain $[0, 2L]$, and using that we will be able to multiply these functions together and talk about their relative orthogonality.

Definition 18.1.3

We define the inner product $\langle f, g \rangle = \int_0^{2L} f(x)g(x) \, dx$.

We can then obtain some orthogonality conditions for h_n and g_n with respect to this inner product. We can compute for $n \neq m$

$$\begin{aligned} \langle h_n, h_m \rangle &= \int_0^{2L} \sin \frac{n\pi x}{L} \sin \frac{m\pi x}{L} \, dx \\ &= \frac{1}{2} \int_0^{2L} \left(\cos \frac{(n-m)\pi}{L} x - \cos \frac{(n+m)\pi}{L} x \right) \, dx \\ &= \frac{1}{2} \frac{L}{\pi} \left[\frac{\sin(n-m)\pi x/L}{n-m} - \frac{\sin(n+m)\pi x/L}{n+m} \right]_0^{2L} \\ &= 0, \end{aligned}$$

and for $n = m$

$$\begin{aligned} \langle h_n, h_n \rangle &= \int_0^{2L} \sin^2 \frac{n\pi x}{L} \, dx \\ &= \int_0^{2L} \frac{1}{2} \left(1 - \cos \frac{2\pi n x}{L} \right) \, dx \\ &= L. \end{aligned}$$

Hence we obtain the orthogonality condition

$$\langle h_n, h_m \rangle = \begin{cases} L\delta_{mn} & \text{if } n, m \neq 0, \\ 0 & \text{if } m = 0. \end{cases}$$

Similarly, it's straightforward to check that

$$\langle g_n, g_m \rangle = \begin{cases} L\delta_{mn} & \text{if } n, m \neq 0, \\ 2L\delta_{0n} & \text{if } m = 0. \end{cases}$$

and

$$\langle h_n, g_m \rangle = 0.$$

These orthogonality conditions are important because we are going to use these functions as a complete orthogonal set which spans the space of ‘well-behaved periodic functions’.

§18.1.2 Definition of a Fourier Series

We can express any ‘well-behaved’ periodic function $f(x)$ with period $2L$ as

$$f(x) = \frac{1}{2}a_0 + \sum_{n=1}^{\infty} a_n \cos \frac{n\pi x}{L} + \sum_{n=1}^{\infty} b_n \sin \frac{n\pi x}{L},$$

where a_n, b_n are constants such that the RHS is convergent for all x where f is continuous. At a discontinuity, the Fourier series approaches the midpoint of the upper and lower limits at that point.

Consider taking the inner product $\langle h_m, f \rangle$ and substitute the expression for f above, to get

$$\int_0^{2L} \sin \frac{m\pi x}{L} f(x) \, dx = \sum_{n=1}^{\infty} L b_n \delta_{nm} = L b_m.$$

Hence we find that (doing something similar with g_n)

$$b_n = \frac{1}{L} \int_0^{2L} f(x) \sin \frac{n\pi x}{L} \, dx,$$

and $a_n = \frac{1}{L} \int_0^{2L} f(x) \cos \frac{n\pi x}{L} \, dx.$

Now, this expression for a_n includes the case $n = 0$, and says that $\frac{1}{2}a_0$ is the average value of the function. Also, the range of integration is one period, and we can equivalently integrate over $[-L, L]$ instead of $[0, 2L]$.

Example 18.1.4 (The Sawtooth Wave)

Consider the function $f(x) = x$ for $-L \leq x \leq L$, with the function being periodic elsewhere.

Here we have

$$a_n = \frac{1}{L} \int_{-L}^L x \cos \frac{n\pi x}{L} \, dx = 0, \quad (\text{integrating an odd function})$$

for all n , and

$$\begin{aligned} b_n &= \frac{2}{L} \int_0^L x \sin \frac{n\pi x}{L} \, dx \\ &= \frac{-2}{n\pi} \left[x \cos \frac{n\pi x}{L} \right]_0^L + \frac{2}{n\pi} \int_0^L \cos \frac{n\pi x}{L} \, dx \\ &= -\frac{2L}{n\pi} \cos n\pi + \frac{2L}{(n\pi)^2} \sin n\pi \\ &= \frac{2L}{n\pi} (-1)^{n+1}. \end{aligned}$$

So the sawtooth Fourier series is

$$2L \sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n\pi} \sin\left(\frac{n\pi x}{L}\right) = \frac{2L}{\pi} \left[\sin\left(\frac{\pi x}{L}\right) - \frac{1}{2} \sin\left(\frac{2\pi x}{L}\right) + \frac{1}{3} \sin\left(\frac{3\pi x}{L}\right) + \cdots \right].$$

which is slowly convergent.

§18.1.3 The Dirichlet Conditions (Fourier's Theorem)

So we need 'well behaved' functions for what we have discussed about Fourier series to work, and for a Fourier series for f to be unique. But what exactly does it mean for a function to be 'well behaved' in this context? This is specified by the Dirichlet conditions, also known as Fourier's theorem.

Theorem 18.1.5 (The Dirichlet Conditions)

If f is a bounded periodic function with period $2L$ and finitely many minima, maxima and discontinuities on $0 \leq x \leq 2L$, then the Fourier series converges to $f(x)$ at all points where f is continuous, and at discontinuities converges to $\frac{1}{2}(f(x_+) + f(x_-))$.

One might note that these conditions are *much weaker* than those needed for Taylor series, but it does eliminate pathological functions such as $\sin 1/x$, $1/x$ and the indicator function on the rationals. The converse of this is *not* true, for example $\sin 1/x$ has a well defined Fourier series.

The proof of this result is *too* difficult, but is best done using complex methods so we will not dwell on it in this course.

The rate of convergence of the Fourier series depends on the 'smoothness' of the function.

Theorem 18.1.6 (Rate of Convergence of Fourier Series)

If $f(x)$ has continuous derivatives up to a p th derivative which is discontinuous, then the Fourier series converges as $\mathcal{O}(n^{-(p+1)})$ as $n \rightarrow \infty$.

Example 18.1.7 (Square Wave)

Consider the function

$$f(x) = \begin{cases} 1 & \text{if } 0 \leq x < 1, \\ -1 & \text{if } -1 \leq x < 0. \end{cases}$$

This function has discontinuous $p = 0$ th derivative (the function is discontinuous!),

and the Fourier series of this function is given by

$$f(x) = 4 \sum_{m=1}^{\infty} \frac{\sin(2m-1)\pi x}{(2m-1)\pi}.$$

It is worth pausing to look at how the partial sums of this series actually behave. Below is the square wave along with the partial sums taking $m \leq 2$ and $m \leq 8$.

Away from the discontinuities the partial sums settle down quite quickly, but near each jump they consistently *overshoot* by roughly 9% of the size of the jump, and this overshoot does not go away as we take more terms – it just gets squeezed into a narrower and narrower region around the discontinuity. This is the **Gibbs phenomenon**. It doesn't contradict the Dirichlet conditions (at each *fixed* x the series still converges), but it does tell us that the convergence is not uniform near a jump.

Integration of Fourier Series

As a general principle, it is *always* valid to integrate the Fourier series of $f(x)$ term-wise to obtain

$$F(x) = \int_{-L}^x f(u) \, du,$$

because $F(x)$ satisfies the Dirichlet conditions if $f(x)$ does.

Differentiation of Fourier Series

As a general principle, you must *take care* when differentiating a Fourier series term-wise. Let's look at an example.

Example 18.1.8 (Differentiating the Square Wave)

Consider the clearly non-differentiable square wave function, defined in [Example 18.1.7](#). We had

$$f(x) = 4 \sum_{m=1}^{\infty} \frac{\sin(2m-1)\pi x}{(2m-1)\pi}.$$

We can try and differentiate this term-wise to get

$$f'(x) \stackrel{?}{=} 4 \sum_{m=1}^{\infty} \cos(2m-1)\pi x,$$

but this series is unbounded!

So we need to be careful. Here's the result about what we can do with differentiation.

Theorem 18.1.9

If $f(x)$ is continuous and satisfies the Dirichlet conditions, and $f'(x)$ satisfies the Dirichlet conditions, then $f'(x)$ can be found by term-wise differentiation of the Fourier series of $f(x)$.

§18.1.4 Parseval's Theorem

Parseval's theorem is a relation between the integral of the square of a function and the square of the Fourier coefficients:

$$\begin{aligned} \int_0^{2L} [f(x)]^2 dx &= \int_0^{2L} dx \left[\frac{1}{2}a_0 + \sum_n a_n \cos \frac{n\pi x}{L} + \sum_n b_n \sin \frac{n\pi x}{L} \right]^2 \\ &= \int_0^{2L} dx \left[\frac{1}{4}a_0^2 + \sum_n a_n^2 \cos^2 \frac{n\pi x}{L} + \sum_n b_n^2 \sin^2 \frac{n\pi x}{L} \right] \\ &= L \left[\frac{1}{2}a_0^2 + \sum_{n=1}^{\infty} (a_n^2 + b_n^2) \right], \end{aligned}$$

where the cross terms all vanish by orthogonality.

This result is also called the completeness relation, since the LHS $\geq$ RHS if any of the basis functions are missing.

Example 18.1.10 (The Basel Problem)

Consider the sawtooth wave $f(x) = x$ on $-L \leq x \leq L$. Then the LHS is

$$\int_{-L}^L x^2 dx = \frac{2}{3}L^3,$$

and the RHS is

$$L \sum_{n=1}^{\infty} \frac{4L^2}{n^2\pi^2} = \frac{4L^3}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2},$$

and thus $\sum_{n=1}^{\infty} 1/n^2 = \pi^2/6$.

§18.1.5 Alternative Fourier Series

There are some alternative forms of Fourier series.

Half-Range Series

Consider $f(x)$ defined only on $0 \leq x < L$. We can extend its range over $-L \leq x < L$ in two simple ways:

1. Require f to be odd, with $f(-x) = -f(x)$. Then considering its Fourier series we would have $a_n = 0$ for all n (as $\cos$ is even), and

$$b_n = \frac{2}{L} \int_0^L f(x) \sin \frac{n\pi x}{L} dx.$$

This implies that $f(x) = \sum_{n=1}^{\infty} b_n \sin \frac{n\pi x}{L}$, which is a **Fourier sine series**.

2. Require f to be even, with $f(-x) = f(x)$, Then $b_n = 0$, and

$$a_n = \frac{2}{L} \int_0^L f(x) \cos \frac{n\pi x}{L} dx,$$

so $f(x) = \frac{1}{2}a_0 + \sum_{n=1}^{\infty} a_n \cos \frac{n\pi x}{L}$, which is a **Fourier cosine series**.

Complex Representation

Recall that we can write

$$\cos \frac{n\pi x}{L} = \frac{1}{2} (e^{in\pi x/L} + e^{-in\pi x/L}) \quad \text{and} \quad \sin \frac{n\pi x}{L} = \frac{1}{2i} (e^{in\pi x/L} - e^{-in\pi x/L}).$$

So the Fourier series is

$$\begin{aligned} f(x) &= \frac{1}{2}a_0 + \sum_{n=1}^{\infty} a_n \cos \frac{n\pi x}{L} + \sum_{n=1}^{\infty} b_n \sin \frac{n\pi x}{L} \\ &= \frac{1}{2}a_0 + \sum_{n=1}^{\infty} \frac{1}{2} (a_n - ib_n) e^{in\pi x/L} + \sum_{n=1}^{\infty} \frac{1}{2} (a_n + ib_n) e^{-in\pi x/L} \\ &= \sum_{m=-\infty}^{\infty} c_m e^{im\pi x/L}, \end{aligned}$$

where for $m > 0$, $c_m = \frac{1}{2}(a_m - ib_m)$, for $m < 0$, $c_m = \frac{1}{2}(a_{-m} + ib_{-m})$, and $c_0 = \frac{1}{2}a_0$. Equivalently,

$$c_m = \frac{1}{2L} \int_{-L}^L f(x) e^{-im\pi x/L} dx.$$

§18.1.6 Some Fourier Series Motivations – Self-Adjoint Matrices

We will now review a few results about matrices. Suppose that $\mathbf{u}, \mathbf{v} \in \mathbb{C}^n$ with inner product $\langle \mathbf{u}, \mathbf{v} \rangle = \mathbf{u}^\dagger \mathbf{v}$. The $n \times n$ matrix A is **self-adjoint** or **hermitian** if

$$\langle A\mathbf{u}, \mathbf{v} \rangle = \langle \mathbf{u}, A\mathbf{v} \rangle,$$

that is, if $A^\dagger = A$.

The eigenvalues λ_i and eigenvectors $\mathbf{v}_i$ satisfy

$$A\mathbf{v}_i = \lambda_i \mathbf{v}_i,$$

and have the following properties

- (i) The eigenvalues are real
- (ii) If $\lambda_i \neq \lambda_j$, then the corresponding eigenvectors are orthogonal with $\langle \mathbf{v}_i, \mathbf{v}_j \rangle = 0$
- (iii) We can rescale to create an orthonormal basis $\{\mathbf{v}_1, \dots, \mathbf{v}_n\}$.

Given $\mathbf{b}$, we can solve for $\mathbf{x}$ in the equation

$$A\mathbf{x} = \mathbf{b}.$$

Express $\mathbf{b} = \sum_{i=1}^n b_i \mathbf{v}_i$, and we seek a solution $\mathbf{x} = \sum_{i=1}^n c_i \mathbf{v}_i$. Substituting this into the above equation, we get

$$A\mathbf{x} = \sum_i A c_i \mathbf{v}_i = \sum_i c_i \lambda_i \mathbf{v}_i = \sum_i b_i \mathbf{v}_i.$$

By orthogonality, we can equate coefficients to get $c_i \lambda_i = b_i$, so our solution is

$$\mathbf{x} = \sum_{i=1}^n \frac{b_i}{\lambda_i} \mathbf{v}_i.$$

So once we have a self-adjoint matrix A and have found all of the eigenvalues, we then have a general methodology for solving any matrix equation of the form $A\mathbf{x} = \mathbf{b}$. It turns out that you can do the same with Fourier series!

We can find a general solution to the differential equation for which cosines and sines are the eigenfunctions.

§18.1.7 Solving Inhomogeneous ODEs with Fourier Series

We wish to find $y(x)$ given $f(x)$ for the differential operator

$$\mathcal{L}[y] \equiv -\frac{d^2 y}{dx^2} = f(x).$$

To solve this, we need some boundary conditions, which we will take as $y(0) = y(L) = 0$.

The related eigenvalue problem is

$$\mathcal{L}[y_n] = \lambda_n y_n,$$

with $y_n(0) = y_n(L) = 0$, which has eigenfunctions and eigenvalues

$$y_n(x) = \sin \frac{n\pi x}{L}, \quad \lambda_n = \left(\frac{n\pi}{L}\right)^2.$$

We seek solutions as half-range sine series. To do that, we will try substitute $y(x) = \sum_{n=1}^{\infty} c_n \sin \frac{n\pi x}{L}$, and expand $f(x)$ in terms of its Fourier series, $f(x) = \sum_{n=1}^{\infty} b_n \sin \frac{n\pi x}{L}$, with $b_n = \frac{2}{L} \int_0^L f(x) \sin \frac{n\pi x}{L} dx$.

Substituting this into the differential equation, we get

$$\mathcal{L}[y] = -\frac{d^2}{dx^2} \left(\sum_{n=1}^{\infty} c_n \sin \frac{n\pi x}{L} \right) = \sum_{n=1}^{\infty} c_n \left(\frac{n\pi}{L} \right)^2 \sin \frac{n\pi x}{L}.$$

By orthogonality, we have $c_n \left(\frac{n\pi}{L} \right)^2 = b_n$, so the solution is

$$y(x) = \sum_{n=1}^{\infty} \frac{b_n}{\left(\frac{n\pi}{L} \right)^2} \sin \frac{n\pi x}{L} = \sum_{n=1}^{\infty} \frac{b_n}{\lambda_n} y_n.$$

Example 18.1.11

Consider the ‘square wave’ source given by $f(x) = 1$ for $0 \leq x < 1$, with the function being odd. This function has Fourier series

$$f(x) = 4 \sum_{m=1}^{\infty} \frac{\sin(2m-1)\pi x}{(2m-1)\pi}.$$

So the solution for y must then be

$$y(x) = \sum_n \frac{b_n}{\lambda_n} y_n = 4 \sum_m \frac{\sin(2m-1)\pi x}{((2m-1)\pi)^3},$$

but this is the Fourier series for $y(x) = \frac{1}{2}x(1-x)!$

§18.2 Sturm–Liouville Theory

In the last section we saw that the operator $\mathcal{L} = -d^2/dx^2$ behaves rather like a self-adjoint matrix: it has real eigenvalues, its eigenfunctions (sin and cos) are orthogonal, and expanding in those eigenfunctions lets us solve $\mathcal{L}[y] = f$ essentially by division. The natural question is: *which* differential operators behave like this? The answer is given by Sturm–Liouville theory, which identifies a large class of second-order operators for which the whole eigenfunction machinery goes through.

§18.2.1 Second Order Linear ODEs

We are going to be working with the general second order linear differential operator

$$\mathcal{L}y \equiv \alpha(x)y'' + \beta(x)y' + \gamma(x)y,$$

on an interval $a \leq x \leq b$, and we wish to solve equations of the form $\mathcal{L}y = f(x)$. Recall from Differential Equations that the general solution of such an equation is $y = y_c + y_p$, where the complementary function $y_c = Ay_1 + By_2$ is the general solution of the homogeneous equation $\mathcal{L}y = 0$, and y_p is any particular integral.

To pin down a unique solution we need two extra conditions. These may be **boundary conditions**, specifying something about y at both ends of the interval (say $y(a)$ and $y(b)$), or **initial conditions**, specifying $y(a)$ and $y'(a)$. Boundary conditions of the form $y(a) = y(b) = 0$ are called **homogeneous** boundary conditions. These are less restrictive than they look: if instead we were given $y(a) = c_1$, $y(b) = c_2$, we can subtract off any function u satisfying $\mathcal{L}u = 0$ (or indeed anything convenient) with $u(a) = c_1$, $u(b) = c_2$, and then $y - u$ satisfies homogeneous conditions. We will therefore usually assume our boundary conditions are homogeneous.

As in the previous section, our strategy for solving $\mathcal{L}y = f$ will be to first solve the related eigenvalue problem

$$\mathcal{L}y = \lambda w(x)y,$$

where $w(x)$ is some non-negative **weight function** which will appear naturally in what follows, and then expand everything in sight in terms of the eigenfunctions.

§18.2.2 Sturm–Liouville Form

For complex valued functions on $[a, b]$, we will use the inner product

$$\langle f, g \rangle = \int_a^b f^*(x)g(x) \, dx.$$

Definition 18.2.1 (Sturm–Liouville Form)

A second order differential operator is in **Sturm–Liouville form** if it is written as

$$\mathcal{L}y = -(p(x)y')' + q(x)y,$$

where p is differentiable and positive on (a, b) . The associated eigenvalue problem is $\mathcal{L}y = \lambda wy$, where the weight $w(x)$ is positive.

This might look like a rather restrictive shape for an operator, but it turns out essentially every second order operator we care about can be put in this form. Indeed, suppose we have the eigenvalue problem

$$\alpha(x)y'' + \beta(x)y' + \gamma(x)y = -\lambda\rho(x)y.$$

Multiply the whole equation by some function $F(x)$, which we will choose in a moment. The first two terms become

$$F\alpha y'' + F\beta y' = (F\alpha y')' - (F\alpha)'y' + F\beta y',$$

so if we choose F such that $(F\alpha)' = F\beta$, the y' terms cancel and we have something of Sturm–Liouville type. This condition rearranges to $F'/F = (\beta - \alpha')/\alpha$, which we can integrate to get the *integrating factor*

$$F(x) = \exp\left(\int^x \frac{\beta(t) - \alpha'(t)}{\alpha(t)} \, dt\right).$$

Note $F > 0$ automatically, being an exponential. With this choice,

$$-(F\alpha y')' - F\gamma y = \lambda F\rho y,$$

so we have Sturm–Liouville form with $p = -F\alpha$, $q = -F\gamma$ and $w = F\rho$ (with signs arranged as appropriate for $p, w > 0$).

Example 18.2.2 (The Hermite Equation)

Consider the equation

$$y'' - 2xy' + 2ny = 0.$$

Here $\alpha = 1$ and $\beta = -2x$, so

$$F = \exp\left(\int^x (-2t) \, dt\right) = e^{-x^2},$$

and multiplying through, the equation in Sturm–Liouville form is

$$-(e^{-x^2}y')' = 2ne^{-x^2}y,$$

an eigenvalue problem with eigenvalue $2n$ and weight function $w = e^{-x^2}$.

§18.2.3 Self-Adjoint Operators

We can now say what it means for a differential operator to be self-adjoint, in direct analogy with matrices.

Definition 18.2.3 (Self-Adjoint Operator)

The operator $\mathcal{L}$ is **self-adjoint** on $[a, b]$, for a given class of functions with given boundary conditions, if

$$\langle y_1, \mathcal{L}y_2 \rangle = \langle \mathcal{L}y_1, y_2 \rangle$$

for all y_1, y_2 in that class.

The point of Sturm–Liouville form is that it makes self-adjointness almost automatic. Take $\mathcal{L}y = -(py')' + qy$ with everything real, and compute

$$\begin{aligned} \langle y_1, \mathcal{L}y_2 \rangle - \langle \mathcal{L}y_1, y_2 \rangle &= \int_a^b [-y_1(py_2')' + y_1qy_2 + y_2(py_1')' - y_2qy_1] \, dx \\ &= \int_a^b [y_2(py_1')' - y_1(py_2')'] \, dx \\ &= \int_a^b [(py_1'y_2)' - (py_1y_2)'] \, dx \\ &= \left[p(y_1'y_2 - y_1y_2') \right]_a^b, \end{aligned}$$

where in the third line we added and subtracted $py_1'y_2'$ inside the integral. So $\mathcal{L}$ is self-adjoint precisely when the boundary term

$$\left[p(y_1'y_2 - y_1y_2') \right]_a^b = 0.$$

This vanishes for a number of natural types of boundary conditions:

- (i) $y(a) = y(b) = 0$, or $y'(a) = y'(b) = 0$, or more generally $y + ky' = 0$ at each endpoint (the **regular Sturm–Liouville problem**);
- (ii) periodic boundary conditions, where y, y' and p take the same values at a and b ;
- (iii) singular endpoints where $p(a) = p(b) = 0$, provided y stays bounded;
- (iv) any combination of the above, one condition at each end.

§18.2.4 Properties of the Eigenfunctions

Now suppose $\mathcal{L}$ is self-adjoint with the boundary conditions in play, and consider the eigenvalue problem

$$\mathcal{L}y_n = \lambda_n w y_n,$$

with $w > 0$. Just as for hermitian matrices, we get a package of results: real eigenvalues, orthogonal eigenfunctions, and (though we won't prove it) completeness.

Proposition 18.2.4 (Eigenvalues are Real)

The eigenvalues of a self-adjoint operator $\mathcal{L}$ (with weight w) are real, and the eigenfunctions can be taken to be real valued.

Proof. Suppose $\mathcal{L}y_n = \lambda_n w y_n$. Since $\mathcal{L}$ and w are real, taking complex conjugates gives $\mathcal{L}y_n^* = \lambda_n^* w y_n^*$. Then using self-adjointness,

$$0 = \langle y_n, \mathcal{L}y_n \rangle - \langle \mathcal{L}y_n, y_n \rangle = (\lambda_n - \lambda_n^*) \int_a^b w |y_n|^2 dx.$$

The integral is strictly positive since $w > 0$ and $y_n \not\equiv 0$, so $\lambda_n = \lambda_n^*$, that is, λ_n is real. Given this, the real and imaginary parts of y_n separately satisfy the eigenvalue equation, so we may take our eigenfunctions to be real. $\square$

Proposition 18.2.5 (Orthogonality of Eigenfunctions)

If $\mathcal{L}y_n = \lambda_n w y_n$ and $\mathcal{L}y_m = \lambda_m w y_m$ with $\lambda_n \neq \lambda_m$, then

$$\int_a^b w y_n y_m dx = 0.$$

Proof. By self-adjointness (taking everything real),

$$0 = \int_a^b (y_m \mathcal{L}y_n - y_n \mathcal{L}y_m) dx = (\lambda_n - \lambda_m) \int_a^b w y_n y_m dx,$$

and since $\lambda_n \neq \lambda_m$ the integral must vanish. $\square$

We say the eigenfunctions are **orthogonal with respect to the weight w** , and we write

$$\langle f, g \rangle_w = \int_a^b w f^* g dx$$

for the corresponding weighted inner product. It's frequently useful to normalise, defining

$$Y_n(x) = \frac{y_n(x)}{\left(\int_a^b w y_n^2 dx\right)^{1/2}}, \quad \text{so that} \quad \langle Y_n, Y_m \rangle_w = \delta_{nm}.$$

The final property, which we will assume without proof, is **completeness**: the eigenfunctions of a Sturm–Liouville problem span the space of ‘well-behaved’ functions on $[a, b]$. That is, any such f can be expanded as

$$f(x) = \sum_{n=1}^{\infty} a_n y_n(x).$$

Taking the weighted inner product with y_m and using orthogonality picks out the coefficients:

$$a_n = \frac{\int_a^b w y_n f dx}{\int_a^b w y_n^2 dx}.$$

Fourier series are exactly the special case $\mathcal{L} = -d^2/dx^2$, $w = 1$, with periodic boundary conditions.

Remark. For the regular Sturm–Liouville problem one can show a little more: the eigenvalues are simple (non-degenerate) and form an increasing sequence $\lambda_1 < \lambda_2 < \dots \rightarrow \infty$. The proof of simplicity is a nice exercise: if u, v are eigenfunctions with the same eigenvalue, then $(p(uv' - u'v))' = 0$, and evaluating the Wronskian-like quantity $p(uv' - u'v)$ at an endpoint shows it vanishes identically, forcing u and v to be proportional.

§18.2.5 Completeness and Parseval's Identity

Let's investigate what completeness really says. Define the partial sum

$$S_N(x) = \sum_{n=1}^N a_n y_n(x),$$

with a_n as above, and consider the mean-square error

$$\epsilon_N = \int_a^b w [f(x) - S_N(x)]^2 dx.$$

Expanding the square and using orthogonality,

$$\begin{aligned} \epsilon_N &= \int_a^b w f^2 dx - 2 \sum_{n=1}^N a_n \int_a^b w f y_n dx + \sum_{n=1}^N a_n^2 \int_a^b w y_n^2 dx \\ &= \int_a^b w f^2 dx - \sum_{n=1}^N a_n^2 \int_a^b w y_n^2 dx. \end{aligned}$$

Completeness is the statement that $\epsilon_N \rightarrow 0$ as $N \rightarrow \infty$; we say S_N **converges in the mean** to f . Note this is a ‘global’ notion of convergence, weaker than pointwise convergence. Sending $N \rightarrow \infty$ above gives the general form of Parseval's identity,

$$\int_a^b w f^2 dx = \sum_{n=1}^{\infty} a_n^2 \int_a^b w y_n^2 dx,$$

and if any eigenfunctions are missing from our set we only get the inequality $\geq$, which is **Bessel's inequality**.

There is one more thing worth extracting from this computation. Suppose we fix N and ask: what choice of coefficients c_n minimises the error $\int_a^b w (f - \sum_{n \leq N} c_n y_n)^2 dx$? Differentiating with respect to c_n ,

$$\frac{\partial \epsilon_N}{\partial c_n} = -2 \int_a^b w y_n \left(f - \sum_{m=1}^N c_m y_m \right) dx = -2 \left(\int_a^b w f y_n dx - c_n \int_a^b w y_n^2 dx \right),$$

which vanishes exactly when $c_n = a_n$ (and this is a minimum, since $\partial^2 \epsilon_N / \partial c_n^2 = 2 \int w y_n^2 dx > 0$). So truncated eigenfunction expansions are the *best possible* approximations in the mean-square sense – the first N coefficients don't need revising when you decide to take $N + 1$ terms.

§18.2.6 Legendre's Equation

Let's now meet the most important Sturm–Liouville problem in this course after Fourier series. **Legendre's equation** is

$$(1 - x^2)y'' - 2xy' + \lambda y = 0, \quad -1 \leq x \leq 1,$$

with the boundary conditions that y remains finite at $x = \pm 1$. This is already in Sturm–Liouville form:

$$-((1-x^2)y')' = \lambda y,$$

with $p = 1 - x^2$, $q = 0$ and $w = 1$. Note that $p(\pm 1) = 0$, so the endpoints are singular points of the equation, and the finiteness condition is exactly the sort of self-adjoint compatible boundary condition we saw earlier.

We solve by a power series about $x = 0$, writing $y = \sum_n c_n x^n$. Substituting in and comparing coefficients of x^n gives

$$(n+2)(n+1)c_{n+2} - n(n-1)c_n - 2nc_n + \lambda c_n = 0,$$

that is, the recursion

$$c_{n+2} = \frac{n(n+1) - \lambda}{(n+1)(n+2)} c_n.$$

Specifying c_0 and c_1 gives two independent solutions, one even and one odd:

$$y_{\text{even}} = c_0 \left[1 - \frac{\lambda}{2!}x^2 + \frac{(6-\lambda)(-\lambda)}{4!}x^4 + \cdots \right], \quad y_{\text{odd}} = c_1 \left[x + \frac{(2-\lambda)}{3!}x^3 + \cdots \right].$$

Now here's the crucial point. As $n \rightarrow \infty$ we have $c_{n+2}/c_n \rightarrow 1$, so these series behave like geometric series in x^2 and diverge at $x = \pm 1$ – one can check they blow up logarithmically, violating our boundary conditions. The only way to get an acceptable solution is for the series to *terminate*, which happens exactly when

$$\lambda = \ell(\ell+1) \quad \text{for some } \ell \in \mathbb{N},$$

killing the numerator at $n = \ell$. For each such λ , one of y_{even} , y_{odd} becomes a polynomial of degree ℓ (and the other still diverges, so we discard it).

Definition 18.2.6 (Legendre Polynomials)

The **Legendre polynomial** $P_\ell(x)$ is the degree ℓ polynomial solution of Legendre's equation with $\lambda = \ell(\ell+1)$, normalised so that $P_\ell(1) = 1$.

The first few are

$$P_0 = 1, \quad P_1 = x, \quad P_2 = \frac{3x^2 - 1}{2}, \quad P_3 = \frac{5x^3 - 3x}{2}, \quad P_4 = \frac{35x^4 - 30x^2 + 3}{8}.$$

P_ℓ has the same parity as ℓ and has exactly ℓ zeros in $(-1, 1)$, so the polynomials oscillate more and more as ℓ grows – exactly like the higher Fourier modes.

Because they are eigenfunctions of a self-adjoint problem with distinct eigenvalues, the Legendre polynomials are automatically orthogonal:

$$\int_{-1}^1 P_n(x)P_m(x) \, dx = 0 \quad \text{for } n \neq m,$$

and one can compute the normalisation

$$\int_{-1}^1 P_n(x)^2 \, dx = \frac{2}{2n+1}.$$

There are a number of useful ways to generate the P_ℓ without solving the recursion each time. There is **Rodrigues' formula**

$$P_\ell(x) = \frac{1}{2^\ell \ell!} \frac{d^\ell}{dx^\ell} (x^2 - 1)^\ell,$$

and the **generating function**

$$\frac{1}{\sqrt{1-2xt+t^2}} = \sum_{\ell=0}^{\infty} P_\ell(x)t^\ell,$$

which we shall derive when we study Laplace's equation (it is secretly the potential of a point charge). There are also recursion relations such as

$$\begin{aligned} (\ell+1)P_{\ell+1}(x) &= (2\ell+1)xP_\ell(x) - \ell P_{\ell-1}(x), \\ \text{and } (2\ell+1)P_\ell(x) &= \frac{d}{dx} [P_{\ell+1}(x) - P_{\ell-1}(x)]. \end{aligned}$$

Since the Legendre polynomials form a complete orthogonal set on $[-1, 1]$, any well-behaved f on $[-1, 1]$ has a **Fourier–Legendre series**

$$f(x) = \sum_{\ell=0}^{\infty} a_\ell P_\ell(x), \quad a_\ell = \frac{2\ell+1}{2} \int_{-1}^1 f(x)P_\ell(x) \, dx.$$

Note that unlike Fourier series, no periodicity of f is required – the boundary conditions here were just finiteness.

§18.2.7 Solving Inhomogeneous ODEs by Eigenfunction Expansion

We now have everything needed to run the ‘self-adjoint matrix’ strategy in general. Suppose we want to solve

$$\mathcal{L}y = f(x) = w(x)F(x)$$

on $[a, b]$ with homogeneous boundary conditions, where $\mathcal{L}$ is in Sturm–Liouville form with eigenfunctions $\mathcal{L}y_n = \lambda_n w y_n$. Expand both the solution and the source:

$$y(x) = \sum_n c_n y_n(x), \quad F(x) = \sum_n a_n y_n(x),$$

where the a_n are known:

$$a_n = \frac{\int_a^b w F y_n \, dx}{\int_a^b w y_n^2 \, dx}.$$

Substituting,

$$\mathcal{L}y = \sum_n c_n \mathcal{L}y_n = w \sum_n c_n \lambda_n y_n = w \sum_n a_n y_n,$$

and by orthogonality we can equate coefficients, giving $c_n = a_n/\lambda_n$. So

$$y(x) = \sum_{n=1}^{\infty} \frac{a_n}{\lambda_n} y_n(x),$$

provided no $\lambda_n = 0$.

A common variant includes a driving term at fixed ‘frequency’: for the equation

$$\mathcal{L}y - \tilde{\lambda}wy = f(x),$$

with $\tilde{\lambda}$ a fixed constant, exactly the same computation gives

$$y(x) = \sum_{n=1}^{\infty} \frac{a_n}{\lambda_n - \tilde{\lambda}} y_n(x).$$

Notice what happens as $\tilde{\lambda}$ approaches an eigenvalue λ_n with $a_n \neq 0$: the response blows up. This is *resonance*, seen here in complete generality.

Towards Green’s Functions

Let’s rewrite our solution in a rather suggestive way. Substituting the integral formula for a_n into the solution, and writing $N_n = \int_a^b w y_n^2 dx$,

$$y(x) = \sum_{n=1}^{\infty} \frac{y_n(x)}{\lambda_n N_n} \int_a^b w(\xi) F(\xi) y_n(\xi) d\xi = \int_a^b \underbrace{\left(\sum_{n=1}^{\infty} \frac{y_n(x) y_n(\xi)}{\lambda_n N_n} \right)}_{G(x, \xi)} \underbrace{w(\xi) F(\xi)}_{f(\xi)} d\xi.$$

That is,

$$y(x) = \int_a^b G(x, \xi) f(\xi) d\xi, \quad \text{where} \quad G(x, \xi) = \sum_{n=1}^{\infty} \frac{y_n(x) y_n(\xi)}{\lambda_n N_n}.$$

The function G , called the **Green’s function**, depends only on $\mathcal{L}$ and the boundary conditions – *not* on the source f . It acts as a kind of inverse operator

$$\mathcal{L}^{-1} = \int_a^b d\xi G(x, \xi),$$

in perfect analogy with $\mathbf{x} = A^{-1}\mathbf{b}$ for matrices. We will return to Green’s functions in earnest later in the course, where we will construct them directly (without infinite sums) and interpret them as responses to point sources.

§18.3 The Wave Equation

It’s time to put our machinery to work on an actual partial differential equation. The star of this section is the **wave equation**

$$\frac{1}{c^2} \frac{\partial^2 y}{\partial t^2} = \frac{\partial^2 y}{\partial x^2},$$

which governs (among many other things) the small vibrations of a stretched string.

§18.3.1 Waves on an Elastic String

Let's first see where the equation comes from. Consider a stretched elastic string with tension T and linear mass density μ , with ends fixed at $x = 0$ and $x = L$, and let $y(x, t)$ be the (small) transverse displacement. We make the key assumption that displacements are small, in the sense that $|\partial y / \partial x| \ll 1$.

Consider the segment of string between x and $x + \delta x$. Tension pulls the segment along the string at each end: at the right end at a small angle θ_2 to the horizontal, and at the left end at angle θ_1 . Resolving horizontally, since the string doesn't move sideways,

$$T_1 \cos \theta_1 = T_2 \cos \theta_2,$$

and as $\cos \theta = 1 + O(\theta^2)$, the tension is uniform along the string to leading order: $T_1 \approx T_2 = T$. Resolving vertically, using $\sin \theta \approx \tan \theta = \partial y / \partial x$ for small angles, the net transverse force is

$$T \left(\left. \frac{\partial y}{\partial x} \right|_{x+\delta x} - \left. \frac{\partial y}{\partial x} \right|_x \right) \approx T \frac{\partial^2 y}{\partial x^2} \delta x.$$

The mass of the segment is $\mu \delta x$, so Newton's second law (including gravity, with g downwards) gives

$$\mu \delta x \frac{\partial^2 y}{\partial t^2} = T \frac{\partial^2 y}{\partial x^2} \delta x - g \mu \delta x.$$

For a taut string the tension term utterly dominates gravity, so we neglect g , and dividing through by $\mu \delta x$ we obtain the wave equation

$$\frac{\partial^2 y}{\partial t^2} = c^2 \frac{\partial^2 y}{\partial x^2}, \quad \text{where } c = \sqrt{\frac{T}{\mu}}$$

is the **wave speed**. Alongside the boundary conditions $y(0, t) = y(L, t) = 0$, a full problem also specifies initial conditions

$$y(x, 0) = p(x), \quad \frac{\partial y}{\partial t}(x, 0) = q(x).$$

Note that we need *two* initial conditions, since the equation is second order in time.

§18.3.2 Separation of Variables

Our main technique for solving the wave equation (and later the diffusion and Laplace equations) is **separation of variables**: we look for solutions in the special product form

$$y(x, t) = X(x)T(t).$$

Substituting into the wave equation gives $\frac{1}{c^2} X \ddot{T} = X'' T$, and dividing by XT ,

$$\frac{1}{c^2} \frac{\ddot{T}}{T} = \frac{X''}{X}.$$

Now here's the trick: the left-hand side depends only on t , and the right-hand side only on x . The only way a function of t can equal a function of x for all x and t is if both are constant. Calling this **separation constant** $-\lambda$, we get two ODEs

$$X'' + \lambda X = 0, \quad \ddot{T} + \lambda c^2 T = 0.$$

We solve the spatial problem first, since it carries the boundary conditions $X(0) = X(L) = 0$. This is exactly a Sturm–Liouville eigenvalue problem! Let's check the possible signs of λ .

- (i) If $\lambda < 0$, write $\chi^2 = -\lambda$; then $X = C \cosh \chi x + D \sinh \chi x$, and the boundary conditions force $C = D = 0$.
- (ii) If $\lambda = 0$, then $X = Ax + B$, and again only the trivial solution survives.
- (iii) If $\lambda > 0$, then $X = A \cos(\sqrt{\lambda}x) + B \sin(\sqrt{\lambda}x)$. Now $X(0) = 0$ gives $A = 0$, and $X(L) = 0$ requires $\sin(\sqrt{\lambda}L) = 0$, i.e. $\sqrt{\lambda}L = n\pi$.

So we find the eigenfunctions and eigenvalues

$$X_n(x) = \sin \frac{n\pi x}{L}, \quad \lambda_n = \left(\frac{n\pi}{L}\right)^2, \quad n = 1, 2, \dots$$

These spatial profiles are called the **normal modes** of the string: the shape in x is frozen, and only the amplitude oscillates in time. The $n = 1$ mode is the **fundamental**, and higher modes are *overtones*, with $n - 1$ stationary points ('nodes') in the interior.

With λ_n fixed, the temporal equation $\ddot{T} + (n\pi c/L)^2 T = 0$ has solutions

$$T_n(t) = C_n \cos \frac{n\pi ct}{L} + D_n \sin \frac{n\pi ct}{L},$$

so each normal mode oscillates at angular frequency $\omega_n = n\pi c/L$. Superposing everything (the equation is linear!), the general solution satisfying the boundary conditions is

$$y(x, t) = \sum_{n=1}^{\infty} \left(C_n \cos \frac{n\pi ct}{L} + D_n \sin \frac{n\pi ct}{L} \right) \sin \frac{n\pi x}{L}.$$

It remains to impose the initial conditions. Setting $t = 0$,

$$y(x, 0) = p(x) = \sum_{n=1}^{\infty} C_n \sin \frac{n\pi x}{L},$$

which is precisely a half-range Fourier sine series, and differentiating in time first,

$$\frac{\partial y}{\partial t}(x, 0) = q(x) = \sum_{n=1}^{\infty} \frac{n\pi c}{L} D_n \sin \frac{n\pi x}{L}.$$

So by our Fourier coefficient formulas,

$$C_n = \frac{2}{L} \int_0^L p(x) \sin \frac{n\pi x}{L} dx, \quad D_n = \frac{2}{n\pi c} \int_0^L q(x) \sin \frac{n\pi x}{L} dx.$$

Example 18.3.1 (The Plucked String)

Take $L = 1$ and pluck the string at the point $x = \xi$: the initial condition is the

‘see-saw’ shape

$$y(x, 0) = p(x) = \begin{cases} x(1 - \xi) & \text{if } 0 \leq x < \xi, \\ \xi(1 - x) & \text{if } \xi \leq x < 1, \end{cases}$$

released from rest, $q(x) = 0$. We computed the Fourier series of this function before:

$$C_n = \frac{2 \sin n\pi\xi}{(n\pi)^2}, \quad D_n = 0,$$

so the subsequent motion is

$$y(x, t) = \sum_{n=1}^{\infty} \frac{2 \sin n\pi\xi}{(n\pi)^2} \sin(n\pi x) \cos(n\pi ct).$$

Notice that if you pluck at the midpoint $\xi = 1/2$, all the even harmonics vanish – plucking position controls the timbre.

Summarising, the general strategy of separation of variables is:

1. write down the linear PDE with its boundary and initial conditions;
2. separate variables to get decoupled ODEs;
3. impose the homogeneous boundary conditions to find the eigenvalues and eigenfunctions;
4. use the separation constants to solve for the remaining variables;
5. superpose the separable solutions into a general series solution;
6. fix the coefficients using the initial (or remaining boundary) conditions.

This exact recipe will reappear for the diffusion equation and Laplace’s equation.

§18.3.3 d’Alembert’s Solution and Characteristics

There’s a completely different way of looking at the wave equation, which doesn’t involve series at all. Using the sum formulas $\sin A \cos B = \frac{1}{2}(\sin(A - B) + \sin(A + B))$ and so on, each standing wave term in our series solution splits as

$$\begin{aligned} y(x, t) = & \frac{1}{2} \sum_{n=1}^{\infty} \left[C_n \sin \frac{n\pi}{L}(x - ct) + D_n \cos \frac{n\pi}{L}(x - ct) \right] \\ & + \frac{1}{2} \sum_{n=1}^{\infty} \left[C_n \sin \frac{n\pi}{L}(x + ct) - D_n \cos \frac{n\pi}{L}(x + ct) \right], \end{aligned}$$

that is, everything is a function of $x - ct$ plus a function of $x + ct$. This is no accident. Changing variables to $u = x - ct$, $v = x + ct$ transforms the wave equation into

$$\frac{\partial^2 y}{\partial u \partial v} = 0,$$

(we will verify this carefully when we study characteristics in general), which integrates immediately to give

$$y(x, t) = f(x - ct) + g(x + ct)$$

for arbitrary functions f and g : a right-moving wave and a left-moving wave, each travelling at speed c with unchanging shape.

Let's fit f and g to initial data on the whole line, $y(x, 0) = p(x)$ and $y_t(x, 0) = q(x)$. At $t = 0$,

$$f(x) + g(x) = p(x), \quad -cf'(x) + cg'(x) = q(x).$$

Differentiating the first equation and combining with the second,

$$g'(x) = \frac{1}{2} \left(p'(x) + \frac{q(x)}{c} \right), \quad f'(x) = \frac{1}{2} \left(p'(x) - \frac{q(x)}{c} \right),$$

and integrating (the constants of integration cancel in $f + g$) we arrive at **d'Alembert's solution**

$$y(x, t) = \frac{1}{2} [p(x - ct) + p(x + ct)] + \frac{1}{2c} \int_{x-ct}^{x+ct} q(s) \, ds.$$

In particular, a string released from rest ($q = 0$) evolves as $y = \frac{1}{2}[p(x - ct) + p(x + ct)]$ – the initial shape splits into two half-size copies moving apart.

d'Alembert's formula makes a physically important point manifest: the solution at position x and time t depends only on the initial data in the interval $[x - ct, x + ct]$. Information propagates no faster than speed c .

The lines $x \pm ct = \text{const}$ are called the **characteristics** of the wave equation. The shaded triangle is the **domain of dependence** of the point (x, t) ; dually, initial data at a point $(x_0, 0)$ can only ever influence the forward wedge $\{(x, t) : |x - x_0| \leq ct\}$, its **range of influence**.

§18.3.4 Energy of Oscillations

A vibrating string carries energy, and tracking it is both physically illuminating and a nice application of Parseval. The kinetic energy is

$$\text{KE} = \frac{1}{2} \mu \int_0^L \left(\frac{\partial y}{\partial t} \right)^2 dx,$$

and the potential energy is the work done stretching the string against tension. The stretched length element is $\sqrt{1 + (\partial y / \partial x)^2} dx$, so

$$\text{PE} = T \int_0^L \left(\sqrt{1 + \left(\frac{\partial y}{\partial x} \right)^2} - 1 \right) dx \approx \frac{T}{2} \int_0^L \left(\frac{\partial y}{\partial x} \right)^2 dx,$$

using the small-slope assumption. Hence, using $c^2 = T/\mu$, the total energy is

$$E = \frac{1}{2} \mu \int_0^L \left[\left(\frac{\partial y}{\partial t} \right)^2 + c^2 \left(\frac{\partial y}{\partial x} \right)^2 \right] dx.$$

Substituting our normal mode expansion and integrating using orthogonality (all the cross terms die, and $\int_0^L \sin^2 = \int_0^L \cos^2 = L/2$),

$$E = \frac{1}{4}\mu \sum_{n=1}^{\infty} \frac{n^2 \pi^2 c^2}{L} (C_n^2 + D_n^2),$$

where the time dependence has cancelled via $\cos^2 + \sin^2 = 1$. So the energy is *constant in time*, as it should be, and moreover it decomposes as a sum over normal modes – each mode holds its own energy and never trades it with the others. This is really Parseval’s theorem wearing a physics costume.

§18.3.5 Wave Reflection and Transmission

Let’s briefly consider what happens when a travelling wave meets a change in the medium. A **simple harmonic travelling wave** has the form

$$y = \text{Re} \left[A e^{i\omega(t-x/c)} \right] = |A| \cos(\omega(t-x/c) + \phi),$$

where the phase $\phi = \arg A$ and the wavelength is $2\pi c/\omega$.

Suppose the density of the string jumps at $x = 0$:

$$\mu = \begin{cases} \mu_- & \text{if } x < 0, \\ \mu_+ & \text{if } x > 0, \end{cases} \quad \text{so } c_{\pm} = \sqrt{T/\mu_{\pm}},$$

with the tension T constant throughout. Send in a wave $A e^{i\omega(t-x/c_-)}$ from the left. At the join, some of the wave is reflected, $B e^{i\omega(t+x/c_-)}$, and some is transmitted, $D e^{i\omega(t-x/c_+)}$. Note all three waves must share the frequency ω to have any hope of matching at $x = 0$ for all time.

The physical matching conditions at $x = 0$ are:

- (i) y is continuous (the string doesn’t break), giving $A + B = D$;
- (ii) the transverse force $T\partial y/\partial x$ is continuous (else a massless point would suffer infinite acceleration), giving

$$\frac{-i\omega A}{c_-} + \frac{i\omega B}{c_-} = \frac{-i\omega D}{c_+}.$$

Solving these two equations,

$$D = \frac{2c_+}{c_+ + c_-} A, \quad B = \frac{c_+ - c_-}{c_+ + c_-} A.$$

Various limits of this formula are illuminating:

- (i) If $c_- = c_+$ (no jump at all), then $D = A$ and $B = 0$: full transmission.
- (ii) If $\mu_+/\mu_- \rightarrow \infty$, the right half becomes infinitely heavy – effectively a fixed end (a *Dirichlet* boundary condition at $x = 0$). Then $c_+/c_- \rightarrow 0$, so $D = 0$ and $B = -A$: total reflection with phase flipped by π .
- (iii) If $\mu_+/\mu_- \rightarrow 0$, the right half is massless – a free end (a *Neumann* condition). Then $c_+/c_- \rightarrow \infty$, giving $B = A$: total reflection in phase (and the formula gives $D = 2A$, but this carries no energy as $\mu_+ \rightarrow 0$).

§18.3.6 The Wave Equation in Plane Polar Coordinates

So far our string has been one-dimensional. Let's now solve the two-dimensional wave equation on the unit disc – physically, a circular drum. We want $u(r, \theta, t)$ satisfying

$$\frac{1}{c^2} \frac{\partial^2 u}{\partial t^2} = \nabla^2 u,$$

with boundary condition $u(1, \theta, t) = 0$ (the drum skin is clamped at the rim) and initial conditions

$$u(r, \theta, 0) = \phi(r, \theta), \quad \frac{\partial u}{\partial t}(r, \theta, 0) = \psi(r, \theta).$$

We separate off time first: substituting $u = T(t)V(r, \theta)$ gives

$$\ddot{T} + \lambda c^2 T = 0, \quad \nabla^2 V + \lambda V = 0.$$

In plane polars the spatial equation reads

$$\frac{\partial^2 V}{\partial r^2} + \frac{1}{r} \frac{\partial V}{\partial r} + \frac{1}{r^2} \frac{\partial^2 V}{\partial \theta^2} + \lambda V = 0,$$

and separating again with $V = R(r)\Theta(\theta)$,

$$\Theta'' + \mu\Theta = 0, \quad r^2 R'' + rR' + (\lambda r^2 - \mu)R = 0.$$

On the disc, Θ must be 2π -periodic, which forces $\mu = m^2$ with $m \in \mathbb{N}$, and

$$\Theta_m(\theta) = A_m \cos m\theta + B_m \sin m\theta.$$

§18.3.7 Bessel's Equation

Now for the radial equation. Dividing by r puts it in Sturm–Liouville form,

$$-(rR')' + \frac{m^2}{r}R = \lambda rR,$$

with $p(r) = r$, $q(r) = m^2/r$ and weight $w(r) = r$. Note $p(0) = 0$, so $r = 0$ is a singular point, and the correct ‘boundary condition’ there is just that R stays bounded; at the rim we have $R(1) = 0$. Substituting $z = \sqrt{\lambda}r$ tidies away λ and yields **Bessel's equation**

$$z^2 \frac{d^2 R}{dz^2} + z \frac{dR}{dz} + (z^2 - m^2)R = 0.$$

Since $z = 0$ is a regular singular point, we solve by Frobenius' method, trying $R = z^p \sum_{n \geq 0} a_n z^n$. The lowest power of z gives the indicial equation

$$p^2 - m^2 = 0 \implies p = \pm m.$$

Taking the regular root $p = m$, comparing coefficients of z^{n+m} gives the recursion

$$((n+m)^2 - m^2)a_n + a_{n-2} = 0 \implies a_n = \frac{-a_{n-2}}{n(n+2m)},$$

so only even n appear, and iterating,

$$a_{2k} = \frac{(-1)^k a_0}{2^{2k} k! (m+1)(m+2) \cdots (m+k)}.$$

With the conventional normalisation $a_0 = 1/(2^m m!)$ we obtain the **Bessel function of the first kind**

$$J_m(z) = \left(\frac{z}{2}\right)^m \sum_{k=0}^{\infty} \frac{(-1)^k}{k!(k+m)!} \left(\frac{z}{2}\right)^{2k}.$$

The second solution (from $p = -m$, suitably interpreted) is the Bessel function of the second kind $Y_m(z)$, which diverges as $z \rightarrow 0$; boundedness at the origin will always eliminate it for us.

For small z , the leading behaviour is $J_0(z) \approx 1$ and $J_m(z) \approx \frac{1}{m!}(z/2)^m$. For large z , the Bessel functions become decaying oscillations:

$$J_m(z) \approx \sqrt{\frac{2}{\pi z}} \cos\left(z - \frac{m\pi}{2} - \frac{\pi}{4}\right).$$

In particular each J_m has infinitely many positive zeros. We write j_{mn} for the n th positive zero of J_m ; from the asymptotic form,

$$j_{mn} \approx n\pi + \frac{m\pi}{2} - \frac{\pi}{4} \quad \text{for large } n.$$

The zeros play exactly the role that $n\pi$ played for $\sin$: they are what the boundary condition will latch onto. (For reference, $j_{01} \approx 2.405$.)

§18.3.8 The Vibrating Drum

Let's assemble the solution of the drum problem. The radial solutions are $R(r) = AJ_m(\sqrt{\lambda}r) + BY_m(\sqrt{\lambda}r)$; boundedness at the centre gives $B = 0$, and the clamped rim $R(1) = 0$ requires

$$J_m(\sqrt{\lambda}) = 0 \implies \sqrt{\lambda} = j_{mn}, \quad \text{i.e. } \lambda_{mn} = j_{mn}^2.$$

So the spatial normal modes of the drum are

$$V_{mn}(r, \theta) = (A_{mn} \cos m\theta + B_{mn} \sin m\theta) J_m(j_{mn}r),$$

with frequencies $\omega_{mn} = j_{mn}c$. The mode (m, n) has m nodal diameters and $n - 1$ interior nodal circles.

The full solution is a superposition over all modes,

$$u(r, \theta, t) = \sum_{m=0}^{\infty} \sum_{n=1}^{\infty} J_m(j_{mn}r) \left[(A_{mn} \cos m\theta + B_{mn} \sin m\theta) \cos(j_{mn}ct) \right. \\ \left. + (C_{mn} \cos m\theta + D_{mn} \sin m\theta) \sin(j_{mn}ct) \right],$$

and the coefficients are fixed by the initial conditions using the orthogonality of $\cos m\theta$, $\sin m\theta$ and of the Bessel functions themselves. Indeed, since the $J_m(j_{mn}r)$ for fixed m are eigenfunctions of a Sturm–Liouville problem with weight r , we have

$$\int_0^1 J_m(j_{mn}r) J_m(j_{mk}r) r \, dr = \frac{1}{2} [J_{m+1}(j_{mn})]^2 \delta_{nk}.$$

Example 18.3.2 (A Radially Symmetric Drum Strike)

Suppose the drum starts at rest from the radially symmetric profile $u(r, \theta, 0) = \phi(r) = 1 - r^2$. By symmetry only the $m = 0$ modes are excited, and starting from rest kills the $\sin(j_{0n}ct)$ terms, so

$$u(r, \theta, t) = \sum_{n=1}^{\infty} A_{0n} J_0(j_{0n}r) \cos(j_{0n}ct),$$

where

$$A_{0n} = \frac{\int_0^1 (1 - r^2) J_0(j_{0n}r) r \, dr}{\frac{1}{2} J_1(j_{0n})^2}.$$

Working out the integral using Bessel recursion relations, one finds

$$A_{0n} = \frac{8J_2(j_{0n})}{j_{0n}^2 J_1(j_{0n})^2}.$$

The fundamental frequency of a drum of diameter d is $\omega = j_{01}c \cdot 2/d \approx 4.8c/d$, compared with $\pi c/d \approx 3.1c/d$ for a string of length d . Moreover the overtone frequencies j_{0n} are *not* integer multiples of j_{01} – which is why a drum sounds like a thud rather than a note.

§18.4 The Diffusion Equation

The next equation in our collection is the **diffusion equation** (or *heat equation*)

$$\frac{\partial \theta}{\partial t} = D \nabla^2 \theta,$$

which describes how heat, or the concentration of diffusing particles, spreads out over time. It is first order in time – a fact with real consequences, as we’ll see: unlike the wave equation, diffusion has an arrow of time.

§18.4.1 Deriving the Diffusion Equation

Via Fourier's Law

Consider the temperature $\theta(\mathbf{x}, t)$ in a conducting body. The heat energy in a fixed volume V is

$$Q = \int_V c_V \rho \theta \, dV,$$

where c_V is the specific heat and ρ the density, so

$$\frac{dQ}{dt} = \int_V c_V \rho \frac{\partial \theta}{\partial t} \, dV.$$

Empirically, heat flows from hot to cold at a rate proportional to the temperature gradient. This is **Fourier's law**:

$$\mathbf{q} = -k \nabla \theta,$$

where $\mathbf{q}$ is the heat flux and k the conductivity. The heat leaving V through its boundary is then

$$-\frac{dQ}{dt} = \int_{\partial V} \mathbf{q} \cdot \hat{\mathbf{n}} \, dS = \int_{\partial V} (-k \nabla \theta) \cdot \hat{\mathbf{n}} \, dS = - \int_V k \nabla^2 \theta \, dV,$$

using the divergence theorem. Equating the two expressions,

$$\int_V \left(c_V \rho \frac{\partial \theta}{\partial t} - k \nabla^2 \theta \right) \, dV = 0,$$

and since V was arbitrary, the integrand must vanish identically. Writing $D = k/(c_V \rho)$, the **diffusion constant** (or diffusivity), we get the diffusion equation

$$\frac{\partial \theta}{\partial t} = D \nabla^2 \theta.$$

Via Random Walks

There is a rather different derivation which explains why the same equation governs diffusing gas particles. Suppose a particle takes a random step of displacement ξ every time interval Δt , where ξ is drawn from a probability density $p(\xi)$ with no directional bias, $\langle \xi \rangle = \int \xi p(\xi) \, d\xi = 0$. If $P(x, N\Delta t)$ is the probability density for the particle's position after N steps, then conditioning on the last step,

$$P(x, (N+1)\Delta t) = \int_{-\infty}^{\infty} p(\xi) P(x - \xi, N\Delta t) \, d\xi.$$

Taylor expanding P in its first argument about x ,

$$P(x, (N+1)\Delta t) \approx P(x, N\Delta t) - \langle \xi \rangle \frac{\partial P}{\partial x} + \frac{\langle \xi^2 \rangle}{2} \frac{\partial^2 P}{\partial x^2} = P(x, N\Delta t) + \frac{\langle \xi^2 \rangle}{2} \frac{\partial^2 P}{\partial x^2},$$

using $\int p = 1$ and $\langle \xi \rangle = 0$. So provided the variance scales with the time step as $\langle \xi^2 \rangle = 2D\Delta t$, taking Δt small gives

$$\frac{\partial P}{\partial t} = D \frac{\partial^2 P}{\partial x^2},$$

the diffusion equation again. The scaling $\langle \xi^2 \rangle \propto \Delta t$ is the fingerprint of diffusion: distance travelled grows like $\sqrt{t}$, not t .

§18.4.2 Similarity Solutions

That $\sqrt{t}$ scaling suggests that the combination $x/\sqrt{t}$ might be a natural variable, and indeed the diffusion equation admits **similarity solutions** depending only on the dimensionless variable

$$\eta = \frac{x}{2\sqrt{Dt}}.$$

Let's look for a solution $\theta(x, t) = \theta(\eta)$. Using the chain rule,

$$\frac{\partial \theta}{\partial t} = -\frac{1}{2} \frac{\eta}{t} \theta'(\eta), \quad D \frac{\partial^2 \theta}{\partial x^2} = D \left(\frac{1}{2\sqrt{Dt}} \right)^2 \theta''(\eta) = \frac{1}{4t} \theta''(\eta),$$

so the PDE collapses to the ODE

$$\theta'' = -2\eta \theta'.$$

Setting $\psi = \theta'$, we have $\psi'/\psi = -2\eta$, giving $\psi = Ce^{-\eta^2}$, and integrating once more (choosing the constant conveniently)

$$\theta(\eta) = \theta_0 \operatorname{erf}(\eta) = \theta_0 \operatorname{erf}\left(\frac{x}{2\sqrt{Dt}}\right), \quad \text{where} \quad \operatorname{erf}(z) = \frac{2}{\sqrt{\pi}} \int_0^z e^{-u^2} du$$

is the **error function**.

This solution describes an initial step in temperature – say $\theta = \pm\theta_0$ for $x \gtrless 0$ at $t = 0^+$ – smoothing itself out, with the transition region spreading like $\sqrt{Dt}$:

Notice that at any $t > 0$, no matter how small, the solution is perfectly smooth and is nonzero at every x . Diffusion smooths instantly, and (formally) propagates information infinitely fast – in sharp contrast with the wave equation's strict speed limit c .

§18.4.3 Heat Conduction in a Finite Bar

Now let's do a full boundary value problem by separation of variables. Take a bar of length $2L$ occupying $-L \leq x \leq L$, with initial temperature a step,

$$\theta(x, 0) = H(x) = \begin{cases} 1 & \text{if } 0 \leq x \leq L, \\ 0 & \text{if } -L \leq x < 0, \end{cases}$$

and ends held at fixed temperatures $\theta(L, t) = 1$ and $\theta(-L, t) = 0$.

There's an immediate obstacle: the boundary conditions aren't homogeneous, so our Sturm–Liouville machinery doesn't apply directly. The fix is to subtract off the **steady state** – the time-independent solution the bar will relax towards. Steady solutions of

the heat equation in one dimension satisfy $\theta_s'' = 0$, so $\theta_s = Ax + B$, and matching the boundary values,

$$\theta_s(x) = \frac{x + L}{2L}.$$

Now write $\hat{\theta}(x, t) = \theta(x, t) - \theta_s(x)$. Then $\hat{\theta}$ still satisfies the diffusion equation, but now with *homogeneous* boundary conditions $\hat{\theta}(\pm L, t) = 0$ and initial condition $\hat{\theta}(x, 0) = H(x) - \frac{x+L}{2L}$.

Separating variables, $\hat{\theta} = X(x)T(t)$ gives

$$X'' = -\lambda X, \quad \dot{T} = -D\lambda T.$$

The boundary conditions force $\lambda > 0$ as usual. Our initial condition $\hat{\theta}(x, 0)$ is an odd function of x (check this!), so we only need the odd eigenfunctions

$$X_n(x) = \sin \frac{n\pi x}{L}, \quad \lambda_n = \frac{n^2\pi^2}{L^2},$$

and the corresponding temporal solutions are decaying exponentials,

$$T_n(t) = \exp\left(-\frac{Dn^2\pi^2}{L^2}t\right).$$

So

$$\hat{\theta}(x, t) = \sum_{n=1}^{\infty} b_n \sin \frac{n\pi x}{L} \exp\left(-\frac{Dn^2\pi^2}{L^2}t\right).$$

At $t = 0$ this is a Fourier sine series, so

$$b_n = \frac{2}{L} \int_0^L \left(H(x) - \frac{x+L}{2L}\right) \sin \frac{n\pi x}{L} dx = \frac{2}{L} \int_0^L \frac{1}{2} \sin \frac{n\pi x}{L} dx - \frac{2}{L} \int_0^L \frac{x}{2L} \sin \frac{n\pi x}{L} dx.$$

The first integral is half a square wave, contributing $\frac{2}{n\pi}$ for odd n and 0 for even n ; the second is half a sawtooth, contributing $-\frac{(-1)^{n+1}}{n\pi}$. Rather pleasingly, in both the odd and even cases the total comes to the same thing:

$$b_n = \frac{1}{n\pi}.$$

Hence, restoring the steady state, the temperature of the bar is

$$\theta(x, t) = \frac{x+L}{2L} + \sum_{n=1}^{\infty} \frac{1}{n\pi} \sin \frac{n\pi x}{L} \exp\left(-\frac{Dn^2\pi^2}{L^2}t\right).$$

There are two things worth noticing here. First, mode n decays at rate $Dn^2\pi^2/L^2$ – high harmonics die *extremely* fast, so the solution becomes smooth almost immediately and the late-time behaviour is dominated by the steady state plus the slowest mode. Secondly, for early times the series converges slowly, but there the similarity solution $\frac{1}{2} \left(1 + \operatorname{erf}\left(x/2\sqrt{Dt}\right)\right)$ is an excellent approximation, since the step hasn't yet 'felt' the boundaries. The two descriptions hand over to each other around $t \sim L^2/D$, the natural diffusion timescale.

§18.5 Laplace's Equation

If we look for *steady* states of the wave or diffusion equations – solutions with no time dependence at all – both reduce to **Laplace's equation**

$$\nabla^2 \phi = 0.$$

Solutions of Laplace's equation are called **harmonic functions**. The equation shows up everywhere: steady heat flow, electrostatic and gravitational potentials ($\mathbf{F} = -\nabla\phi$), and irrotational incompressible fluid flow ($\mathbf{v} = \nabla\phi$).

Laplace's equation is solved on a domain D , with data on the boundary ∂D rather than initial conditions. The two standard types are:

- (i) **Dirichlet conditions**: ϕ specified on ∂D ;
- (ii) **Neumann conditions**: the normal derivative $\partial\phi/\partial n = \hat{\mathbf{n}} \cdot \nabla\phi$ specified on ∂D .

§18.5.1 Uniqueness

Before solving anything, let's establish that boundary data pins the solution down.

Theorem 18.5.1 (Uniqueness for the Dirichlet Problem)

Suppose $\nabla^2 \phi = 0$ on a bounded domain D with $\phi = f$ given on ∂D . Then the solution, if it exists, is unique.

Proof. Suppose ϕ_1, ϕ_2 are both solutions and let $\psi = \phi_1 - \phi_2$, so that $\nabla^2 \psi = 0$ in D and $\psi = 0$ on ∂D . Consider

$$\int_D |\nabla\psi|^2 \, dV = \int_D [\nabla \cdot (\psi \nabla\psi) - \psi \nabla^2 \psi] \, dV = \int_{\partial D} \psi \frac{\partial\psi}{\partial n} \, dS = 0,$$

using the divergence theorem and then both $\nabla^2 \psi = 0$ and $\psi = 0$ on ∂D . Since $|\nabla\psi|^2 \geq 0$ and integrates to zero, $\nabla\psi \equiv 0$, so ψ is constant on D ; the boundary condition then forces $\psi \equiv 0$. $\square$

For Neumann conditions the same argument shows the solution is unique *up to an additive constant*, which is the best one could hope for.

The plan for the rest of this section is to run separation of variables in each of the standard coordinate systems – Cartesian, plane polar, cylindrical and spherical – and see which special functions each geometry summons.

§18.5.2 Cartesian Coordinates

In $\mathbb{R}^3$, Laplace's equation reads $\phi_{xx} + \phi_{yy} + \phi_{zz} = 0$. Seeking $\phi = X(x)Y(y)Z(z)$ and dividing by XYZ ,

$$\frac{X''}{X} + \frac{Y''}{Y} + \frac{Z''}{Z} = 0.$$

Each ratio must be constant, and the three constants sum to zero – so they can't all have the same sign. If the boundary conditions make X and Y oscillatory, say $X''/X = -\lambda_\ell$

and $Y''/Y = -\lambda_m$ with $\lambda_\ell, \lambda_m > 0$, then necessarily

$$\frac{Z''}{Z} = \lambda_\ell + \lambda_m > 0,$$

and Z is a growing/decaying exponential. This is characteristic of Laplace's equation: it cannot oscillate in every direction at once.

Example 18.5.2 (Steady Heat Flow in a Semi-Infinite Bar)

Consider a bar with rectangular cross-section, occupying $0 \leq x \leq a$, $0 \leq y \leq b$, $z \geq 0$. The four long sides are held at $\phi = 0$, the end $z = 0$ is held at $\phi = 1$, and $\phi \rightarrow 0$ far down the bar as $z \rightarrow \infty$. What is the steady temperature inside?

The homogeneous conditions $X(0) = X(a) = 0$ and $Y(0) = Y(b) = 0$ give the familiar eigenfunctions

$$X_\ell(x) = \sin \frac{\ell\pi x}{a}, \quad \lambda_\ell = \frac{\ell^2\pi^2}{a^2}, \quad Y_m(y) = \sin \frac{m\pi y}{b}, \quad \lambda_m = \frac{m^2\pi^2}{b^2}.$$

Then $Z'' = (\lambda_\ell + \lambda_m)Z$, and discarding the growing exponential (since $\phi \rightarrow 0$ as $z \rightarrow \infty$),

$$Z_{\ell m}(z) = \exp \left[- \left(\frac{\ell^2}{a^2} + \frac{m^2}{b^2} \right)^{1/2} \pi z \right].$$

The general solution is

$$\phi = \sum_{\ell, m \geq 1} a_{\ell m} \sin \frac{\ell\pi x}{a} \sin \frac{m\pi y}{b} \exp \left[- \left(\frac{\ell^2}{a^2} + \frac{m^2}{b^2} \right)^{1/2} \pi z \right],$$

and imposing $\phi = 1$ at $z = 0$ is a double Fourier sine series:

$$a_{\ell m} = \left(\frac{2}{a} \int_0^a \sin \frac{\ell\pi x}{a} dx \right) \left(\frac{2}{b} \int_0^b \sin \frac{m\pi y}{b} dy \right) = \frac{4}{\ell\pi} \cdot \frac{4}{m\pi} = \frac{16}{\pi^2 \ell m}$$

for ℓ, m both odd, and 0 otherwise (each factor is the square wave computation from before). Note that far down the bar, the solution is utterly dominated by the $(\ell, m) = (1, 1)$ mode: boundary detail at $z = 0$ is exponentially forgotten, with the crudest features persisting longest.

§18.5.3 Plane Polar Coordinates

In two dimensions with polar coordinates (r, θ) , Laplace's equation is

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial \phi}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 \phi}{\partial \theta^2} = 0.$$

Separating $\phi = R(r)\Theta(\theta)$ gives

$$\Theta'' + \mu\Theta = 0, \quad r(rR')' - \mu R = 0.$$

Periodicity of Θ forces $\mu = m^2$, $m \in \mathbb{N}$, with $\Theta_m = \cos m\theta, \sin m\theta$.

The radial equation this time is *not* Bessel's equation – there is no second separation constant (compare the wave equation on the disc, where λ appeared). It is an equidimensional equation, so we try $R = r^\beta$:

$$\beta^2 = m^2 \implies \beta = \pm m,$$

giving $R_m = r^m$ and r^{-m} for $m \geq 1$. For $m = 0$ we get $(rR')' = 0$, so $R' = c/r$ and

$$R_0 = \text{const}, \log r.$$

The general solution is therefore

$$\phi(r, \theta) = \frac{a_0}{2} + c_0 \log r + \sum_{m=1}^{\infty} (a_m \cos m\theta + b_m \sin m\theta) r^m + \sum_{m=1}^{\infty} (c_m \cos m\theta + d_m \sin m\theta) r^{-m}.$$

On a domain containing the origin, regularity kills $\log r$ and all the r^{-m} ; on an exterior domain, boundedness kills the r^m instead.

Example 18.5.3 (A Soap Film on a Distorted Wire)

Take a circular wire of radius 1, distorted slightly out of its plane so that its height is $f(\theta)$, and dip it in soap solution. The (small) height $\phi(r, \theta)$ of the resulting film satisfies Laplace's equation on the unit disc with $\phi(1, \theta) = f(\theta)$.

Regularity at the origin leaves

$$\phi(r, \theta) = \frac{a_0}{2} + \sum_{m=1}^{\infty} (a_m \cos m\theta + b_m \sin m\theta) r^m,$$

and at $r = 1$ this is exactly the Fourier series of f :

$$a_m = \frac{1}{\pi} \int_0^{2\pi} f(\theta) \cos m\theta \, d\theta, \quad b_m = \frac{1}{\pi} \int_0^{2\pi} f(\theta) \sin m\theta \, d\theta.$$

The factor r^m means the high harmonics of the wire's wobble decay rapidly towards the centre of the film: near $r = 0$ the film is almost flat at the average height $\frac{1}{2}a_0$. Once again, Laplace's equation smooths.

§18.5.4 Cylindrical Polar Coordinates

In cylindrical polars (r, θ, z) ,

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial \phi}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 \phi}{\partial \theta^2} + \frac{\partial^2 \phi}{\partial z^2} = 0.$$

Separating $\phi = R(r)\Theta(\theta)Z(z)$ gives

$$\Theta'' = -m^2\Theta, \quad Z'' = k^2Z, \quad r(rR')' + (k^2r^2 - m^2)R = 0.$$

Now the radial equation *is* Bessel's equation (in the variable kr), because the z separation supplies the second constant k^2 . The bounded-at-the-axis solutions are $R = J_m(kr)$.

If, say, we solve inside a cylinder of radius a with $\phi = 0$ on the curved surface, then $J_m(ka) = 0$ quantises $k = j_{mn}/a$, and the general solution decaying as $z \rightarrow \infty$ is

$$\phi(r, \theta, z) = \sum_{m=0}^{\infty} \sum_{n=1}^{\infty} (a_{mn} \cos m\theta + b_{mn} \sin m\theta) J_m\left(\frac{j_{mn}}{a}r\right) e^{-j_{mn}z/a},$$

with coefficients determined from the data on the end $z = 0$ using the orthogonality relation for Bessel functions from before. Structurally this is identical to the Cartesian semi-infinite bar: oscillation across the cross-section, exponential decay along the axis.

§18.5.5 Spherical Polar Coordinates

Finally, spherical polars (r, θ, φ) , where

$$\frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial \phi}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial \phi}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 \phi}{\partial \varphi^2} = 0.$$

We will restrict to the **axisymmetric** case, where $\phi = \phi(r, \theta)$ has no φ dependence. Separating $\phi = R(r)\Theta(\theta)$,

$$(\sin \theta \Theta')' + \lambda \sin \theta \Theta = 0, \quad (r^2 R')' = \lambda R.$$

For the angular equation, substitute $x = \cos \theta$ (so $x \in [-1, 1]$, and $\frac{d}{d\theta} = -\sin \theta \frac{d}{dx}$):

$$\frac{d}{dx} \left[(1-x^2) \frac{d\Theta}{dx} \right] + \lambda \Theta = 0.$$

This is precisely Legendre's equation! Requiring finiteness at the poles $\theta = 0, \pi$ (i.e. $x = \pm 1$) gives

$$\lambda_\ell = \ell(\ell+1), \quad \Theta_\ell(\theta) = P_\ell(\cos \theta).$$

So this is where the Legendre polynomials live: they are the natural angular harmonics on the sphere.

The radial equation $(r^2 R')' = \ell(\ell+1)R$ is again equidimensional; trying $R = r^\beta$ gives

$$\beta(\beta+1) = \ell(\ell+1) \implies \beta = \ell \text{ or } -\ell-1,$$

so the general axisymmetric harmonic function is

$$\phi(r, \theta) = \sum_{\ell=0}^{\infty} \left(a_\ell r^\ell + \frac{b_\ell}{r^{\ell+1}} \right) P_\ell(\cos \theta).$$

Interior problems keep only r^ℓ ; exterior problems (with $\phi \rightarrow 0$ at infinity) keep only $r^{-\ell-1}$.

Example 18.5.4 (Boundary Data on the Unit Sphere)

Solve $\nabla^2 \phi = 0$ inside the unit sphere with $\phi(1, \theta) = f(\theta)$. Regularity gives $b_\ell = 0$, so writing $f(\theta) = F(\cos \theta)$,

$$F(x) = \sum_{\ell=0}^{\infty} a_\ell P_\ell(x) \implies a_\ell = \frac{2\ell+1}{2} \int_{-1}^1 F(x) P_\ell(x) dx,$$

a Fourier–Legendre series. For instance if $f(\theta) = \cos^2 \theta$, then $x^2 = \frac{1}{3}P_0(x) + \frac{2}{3}P_2(x)$, so

$$\phi(r, \theta) = \frac{1}{3} + \frac{2}{3}r^2 P_2(\cos \theta),$$

and no infinite series is needed at all.

The Generating Function for Legendre Polynomials

We can now pay off a debt from Sturm–Liouville theory. Place a unit point charge at the north pole of the unit sphere, $\mathbf{r}_0 = (0, 0, 1)$. Its potential at the point with spherical coordinates (r, θ) is

$$\Phi = \frac{1}{|\mathbf{r} - \mathbf{r}_0|} = \frac{1}{\sqrt{r^2 - 2r \cos \theta + 1}},$$

expanding $|\mathbf{r} - \mathbf{r}_0|^2 = r^2 \sin^2 \theta + (r \cos \theta - 1)^2$. Away from the charge this is an axisymmetric harmonic function, regular at the origin, so for $r < 1$ it *must* have an expansion

$$\frac{1}{\sqrt{r^2 - 2rx + 1}} = \sum_{\ell=0}^{\infty} a_{\ell} P_{\ell}(x) r^{\ell}, \quad x = \cos \theta.$$

To find the a_{ℓ} , look along the axis $x = 1$: the left side is $1/(1-r) = \sum_{\ell} r^{\ell}$, and $P_{\ell}(1) = 1$, so $a_{\ell} = 1$ for every ℓ . Hence

$$\frac{1}{\sqrt{1 - 2xt + t^2}} = \sum_{\ell=0}^{\infty} P_{\ell}(x) t^{\ell},$$

which is the generating function quoted earlier. Expanding the potential of a localised charge distribution in powers of $1/r$ using this identity gives the *multipole expansion* of electrostatics: monopole, dipole, quadrupole terms proportional to P_0, P_1, P_2 and so on.

§18.6 The Dirac Delta Function and Distributions

We have repeatedly hinted that the right way to think about Green’s functions is as responses to *point sources*: a unit impulse concentrated at a single point. To make sense of that we need a ‘function’ which is zero everywhere except one point, yet has total integral 1. No actual function does this, but the idea is far too useful to abandon – so in this section we develop the object that makes it precise.

§18.6.1 The Delta Function

Definition 18.6.1 (Dirac Delta)

The **Dirac delta function** $\delta(x - \xi)$ is the generalised function satisfying

- (i) $\delta(x - \xi) = 0$ for all $x \neq \xi$;
- (ii) $\int_{-\infty}^{\infty} \delta(x - \xi) dx = 1$.

Its defining role is the **sampling property**: for any f well-behaved near ξ ,

$$\int_{-\infty}^{\infty} f(x) \delta(x - \xi) dx = f(\xi).$$

Strictly, δ is not a function at all but a *distribution*, and it only really makes sense sitting inside an integral (though we will happily write equations involving δ outside integrals, with an integral always implied). Physically, $\delta(x - \xi)$ represents a unit point mass, charge, or impulse located at ξ .

A good mental model for δ is as the limit of increasingly tall, thin spikes of unit area. For instance, take the Gaussians

$$\delta_\epsilon(x) = \frac{1}{\epsilon\sqrt{\pi}} \exp\left(-\frac{x^2}{\epsilon^2}\right),$$

as $\epsilon \rightarrow 0$:

Let's verify the sampling property for this family. Substituting $y = x/\epsilon$,

$$\begin{aligned} \lim_{\epsilon \rightarrow 0} \int_{-\infty}^{\infty} \delta_\epsilon(x) f(x) \, dx &= \lim_{\epsilon \rightarrow 0} \int_{-\infty}^{\infty} \frac{1}{\sqrt{\pi}} e^{-y^2} f(\epsilon y) \, dy \\ &= \lim_{\epsilon \rightarrow 0} \int_{-\infty}^{\infty} \frac{1}{\sqrt{\pi}} e^{-y^2} [f(0) + \epsilon y f'(0) + \cdots] \, dy = f(0), \end{aligned}$$

using $\int e^{-y^2} \, dy = \sqrt{\pi}$. The Gaussian family is not special: the *Dirichlet kernel* $\delta_n(x) = \frac{\sin nx}{\pi x}$ and spike families like $\frac{n}{2} \operatorname{sech}^2(nx)$ work equally well as $n \rightarrow \infty$. The limit object is the same δ in every case.

§18.6.2 Distributions and Test Functions

Let's spend a moment making this respectable. The trick is to stop asking for the value of δ at points, and instead define it by *how it acts on nice functions*.

Definition 18.6.2 (Test Function)

A **test function** $\varphi : \mathbb{R} \rightarrow \mathbb{R}$ is a smooth function which vanishes outside some bounded interval.

Definition 18.6.3 (Distribution)

A **distribution** (or **generalised function**) T is a continuous linear map from test functions to $\mathbb{R}$, written

$$T[\varphi] = \int_{-\infty}^{\infty} T(x) \varphi(x) \, dx,$$

where the integral notation is formal.

Every ordinary (integrable) function f defines a distribution via $\varphi \mapsto \int f \varphi \, dx$, but there are more distributions than functions: the delta function is the distribution

$$\delta[\varphi] = \varphi(0),$$

which is a perfectly well-defined linear map, even though no function represents it.

The real payoff is that distributions can always be differentiated. If T were an honest differentiable function, integration by parts would give $\int T'\varphi \, dx = -\int T\varphi' \, dx$ (the boundary terms vanish since φ has bounded support). So we simply *define* the **distributional derivative** by

$$T'[\varphi] = -T[\varphi'].$$

With this definition every distribution is infinitely differentiable, and we can differentiate functions with corners and jumps without guilt.

Example 18.6.4 (Derivative of the Heaviside Function)

The **Heaviside step function** is

$$H(x) = \begin{cases} 1 & \text{if } x \geq 0, \\ 0 & \text{if } x < 0. \end{cases}$$

As a distribution,

$$H'[\varphi] = -H[\varphi'] = -\int_0^\infty \varphi'(x) \, dx = \varphi(0) = \delta[\varphi],$$

so $H' = \delta$ in the sense of distributions – the jump differentiates to a spike. Consistently, $H(x) = \int_{-\infty}^x \delta(t) \, dt$.

Example 18.6.5 (Derivative of the Delta Function)

Similarly δ' is defined by

$$\int_{-\infty}^\infty \delta'(x - \xi) f(x) \, dx = -\int_{-\infty}^\infty \delta(x - \xi) f'(x) \, dx = -f'(\xi),$$

valid whenever f is smooth at ξ . One can visualise δ' as the limit of the derivatives of our Gaussian spikes: a violent up-down pair, which ‘measures’ minus the slope of f at the point.

§18.6.3 Properties of the Delta Function

The following properties get used constantly; each is proved by substitution inside an integral against a well-behaved f .

(i) (Sampling on an interval)

$$\int_a^b f(x) \delta(x - \xi) \, dx = \begin{cases} f(\xi) & \text{if } a < \xi < b, \\ 0 & \text{otherwise.} \end{cases}$$

(ii) (Evenness) $\delta(-(x - \xi)) = \delta(x - \xi)$, by the substitution $u = -(x - \xi)$.

(iii) (Scaling) For $a \neq 0$,

$$\delta(a(x - \xi)) = \frac{1}{|a|} \delta(x - \xi).$$

(iv) (Composition) If g has isolated simple roots $x_1, \dots, x_n$ (so $g'(x_i) \neq 0$), then

$$\delta(g(x)) = \sum_{i=1}^n \frac{\delta(x - x_i)}{|g'(x_i)|},$$

since near each root $g(x) \approx g'(x_i)(x - x_i)$ and we can apply scaling.

(v) (Isolation) If g is continuous at ξ then $g(x)\delta(x - \xi) = g(\xi)\delta(x - \xi)$.

§18.6.4 Eigenfunction Expansions of the Delta Function

Here is a question that will matter a lot for Green's functions: what is the Fourier series of $\delta(x)$? Working on $[-L, L]$ with the complex series $\delta(x) = \sum_n c_n e^{in\pi x/L}$, the coefficients are

$$c_n = \frac{1}{2L} \int_{-L}^L \delta(x) e^{-in\pi x/L} dx = \frac{1}{2L},$$

all equal! So

$$\delta(x) = \frac{1}{2L} \sum_{n=-\infty}^{\infty} e^{in\pi x/L}.$$

This series diverges wildly at $x = 0$, exactly as it should. It is 'equal' to δ in the distributional sense: integrated against any Fourier-expandable f , term-by-term integration gives $f(0)$. Extended periodically, this is a sum of delta spikes at $x = 2mL$ for $m \in \mathbb{Z}$, called the **Dirac comb**.

More generally, take any Sturm–Liouville system $\{y_n\}$ with weight w on $[a, b]$. Expanding $\delta(x - \xi) = \sum_n a_n y_n(x)$ using the standard coefficient formula,

$$a_n = \frac{\int_a^b w(x) y_n(x) \delta(x - \xi) dx}{\int_a^b w y_n^2 dx} = \frac{w(\xi) y_n(\xi)}{N_n}, \quad N_n = \int_a^b w y_n^2 dx,$$

so

$$\delta(x - \xi) = w(\xi) \sum_{n=1}^{\infty} \frac{y_n(\xi) y_n(x)}{N_n} = w(x) \sum_{n=1}^{\infty} \frac{y_n(\xi) y_n(x)}{N_n},$$

where swapping $w(\xi)$ for $w(x)$ is legitimate by the isolation property. This formula is the *completeness relation* in disguise – indeed, it's often taken as the definition of completeness of the family $\{y_n\}$.

Example 18.6.6

For the sine functions $y_n = \sin n\pi x$ on $[0, 1]$ (so $w = 1$, $N_n = 1/2$),

$$\delta(x - \xi) = 2 \sum_{n=1}^{\infty} \sin(n\pi\xi) \sin(n\pi x), \quad 0 < \xi < 1.$$

§18.7 Green's Functions for ODEs

We now come back to the idea we extracted from Sturm–Liouville theory: solving $\mathcal{L}y = f$ by finding an integral kernel G with

$$y(x) = \int_a^b G(x, \xi) f(\xi) d\xi.$$

Armed with the delta function, we can now say precisely what G is, and construct it directly.

§18.7.1 Motivation: A Massive String

Consider a static string with tension T and mass density μ , suspended between fixed ends $y(0) = y(1) = 0$ and sagging under gravity. Balancing forces as in our wave equation derivation (but with no time dependence),

$$T \frac{d^2 y}{dx^2} - \mu g = 0, \quad \text{i.e.} \quad -y'' = f, \quad f = -\frac{\mu g}{T}.$$

We can of course just integrate twice: imposing the boundary conditions gives

$$y(x) = -\frac{\mu g}{T} \cdot \frac{1}{2} x(1-x).$$

But here is a more instructive route. Imagine replacing the continuous string by a very light string carrying a single point mass $\delta m = \mu \delta x$ at position ξ . The string is then straight on either side of the mass, and resolving forces at the mass point (small angles again) gives the tent-shaped displacement

$$y(x) = -\frac{\delta m g}{T} \times \begin{cases} x(1-\xi) & \text{if } x < \xi, \\ \xi(1-x) & \text{if } x > \xi. \end{cases}$$

Now, the equation is linear, so we can superpose: hanging point masses at positions $\xi_1, \xi_2, \dots$ adds the corresponding displacements. Taking the continuum limit, with $f(\xi) d\xi$ playing the role of the force from the mass element at ξ ,

$$y(x) = \int_0^1 f(\xi) G(x, \xi) d\xi, \quad \text{where } G(x, \xi) = \begin{cases} x(1-\xi) & \text{if } x < \xi, \\ \xi(1-x) & \text{if } x > \xi \end{cases}$$

is the response to a *unit* point force at ξ . You can check by direct integration that this reproduces $y = -\frac{\mu g}{2T} x(1-x)$ exactly. The function G – the shape of a string plucked by a unit point load – is the Green's function of the operator $-d^2/dx^2$ with these boundary conditions.

§18.7.2 Definition and the Jump Condition

Definition 18.7.1 (Green's Function)

Let $\mathcal{L}y = \alpha(x)y'' + \beta(x)y' + \gamma(x)y$ on $a \leq x \leq b$, with $\alpha \neq 0$ and α, β, γ continuous and bounded, with homogeneous boundary conditions $y(a) = y(b) = 0$. The **Green's function** of $\mathcal{L}$ is the solution $G(x, \xi)$, satisfying the boundary conditions, of

$$\mathcal{L}G(x, \xi) = \delta(x - \xi).$$

Given the Green's function, the solution of $\mathcal{L}y = f$ is immediate. Setting

$$y(x) = \int_a^b G(x, \xi) f(\xi) d\xi,$$

we can check

$$\mathcal{L}y = \int_a^b \mathcal{L}G(x, \xi) f(\xi) d\xi = \int_a^b \delta(x - \xi) f(\xi) d\xi = f(x),$$

and y inherits the homogeneous boundary conditions from G . So G genuinely is the inverse operator: $\mathcal{L}^{-1} = \int_a^b d\xi G(x, \xi)$.

What does G look like? Away from $x = \xi$ the delta function vanishes, so G solves the *homogeneous* equation on each side:

$$G(x, \xi) = \begin{cases} G_1(x, \xi) & \text{if } a \leq x < \xi, \\ G_2(x, \xi) & \text{if } \xi < x \leq b, \end{cases} \quad \mathcal{L}G_1 = \mathcal{L}G_2 = 0,$$

with $G_1(a, \xi) = 0$ and $G_2(b, \xi) = 0$. It remains to see how the two halves glue at $x = \xi$, and this is where the delta function makes itself felt:

- (i) *Continuity*: $G_1(\xi, \xi) = G_2(\xi, \xi)$;
- (ii) *Jump condition*: the derivative jumps by exactly

$$\left[\frac{\partial G}{\partial x} \right]_{\xi-}^{\xi+} = \frac{1}{\alpha(\xi)}.$$

To see why, integrate $\mathcal{L}G = \delta(x - \xi)$ over a shrinking interval $[\xi - \epsilon, \xi + \epsilon]$. The right side integrates to 1. On the left, $\int \alpha G'' dx \rightarrow \alpha(\xi)[G']_{\xi-}^{\xi+}$, while the $\beta G'$ and γG terms contribute nothing in the limit *provided* G is continuous (a jump in G itself would make G'' too singular – a δ' – which nothing on the right-hand side could match). Hence the two conditions above.

So the picture to hold in mind: $G(\cdot, \xi)$ is built from homogeneous solutions on either side, tied down at the ends, continuous at ξ , with a kink there of size $1/\alpha(\xi)$.

§18.7.3 Explicit Construction

Let's carry out the construction in general. Let y_1, y_2 be independent solutions of $\mathcal{L}y = 0$. Some linear combination $y_-(x)$ satisfies the left boundary condition $y_-(a) = 0$, and some combination $y_+(x)$ satisfies $y_+(b) = 0$. Then

$$G_1 = Cy_-(x), \quad G_2 = Dy_+(x),$$

for constants (in x !) C, D which may depend on ξ . The gluing conditions read

$$Cy_-(\xi) = Dy_+(\xi), \quad Dy'_+(\xi) - Cy'_-(\xi) = \frac{1}{\alpha(\xi)}.$$

Solving this pair of linear equations,

$$C(\xi) = \frac{y_+(\xi)}{\alpha(\xi)W(\xi)}, \quad D(\xi) = \frac{y_-(\xi)}{\alpha(\xi)W(\xi)},$$

where

$$W(\xi) = y_-(\xi)y'_+(\xi) - y_+(\xi)y'_-(\xi)$$

is the **Wronskian** of y_- and y_+ , which is nonzero as long as y_- and y_+ are independent.¹ Hence

$$G(x, \xi) = \begin{cases} \frac{y_-(x)y_+(\xi)}{\alpha(\xi)W(\xi)} & \text{if } a \leq x \leq \xi, \\ \frac{y_-(\xi)y_+(x)}{\alpha(\xi)W(\xi)} & \text{if } \xi \leq x \leq b, \end{cases}$$

and the solution to our boundary value problem is

$$y(x) = y_+(x) \int_a^x \frac{y_-(\xi)f(\xi)}{\alpha(\xi)W(\xi)} d\xi + y_-(x) \int_x^b \frac{y_+(\xi)f(\xi)}{\alpha(\xi)W(\xi)} d\xi.$$

(Note which piece of G applies in which integral: for $\xi < x$ we are to the right of the source, so $G = G_2$.)

A pleasant fact: if $\mathcal{L}$ is in Sturm–Liouville form, then $\beta = \alpha'$, and a quick computation shows $(\alpha W)' = \alpha W' + \alpha' W = 0$ using the ODE – so $\alpha(\xi)W(\xi)$ is a *constant*, and the Green's function is manifestly symmetric:

$$G(x, \xi) = G(\xi, x).$$

This is the analogue of a self-adjoint matrix having a symmetric inverse, and physically it is a reciprocity principle: the response at x to a source at ξ equals the response at ξ to a source at x .

Example 18.7.2

Let's solve $y'' - y = f(x)$ with $y(0) = y(1) = 0$. The homogeneous solutions are $e^{\pm x}$, and the combinations adapted to the boundary conditions are

$$y_-(x) = \sinh x, \quad y_+(x) = \sinh(1 - x).$$

Here $\alpha = 1$ and

$$\alpha W = \sinh x \cdot (-\cosh(1 - x)) - \sinh(1 - x) \cosh x = -\sinh 1,$$

using the addition formula (constant, as promised). So

$$G(x, \xi) = \begin{cases} -\frac{\sinh x \sinh(1 - \xi)}{\sinh 1} & \text{if } 0 \leq x \leq \xi, \\ -\frac{\sinh \xi \sinh(1 - x)}{\sinh 1} & \text{if } \xi \leq x \leq 1, \end{cases}$$

and

$$y(x) = -\frac{\sinh(1 - x)}{\sinh 1} \int_0^x \sinh \xi f(\xi) d\xi - \frac{\sinh x}{\sinh 1} \int_x^1 \sinh(1 - \xi) f(\xi) d\xi.$$

If the boundary conditions are *inhomogeneous*, say $y(0) = 0$, $y(1) = 1$, we handle them exactly as in the heat conduction problem: find any homogeneous solution y_p with $\mathcal{L}y_p = 0$ matching the boundary values (here $y_p = \sinh x / \sinh 1$), subtract it off, and solve the resulting homogeneous-boundary problem with the Green's function.

¹If y_- and y_+ are *not* independent, then there is a nontrivial homogeneous solution satisfying both boundary conditions – i.e. $\lambda = 0$ is an eigenvalue – and no Green's function exists. Compare trying to invert a singular matrix.

§18.7.4 Eigenfunction Expansion of the Green's Function

We derived at the end of Sturm–Liouville theory the formula

$$G(x, \xi) = \sum_{n=1}^{\infty} \frac{y_n(x)y_n(\xi)}{\lambda_n N_n}.$$

Let's re-derive it from our new definition, as a consistency check. Seek $G(x, \xi) = \sum_n A_n y_n(x)$ satisfying $\mathcal{L}G = \delta(x - \xi)$. Then

$$\mathcal{L}G = \sum_n A_n \lambda_n w(x) y_n(x),$$

while the delta function has the expansion $\delta(x - \xi) = w(x) \sum_n y_n(\xi) y_n(x) / N_n$ from the last section. Comparing coefficients,

$$A_n = \frac{y_n(\xi)}{\lambda_n N_n},$$

which is exactly the earlier formula. Note again that this only makes sense if no $\lambda_n = 0$.

§18.7.5 Initial Value Problems

Green's functions work just as well for initial value problems, with one striking new feature. Suppose we want to solve

$$\mathcal{L}y = f(t), \quad t \geq a, \quad y(a) = y'(a) = 0,$$

via $G(t, \tau)$ with $\mathcal{L}G = \delta(t - \tau)$ and $G(a, \tau) = G'(a, \tau) = 0$ (derivatives in t).

For $t < \tau$: G_1 is a homogeneous solution with $G_1(a) = G'_1(a) = 0$. But a homogeneous solution with both initial conditions zero is identically zero (writing $G_1 = Ay_1 + By_2$, the conditions form a linear system whose determinant is the Wronskian of y_1, y_2 at a , which is nonzero). So

$$G_1 \equiv 0 \quad \text{for } t < \tau:$$

nothing happens before the impulse.

For $t > \tau$: continuity forces $G_2(\tau, \tau) = 0$, so $G_2 = Dy_+(t)$ where y_+ is the homogeneous solution with $y_+(\tau) = 0$, and the jump condition $G'_2(\tau_+) = 1/\alpha(\tau)$ fixes $D = 1/(\alpha(\tau)y'_+(\tau))$. Hence

$$G(t, \tau) = \begin{cases} 0 & \text{if } t < \tau, \\ \frac{y_+(t)}{\alpha(\tau)y'_+(\tau)} & \text{if } t > \tau, \end{cases}$$

and

$$y(t) = \int_a^t G(t, \tau) f(\tau) \, d\tau.$$

Note the upper limit: only forcing *before* time t contributes. **Causality** is built into the structure of the Green's function – an idea that will return with force when we study signal processing and PDEs.

Example 18.7.3

Solve $y'' - y = f(t)$ with $y(0) = y'(0) = 0$. For $t > \tau$ we need the homogeneous solution vanishing at τ , namely $y_+ = \sinh(t - \tau)$, and the jump condition gives ($\alpha = 1$, $y'_+(\tau) = \cosh 0 = 1$) coefficient 1. So

$$y(t) = \int_0^t \sinh(t - \tau) f(\tau) \, d\tau.$$

Compare this with the boundary value problem for the same operator above – same equation, completely different Green's function. The Green's function belongs to the operator *together with* its boundary conditions.

Remark (Higher Order Equations). Everything generalises to an n th order operator $\mathcal{L}$ with leading coefficient $\alpha(x)$: the Green's function is built from homogeneous solutions satisfying the boundary conditions, with $G, G', \dots, G^{(n-2)}$ all continuous at $x = \xi$ and a jump

$$G^{(n-1)}(\xi_+) - G^{(n-1)}(\xi_-) = \frac{1}{\alpha(\xi)}$$

in the top derivative.

§18.8 Fourier Transforms

Fourier series decompose periodic functions into harmonics. But plenty of interesting functions – a solitary pulse, a decaying signal – are not periodic at all, and live on the whole real line. The **Fourier transform** is what Fourier series become when the period is sent to infinity: the discrete spectrum of harmonics merges into a continuum.

§18.8.1 Definition and the Inversion Theorem**Definition 18.8.1** (Fourier Transform)

The **Fourier transform** of $f(x)$ is

$$\tilde{f}(k) = \mathcal{F}[f](k) = \int_{-\infty}^{\infty} f(x) e^{-ikx} \, dx,$$

and the **inverse Fourier transform** is

$$f(x) = \mathcal{F}^{-1}[\tilde{f}](x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{f}(k) e^{ikx} \, dk.$$

(Beware: other books scatter the 2π differently – some split it symmetrically as $1/\sqrt{2\pi}$ on each – and any internally consistent convention is fine.)

Theorem 18.8.2 (Fourier Inversion Theorem)

If f and $\tilde{f}$ are absolutely integrable, then

$$\mathcal{F}^{-1}[\mathcal{F}[f]](x) = f(x)$$

at all points where f is continuous; at a jump the right-hand side gives $\frac{1}{2}(f(x_+) + f(x_-))$, just as for Fourier series.

Rather than prove this, let's see why it's plausible by deriving the transform as a limit of Fourier series. Take f on $[-L, L]$ with complex Fourier series

$$f(x) = \sum_{n=-\infty}^{\infty} c_n e^{ik_n x}, \quad k_n = \frac{n\pi}{L},$$

and write $\Delta k = \pi/L$ for the spacing of the wavenumbers. Then

$$c_n = \frac{1}{2L} \int_{-L}^L f(u) e^{-ik_n u} du = \frac{\Delta k}{2\pi} \int_{-L}^L f(u) e^{-ik_n u} du,$$

so

$$f(x) = \sum_{n=-\infty}^{\infty} \frac{\Delta k}{2\pi} e^{ik_n x} \int_{-L}^L f(u) e^{-ik_n u} du.$$

As $L \rightarrow \infty$, $\Delta k \rightarrow 0$, and the sum over n is a Riemann sum for an integral over k :

$$f(x) \rightarrow \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{ikx} \left(\int_{-\infty}^{\infty} f(u) e^{-iku} du \right) dk = \mathcal{F}^{-1}[\mathcal{F}[f]](x).$$

Example 18.8.3 (The Gaussian)

Let $f(x) = \frac{1}{\sigma\sqrt{\pi}} e^{-x^2/\sigma^2}$. Since $\sin kx$ is odd, only the cosine part survives:

$$\tilde{f}(k) = \frac{1}{\sigma\sqrt{\pi}} \int_{-\infty}^{\infty} e^{-x^2/\sigma^2} \cos(kx) dx.$$

Differentiating under the integral sign and integrating by parts,

$$\frac{d\tilde{f}}{dk} = \frac{-1}{\sigma\sqrt{\pi}} \int_{-\infty}^{\infty} x e^{-x^2/\sigma^2} \sin(kx) dx = -\frac{k\sigma^2}{2} \tilde{f}(k).$$

This little ODE gives $\tilde{f}(k) = C e^{-k^2\sigma^2/4}$, and setting $k = 0$ (where the integral is just the total area, 1) gives $C = 1$:

$$\tilde{f}(k) = e^{-k^2\sigma^2/4}.$$

So the transform of a Gaussian is another Gaussian, with *inverted* width: a narrow pulse has a broad spectrum and vice versa. (Readers who have met quantum mechanics will recognise the germ of the uncertainty principle.)

§18.8.2 Properties of the Fourier Transform

The Fourier transform converts awkward operations into easy ones. Throughout, $\tilde{f} = \mathcal{F}[f]$.

- (i) (Linearity) $\mathcal{F}[\lambda f + \mu g] = \lambda \tilde{f} + \mu \tilde{g}$.
- (ii) (Translation) $\mathcal{F}[f(x - \lambda)](k) = e^{-i\lambda k} \tilde{f}(k)$.

- (iii) (Frequency shift) $\mathcal{F}[e^{i\lambda x} f(x)](k) = \tilde{f}(k - \lambda)$.
- (iv) (Scaling) $\mathcal{F}[f(\lambda x)](k) = \frac{1}{|\lambda|} \tilde{f}(k/\lambda)$.
- (v) (Multiplication by x) $\mathcal{F}[xf(x)](k) = i\tilde{f}'(k)$.
- (vi) (Differentiation) $\mathcal{F}[f'(x)](k) = ik\tilde{f}(k)$.

Each is a one-line substitution or integration by parts; let's do the most important, (vi):

$$\int_{-\infty}^{\infty} f'(x)e^{-ikx} dx = \left[f(x)e^{-ikx} \right]_{-\infty}^{\infty} + ik \int_{-\infty}^{\infty} f(x)e^{-ikx} dx = ik\tilde{f}(k),$$

where the boundary term dies since $f \rightarrow 0$ at infinity (a consequence of absolute integrability). *Differentiation becomes multiplication by ik* – this single fact is why Fourier transforms solve differential equations.

There is also a pleasing **duality**: the inversion formula says $f(-x) = \frac{1}{2\pi} \int \tilde{f}(k)e^{-ikx} dk$, which upon relabelling $x \leftrightarrow k$ reads

$$\mathcal{F}[\tilde{f}](k) = 2\pi f(-k).$$

Transforming four times gets you home: $\mathcal{F}^4[f] = 4\pi^2 f$. In practice duality lets every transform we compute do double duty.

Example 18.8.4 (The Top Hat and sinc)

Let f be the ‘top hat’

$$f(x) = \begin{cases} 1 & \text{if } |x| \leq a, \\ 0 & \text{otherwise.} \end{cases}$$

Then

$$\tilde{f}(k) = \int_{-a}^a e^{-ikx} dx = \int_{-a}^a \cos(kx) dx = \frac{2 \sin ka}{k},$$

a scaled *sinc* function.

Notice that f has bounded support but $\tilde{f}$ spreads over all k , decaying only like $1/k$ – the slow decay is the price of the sharp edges. As a bonus, applying the inversion theorem at $x = 0$ (where f is continuous, $f(0) = 1$) gives

$$1 = \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{2 \sin ka}{k} dk,$$

from which (relabelling and using evenness) we obtain the **Dirichlet discontinuous**

formula

$$\int_0^\infty \frac{\sin ax}{x} dx = \frac{\pi}{2} \operatorname{sgn} a = \begin{cases} \pi/2 & \text{if } a > 0, \\ 0 & \text{if } a = 0, \\ -\pi/2 & \text{if } a < 0. \end{cases}$$

§18.8.3 Convolution and Parseval's Theorem

Multiplication of transforms corresponds to a mixing operation on the original functions.

Definition 18.8.5 (Convolution)

The **convolution** of f and g is

$$(f * g)(x) = \int_{-\infty}^{\infty} f(y)g(x-y) dy.$$

Theorem 18.8.6 (Convolution Theorem)

$\mathcal{F}[f * g] = \tilde{f}(k) \tilde{g}(k)$. Dually, $\mathcal{F}[fg] = \frac{1}{2\pi} (\tilde{f} * \tilde{g})$.

Proof. Start from the product and invert:

$$\begin{aligned} \mathcal{F}^{-1}[\tilde{f}\tilde{g}](x) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{f}(k)\tilde{g}(k)e^{ikx} dk \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \left(\int_{-\infty}^{\infty} f(y)e^{-iky} dy \right) \tilde{g}(k)e^{ikx} dk \\ &= \int_{-\infty}^{\infty} f(y) \left(\frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{g}(k)e^{ik(x-y)} dk \right) dy \\ &= \int_{-\infty}^{\infty} f(y) g(x-y) dy = (f * g)(x). \square \end{aligned}$$

Theorem 18.8.7 (Parseval's Theorem for Fourier Transforms)

$$\int_{-\infty}^{\infty} |f(x)|^2 dx = \frac{1}{2\pi} \int_{-\infty}^{\infty} |\tilde{f}(k)|^2 dk.$$

Proof. First note that if $h(x) = g^*(-x)$ then $\tilde{h}(k) = \tilde{g}^*(k)$ (substitute and conjugate). Applying the convolution theorem to f and $g^*(-\cdot)$ and evaluating at $x = 0$,

$$\int_{-\infty}^{\infty} f(y) g^*(y) dy = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{f}(k) \tilde{g}^*(k) dk,$$

which says the Fourier transform preserves inner products up to the factor 2π : $\langle g, f \rangle = \frac{1}{2\pi} \langle \tilde{g}, \tilde{f} \rangle$. Taking $g = f$ gives the result. $\square$

§18.8.4 Fourier Transforms of Generalised Functions

The class of functions with honest Fourier transforms is a bit restrictive ($f \rightarrow 0$ at infinity, etc.), but distributions let us transform far more. The key identity comes from writing out the inversion theorem in full:

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \left(\int_{-\infty}^{\infty} f(u) e^{-iku} \, du \right) e^{ikx} \, dk = \int_{-\infty}^{\infty} f(u) \left[\frac{1}{2\pi} \int_{-\infty}^{\infty} e^{ik(x-u)} \, dk \right] \, du.$$

For this to spit out $f(x)$ for every f , the bracket must be precisely a delta function:

$$\delta(x-u) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{ik(x-u)} \, dk.$$

This wildly divergent-looking integral is a perfectly good distributional statement, and it immediately gives a dictionary:

- (i) $\mathcal{F}[\delta(x)] = 1$, and more generally $\mathcal{F}[\delta(x-a)] = e^{-ika}$;
- (ii) $\mathcal{F}[1] = 2\pi\delta(k)$ (an infinitely spread function has an infinitely concentrated spectrum);
- (iii) $\mathcal{F}[\cos \omega x] = \pi(\delta(k-\omega) + \delta(k+\omega))$ and $\mathcal{F}[\sin \omega x] = i\pi(\delta(k+\omega) - \delta(k-\omega))$ – a pure tone has a spectrum concentrated at $\pm$ its frequency;
- (iv) from the Dirichlet discontinuous formula, $\mathcal{F}\left[\frac{1}{2} \operatorname{sgn} x\right] = \frac{1}{ik}$;
- (v) for the Heaviside function, writing $H(x) = \frac{1}{2} + \frac{1}{2} \operatorname{sgn} x$,

$$\mathcal{F}[H](k) = \pi\delta(k) + \frac{1}{ik}.$$

As a sanity check on (v): $H' = \delta$ requires $ik\tilde{H} = 1$, which holds since $k\delta(k) = 0$; and $H(x) + H(-x) = 1$ requires $\tilde{H}(k) + \tilde{H}(-k) = 2\pi\delta(k)$, which also checks out. Neither condition alone pins $\tilde{H}$ down – together they do.

§18.8.5 Solving Differential Equations with Fourier Transforms

Here's the general scheme: transform the equation (derivatives become multiplications), solve *algebraically*, and transform back (usually via the convolution theorem).

Example 18.8.8 (A Boundary Value Problem on the Line)

Solve $y'' - y = f(x)$ with $y \rightarrow 0$ as $x \rightarrow \pm\infty$. Transforming,

$$(ik)^2 \tilde{y} - \tilde{y} = \tilde{f} \implies \tilde{y}(k) = \frac{-\tilde{f}(k)}{1+k^2} = \tilde{f}(k) \tilde{g}(k), \quad \tilde{g}(k) = \frac{-1}{1+k^2}.$$

One can check (by computing the transform of $e^{-|x|}$) that $\tilde{g}$ is the transform of $g(x) = -\frac{1}{2}e^{-|x|}$. So by the convolution theorem,

$$y(x) = (f * g)(x) = -\frac{1}{2} \int_{-\infty}^{\infty} f(u) e^{-|x-u|} \, du.$$

This is exactly a Green's function solution, with $G(x, u) = -\frac{1}{2}e^{-|x-u|}$ – which is just

what we would have built with jump conditions, with the boundary conditions now imposed at $\pm\infty$. The Fourier transform found it for us automatically.

§18.8.6 Signal Processing and Transfer Functions

A common situation: a physical system (an amplifier, a suspension bridge, a circuit) receives an input signal $\mathcal{I}(t)$ and produces an output $\mathcal{O}(t)$, with the relationship linear and time-invariant. In the frequency domain such a system can only do one thing: multiply each frequency component by a fixed complex number. That is,

$$\tilde{\mathcal{O}}(\omega) = \tilde{\mathcal{R}}(\omega) \tilde{\mathcal{I}}(\omega),$$

where $\tilde{\mathcal{R}}(\omega)$ is the **transfer function** of the system. Its inverse transform $\mathcal{R}(t)$ is the **response function**, and by the convolution theorem

$$\mathcal{O}(t) = \int_{-\infty}^{\infty} \mathcal{I}(u) \mathcal{R}(t-u) du.$$

The response function is the output produced by a delta-function kick at $t=0$ – it is a Green's function by another name. For a physically realisable system, *causality* demands $\mathcal{R}(t) = 0$ for $t < 0$ (no output before the input), so if the input starts at $t=0$,

$$\mathcal{O}(t) = \int_0^t \mathcal{I}(u) \mathcal{R}(t-u) du,$$

which has precisely the shape of our initial value problem Green's function solutions.

Suppose the system is governed by an ODE,

$$\mathcal{L}\mathcal{O}(t) = \left(a_n \frac{d^n}{dt^n} + \cdots + a_1 \frac{d}{dt} + a_0 \right) \mathcal{O}(t) = \mathcal{I}(t).$$

Transforming, each derivative becomes $i\omega$, so

$$\tilde{\mathcal{R}}(\omega) = \frac{1}{a_0 + a_1(i\omega) + \cdots + a_n(i\omega)^n}.$$

To invert, factor the denominator over its roots and expand in partial fractions:

$$\tilde{\mathcal{R}}(\omega) = \sum_{j=1}^J \sum_{m=1}^{k_j} \frac{\Gamma_{jm}}{(i\omega - c_j)^m}.$$

The basic inverse transform (computable directly, for $\text{Re } c < 0$) is

$$\mathcal{F}^{-1} \left[\frac{1}{i\omega - c} \right] (t) = \begin{cases} e^{ct} & \text{if } t > 0, \\ 0 & \text{if } t < 0, \end{cases}$$

and repeatedly applying the 'multiplication by t ' rule gives

$$\mathcal{F}^{-1} \left[\frac{1}{(i\omega - c)^m} \right] (t) = \frac{t^{m-1}}{(m-1)!} e^{ct} \quad (t > 0).$$

So provided all roots satisfy $\text{Re } c_j < 0$ (a *stable* system – no exponentially growing responses), the response function is

$$\mathcal{R}(t) = \sum_{j=1}^J \sum_{m=1}^{k_j} \Gamma_{jm} \frac{t^{m-1}}{(m-1)!} e^{c_j t} \quad \text{for } t > 0,$$

and zero for $t < 0$. Causality has appeared automatically.

Example 18.8.9 (The Damped Oscillator)

Consider $y'' + 2py' + (p^2 + q^2)y = f(t)$ with $p > 0$ and $y(0) = y'(0) = 0$. The transfer function is

$$\tilde{\mathcal{R}}(\omega) = \frac{1}{(i\omega)^2 + 2p(i\omega) + p^2 + q^2} = \frac{1}{(i\omega + p)^2 + q^2},$$

with roots $i\omega = -p \pm iq$, both with negative real part. Partial fractions and the table above give

$$\mathcal{R}(t) = \frac{1}{q} e^{-pt} \sin(qt) \quad (t > 0),$$

a decaying oscillation, and the solution is

$$y(t) = \frac{1}{q} \int_0^t e^{-p(t-\tau)} \sin(q(t-\tau)) f(\tau) d\tau.$$

One can verify directly that $\mathcal{R}(t - \tau)$ satisfies $\mathcal{L}\mathcal{R} = \delta(t - \tau)$: it is the initial-value Green's function of the damped oscillator.

§18.8.7 Discrete Sampling and the Nyquist Frequency

In the real world we don't measure signals continuously; we *sample* them, at times $t_n = n\Delta$ for some fixed time step Δ . How much do we lose?

The natural frequency scale is the **Nyquist frequency**

$$f_c = \frac{1}{2\Delta},$$

the highest frequency the sampling can resolve – one sample per half-period. Consider sampling a pure tone $g_f(t) = A \cos(2\pi ft + \varphi)$. If $f = f_c$ exactly, then

$$g_{f_c}(t_n) = A \cos(\pi n + \varphi) = A \cos(\varphi) \cos(\pi n),$$

so the samples only see the combination $A \cos \varphi$: amplitude and phase have become degenerate, and half the information is gone. Worse, for a frequency *above* Nyquist, $f = f_c + \delta f$, the samples satisfy

$$g_{f_c+\delta f}(t_n) = g_{f_c-\delta f}(t_n) \quad (\text{up to phase}),$$

so the high frequency masquerades as the lower frequency $f_c - \delta f$. This is called **aliasing**, and it's why car wheels appear to spin backwards on film.

If, however, the signal contains *no* frequencies above some $\omega_{\max}$ (it is **bandwidth-limited**), sampling loses nothing at all:

Theorem 18.8.10 (Nyquist–Shannon Sampling Theorem)

Let g be bandwidth-limited with $\tilde{g}(\omega) = 0$ for $|\omega| > \omega_{\max}$, and sample at the Nyquist rate, $\Delta = \pi/\omega_{\max}$, giving samples $g_n = g(n\Delta)$. Then g is *exactly* reconstructible:

$$g(t) = \sum_{n=-\infty}^{\infty} g_n \frac{\sin(\omega_{\max} t - n\pi)}{\omega_{\max} t - n\pi}.$$

Proof. Since $\tilde{g}$ is supported on the bounded interval $[-\omega_{\max}, \omega_{\max}]$, we can expand it there in a *Fourier series* (in ω !): the coefficients of that series are, up to constants, exactly the samples g_n , since

$$g_n = \frac{1}{2\pi} \int_{-\omega_{\max}}^{\omega_{\max}} \tilde{g}(\omega) e^{i\pi n \omega / \omega_{\max}} d\omega.$$

So the samples determine the periodic extension $\tilde{g}_{\text{per}}(\omega) = \frac{\pi}{\omega_{\max}} \sum_n g_n e^{-i\pi n \omega / \omega_{\max}}$, and multiplying by the top hat on $[-\omega_{\max}, \omega_{\max}]$ recovers $\tilde{g}$ exactly. Inverting,

$$g(t) = \frac{1}{2\omega_{\max}} \sum_{n=-\infty}^{\infty} g_n \int_{-\omega_{\max}}^{\omega_{\max}} e^{i\omega(t-n\pi/\omega_{\max})} d\omega,$$

and each integral is a sinc, giving the stated formula. $\square$

The sinc functions are doing interpolation duty: the n th term equals g_n at $t = t_n$ and vanishes at every other sample point.

§18.8.8 The Discrete Fourier Transform

Finally, suppose we have only finitely many samples $h_m = h(t_m)$, $t_m = m\Delta$, $m = 0, \dots, N-1$. We estimate the Fourier transform at the N frequencies $f_n = \frac{n}{N\Delta}$ (which, thanks to aliasing, is the honest number of distinct frequencies available):

$$\tilde{h}(f_n) = \int_{-\infty}^{\infty} h(t) e^{-2\pi i f_n t} dt \approx \Delta \sum_{m=0}^{N-1} h_m e^{-2\pi i m n / N} = \Delta \tilde{h}_n.$$

Definition 18.8.11 (Discrete Fourier Transform)

The **discrete Fourier transform** of the vector $(h_0, \dots, h_{N-1})$ is

$$\tilde{h}_n = \sum_{m=0}^{N-1} h_m \omega^{mn}, \quad \omega = e^{-2\pi i / N},$$

i.e. $\tilde{h} = [\text{DFT}] h$ where $[\text{DFT}]_{nm} = \omega^{nm}$ is an $N \times N$ matrix of roots of unity.

The DFT matrix is (up to scaling) unitary: $[\text{DFT}]^{-1} = \frac{1}{N} [\text{DFT}]^\dagger$, so inversion is

$$h_m = \frac{1}{N} \sum_{n=0}^{N-1} \tilde{h}_n e^{2\pi i m n / N}.$$

For example, with $N = 4$ we have $\omega = -i$ and

$$[\text{DFT}] = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & -i & -1 & i \\ 1 & -1 & 1 & -1 \\ 1 & i & -1 & -i \end{pmatrix}.$$

The discrete analogues of our earlier theorems hold, e.g. Parseval becomes $\sum_m |h_m|^2 = \frac{1}{N} \sum_n |\tilde{h}_n|^2$, and convolution (defined cyclically) again maps to multiplication.

Remark (The Fast Fourier Transform). Computing the DFT naively costs $O(N^2)$ operations. The *fast Fourier transform* does it in $O(N \log N)$, by splitting the sum into even and odd samples: since $\omega_N^2 = \omega_{N/2}$,

$$\tilde{h}_k = \sum_{m=0}^{N/2-1} h_{2m} \omega_{N/2}^{mk} + \omega_N^k \sum_{m=0}^{N/2-1} h_{2m+1} \omega_{N/2}^{mk},$$

two DFTs of half the size, and recursing. This algorithm (this material is non-examinable, but too good to omit) is quietly running inside essentially every piece of modern signal-processing equipment.

§18.9 The Method of Characteristics

We now step back and develop a more geometric way of thinking about PDEs, which explains – among other things – where d’Alembert’s solution really came from, and why the wave, diffusion and Laplace equations behave so differently.

§18.9.1 Well-Posed Cauchy Problems

A **Cauchy problem** consists of a PDE for some function ϕ together with auxiliary data (values of ϕ and/or its derivatives) specified on some surface – in two dimensions, a curve. The data is called **Cauchy data**. Following Hadamard, we say the problem is **well-posed** if

- (i) a solution exists (we haven’t demanded too much),
- (ii) the solution is unique (we haven’t demanded too little), and
- (iii) the solution depends continuously on the data (small measurement errors don’t explode).

Which kinds of data make a problem well-posed depends dramatically on the equation: initial data suits the wave and diffusion equations, boundary data suits Laplace’s equation, and mixing these up goes badly wrong. The method of characteristics is the tool that explains why.

§18.9.2 Characteristics of First Order PDEs

Consider a curve C in the plane, parametrised as $(x(s), y(s))$, with tangent vector $\mathbf{u} = (dx/ds, dy/ds)$. The derivative of a function ϕ along the curve is

$$\left. \frac{d\phi}{ds} \right|_C = \frac{dx}{ds} \frac{\partial \phi}{\partial x} + \frac{dy}{ds} \frac{\partial \phi}{\partial y} = \mathbf{u} \cdot \nabla \phi.$$

Now consider the general homogeneous first order linear PDE

$$\alpha(x, y) \frac{\partial \phi}{\partial x} + \beta(x, y) \frac{\partial \phi}{\partial y} = 0.$$

The left-hand side is exactly the directional derivative of ϕ along the vector field $\mathbf{u} = (\alpha, \beta)$! So the PDE says something beautifully simple: *ϕ is constant along the integral curves of $\mathbf{u}$* , i.e. the curves solving

$$\frac{dx}{ds} = \alpha(x, y), \quad \frac{dy}{ds} = \beta(x, y).$$

These curves are called the **characteristic curves** (or just characteristics) of the PDE. Solving a PDE has been reduced to solving a family of ODEs.

To pose a Cauchy problem, we specify $\phi = f(t)$ along some initial curve B , parametrised by t as $(x(t), y(t))$, chosen *transverse* to the characteristics (nowhere tangent to them). Each characteristic then picks up its constant value where it crosses B , and carries it across the plane: labelling characteristics by their crossing point t , with s the parameter along each (set $s = 0$ on B), we get coordinates (s, t) in which the solution is simply

$$\phi(s, t) = f(t).$$

Finally, provided the Jacobian $J = x_t y_s - x_s y_t$ of the map $(s, t) \mapsto (x, y)$ is nonzero (this is what transversality buys us), we can invert to find $s(x, y)$, $t(x, y)$ and hence $\phi(x, y) = f(t(x, y))$.

In summary, the recipe is:

1. write down the characteristic equations $dx/ds = \alpha$, $dy/ds = \beta$;
2. parametrise the initial curve B by $(x(t), y(t))$;
3. solve the characteristic equations with initial conditions on B at $s = 0$, obtaining $x(s, t)$, $y(s, t)$;
4. observe ϕ is constant along characteristics, so $\phi(s, t) = f(t)$;
5. invert to express (s, t) in terms of (x, y) .

Example 18.9.1

Solve $e^x \phi_x + \phi_y = 0$ with $\phi(x, 0) = \cosh x$. The characteristic equations are

$$\frac{dx}{ds} = e^x, \quad \frac{dy}{ds} = 1,$$

and the initial curve is $(x, y) = (t, 0)$ at $s = 0$. Solving: $-e^{-x} = s - e^{-t}$ and $y = s$. So along each characteristic, $e^{-x} + y = e^{-t}$, i.e. the characteristics are the curves $y = e^{-t} - e^{-x}$, and

$$t = -\log(y + e^{-x}).$$

Since ϕ is constant along characteristics, $\phi(s, t) = \cosh t$, so

$$\phi(x, y) = \cosh[\log(y + e^{-x})] = \frac{1}{2} \left(y + e^{-x} + \frac{1}{y + e^{-x}} \right).$$

One can check directly that this satisfies the PDE and the data.

§18.9.3 Inhomogeneous First Order PDEs

Now add a source:

$$\alpha(x, y)\phi_x + \beta(x, y)\phi_y = \gamma(x, y), \quad \phi = f(t) \text{ on } B.$$

The characteristics are unchanged, but ϕ is no longer constant along them – instead

$$\left. \frac{d\phi}{ds} \right|_C = \gamma(x(s), y(s)),$$

an ODE to be solved *along each characteristic*, with initial value $f(t)$ at $s = 0$. The geometry is the same; the data is now transported with modification rather than unchanged.

Example 18.9.2

Solve $\phi_x + 2\phi_y = ye^x$ with $\phi = \sin x$ on the line $y = x$. Characteristics: $dx/ds = 1$, $dy/ds = 2$, with $(x, y) = (t, t)$ at $s = 0$, giving

$$x = s + t, \quad y = 2s + t.$$

Along a characteristic,

$$\frac{d\phi}{ds} = ye^x = (2s + t)e^{s+t},$$

and integrating with respect to s (noting $\int 2se^s ds = 2(s-1)e^s$),

$$\phi(s, t) = (2s + t - 2)e^{s+t} + c(t).$$

The initial condition $\phi(0, t) = \sin t$ gives $c(t) = \sin t - (t-2)e^t$. Inverting $s = y - x$, $t = 2x - y$,

$$\phi(x, y) = (y - 2)e^x + (2 - 2x + y)e^{2x-y} + \sin(2x - y).$$

§18.9.4 Classification of Second Order PDEs

Let's now bring these ideas to second order equations. The general second order linear PDE in two variables is

$$a(x, y)\phi_{xx} + 2b(x, y)\phi_{xy} + c(x, y)\phi_{yy} + d\phi_x + e\phi_y + f\phi = 0,$$

and its behaviour is governed by the **principal part** – the top order terms – encoded in the symmetric matrix

$$A = \begin{pmatrix} a & b \\ b & c \end{pmatrix}.$$

Definition 18.9.3 (Classification)

The PDE is

- (i) **elliptic** if $b^2 - ac < 0$ (eigenvalues of A of the same sign) – e.g. Laplace's equation;
- (ii) **hyperbolic** if $b^2 - ac > 0$ (eigenvalues of opposite signs) – e.g. the wave equation;

(iii) **parabolic** if $b^2 - ac = 0$ (a zero eigenvalue) – e.g. the diffusion equation.

The terminology comes from the conic sections $ak_1^2 + 2bk_1k_2 + ck_2^2 = \text{const.}$ Note that the classification is pointwise: an equation with variable coefficients can be hyperbolic in one region and elliptic in another.

We say a curve along which $u(x, y)$ is constant is a **characteristic curve** of the equation if

$$\begin{pmatrix} u_x & u_y \end{pmatrix} \begin{pmatrix} a & b \\ b & c \end{pmatrix} \begin{pmatrix} u_x \\ u_y \end{pmatrix} = 0.$$

(For first order equations this reduces to our earlier condition $\mathbf{u} \cdot \nabla u = 0$ along characteristics.) Writing the curve as $y = y(x)$ and using $u_x + u_y \frac{dy}{dx} = 0$ along it, the condition becomes a quadratic for the slope:

$$a \left(\frac{dy}{dx} \right)^2 - 2b \frac{dy}{dx} + c = 0 \implies \frac{dy}{dx} = \frac{b \pm \sqrt{b^2 - ac}}{a}.$$

So we can read the classification off geometrically:

- (i) hyperbolic equations have *two* families of real characteristics;
- (ii) parabolic equations have exactly one;
- (iii) elliptic equations have none.

Characteristics are the curves along which information (and discontinuities in derivatives of the solution) propagate. The wave equation moves data along its two families of characteristics; Laplace's equation, with no real characteristics, moves nothing – its solutions are instantly smooth everywhere, and only boundary data makes sense.

§18.9.5 Characteristic Coordinates

For a hyperbolic equation, using the two families of characteristics as a coordinate system (u, v) kills both the ϕ_{uu} and ϕ_{vv} terms, reducing the equation to **canonical form**

$$\frac{\partial^2 \phi}{\partial u \partial v} + (\text{lower order terms}) = 0.$$

(For parabolic equations the canonical form is $\phi_{vv} + \dots = 0$, and for elliptic ones $\phi_{uu} + \phi_{vv} + \dots = 0$.)

Example 18.9.4

Consider $-y\phi_{xx} + \phi_{yy} = 0$. Here $a = -y$, $b = 0$, $c = 1$, so $b^2 - ac = y$: the equation is hyperbolic for $y > 0$, parabolic on $y = 0$ and elliptic for $y < 0$. In the hyperbolic region, the characteristic slopes are

$$\frac{dy}{dx} = \pm \frac{1}{\sqrt{y}} \implies \frac{2}{3}y^{3/2} \mp x = \text{const.},$$

so we take characteristic coordinates

$$u = \frac{2}{3}y^{3/2} + x, \quad v = \frac{2}{3}y^{3/2} - x.$$

Computing derivatives ($u_x = 1, u_y = \sqrt{y}, v_x = -1, v_y = \sqrt{y}$) and substituting, all

the ϕ_{uu} and ϕ_{vv} terms cancel, leaving

$$4\phi_{uv} + \frac{1}{6(u+v)}(\phi_u + \phi_v) = 0,$$

using $u + v = \frac{4}{3}y^{3/2}$. This is the canonical form.

§18.9.6 The General Solution of the Wave Equation

We can now settle a promise from earlier: the wave equation

$$\frac{1}{c^2}\phi_{tt} - \phi_{xx} = 0$$

has $a = 1/c^2$, $b = 0$, $c = -1$ (in variables (t, x)), so $b^2 - ac = 1/c^2 > 0$: hyperbolic, everywhere. The characteristic slopes are

$$\frac{dx}{dt} = \pm c,$$

giving the two straight-line families $x \mp ct = \text{const}$ and the characteristic coordinates

$$u = x - ct, \quad v = x + ct.$$

In these coordinates the chain rule gives $\phi_{tt} = c^2(\phi_{uu} - 2\phi_{uv} + \phi_{vv})$ and $\phi_{xx} = \phi_{uu} + 2\phi_{uv} + \phi_{vv}$, so the wave equation collapses to the canonical form

$$\frac{\partial^2 \phi}{\partial u \partial v} = 0.$$

Integrating with respect to v : $\phi_u = (\text{function of } u)$; integrating again:

$$\phi = G(u) + H(v) = G(x - ct) + H(x + ct),$$

confirming the travelling wave decomposition we used in §3, and fitting the initial data exactly as before recovers d'Alembert's formula

$$\phi(x, t) = \frac{1}{2} [f(x - ct) + f(x + ct)] + \frac{1}{2c} \int_{x-ct}^{x+ct} g(s) ds,$$

for data $\phi(x, 0) = f(x)$, $\phi_t(x, 0) = g(x)$. The domain of dependence picture from §3 is now revealed as a completely general fact about hyperbolic equations: data propagates along characteristics, and the solution at a point can only feel data between the two characteristics through that point.

§18.10 Green's Functions for PDEs

For our final act, we combine everything – Fourier transforms, delta functions, Green's functions and our knowledge of the classical equations – to construct Green's functions for PDEs: the response of the heat, wave and Laplace equations to point sources.

§18.10.1 The Fundamental Solution of the Diffusion Equation

Consider the heat equation on the whole line,

$$\frac{\partial \theta}{\partial t} - D \frac{\partial^2 \theta}{\partial x^2} = 0, \quad \theta(x, 0) = h(x), \quad \theta \rightarrow 0 \text{ as } x \rightarrow \pm\infty.$$

Take the Fourier transform in x . Then $\partial^2/\partial x^2$ becomes $-k^2$, and for each fixed k we have an ODE in time:

$$\frac{\partial \tilde{\theta}}{\partial t}(k, t) = -Dk^2 \tilde{\theta}(k, t) \implies \tilde{\theta}(k, t) = \tilde{h}(k) e^{-Dk^2 t}.$$

Each Fourier mode simply decays, at a rate proportional to k^2 – there is the smoothing of high frequencies again, now completely explicit. To return to real space, note $e^{-Dk^2 t}$ is a Gaussian in k , whose inverse transform (by our Gaussian example, suitably scaled) is another Gaussian. The convolution theorem then gives

$$\theta(x, t) = \int_{-\infty}^{\infty} h(u) S_d(x - u, t) du,$$

where

$$S_d(x, t) = \frac{1}{\sqrt{4\pi Dt}} \exp\left(-\frac{x^2}{4Dt}\right)$$

is the **fundamental solution** (or *heat kernel*). If the initial condition is a point source of heat, $\theta(x, 0) = \theta_0 \delta(x)$, then $\theta = \theta_0 S_d(x, t)$ exactly: an ever-broadening Gaussian of constant area, with width $\sqrt{2Dt}$ – our similarity variable $\eta = x/2\sqrt{Dt}$ yet again.

Example 18.10.1 (An Initially Gaussian Temperature)

Suppose $\theta(x, 0) = \sqrt{\frac{a}{\pi}} \theta_0 e^{-ax^2}$, a Gaussian pulse of area θ_0 . The solution is the convolution of two Gaussians, which (completing the square in the exponent, or transforming and multiplying) is another Gaussian:

$$\theta(x, t) = \theta_0 \sqrt{\frac{a}{\pi(1 + 4aDt)}} \exp\left(\frac{-ax^2}{1 + 4aDt}\right).$$

The width grows like $\sqrt{t}$, the height falls correspondingly, and the area – the total heat – stays fixed at θ_0 .

§18.10.2 The Forced Diffusion Equation and Duhamel's Principle

Now add a source term:

$$\frac{\partial \theta}{\partial t} - D \frac{\partial^2 \theta}{\partial x^2} = f(x, t), \quad \theta(x, 0) = 0.$$

We build the Green's function $G(x, t; \xi, \tau)$, the response to a point source in both space and time:

$$\frac{\partial G}{\partial t} - D \frac{\partial^2 G}{\partial x^2} = \delta(x - \xi) \delta(t - \tau), \quad G = 0 \text{ at } t = 0.$$

Fourier transforming in x ,

$$\frac{\partial \tilde{G}}{\partial t} + Dk^2 \tilde{G} = e^{-ik\xi} \delta(t - \tau).$$

Multiplying by the integrating factor $e^{Dk^2 t}$ and integrating from 0 to t , the delta function fires only if $\tau < t$:

$$\tilde{G}(k, t; \xi, \tau) = e^{-ik\xi} e^{-Dk^2(t-\tau)} H(t - \tau).$$

But we recognise this: apart from the causality factor $H(t - \tau)$ and the shift $e^{-ik\xi}$, it's the transform of the heat kernel with t replaced by $t - \tau$. Inverting,

$$G(x, t; \xi, \tau) = H(t - \tau) S_d(x - \xi, t - \tau),$$

and the solution to the forced problem is

$$\theta(x, t) = \int_0^t \int_{-\infty}^{\infty} f(\xi, \tau) S_d(x - \xi, t - \tau) d\xi d\tau.$$

Look carefully at the structure of this answer. The inner integral is exactly the solution of the *unforced* heat equation started at time τ from initial data $f(\cdot, \tau)$. So the forced solution is a superposition, over all past times τ , of free evolutions seeded by the forcing at time τ : forcing acts as a continuous stream of fresh initial conditions. This correspondence between the forced problem with homogeneous initial data and the homogeneous problem with initial data is called **Duhamel's principle**.

§18.10.3 The Forced Wave Equation

The same programme for the wave equation:

$$\frac{\partial^2 \phi}{\partial t^2} - c^2 \frac{\partial^2 \phi}{\partial x^2} = f(x, t), \quad \phi(x, 0) = \phi_t(x, 0) = 0.$$

Transforming the Green's function equation in x ,

$$\frac{\partial^2 \tilde{G}}{\partial t^2} + c^2 k^2 \tilde{G} = e^{-ik\xi} \delta(t - \tau).$$

For each k this is an initial value problem for a simple harmonic oscillator kicked at $t = \tau$ – which we solved in §7! The causal solution is

$$\tilde{G} = e^{-ik\xi} \frac{\sin(kc(t - \tau))}{kc} H(t - \tau).$$

Inverting, with $A = x - \xi$ and $B = c(t - \tau)$, oddness kills the sine part of e^{ikA} and

$$\begin{aligned} G &= \frac{H(t - \tau)}{\pi c} \int_0^\infty \frac{\cos(kA) \sin(kB)}{k} dk \\ &= \frac{H(t - \tau)}{2\pi c} \int_0^\infty \frac{\sin k(A + B) - \sin k(A - B)}{k} dk, \end{aligned}$$

and by the Dirichlet discontinuous formula each integral is $\frac{\pi}{2} \operatorname{sgn}(\cdot)$, giving

$$G(x, t; \xi, \tau) = \frac{H(t - \tau)}{4c} [\operatorname{sgn}(A + B) - \operatorname{sgn}(A - B)] = \frac{1}{2c} H(c(t - \tau) - |x - \xi|).$$

The Green's function of the wave equation is a spreading 'top hat' of height $1/2c$: an impulse at (ξ, τ) affects exactly those points within distance $c(t - \tau)$ – the range of influence from the characteristics picture, reappearing from pure Fourier analysis. The solution is

$$\phi(x, t) = \frac{1}{2c} \int_0^t \int_{x-c(t-\tau)}^{x+c(t-\tau)} f(\xi, \tau) \, d\xi \, d\tau,$$

an integral of the forcing over the backwards light cone.

§18.10.4 Poisson's Equation and the Free-Space Green's Function

Finally, the elliptic case. **Poisson's equation** is the inhomogeneous Laplace equation

$$\nabla^2 \phi = -\rho(\mathbf{r}),$$

say in three dimensions (in electrostatics, ρ is the charge density up to constants). The delta function generalises to $\mathbb{R}^3$ in the obvious way: $\delta^{(3)}(\mathbf{r} - \mathbf{r}') = 0$ for $\mathbf{r} \neq \mathbf{r}'$ and $\int f(\mathbf{r}) \delta^{(3)}(\mathbf{r} - \mathbf{r}') \, dV = f(\mathbf{r}')$.

First we work on all of $\mathbb{R}^3$ with $\phi \rightarrow 0$ at infinity, seeking the **free-space Green's function**

$$\nabla^2 G_{\text{FS}}(\mathbf{r}; \mathbf{r}') = \delta^{(3)}(\mathbf{r} - \mathbf{r}').$$

Translating so $\mathbf{r}' = 0$, everything is spherically symmetric, so $G_{\text{FS}} = G(r)$. Integrate the defining equation over a ball B_r of radius r centred at the origin: the right side gives 1, while the divergence theorem turns the left side into a flux,

$$\int_{B_r} \nabla^2 G \, dV = \int_{\partial B_r} \nabla G \cdot \hat{\mathbf{n}} \, dS = 4\pi r^2 \frac{dG}{dr}.$$

Hence

$$\frac{dG}{dr} = \frac{1}{4\pi r^2} \implies G = -\frac{1}{4\pi r} + \text{const},$$

and decay at infinity kills the constant. Restoring the source point,

$$G_{\text{FS}}(\mathbf{r}; \mathbf{r}') = \frac{-1}{4\pi |\mathbf{r} - \mathbf{r}'|},$$

which is (minus) the Coulomb potential of a unit point charge. The solution of Poisson's equation in free space is therefore

$$\phi(\mathbf{r}) = \frac{1}{4\pi} \int_{\mathbb{R}^3} \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \, dV',$$

exactly the superposition-of-point-charges formula from electrostatics.

Remark. In two dimensions the same computation gives $G_{\text{FS}} = \frac{1}{2\pi} \log r$ – the $\log r$ solution we discarded by regularity when separating variables in plane polars was the point-source solution all along.

§18.10.5 Green's Identities and Boundary Value Problems

To handle Poisson's equation on a bounded domain D with boundary data, we need a few integral identities. For twice differentiable ϕ, ψ , the divergence theorem applied to $\phi \nabla \psi$ gives **Green's first identity**

$$\int_{\partial D} \phi \frac{\partial \psi}{\partial n} dS = \int_D (\phi \nabla^2 \psi + \nabla \phi \cdot \nabla \psi) dV,$$

and antisymmetrising in $\phi \leftrightarrow \psi$, **Green's second identity**

$$\int_{\partial D} \left(\phi \frac{\partial \psi}{\partial n} - \psi \frac{\partial \phi}{\partial n} \right) dS = \int_D (\phi \nabla^2 \psi - \psi \nabla^2 \phi) dV.$$

Now take $\psi = G_{\text{FS}}(\mathbf{r}; \mathbf{r}')$ and let ϕ solve $\nabla^2 \phi = -\rho$. There's a subtlety: G_{FS} is singular at $\mathbf{r}'$, so we excise a small ball $\mathcal{B}_\epsilon$ around $\mathbf{r}'$ and apply the second identity on $D \setminus \mathcal{B}_\epsilon$. On the small sphere $\partial \mathcal{B}_\epsilon$, we have $G_{\text{FS}} \sim -1/4\pi\epsilon$ and $\partial G_{\text{FS}}/\partial n \sim -1/4\pi\epsilon^2$ (with the normal pointing towards $\mathbf{r}'$), so as $\epsilon \rightarrow 0$,

$$\int_{\partial \mathcal{B}_\epsilon} \left(\phi \frac{\partial G_{\text{FS}}}{\partial n} - G_{\text{FS}} \frac{\partial \phi}{\partial n} \right) dS \rightarrow -\phi(\mathbf{r}'),$$

since the first term integrates ϕ against a shrinking sphere of total 'weight' -1 and the second vanishes like ϵ . The result is **Green's third identity**:

$$\phi(\mathbf{r}') = - \int_D G_{\text{FS}}(\mathbf{r}; \mathbf{r}') \rho(\mathbf{r}) dV + \int_{\partial D} \left(\phi \frac{\partial G_{\text{FS}}}{\partial n} - G_{\text{FS}} \frac{\partial \phi}{\partial n} \right) dS.$$

This expresses ϕ anywhere inside D in terms of the source and *both* ϕ and $\partial \phi / \partial n$ on the boundary. But for a Dirichlet problem we only *know* ϕ on the boundary – the normal derivative term is unwanted baggage.

The fix is elegant. Define the **Dirichlet Green's function** of the domain by

$$G(\mathbf{r}; \mathbf{r}') = G_{\text{FS}}(\mathbf{r}; \mathbf{r}') + H(\mathbf{r}; \mathbf{r}'),$$

where H is harmonic in D ($\nabla^2 H = 0$) and is chosen so that $G = 0$ for $\mathbf{r} \in \partial D$. Running Green's second identity with H (which has no singularity) and adding it to the third identity, all the H corrections combine and the $\partial \phi / \partial n$ term drops out (its coefficient G vanishes on ∂D). With Dirichlet data $\phi = h$ on ∂D :

$$\phi(\mathbf{r}') = - \int_D G(\mathbf{r}; \mathbf{r}') \rho(\mathbf{r}) dV + \int_{\partial D} h(\mathbf{r}) \frac{\partial G}{\partial n}(\mathbf{r}; \mathbf{r}') dS.$$

The first term is the familiar Green's function solution; the second implements the inhomogeneous boundary conditions.

§18.10.6 The Method of Images

Everything now rests on finding the harmonic correction H – and for symmetric domains there is a lovely trick: place fictitious **image sources** *outside* the domain, positioned so that their combined potential cancels on the boundary.

Example 18.10.2 (Laplace's Equation on a Half-Space)

Solve $\nabla^2 \phi = 0$ in the half-space $z > 0$, with $\phi(x, y, 0) = h(x, y)$ and $\phi \rightarrow 0$ at infinity. For a source at $\mathbf{r}' = (x', y', z')$ with $z' > 0$, place an equal and *opposite* image at the mirror point $\mathbf{r}'' = (x', y', -z')$:

$$G(\mathbf{r}; \mathbf{r}') = \frac{-1}{4\pi|\mathbf{r} - \mathbf{r}'|} + \frac{1}{4\pi|\mathbf{r} - \mathbf{r}''|}.$$

The image term is harmonic inside $z > 0$ (its singularity is at $z < 0$), and on the plane $z = 0$ every point is equidistant from $\mathbf{r}'$ and $\mathbf{r}''$, so $G = 0$ there: this *is* the Dirichlet Green's function. Computing the normal derivative on the boundary,

$$\left. \frac{\partial G}{\partial n} \right|_{z=0} = \frac{z'}{2\pi} [(x - x')^2 + (y - y')^2 + z'^2]^{-3/2},$$

so the solution of the boundary value problem is

$$\phi(x', y', z') = \frac{z'}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{h(x, y) \, dx \, dy}{[(x - x')^2 + (y - y')^2 + z'^2]^{3/2}}.$$

Example 18.10.3 (Images for the Wave Equation)

The method works for time-dependent problems too. To solve the wave equation on the half-line $x > 0$ with a fixed end $\phi(0, t) = 0$, take the free-space causal Green's function and subtract its mirror image:

$$G(x, t; \xi, \tau) = \frac{1}{2c} H(c(t - \tau) - |x - \xi|) - \frac{1}{2c} H(c(t - \tau) - |x + \xi|),$$

which vanishes at $x = 0$ for all time. (Adding instead of subtracting the image gives a free end – a Neumann condition.) Concretely, a leftward-travelling pulse started near $\xi > 0$ meets its opposite-signed image emerging from the boundary, and the result is the familiar picture of a wave reflecting off a fixed end with inverted phase – in agreement with the $B = -A$ limit of our reflection analysis in §3.

And with that, the toolbox is complete. It is worth stepping back to admire how the pieces interlock: separation of variables turns PDEs into Sturm–Liouville problems; completeness of eigenfunctions is the delta function's expansion; the delta function defines Green's functions; Fourier transforms construct them; and the characteristics of the equation dictate the causal structure that the Green's functions faithfully reproduce. Linearity, exploited from every possible direction.

19 Numerical Analysis

Almost none of the problems that we would like to solve can actually be solved. Most integrals have no closed form, most differential equations have no solution in terms of familiar functions, and a large linear system is not something one inverts by hand. Numerical analysis is the study of what to do about this: how to replace an infinite-dimensional problem by a finite-dimensional one whose answer we can compute, and – crucially – how to say something rigorous about the difference between the two.

So this is not a course about computers, and it is certainly not a course about programming. It is a course about *approximation*, and about the two questions that any approximation scheme must answer. How accurate is it? And how expensive is it? Almost every result in these notes is an answer to one of those two questions, and a surprising amount of quite beautiful classical mathematics – orthogonal polynomials, Rolle’s theorem, the maximum modulus principle – turns out to be exactly what is needed to answer them.

This article constitutes my notes for the ‘Numerical Analysis’ course, held in Lent 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§19.1 Polynomial Interpolation

Polynomials are the simplest functions we know how to compute with: to evaluate one we need only additions and multiplications, and to integrate or differentiate one we need only the power rule. It is therefore natural that our first move, when confronted with an awkward function f , is to replace it by a polynomial that agrees with f at a handful of points. This is the *interpolation problem*, and it is the foundation on which almost everything else in this course is built – quadrature rules, multistep methods for differential equations and error estimates all come, in the end, from interpolating polynomials.

Throughout, we write $\mathcal{P}_n$ (or $\mathcal{P}_n[x]$ when we want to emphasise the variable) for the vector space of real polynomials of degree at most n . Note that $\dim \mathcal{P}_n = n + 1$, since a polynomial in $\mathcal{P}_n$ is determined by its $n + 1$ coefficients. That number, $n + 1$, is worth keeping in mind: it is exactly the number of data points that we shall be able to fit.

§19.1.1 Lagrange and Newton Polynomials

Let $f : [a, b] \rightarrow \mathbb{R}$ be a real-valued continuous function defined on some interval $[a, b]$ and let $(x_i)_{i=0}^n$ be $n + 1$ distinct points in $[a, b]$. We wish to construct a polynomial p of degree n which interpolates f at these points, i.e., satisfies

$$p(x_i) = f(x_i), \quad i = \overline{0, n}, \quad p \in \mathcal{P}_n$$

Theorem 19.1.1 (Existence and Uniqueness)

Given $f \in C[a, b]$ and $n + 1$ distinct points $(x_i)_{i=0}^n \in [a, b]$, there is exactly one

polynomial $p \in \mathcal{P}_n$ such that $p(x_i) = f(x_i)$ for all i .

Proof. Existence. There is at least one polynomial interpolant $p \in \mathcal{P}_n$, the one in the Lagrange form,

$$p(x) = \sum_{i=0}^n f(x_i) \ell_i(x) \quad \text{with} \quad \ell_i(x) := \prod_{\substack{j=0 \\ j \neq i}}^n \frac{x - x_j}{x_i - x_j}, \quad i = 0, \dots, n, \quad (\dagger)$$

the ℓ_i s are called the **fundamental Lagrange polynomials**. Each ℓ_i is the product of n linear factors, hence $\ell_i \in \mathcal{P}_n$. It also equals 1 at x_i and vanishes at $x_j \neq x_i$, i.e., $\ell_i(x_j) = \delta_{ij}$. Therefore $p \in \mathcal{P}_n$ and

$$p(x_j) = \sum_{i=0}^n f(x_i) \ell_i(x_j) = f(x_j).$$

Uniqueness. There is at most one polynomial interpolant $p \in \mathcal{P}_n$ to f on $(x_i)_{i=0}^n$. For if there are two, $p, q \in \mathcal{P}_n$, then the polynomial $r := p - q$ is of degree n and vanishes at $n + 1$ points, whence $r \equiv 0$. $\square$

Let us introduce the so-called **nodal polynomial**

$$\omega(x) = \prod_{i=0}^n (x - x_i).$$

Then, in the expression $(\dagger)$ for ℓ_i , the numerator is simply $\omega(x)/(x - x_i)$ while the denominator is equal to $\omega'(x_i)$. With that we arrive to a compact Lagrange form

$$p(x) = \sum_{i=0}^n f(x_i) \ell_i(x) = \sum_{i=0}^n \frac{f(x_i)}{\omega'(x_i)} \frac{\omega(x)}{x - x_i}.$$

The lagrange forms above and in $(\dagger)$ for interpolating polynomials are easy to manipulate, but they are unsuitable for numerical evaluation. An alternative is the *Newton form* which has an *adaptive* nature.

Method 19.1.2 (Newton Form)

For $k = 0, 1, \dots, n$, let $p_k \in \mathcal{P}_k$ be the polynomial interpolant to f on $x_0, \dots, x_k$. Then two subsequent p_{k-1} and p_k interpolate the same values $f(x_i)$ for $i \leq k - 1$, hence their difference is a polynomial of degree k that vanishes at k points $x_0, \dots, x_{k-1}$. Thus

$$p_k(x) - p_{k-1}(x) = A_k \prod_{i=0}^{k-1} (x - x_i), \quad (19.1)$$

with some constant A_k which is seen to be equal to the leading coefficient of p_k .

It follows that $p = p_n$ can be built step by step as one constructs the sequence $(p_0, p_1, \dots)$, with p_k obtained from p_{k-1} by adding the term on the right-hand side

of (19.1), so that finally

$$p(x) = p_n(x) = p_0(x) + \sum_{k=1}^n [p_k(x) - p_{k-1}(x)] = \sum_{k=0}^n A_k \prod_{i=0}^{k-1} (x - x_i).$$

The coefficients A_k appearing here are important enough to be given a name of their own.

Definition 19.1.3 (Divided Difference)

Given $f \in C[a, b]$ and $k + 1$ distinct points $(x_i)_{i=0}^k \in [a, b]$, the **divided difference** $f[x_0, \dots, x_k]$ of order k is the leading coefficient of the polynomial $p_k \in \mathcal{P}_k$ which interpolates f at these points.

The divided difference is a symmetric function of the variables $[x_0, \dots, x_k]$, since the interpolating polynomial does not care about the order in which we list the interpolation points. Also, if $f(x) = x^m$ with $m \leq k$, then $p_k = f$ and so $f[x_0, \dots, x_k] = \delta_{km}$. The two lowest-order cases are worth recording: $f[x_0] = f(x_0)$, and $f[x_0, x_1]$ is the slope

$$f[x_0, x_1] = \frac{f(x_1) - f(x_0)}{x_1 - x_0}$$

of the straight line through $(x_0, f(x_0))$ and $(x_1, f(x_1))$, which is where the name ‘divided difference’ comes from.

With this definition we arrive at the **Newton formula** for the interpolating polynomial.

Theorem 19.1.4 (Newton Formula)

Given $n + 1$ distinct points $(x_i)_{i=0}^n$, let $p_n \in \mathcal{P}_n$ be the polynomial that interpolates f at these points. Then it may be written in the Newton form

$$p_n(x) = f[x_0] + f[x_0, x_1](x - x_0) + f[x_0, x_1, x_2](x - x_0)(x - x_1) + \dots \\ \dots + f[x_0, x_1, \dots, x_n](x - x_0)(x - x_1) \dots (x - x_{n-1}),$$

or, more compactly,

$$p_n(x) = \sum_{k=0}^n f[x_0, \dots, x_k] \prod_{i=0}^{k-1} (x - x_i)$$

To make this formula of any use, we need an expression for $f[x_0, \dots, x_k]$. One such can be derived from the Lagrange formula by identifying the leading coefficient of p . This turns out to be

$$f[x_0, \dots, x_n] = \sum_{i=0}^n \frac{f(x_i)}{\omega'(x_i)}, \quad \omega(x) := \prod_{i=0}^n (x - x_i).$$

However, this expression has computational disadvantages as the Lagrange form itself. A useful way to calculate divided difference is again an adaptive (or recurrence) approach.

Theorem 19.1.5 (Recurrence Relation)

For distinct $x_0, x_1, \dots, x_k$ with $k \geq 1$, we have

$$f[x_0, \dots, x_k] = \frac{f[x_1, \dots, x_k] - f[x_0, \dots, x_{k-1}]}{x_k - x_0}. \quad (19.2)$$

Proof. Let $q_0, q_1 \in \mathcal{P}_{k-1}$ be the polynomials such that q_0 interpolates f on $(x_0, x_1, \dots, x_{k-1})$ and q_1 interpolates on $(x_1, \dots, x_k)$. Consider the polynomial

$$p(x) = \frac{x - x_0}{x_k - x_0} q_1(x) + \frac{x_k - x}{x_k - x_0} q_0(x), \quad p \in \mathcal{P}_k.$$

One readily sees that $p(x_i) = f(x_i)$ for all i : at x_0 the first term vanishes and the second has coefficient 1, at x_k the reverse happens, and at an intermediate x_i both q_0 and q_1 return $f(x_i)$ while the two coefficients sum to 1. Hence p is the k -th degree interpolating polynomial to f . Moreover, the leading coefficient of p is equal to the difference of those of q_1 and q_0 divided by $x_k - x_0$, and that is exactly what the recurrence (19.2) says. $\square$

The recursive relation allows for the fast evaluation of the **divided difference table**

x_i	f_i	$f[*,*]$	$f[*,*,*]$	$\dots$	$f[*, \dots, *]$
x_0	$f[x_0]$				
		$f[x_0, x_1]$			
x_1	$f[x_1]$		$f[x_0, x_1, x_2]$		
		$f[x_1, x_2]$		$\ddots$	
x_2	$f[x_2]$		$f[x_2, x_3, x_4]$	$\dots$	$f[x_0, x_1, \dots, x_n]$
		$f[x_2, x_3]$		$\ddots$	
x_3	$f[x_3]$		$\ddots$		
$\vdots$	$\vdots$	$\ddots$			
x_n	$f[x_n]$				

This can be done in $\mathcal{O}(n^2)$ operations and the outcome is the numbers $\{f[x_0, \dots, x_k]\}_{k=0}^n$ at the head of the columns which can be used in the Newton form.

Pictorially, each entry is obtained from its two neighbours to the left, in the pattern

$$\begin{array}{ccc}
 f[x_0, \dots, x_{k-1}] & \xrightarrow{-} & \\
 & \searrow & \\
 & & f[x_0, \dots, x_k] \\
 f[x_1, \dots, x_k] & \xrightarrow{+} & \text{then divide by } x_k - x_0
 \end{array}$$

so that the table is filled column by column, each column being one entry shorter than the last.

Finally evaluation of p at a given point x using Newton formula (provided that divided differences $A_k = f[x_0, \dots, x_k]$ are known) requires just n multiplications, as long as we

do it by the **Horner scheme**

$$p_n(x) = \{ \cdots \{ \{ A_n \times (x - x_{n-1}) + A_{n-1} \} \times (x - x_{n-2}) + A_{n-2} \} \\ \times (x - x_{n-3}) + \cdots + A_1 \} \times (x - x_0) + A_0.$$

It is worth pausing to compare the two forms. Both cost $\mathcal{O}(n^2)$ operations to set up. The Lagrange form is the one to reach for when we want to *manipulate* the interpolant symbolically – to integrate it, say, or to differentiate it – because f appears in it linearly, through the values $f(x_i)$, with coefficients ℓ_i that do not depend on f at all. This is exactly what we will exploit when we build quadrature rules in Section 3. The Newton form, on the other hand, is the one to reach for when we want to *compute*: adding a new interpolation point x_{n+1} costs only one extra term, whereas in the Lagrange form every single ℓ_i has to be recomputed from scratch.

§19.1.2 Examples

We will now look at some examples of these methods in use.

Example 19.1.6 (Interpolating Polynomial)

Given the data

x_i	0	1	2	3
$f(x_i)$	-3	-3	-1	9

we want to find the interpolating polynomial $p \in \mathcal{P}_3$ in both Lagrange and Newton forms.

Fundamental Lagrange polynomials. We have

$$\begin{aligned} \ell_0(x) &= \frac{(x-1)(x-2)(x-3)}{-6} = -\frac{1}{6}(x^3 - 6x^2 + 11x - 6), \\ \ell_1(x) &= \frac{x(x-2)(x-3)}{2} = \frac{1}{2}(x^3 - 5x^2 + 6x), \\ \ell_2(x) &= \frac{x(x-1)(x-3)}{-2} = -\frac{1}{2}(x^3 - 4x^2 + 3x), \\ \ell_3(x) &= \frac{x(x-1)(x-2)}{6} = \frac{1}{6}(x^3 - 3x^2 + 2x). \end{aligned}$$

Lagrange form. Using the polynomials above, we can write

$$\begin{aligned} p(x) &= (-3) \cdot \ell_0(x) + (-3) \cdot \ell_1(x) + (-1) \cdot \ell_2(x) + 9 \cdot \ell_3(x) \\ &= \left(\frac{1}{2} - \frac{3}{2} + \frac{1}{2} + \frac{3}{2} \right) x^3 + \left(-3 + \frac{15}{2} - 2 - \frac{9}{2} \right) x^2 + \left(\frac{11}{2} - 9 + \frac{3}{2} + 3 \right) x - 3 \\ &= x^3 - 2x^2 + x - 3. \end{aligned}$$

Newton form. Here we build the divided difference table, filling it in column by column using the recurrence (19.2). Since the nodes are spaced one apart, the denominators $x_k - x_0$ are 1, 2, 3 in the three successive columns.

x_i	$f[x_i]$	$f[*,*]$	$f[*,*,*]$	$f[*,*,*,*]$
0	-3			
		0		
1	-3		1	
		2		1
2	-1		4	
		10		
3	9			

Reading off the numbers at the head of each column gives

$$p(x) = -3 + 0 \cdot (x - 0) + 1 \cdot (x - 0)(x - 1) + 1 \cdot (x - 0)(x - 1)(x - 2),$$

and expanding this out we do indeed recover $p(x) = x^3 - 2x^2 + x - 3$, as we must.

Notice how much less work the second computation was. The advantage becomes more pronounced still if the data arrives one point at a time.

Example 19.1.7 (Adding a Point)

Suppose that to the data of the previous example we now append the point $x_4 = 4$, $f(x_4) = 33$. In the Lagrange form we would have to start again. In the Newton form we merely extend the table by one diagonal:

$$f[x_3, x_4] = \frac{33 - 9}{1} = 24, \quad f[x_2, x_3, x_4] = \frac{24 - 10}{2} = 7, \quad f[x_1, \dots, x_4] = \frac{7 - 4}{2} = \frac{3}{2},$$

and finally $f[x_0, \dots, x_4] = (\frac{3}{2} - 1)/4 = \frac{1}{8}$. Hence

$$p_4(x) = p_3(x) + \frac{1}{8}x(x - 1)(x - 2)(x - 3).$$

All the work done for p_3 has been retained.

Example 19.1.8 (A Divided Difference Table with Non-uniform Nodes)

Let $f(x) = \sqrt{x}$ and take the nodes $x_0 = 1$, $x_1 = 4$, $x_2 = 9$. Then

$$f[x_0, x_1] = \frac{2 - 1}{4 - 1} = \frac{1}{3}, \quad f[x_1, x_2] = \frac{3 - 2}{9 - 4} = \frac{1}{5},$$

and so

$$f[x_0, x_1, x_2] = \frac{\frac{1}{5} - \frac{1}{3}}{9 - 1} = -\frac{1}{60}.$$

The interpolant is therefore

$$p_2(x) = 1 + \frac{1}{3}(x - 1) - \frac{1}{60}(x - 1)(x - 4).$$

Evaluating at $x = 2$ gives $p_2(2) = 1 + \frac{1}{3} + \frac{1}{30} = 1.3\bar{6}$, against the true value $\sqrt{2} = 1.41421\dots$. The error is about 0.048, which – as we are about to see – is entirely predictable.

§19.1.3 The Error of Interpolation

An interpolant is only useful if we can say how far it is from f *between* the interpolation points. The following theorem, which is the workhorse of the whole subject, says that the error looks exactly like the next term of a Taylor series, with the monomial $(x-a)^{n+1}$ replaced by the nodal polynomial ω .

Theorem 19.1.9 (Interpolation Error)

Let $f \in C^{n+1}[a, b]$ and let $x_0, \dots, x_n \in [a, b]$ be distinct. Let $p \in \mathcal{P}_n$ interpolate f at these points. Then for every $x \in [a, b]$ there exists $\xi = \xi(x) \in (a, b)$ such that

$$f(x) - p(x) = \frac{1}{(n+1)!} f^{(n+1)}(\xi) \omega(x), \quad \omega(x) = \prod_{i=0}^n (x - x_i).$$

Proof. If $x = x_i$ for some i then both sides vanish and there is nothing to prove, so fix $x \in [a, b]$ with $x \neq x_i$ for all i . In particular $\omega(x) \neq 0$, so we may define $\varphi : [a, b] \rightarrow \mathbb{R}$ by

$$\varphi(t) = f(t) - p(t) - (f(x) - p(x)) \frac{\omega(t)}{\omega(x)}.$$

This is a C^{n+1} function of t , and it has been rigged so that $\varphi(x) = 0$; it also vanishes at each of $x_0, \dots, x_n$, since there $f - p$ and ω both vanish. So φ has at least $n+2$ distinct zeros in $[a, b]$.

Now we apply Rolle's theorem repeatedly. Between consecutive zeros of φ there is a zero of φ' , so φ' has at least $n+1$ distinct zeros; between consecutive zeros of φ' there is a zero of φ'' , so φ'' has at least n distinct zeros; and continuing in this way, $\varphi^{(n+1)}$ has at least one zero, say $\xi \in (a, b)$.

But $p \in \mathcal{P}_n$ has $p^{(n+1)} \equiv 0$, while ω is monic of degree $n+1$ and so $\omega^{(n+1)} \equiv (n+1)!$. Hence

$$0 = \varphi^{(n+1)}(\xi) = f^{(n+1)}(\xi) - (f(x) - p(x)) \frac{(n+1)!}{\omega(x)},$$

and rearranging gives the result. $\square$

The same trick – count zeros, then apply Rolle – gives a very satisfying interpretation of divided differences: they are, up to a factorial, derivatives.

Theorem 19.1.10 (Divided Differences and Derivatives)

Let $x_0, \dots, x_n$ be distinct points and let $[a, b]$ be the smallest interval containing them. If $f \in C^n[a, b]$, then there is some $\xi \in (a, b)$ with

$$f[x_0, \dots, x_n] = \frac{1}{n!} f^{(n)}(\xi).$$

Proof. Let $p \in \mathcal{P}_n$ interpolate f at the $n+1$ points. Then $f - p$ vanishes at $n+1$ distinct points, so by Rolle applied n times, $(f - p)^{(n)}$ vanishes somewhere in (a, b) , say at ξ . But p has leading coefficient $f[x_0, \dots, x_n]$, so $p^{(n)} \equiv n! f[x_0, \dots, x_n]$, and thus

$$0 = f^{(n)}(\xi) - n! f[x_0, \dots, x_n]. \quad \square$$

Remark. This is a pleasing statement in its own right: it says that the divided difference is a ‘discrete derivative’, and it also lets us make sense of $f[x_0, \dots, x_n]$ when some of the points coalesce. Letting all the $x_i \rightarrow x$, the natural definition is $f[x, x, \dots, x] = f^{(n)}(x)/n!$, and with this convention the Newton formula becomes the Taylor expansion of f about x . Interpolation and Taylor expansion are, in this sense, the same thing.

Let us use Theorem 19.1.9 on the example above.

Example 19.1.11

With $f(x) = \sqrt{x}$ and nodes 1, 4, 9, we have $f'''(x) = \frac{3}{8}x^{-5/2}$ and $\omega(2) = (2-1)(2-4)(2-9) = 14$. So

$$\sqrt{2} - p_2(2) = \frac{1}{6} \cdot \frac{3}{8} \xi^{-5/2} \cdot 14 = \frac{7}{8} \xi^{-5/2}$$

for some $\xi \in (1, 9)$. Since $\xi > 1$ we get $|\sqrt{2} - p_2(2)| \leq 7/8$, which is true but useless; a better bound comes from noticing that ξ is in practice near the interval where the action is. The exact error was 0.0476, corresponding to $\xi \approx 2.2$. The moral is that the theorem gives the *form* of the error very precisely, but a crude bound on $f^{(n+1)}$ can throw most of that precision away.

§19.1.4 The Runge Phenomenon

Theorem 19.1.9 contains two factors that we might hope to control. The factor $f^{(n+1)}(\xi)/(n+1)!$ is out of our hands – it is a property of f . But the nodal polynomial ω depends only on where we choose to put our interpolation points, and this we *can* control. The following famous example of Runge shows that the choice matters enormously, and that the obvious choice is a bad one.

Example 19.1.12 (Runge's Example)

Let $f(x) = (1+x^2)^{-1}$ on $[-5, 5]$, and interpolate at the $n+1$ equally spaced points $x_j = -5 + 10j/n$. Below is the case $n = 10$: the function f is in blue, the interpolant p_{10} in red, with the interpolation points marked.

The interpolant is faithful in the middle of the interval and catastrophically bad near the endpoints, where it oscillates with amplitude close to 2 even though $|f| \leq 1$ everywhere. Worse, this does not improve as n grows: one can show that

$$\max_{x \in [-5, 5]} |f(x) - p_n(x)| \rightarrow \infty \quad \text{as } n \rightarrow \infty.$$

Interpolating at more equally spaced points makes matters *worse*, not better.

What has gone wrong? The culprit is the nodal polynomial. For equally spaced nodes on $[-1, 1]$, $|\omega|$ is tiny in the middle of the interval but grows by a factor exponential in n as we approach the ends, so the error bound is wildly non-uniform. If we want $|\omega|$ to be uniformly small, we should not space the nodes uniformly; we should cluster them near the endpoints.

The optimal choice is classical. On $[-1, 1]$ the **Chebyshev points**

$$x_j = \cos\left(\frac{(n-j)\pi}{n}\right), \quad j = 0, 1, \dots, n,$$

are obtained by taking $n+1$ equally spaced points on the upper half of the unit circle and projecting them down onto the real axis. The picture makes the clustering obvious.

With this choice one can show that the nodal polynomial satisfies

$$\max_{x \in [-1, 1]} |\omega(x)| = 2^{-n},$$

and that no other choice of $n+1$ nodes does better. (The nodal polynomial for the Chebyshev points is $2^{-n}T_{n+1}$, where T_{n+1} is the Chebyshev polynomial we shall meet in the next section; the optimality is a consequence of its equioscillation.) For a general interval $[a, b]$ we simply rescale, taking

$$x_j = \frac{a+b}{2} + \frac{b-a}{2} \cos\left(\frac{(n-j)\pi}{n}\right).$$

Repeating Runge's experiment with Chebyshev points, the interpolant converges uniformly to f , and rapidly at that.

Remark. This is a good point to pause and notice what the theory has bought us. Nothing about the function f has changed; all we have done is move the sampling points. But the same theorem that predicted disaster for equispaced nodes predicts success for Chebyshev nodes, because it isolates precisely the quantity (ω) that we are free to choose. This pattern – write down an exact error formula, look at which factor is under our control, and optimise it – recurs throughout the course, and is the whole idea behind Gaussian quadrature.

§19.2 Orthogonal Polynomials

We now change tack somewhat. Rather than asking for a polynomial that agrees with f at finitely many points, we ask for a polynomial that is close to f *on average*, in the sense

of least squares. This turns out to require a good basis for $\mathcal{P}_n$, and the right notion of ‘good’ is orthogonality with respect to a suitable inner product. Orthogonal polynomials are the central objects here, and they will reappear – somewhat unexpectedly – as the key to the most accurate quadrature rules there are.

§19.2.1 Inner Products on Function Spaces

Definition 19.2.1 (Inner Product)

Let V be a real vector space. An **inner product** (or scalar product) on V is a map $\langle \cdot, \cdot \rangle : V \times V \rightarrow \mathbb{R}$ which is

- (i) *symmetric*: $\langle f, g \rangle = \langle g, f \rangle$ for all $f, g \in V$;
- (ii) *bilinear*: linear in each argument;
- (iii) *positive definite*: $\langle f, f \rangle \geq 0$ for all f , with equality if and only if $f = 0$.

We say f and g are **orthogonal** if $\langle f, g \rangle = 0$, and we write $\|f\| = \langle f, f \rangle^{1/2}$ for the induced norm.

For us V will almost always be a space of functions on an interval, and the inner product will be of the following shape.

Definition 19.2.2 (Weight Function)

Let $[a, b] \subseteq \mathbb{R}$ (possibly infinite) and let $w : (a, b) \rightarrow \mathbb{R}$ be continuous, non-negative, and non-zero except at isolated points, with $\int_a^b w(x) dx < \infty$. We call w a **weight function**, and define

$$\langle f, g \rangle = \int_a^b w(x) f(x) g(x) dx.$$

The conditions on w are exactly what is needed for this to be an inner product on $C[a, b]$: symmetry and bilinearity are immediate, and if $\langle f, f \rangle = \int_a^b w f^2 = 0$ with $w f^2 \geq 0$ continuous, then $w f^2 \equiv 0$, and since w vanishes only at isolated points, $f \equiv 0$ by continuity.

A second, more down-to-earth example is available when we only know f at finitely many points.

Example 19.2.3 (Discrete Inner Product)

Let $\xi_1, \dots, \xi_m$ be distinct points and set

$$\langle f, g \rangle = \sum_{j=1}^m f(\xi_j) g(\xi_j).$$

This is symmetric and bilinear, and $\langle f, f \rangle = \sum_j f(\xi_j)^2 \geq 0$. It is *not* positive definite on all of $C[a, b]$ – a function vanishing at every ξ_j has zero norm – but it *is* positive definite on $\mathcal{P}_n$ provided $n < m$, since a nonzero polynomial of degree at most n cannot vanish at $m > n$ points. This is the inner product relevant to fitting a curve to experimental data.

Definition 19.2.4 (Orthogonal Polynomials)

A sequence $p_0, p_1, p_2, \dots$ of polynomials is a sequence of **orthogonal polynomials** with respect to $\langle \cdot, \cdot \rangle$ if $\deg p_n = n$ for every n , and $\langle p_n, p_m \rangle = 0$ whenever $n \neq m$.

Since $\deg p_n = n$ exactly, the polynomials $p_0, \dots, p_n$ are automatically linearly independent (they have distinct degrees), and so they form an orthogonal *basis* of $\mathcal{P}_n$. This is really the point of the definition: we are constructing a basis of $\mathcal{P}_n$ in which computations decouple.

Of course, orthogonal polynomials are only determined up to scaling, so to speak of *the* orthogonal polynomials we should normalise. The usual convention in this course is to take them **monic**, that is, with leading coefficient 1.

Theorem 19.2.5 (Existence and Uniqueness)

For any inner product on the space of polynomials there exists a unique sequence of monic orthogonal polynomials $p_0, p_1, \dots$, and these may be constructed by the Gram–Schmidt formula

$$p_{n+1}(x) = x^{n+1} - \sum_{k=0}^n \frac{\langle x^{n+1}, p_k \rangle}{\langle p_k, p_k \rangle} p_k(x).$$

Proof. We induct on n . For $n = 0$ the only monic polynomial of degree 0 is $p_0 \equiv 1$, so existence and uniqueness are clear. Suppose then that $p_0, \dots, p_n$ have been found. Define p_{n+1} by the displayed formula. The subtracted sum lies in $\mathcal{P}_n$, so p_{n+1} is monic of degree $n + 1$. For each $j \leq n$, using orthogonality of the p_k ,

$$\langle p_{n+1}, p_j \rangle = \langle x^{n+1}, p_j \rangle - \frac{\langle x^{n+1}, p_j \rangle}{\langle p_j, p_j \rangle} \langle p_j, p_j \rangle = 0,$$

so p_{n+1} is orthogonal to $p_0, \dots, p_n$ and hence to all of $\mathcal{P}_n$.

For uniqueness, suppose $\tilde{p}_{n+1}$ were another monic polynomial of degree $n + 1$ orthogonal to $\mathcal{P}_n$. Then $q = p_{n+1} - \tilde{p}_{n+1}$ has degree at most n , so $q \in \mathcal{P}_n$, and q is orthogonal to everything in $\mathcal{P}_n$ – in particular to itself. Hence $\langle q, q \rangle = 0$ and so $q = 0$. $\square$

Remark. Note the characterisation buried in that proof: p_n is the unique monic polynomial of degree n orthogonal to *every* polynomial of lower degree. We will use this form of the statement constantly.

Gram–Schmidt is a perfectly good proof, but it is a poor algorithm: computing p_{n+1} requires all of $p_0, \dots, p_n$, so the cost grows and rounding errors accumulate. For the inner products we care about there is a far better recurrence, which involves only the previous *two* polynomials.

§19.2.3 The Three-Term Recurrence

The key hypothesis is that multiplication by x is self-adjoint. For the weighted-integral inner product this is obvious:

$$\langle xf, g \rangle = \int_a^b w(x) xf(x)g(x) dx = \langle f, xg \rangle,$$

and it holds for the discrete inner product too.

Theorem 19.2.6 (Three-Term Recurrence)

Suppose the inner product satisfies $\langle xf, g \rangle = \langle f, xg \rangle$ for all polynomials f, g . Then the monic orthogonal polynomials satisfy

$$p_{n+1}(x) = (x - \alpha_n)p_n(x) - \beta_n p_{n-1}(x), \quad n \geq 0,$$

with the conventions $p_{-1} \equiv 0$, $p_0 \equiv 1$, β_0 arbitrary, and

$$\alpha_n = \frac{\langle p_n, xp_n \rangle}{\langle p_n, p_n \rangle}, \quad \beta_n = \frac{\langle p_n, p_n \rangle}{\langle p_{n-1}, p_{n-1} \rangle} > 0 \quad (n \geq 1).$$

Proof. Both p_{n+1} and xp_n are monic of degree $n+1$, so their difference lies in $\mathcal{P}_n$, and since $p_0, \dots, p_n$ is a basis of $\mathcal{P}_n$ we may write

$$p_{n+1}(x) - xp_n(x) = \sum_{k=0}^n \gamma_k p_k(x)$$

for some scalars γ_k . Taking the inner product with p_j for $j \leq n$ and using orthogonality of p_{n+1} against $\mathcal{P}_n$,

$$\gamma_j \langle p_j, p_j \rangle = -\langle xp_n, p_j \rangle = -\langle p_n, xp_j \rangle,$$

where the last step is the self-adjointness hypothesis. Now if $j \leq n-2$ then $xp_j \in \mathcal{P}_{n-1}$, which is orthogonal to p_n , so $\gamma_j = 0$. Only $j = n$ and $j = n-1$ survive, giving

$$p_{n+1}(x) = (x - \alpha_n)p_n(x) - \beta_n p_{n-1}(x), \quad \alpha_n = \frac{\langle p_n, xp_n \rangle}{\langle p_n, p_n \rangle}, \quad \beta_n = \frac{\langle p_n, xp_{n-1} \rangle}{\langle p_{n-1}, p_{n-1} \rangle}.$$

Finally, xp_{n-1} is monic of degree n , so $xp_{n-1} - p_n \in \mathcal{P}_{n-1}$ is orthogonal to p_n ; hence $\langle p_n, xp_{n-1} \rangle = \langle p_n, p_n \rangle$, which gives the stated β_n , manifestly positive. $\square$

This is a genuinely useful algorithm: each new polynomial costs $\mathcal{O}(1)$ inner products rather than $\mathcal{O}(n)$, and the recurrence is numerically stable. Let's look at the two examples that matter most.

Example 19.2.7 (Legendre Polynomials)

Take $[a, b] = [-1, 1]$ and $w \equiv 1$, so that $\langle f, g \rangle = \int_{-1}^1 fg dx$. The resulting monic orthogonal polynomials are the (monic) **Legendre polynomials**. By symmetry $\langle p_n, xp_n \rangle = 0$ for every n – the integrand is odd – so $\alpha_n = 0$ throughout, and the

recurrence collapses to $p_{n+1} = xp_n - \beta_n p_{n-1}$. Computing,

$$p_0 = 1, \quad p_1 = x, \quad p_2 = x^2 - \frac{1}{3}, \quad p_3 = x^3 - \frac{3}{5}x, \quad p_4 = x^4 - \frac{6}{7}x^2 + \frac{3}{35}.$$

For instance $\beta_1 = \langle p_1, p_1 \rangle / \langle p_0, p_0 \rangle = (2/3)/2 = 1/3$, giving $p_2 = x \cdot x - \frac{1}{3} = x^2 - \frac{1}{3}$ as claimed. In the literature one usually meets these normalised so that $P_n(1) = 1$; then $P_0 = 1$, $P_1 = x$, $P_2 = \frac{1}{2}(3x^2 - 1)$, and so on.

Example 19.2.8 (Chebyshev Polynomials)

Take $[a, b] = [-1, 1]$ with the weight $w(x) = (1 - x^2)^{-1/2}$, so

$$\langle f, g \rangle = \int_{-1}^1 \frac{f(x)g(x)}{\sqrt{1-x^2}} dx.$$

(The weight blows up at ± 1 , but integrably, so this is fine.) Define T_n by

$$T_n(\cos \theta) = \cos(n\theta).$$

That this really is a polynomial in $x = \cos \theta$ follows by induction from the identity $\cos((n+1)\theta) + \cos((n-1)\theta) = 2 \cos \theta \cos(n\theta)$, which gives at once the recurrence

$$T_{n+1}(x) = 2xT_n(x) - T_{n-1}(x), \quad T_0 = 1, \quad T_1 = x.$$

So $T_2 = 2x^2 - 1$, $T_3 = 4x^3 - 3x$, $T_4 = 8x^4 - 8x^2 + 1$, and in general T_n has leading coefficient 2^{n-1} for $n \geq 1$.

To see orthogonality, substitute $x = \cos \theta$, $dx = -\sin \theta d\theta$, $\sqrt{1-x^2} = \sin \theta$:

$$\langle T_n, T_m \rangle = \int_{-1}^1 \frac{T_n T_m}{\sqrt{1-x^2}} dx = \int_0^\pi \cos(n\theta) \cos(m\theta) d\theta = 0$$

for $n \neq m$, by the usual orthogonality of cosines. The monic Chebyshev polynomials are $2^{1-n}T_n$ for $n \geq 1$.

The Chebyshev polynomials are worth a picture, because their defining feature is visible at a glance: on $[-1, 1]$ they oscillate between -1 and $+1$, attaining those extreme values $n+1$ times.

This *equioscillation* is precisely why the Chebyshev points of the previous section are optimal interpolation nodes: among all monic polynomials of degree n , the monic Chebyshev polynomial $2^{1-n}T_n$ is the one with the smallest maximum modulus on $[-1, 1]$, namely 2^{1-n} . Any other monic q of degree n with $\|q\|_\infty < 2^{1-n}$ would have $2^{1-n}T_n - q$ alternating in sign at the $n+1$ extrema of T_n , hence having n zeros – impossible for a polynomial of degree $n-1$ that is not identically zero.

There are other classical families, each attached to its own weight, which we mention for completeness:

Family	Interval	Weight $w(x)$
Legendre	$[-1, 1]$	1
Chebyshev	$[-1, 1]$	$(1 - x^2)^{-1/2}$
Laguerre	$[0, \infty)$	e^{-x}
Hermite	$(-\infty, \infty)$	e^{-x^2}

§19.2.4 Least-Squares Approximation by Polynomials

We can now solve the approximation problem we set out with. Given f and an inner product, we seek the $p \in \mathcal{P}_n$ minimising $\|f - p\|$. Since $\mathcal{P}_n$ is a finite-dimensional subspace, the answer is of course the orthogonal projection of f onto it – and having an orthogonal basis to hand makes that projection completely explicit.

Theorem 19.2.9 (Least-Squares Approximation)

Let $p_0, p_1, \dots$ be the orthogonal polynomials for $\langle \cdot, \cdot \rangle$. Then the unique minimiser of $\|f - p\|$ over $p \in \mathcal{P}_n$ is

$$\hat{p}_n = \sum_{k=0}^n \frac{\langle f, p_k \rangle}{\langle p_k, p_k \rangle} p_k.$$

Proof. Any $p \in \mathcal{P}_n$ may be written $p = \sum_{k=0}^n c_k p_k$. Expanding and using orthogonality,

$$\begin{aligned} \|f - p\|^2 &= \langle f - \sum_k c_k p_k, f - \sum_k c_k p_k \rangle \\ &= \langle f, f \rangle - 2 \sum_{k=0}^n c_k \langle f, p_k \rangle + \sum_{k=0}^n c_k^2 \langle p_k, p_k \rangle. \end{aligned}$$

The cross terms $\langle p_j, p_k \rangle$ with $j \neq k$ have vanished, so this is a sum of $n + 1$ independent quadratics in the c_k . Completing the square in each,

$$\|f - p\|^2 = \langle f, f \rangle - \sum_{k=0}^n \frac{\langle f, p_k \rangle^2}{\langle p_k, p_k \rangle} + \sum_{k=0}^n \langle p_k, p_k \rangle \left(c_k - \frac{\langle f, p_k \rangle}{\langle p_k, p_k \rangle} \right)^2.$$

Since $\langle p_k, p_k \rangle > 0$, this is minimised precisely when every bracket vanishes, i.e. $c_k = \langle f, p_k \rangle / \langle p_k, p_k \rangle$, and the minimiser is unique. $\square$

Notice the structural virtue of this answer: the coefficient of p_k does not depend on n . If we decide we want a better approximation, we simply compute one more coefficient and append one more term; nothing already computed is wasted. This is exactly the adaptivity we admired in the Newton form.

Reading off the value at the minimum in the proof gives the error, and this is worth recording separately.

Corollary 19.2.10 (Bessel's Inequality and Pythagoras)

With $\hat{p}_n$ as above,

$$\|f - \hat{p}_n\|^2 = \langle f, f \rangle - \sum_{k=0}^n \frac{\langle f, p_k \rangle^2}{\langle p_k, p_k \rangle} = \|f\|^2 - \|\hat{p}_n\|^2.$$

In particular $\sum_{k=0}^n \langle f, p_k \rangle^2 / \langle p_k, p_k \rangle \leq \|f\|^2$, and $\langle f - \hat{p}_n, \hat{p}_n \rangle = 0$.

That last statement – the error is orthogonal to the approximation – is Pythagoras’ theorem, and it is the geometric content of the whole business. It also gives an alternative one-line proof of the theorem: for any $p \in \mathcal{P}_n$ we have $f - p = (f - \hat{p}_n) + (\hat{p}_n - p)$ with the two summands orthogonal, so $\|f - p\|^2 = \|f - \hat{p}_n\|^2 + \|\hat{p}_n - p\|^2 \geq \|f - \hat{p}_n\|^2$.

Since $\|f - \hat{p}_n\|$ is decreasing in n , it converges; the natural question is whether it converges to zero. It does, and the reason is a theorem from outside numerical analysis entirely.

Theorem 19.2.11 (Weierstrass Approximation Theorem)

Let $f \in C[a, b]$ with $[a, b]$ finite. For every $\varepsilon > 0$ there is a polynomial q with $|f(x) - q(x)| < \varepsilon$ for all $x \in [a, b]$.

We shall not prove this here – it is a piece of analysis rather than numerical analysis, and the reader will meet it elsewhere. What we want is the consequence.

Corollary 19.2.12 (Convergence of Least-Squares Approximation)

Let $\langle f, g \rangle = \int_a^b wfg \, dx$ with $[a, b]$ finite and w a weight function. Then for $f \in C[a, b]$ we have $\|f - \hat{p}_n\| \rightarrow 0$ as $n \rightarrow \infty$.

Proof. Let $\varepsilon > 0$ and set $W = \int_a^b w(x) \, dx < \infty$. By Weierstrass there is a polynomial q , of degree m say, with $|f - q| < \varepsilon$ pointwise on $[a, b]$. Then

$$\|f - q\|^2 = \int_a^b w(x)(f(x) - q(x))^2 \, dx \leq \varepsilon^2 W.$$

For $n \geq m$ we have $q \in \mathcal{P}_n$, so by minimality $\|f - \hat{p}_n\| \leq \|f - q\| \leq \varepsilon \sqrt{W}$. As ε was arbitrary and $\|f - \hat{p}_n\|$ is non-increasing, the result follows. $\square$

Corollary 19.2.13 (Parseval’s Identity)

Under the hypotheses above,

$$\sum_{k=0}^{\infty} \frac{\langle f, p_k \rangle^2}{\langle p_k, p_k \rangle} = \langle f, f \rangle.$$

Proof. Immediate from $\|f\|^2 - \sum_{k=0}^n \langle f, p_k \rangle^2 / \langle p_k, p_k \rangle = \|f - \hat{p}_n\|^2 \rightarrow 0$. $\square$

Example 19.2.14 (Least Squares Fit of $|x|$)

Take $[a, b] = [-1, 1]$, $w \equiv 1$, and $f(x) = |x|$, and let us find the best quadratic approximation. Using the monic Legendre polynomials $p_0 = 1$, $p_1 = x$, $p_2 = x^2 - \frac{1}{3}$, we compute

$$\langle f, p_0 \rangle = \int_{-1}^1 |x| \, dx = 1, \quad \langle f, p_1 \rangle = \int_{-1}^1 |x| x \, dx = 0,$$

$$\langle f, p_2 \rangle = \int_{-1}^1 |x| \left(x^2 - \frac{1}{3}\right) dx = 2 \int_0^1 \left(x^3 - \frac{x}{3}\right) dx = 2 \left(\frac{1}{4} - \frac{1}{6}\right) = \frac{1}{6}.$$

Also $\langle p_0, p_0 \rangle = 2$ and $\langle p_2, p_2 \rangle = \int_{-1}^1 \left(x^2 - \frac{1}{3}\right)^2 dx = \frac{8}{45}$. Hence

$$\hat{p}_2(x) = \frac{1}{2} + \frac{1/6}{8/45} \left(x^2 - \frac{1}{3}\right) = \frac{15}{16}x^2 + \frac{3}{16}.$$

A quick sanity check: $\hat{p}_2(\pm 1) = 18/16 > 1$ and $\hat{p}_2(0) = 3/16 > 0$, so the fit overshoots at the ends and at the kink, which is what one expects of a smooth curve chasing a corner.

§19.2.5 Least Squares with Discrete Data

In practice one rarely knows f everywhere; one knows m measurements $f(\xi_1), \dots, f(\xi_m)$ at distinct points and wants the $p \in \mathcal{P}_n$ minimising

$$\sum_{j=1}^m (f(\xi_j) - p(\xi_j))^2.$$

This is precisely the least-squares problem for the discrete inner product

$$\langle g, h \rangle = \sum_{j=1}^m g(\xi_j)h(\xi_j),$$

which as we noted is a genuine inner product on $\mathcal{P}_n$ as long as $n < m$. Everything above goes through verbatim: we build the orthogonal polynomials $p_0, \dots, p_n$ for this inner product using the three-term recurrence, which applies because multiplication by x is again self-adjoint, and then Theorem 19.2.9 hands us the answer.

Remark. The naive alternative is to write $p = \sum_k c_k x^k$ and solve the resulting $(n+1) \times (n+1)$ linear system for the c_k – the so-called *normal equations*. This works, but the matrix involved is close to the notorious Hilbert matrix and is horribly ill-conditioned even for modest n . Orthogonalising first turns the linear system into a diagonal one, and the improvement in accuracy is dramatic. We will meet the same phenomenon again, from a different direction, when we discuss the QR factorisation in Section 19.8.

§19.3 Approximation of Linear Functionals

Almost every quantity we might want to extract from a function – its value at a point, its derivative there, its integral over an interval – is a *linear* function of f . This section is about approximating such quantities using only the simplest data of all, namely point values of f .

Definition 19.3.1 (Linear Functional)

A **linear functional** on a real vector space V of functions is a linear map $L : V \rightarrow \mathbb{R}$.

We usually do not fuss over the space V ; we write down a formula for L and take V to be whatever space of functions makes the formula sensible.

Example 19.3.2

The following are all linear functionals.

- (i) $L(f) = f(\xi)$ for some fixed ξ , on $V = C[a, b]$.
- (ii) $L(f) = f'(\eta)$ for some fixed η , on $V = C^1[a, b]$.
- (iii) $L(f) = \int_a^b w(x)f(x) \, dx$, on $V = C[a, b]$.
- (iv) Any linear combination of the above, for instance

$$L(f) = f(\beta) - f(\alpha) - \frac{\beta - \alpha}{2}(f'(\beta) + f'(\alpha)).$$

Our aim is to approximate a complicated L (typically an integral) by a finite combination of simple ones,

$$L(f) \approx \sum_{i=0}^N a_i f(x_i),$$

where $x_0, \dots, x_N \in [a, b]$ are distinct. How should we choose the a_i , and the x_i ?

The natural idea is one we already have: replace f by its interpolating polynomial and apply L to that. Using the fundamental Lagrange polynomials for the nodes x_i ,

$$f(x) \approx \sum_{i=0}^N f(x_i) \ell_i(x) \quad \implies \quad L(f) \approx \sum_{i=0}^N L(\ell_i) f(x_i),$$

so we should take $a_i = L(\ell_i)$. With this choice the approximation is *exact* for $f \in \mathcal{P}_N$, since then the interpolant is f itself.

That is $N + 1$ free parameters buying exactness on an $(N + 1)$ -dimensional space, which sounds like a fair deal. But we have another $N + 1$ parameters that we have not used at all – the nodes x_i . If we choose those cleverly too, we might hope for exactness on $\mathcal{P}_{2N+1}$. Remarkably, for integrals we can achieve exactly that. This is Gaussian quadrature, and it is the subject of the rest of this section.

§19.3.1 Newton–Cotes Formulae

First, though, let us see what the naive choice gives. If we take the nodes to be equally spaced and $L(f) = \int_a^b f$, the resulting rules are the classical **Newton–Cotes formulae**.

Definition 19.3.3 (Newton–Cotes)

Fix $\nu \geq 1$ and let $x_i = a + i(b - a)/\nu$ for $i = 0, \dots, \nu$. The closed Newton–Cotes

rule of order ν is

$$\int_a^b f(x) \, dx \approx \sum_{i=0}^{\nu} a_i f(x_i), \quad a_i = \int_a^b \ell_i(x) \, dx.$$

Example 19.3.4 (The Trapezoidal Rule)

With $\nu = 1$ we have $\ell_0(x) = (b - x)/(b - a)$ and $\ell_1(x) = (x - a)/(b - a)$, each of which integrates to $(b - a)/2$. Hence

$$\int_a^b f(x) \, dx \approx \frac{b - a}{2} (f(a) + f(b)),$$

which is just the area of the trapezium under the chord joining the two endpoints.

Example 19.3.5 (Simpson's Rule)

With $\nu = 2$ and nodes a , $m = (a + b)/2$, b , a short computation gives $a_0 = a_2 = (b - a)/6$ and $a_1 = 2(b - a)/3$, so

$$\int_a^b f(x) \, dx \approx \frac{b - a}{6} \left(f(a) + 4f\left(\frac{a + b}{2}\right) + f(b) \right).$$

By construction this is exact for $f \in \mathcal{P}_2$. In fact it is exact for $f \in \mathcal{P}_3$: taking $[a, b] = [-1, 1]$ for convenience, $\int_{-1}^1 x^3 \, dx = 0$ and the rule returns $\frac{1}{3}(-1 + 0 + 1) = 0$ as well. This extra order ‘for free’ is a general feature of Newton–Cotes rules with an even number of subintervals, and comes from the symmetry of the nodes.

Geometrically, the trapezoidal rule replaces f by a chord and Simpson's rule replaces it by a parabola through three points:

Remark. One might hope that taking ν larger and larger gives better and better rules. It does not: for $\nu \geq 8$ some of the weights a_i become negative, and by $\nu = 30$ they are enormous, so that rounding errors are amplified catastrophically. This is the Runge phenomenon again, wearing a different hat. In practice one instead uses a *composite* rule: chop $[a, b]$ into many small subintervals and apply a low-order rule (usually the trapezoidal or Simpson's rule) on each.

§19.3.2 Gaussian Quadrature

Now we use our remaining freedom. We work with a weighted integral

$$L(f) = \int_a^b w(x)f(x) \, dx,$$

and seek **weights** $b_1, \dots, b_\nu$ and **nodes** $c_1, \dots, c_\nu \in [a, b]$ such that

$$\int_a^b w(x)f(x) \, dx \approx \sum_{k=1}^{\nu} b_k f(c_k)$$

is exact for polynomials of as high a degree as possible. (The notation is traditional for this topic and clashes slightly with the rest of the course; we shall live with it.)

First, a limit on our ambitions.

Proposition 19.3.6

No choice of ν nodes and weights gives a formula exact for all $f \in \mathcal{P}_{2\nu}$.

Proof. Consider $q(x) = \prod_{k=1}^{\nu} (x - c_k)$, so that $q^2 \in \mathcal{P}_{2\nu}$. Then $\sum_k b_k q^2(c_k) = 0$, whereas

$$\int_a^b w(x)q(x)^2 \, dx > 0,$$

since $wq^2 \geq 0$ is continuous and not identically zero. $\square$

So $2\nu - 1$ is the best we could possibly hope for, and we shall achieve it. The clue is in the proof: we need the nodes to be the roots of a polynomial that is orthogonal to everything of low degree. Before that, we must check that such roots are usable at all – they had better be real, distinct, and inside (a, b) .

Theorem 19.3.7 (Zeros of Orthogonal Polynomials)

For $\nu \geq 1$, the monic orthogonal polynomial p_ν associated with $\langle f, g \rangle = \int_a^b wfg \, dx$ has ν distinct real zeros, all lying in (a, b) .

Proof. Since $p_0 \equiv 1$ and $\langle p_\nu, p_0 \rangle = 0$ for $\nu \geq 1$, we have

$$\int_a^b w(x)p_\nu(x) \, dx = 0,$$

and as $w \geq 0$ is not identically zero, p_ν must change sign somewhere in (a, b) .

Let $\varphi_1, \dots, \varphi_m$ be the points of (a, b) at which p_ν changes sign; we have just shown $m \geq 1$, and certainly $m \leq \nu$ since these are among the zeros of p_ν . Put

$$q(x) = \prod_{j=1}^m (x - \varphi_j) \in \mathcal{P}_m.$$

Then q changes sign at exactly the same points as p_ν , so qp_ν has constant sign on (a, b) and is not identically zero; hence $\langle q, p_\nu \rangle = \int_a^b wqp_\nu \, dx \neq 0$. But p_ν is

orthogonal to every polynomial of degree less than ν , so we must have $m \geq \nu$, and therefore $m = \nu$.

Thus p_ν has ν distinct sign changes in (a, b) , which accounts for all ν of its zeros; they are real, distinct, and lie in (a, b) . $\square$

Before choosing the nodes, let us record what the interpolatory choice of weights gives for *any* nodes.

Theorem 19.3.8 (Ordinary Quadrature)

Let $c_1, \dots, c_\nu \in [a, b]$ be distinct, with fundamental Lagrange polynomials $\ell_1, \dots, \ell_\nu$. If we choose

$$b_k = \int_a^b w(x) \ell_k(x) \, dx,$$

then the quadrature formula is exact for all $f \in \mathcal{P}_{\nu-1}$.

Proof. For $f \in \mathcal{P}_{\nu-1}$, interpolation at ν points reproduces f exactly, so $f = \sum_k f(c_k) \ell_k$. Integrating against w gives $\int_a^b w f = \sum_k f(c_k) b_k$. $\square$

And now the theorem that makes it all worthwhile.

Theorem 19.3.9 (Gaussian Quadrature)

Choose the nodes $c_1, \dots, c_\nu$ to be the zeros of the orthogonal polynomial p_ν , and the weights b_k as in Theorem 19.3.8. Then the quadrature formula

$$\int_a^b w(x) f(x) \, dx \approx \sum_{k=1}^{\nu} b_k f(c_k)$$

is exact for all $f \in \mathcal{P}_{2\nu-1}$. Moreover every weight b_k is strictly positive.

Proof. Let $f \in \mathcal{P}_{2\nu-1}$. Dividing by p_ν we may write

$$f = qp_\nu + r, \quad q, r \in \mathcal{P}_{\nu-1}.$$

Since p_ν is orthogonal to all of $\mathcal{P}_{\nu-1}$, we have $\int_a^b w qp_\nu \, dx = \langle q, p_\nu \rangle = 0$, so

$$\int_a^b w(x) f(x) \, dx = \int_a^b w(x) r(x) \, dx.$$

On the other side, each c_k is a zero of p_ν , so $f(c_k) = r(c_k)$ and hence

$$\sum_{k=1}^{\nu} b_k f(c_k) = \sum_{k=1}^{\nu} b_k r(c_k).$$

But $r \in \mathcal{P}_{\nu-1}$, so by Theorem 19.3.8 the two right-hand sides agree. Hence the formula is exact for f .

For positivity, apply exactness to $f = \ell_k^2 \in \mathcal{P}_{2\nu-2}$. Then

$$0 < \int_a^b w(x) \ell_k(x)^2 dx = \sum_{j=1}^{\nu} b_j \ell_k(c_j)^2 = \sum_{j=1}^{\nu} b_j \delta_{jk} = b_k. \quad \square$$

Together with Proposition 19.3.6, this says that Gaussian quadrature is optimal: $2\nu - 1$ is achieved and 2ν is impossible. The positivity of the weights is not a footnote either – it is what makes the rule numerically stable, since it means there is no cancellation between the terms and rounding errors cannot be amplified.

For the Legendre weight $w \equiv 1$ on $[-1, 1]$ the nodes are the zeros of the Legendre polynomials. Here is P_4 with its four zeros marked; these are the nodes of the four-point Gauss–Legendre rule, which is exact for all polynomials of degree up to 7.

Example 19.3.10 (Gauss–Legendre Rules)

For $w \equiv 1$ on $[-1, 1]$ the first few rules are as follows.

ν	nodes c_k	weights b_k	exact on
1	0	2	$\mathcal{P}_1$
2	$\pm 1/\sqrt{3}$	1, 1	$\mathcal{P}_3$
3	$0, \pm\sqrt{3/5}$	8/9, 5/9, 5/9	$\mathcal{P}_5$
4	$\pm 0.3399810, \pm 0.8611363$	0.6521452, 0.3478548	$\mathcal{P}_7$

Let us check the case $\nu = 2$ directly. The nodes are the zeros of $p_2 = x^2 - \frac{1}{3}$, namely $\pm 1/\sqrt{3}$. The rule $\int_{-1}^1 f \approx f(-1/\sqrt{3}) + f(1/\sqrt{3})$ certainly integrates 1 and x correctly. For x^2 it gives $2/3$, which is right; for x^3 it gives 0, which is right. And for x^4 it gives $2/9$ against the true value $2/5$ – so exactness stops at degree $3 = 2\nu - 1$, exactly as predicted.

Example 19.3.11 (Gauss Beats Simpson)

Let us approximate $\int_0^1 e^x dx = e - 1 = 1.718282$. Substituting $x = (t + 1)/2$ turns this into $\frac{1}{2} \int_{-1}^1 e^{(t+1)/2} dt$, and the two-point Gauss rule gives

$$\frac{1}{2} \left(e^{(1-1/\sqrt{3})/2} + e^{(1+1/\sqrt{3})/2} \right) = \frac{1}{2} (1.235345 + 2.200455) = 1.717900,$$

an error of 3.8×10^{-4} , using *two* evaluations of f . Simpson's rule, using *three* evaluations, gives

$$\frac{1}{6} \left(1 + 4e^{1/2} + e \right) = 1.718861,$$

an error of 5.8×10^{-4} . The trapezoidal rule gives 1.859141, an error of 0.14. Gaussian quadrature does more with less.

Remark. The price of Gaussian quadrature is that the nodes are irrational and must be looked up or computed (they are eigenvalues of the tridiagonal matrix formed from the three-term recurrence coefficients, which is how one actually computes them). Also, unlike a composite Newton–Cotes rule, refining from ν to $\nu + 1$ points reuses none of the old function evaluations. Both objections are real, and both have been engineered around; but the exactness result of Theorem 19.3.9 is why Gaussian quadrature remains the default for smooth integrands.

§19.4 Expressing Errors in Terms of Derivatives

We now have a supply of approximations to linear functionals, each of them exact on some space $\mathcal{P}_k$ of polynomials. What we do not yet have is a systematic way to say how large the error is when f is *not* a polynomial. The Peano kernel theorem provides exactly that: it converts the statement ‘the error annihilates $\mathcal{P}_k$ ’ into an exact integral formula for the error in terms of $f^{(k+1)}$.

The setup is as follows. We have a linear functional L , an approximation $\sum_{i=0}^n a_i L_i(f)$ built from simpler functionals L_i , and the error functional

$$e_L(f) = L(f) - \sum_{i=0}^n a_i L_i(f),$$

which is again linear. We suppose that $e_L(f) = 0$ for all $f \in \mathcal{P}_k$; we say that e_L **annihilates** $\mathcal{P}_k$.

Example 19.4.1

Suppose we approximate $L(f) = f(\beta)$ by the (rather silly) formula

$$L(f) \approx f(\alpha) + \frac{\beta - \alpha}{2} (f'(\alpha) + f'(\beta)), \quad \alpha \neq \beta.$$

Then

$$e_L(f) = f(\beta) - f(\alpha) - \frac{\beta - \alpha}{2} (f'(\alpha) + f'(\beta)).$$

One checks directly that this vanishes for $f = 1, x, x^2$: for $f = x^2$, the left-hand piece is $\beta^2 - \alpha^2$ and the right-hand piece is $(\beta - \alpha)(\alpha + \beta)$, which agree. It does not vanish for $f = x^3$. So e_L annihilates $\mathcal{P}_2$.

We want a bound of the form

$$|e_L(f)| \leq c_L \left\| f^{(k+1)} \right\|_{\infty},$$

with c_L as small as possible. For this we need $[a, b]$ to be finite, so that the suprema exist.

Definition 19.4.2 (Sharp Constant)

The constant c_L is **sharp** if for every $\varepsilon > 0$ there is some $f_\varepsilon \in C^{k+1}[a, b]$ with

$$|e_L(f_\varepsilon)| \geq (c_L - \varepsilon) \left\| f_\varepsilon^{(k+1)} \right\|_\infty.$$

§19.4.1 The Peano Kernel Theorem

The tool is Taylor's theorem with integral remainder,

$$f(x) = f(a) + (x-a)f'(a) + \cdots + \frac{(x-a)^k}{k!} f^{(k)}(a) + \frac{1}{k!} \int_a^x (x-\theta)^k f^{(k+1)}(\theta) d\theta.$$

The awkwardness is that x appears in the limit of the integral, which stops us from interchanging e_L with $\int$. We fix this with a piece of notation.

Definition 19.4.3 (Truncated Power Function)

For $k \geq 0$ we define

$$(x-\theta)_+^k = \begin{cases} (x-\theta)^k & x \geq \theta, \\ 0 & x < \theta. \end{cases}$$

Note that for $k \geq 1$ this is a C^{k-1} function of x : it is smooth except at $x = \theta$, where the first $k-1$ derivatives all vanish from both sides. With it, the Taylor remainder becomes

$$\frac{1}{k!} \int_a^b (x-\theta)_+^k f^{(k+1)}(\theta) d\theta,$$

where now the limits do not involve x .

Theorem 19.4.4 (Peano Kernel Theorem)

Let $[a, b]$ be finite and let e_L be a linear functional annihilating $\mathcal{P}_k$ which commutes with the integral in the sense below. Then for all $f \in C^{k+1}[a, b]$,

$$e_L(f) = \frac{1}{k!} \int_a^b K(\theta) f^{(k+1)}(\theta) d\theta, \quad K(\theta) = e_L((x-\theta)_+^k),$$

where e_L acts on $(x-\theta)_+^k$ as a function of x , with θ held fixed.

Proof. Write $f = T + R$ where $T \in \mathcal{P}_k$ is the Taylor polynomial of f about a of degree k and

$$R(x) = \frac{1}{k!} \int_a^b (x-\theta)_+^k f^{(k+1)}(\theta) d\theta$$

is the remainder. Since e_L annihilates $\mathcal{P}_k$ we have $e_L(T) = 0$, so by linearity $e_L(f) = e_L(R)$. Interchanging e_L with the integral,

$$e_L(f) = \frac{1}{k!} \int_a^b e_L((x-\theta)_+^k) f^{(k+1)}(\theta) d\theta = \frac{1}{k!} \int_a^b K(\theta) f^{(k+1)}(\theta) d\theta. \quad \square$$

Remark. The interchange of e_L with the integral is the only step needing care. For the functionals we use in this course – point values, point values of derivatives, and integrals, together with finite linear combinations of these – the interchange is valid and can be

verified directly in each case (for integrals it is Fubini, for point evaluations it is trivial, and for derivatives one differentiates under the integral sign). A sufficiently determined pure mathematician can construct linear functionals for which it fails, but we shall not meet any.

The point of the theorem is that K depends only on L and not at all on f . So having computed K once, we get a whole family of bounds by applying Hölder's inequality in different ways:

$$|e_L(f)| \leq \frac{1}{k!} \begin{cases} \left(\int_a^b |K(\theta)| \, d\theta \right) \|f^{(k+1)}\|_\infty, \\ \left(\int_a^b |K(\theta)|^2 \, d\theta \right)^{1/2} \|f^{(k+1)}\|_2, \\ \|K\|_\infty \|f^{(k+1)}\|_1. \end{cases}$$

These constants can be shown to be sharp. And do not forget the factor $1/k!$ when computing c_L – it is the most commonly dropped piece of the whole formula.

There is one very common situation in which we can say considerably more.

Proposition 19.4.5 (Sign-Definite Kernels)

If K does not change sign on $[a, b]$, then for every $f \in C^{k+1}[a, b]$ there is some $\xi \in (a, b)$, depending on f , with

$$e_L(f) = \frac{1}{k!} \left(\int_a^b K(\theta) \, d\theta \right) f^{(k+1)}(\xi).$$

Moreover the constant $c_L = \frac{1}{k!} \left| \int_a^b K \right|$ in the $\|\cdot\|_\infty$ bound is attained, by $f(x) = x^{k+1}$.

Proof. Since K has constant sign, the integral mean value theorem applies to $\int_a^b K f^{(k+1)}$ and yields $f^{(k+1)}(\xi) \int_a^b K$ for some ξ . For the second statement, $f = x^{k+1}$ has $f^{(k+1)} \equiv (k+1)!$ constant, so the inequality $|\int K f^{(k+1)}| \leq \int |K| \cdot \|f^{(k+1)}\|_\infty$ is an equality. $\square$

§19.4.2 Worked Kernels

Peano kernels are computed by brute force: substitute $(x - \theta)_+^k$ into the formula for e_L , and remember that the truncated power vanishes when its argument is negative, so the answer is piecewise.

Example 19.4.6 (The Trapezoidal Rule)

Take $[a, b] = [0, 1]$ and

$$e_L(f) = \int_0^1 f(x) \, dx - \frac{1}{2}(f(0) + f(1)),$$

which annihilates $\mathcal{P}_1$, so $k = 1$. Then for $\theta \in [0, 1]$,

$$K(\theta) = \int_0^1 (x - \theta)_+ \, dx - \frac{1}{2}((0 - \theta)_+ + (1 - \theta)_+) = \int_\theta^1 (x - \theta) \, dx - \frac{1}{2}(1 - \theta),$$

since $(0 - \theta)_+ = 0$ for $\theta \geq 0$. Hence

$$K(\theta) = \frac{(1 - \theta)^2}{2} - \frac{1 - \theta}{2} = -\frac{\theta(1 - \theta)}{2}.$$

This is a downward parabola vanishing at both endpoints, so $K \leq 0$ throughout and Proposition 19.4.5 applies. We have $\int_0^1 K = -\frac{1}{2}(\frac{1}{2} - \frac{1}{3}) = -\frac{1}{12}$, so

$$e_L(f) = -\frac{1}{12}f''(\xi), \quad |e_L(f)| \leq \frac{1}{12} \|f''\|_\infty,$$

which is the classical trapezoidal rule error, now derived rather than conjured.

Example 19.4.7 (Simpson's Rule)

Take $[a, b] = [-1, 1]$ and

$$e_L(f) = \int_{-1}^1 f(x) \, dx - \frac{1}{3}(f(-1) + 4f(0) + f(1)).$$

We saw that this annihilates $\mathcal{P}_3$, so we may take $k = 3$. For $\theta \in [0, 1]$ only the $f(1)$ term survives the truncation, and

$$K(\theta) = \int_\theta^1 (x - \theta)^3 \, dx - \frac{1}{3}(1 - \theta)^3 = \frac{(1 - \theta)^4}{4} - \frac{(1 - \theta)^3}{3}.$$

For $\theta \in [-1, 0]$ the $f(0)$ term also contributes, giving

$$K(\theta) = \frac{(1 - \theta)^4}{4} - \frac{1}{3}(4(-\theta)^3 + (1 - \theta)^3).$$

One checks that the two branches agree at $\theta = 0$, both giving $\frac{1}{4} - \frac{1}{3} = -\frac{1}{12}$, and that $K(\pm 1) = 0$. In fact K is symmetric, $K(-\theta) = K(\theta)$, and negative on $(-1, 1)$.

Here is the kernel of Example 19.4.7, plotted on $[-1, 1]$.

Since $K \leq 0$ we may use Proposition 19.4.5. Computing the integral,

$$\int_{-1}^1 K(\theta) \, d\theta = 2 \int_0^1 \left(\frac{(1 - \theta)^4}{4} - \frac{(1 - \theta)^3}{3} \right) \, d\theta = 2 \left(\frac{1}{20} - \frac{1}{12} \right) = -\frac{1}{15},$$

and hence, with $k = 3$ so that $1/k! = 1/6$,

$$e_L(f) = -\frac{1}{90}f^{(4)}(\xi), \quad |e_L(f)| \leq \frac{1}{90} \|f^{(4)}\|_\infty$$

for some $\xi \in (-1, 1)$. Rescaling to a general interval gives the familiar $-\frac{(b-a)^5}{2880} f^{(4)}(\xi)$. The theorem applies just as well to functionals that have nothing to do with integration.

Example 19.4.8 (A Derivative Formula)

Suppose we approximate $f'(0)$ by the one-sided formula

$$f'(0) \approx -\frac{3}{2}f(0) + 2f(1) - \frac{1}{2}f(2),$$

so that $e_L(f) = f'(0) + \frac{3}{2}f(0) - 2f(1) + \frac{1}{2}f(2)$ on $[0, 2]$. Checking on $1, x, x^2$: for $f = 1$ we get $0 + \frac{3}{2} - 2 + \frac{1}{2} = 0$; for $f = x$ we get $1 + 0 - 2 + 1 = 0$; for $f = x^2$ we get $0 + 0 - 2 + 2 = 0$. For $f = x^3$ we get $0 + 0 - 2 + 4 = 2 \neq 0$. So e_L annihilates $\mathcal{P}_2$ and $k = 2$.

The kernel is $K(\theta) = e_L((x - \theta)_+^2)$. Since $\frac{d}{dx}(x - \theta)_+^2 = 2(x - \theta)_+$, the derivative term contributes $2(0 - \theta)_+ = 0$ for $\theta \geq 0$, as does the $f(0)$ term. So

$$K(\theta) = -2(1 - \theta)_+^2 + \frac{1}{2}(2 - \theta)_+^2 = \begin{cases} 2\theta - \frac{3}{2}\theta^2, & \theta \in [0, 1], \\ \frac{1}{2}(2 - \theta)^2, & \theta \in [1, 2]. \end{cases}$$

(The two branches agree at $\theta = 1$, both giving $\frac{1}{2}$.) Both branches are non-negative, so $K \geq 0$ and Proposition 19.4.5 applies. We have

$$\int_0^2 K(\theta) d\theta = \int_0^1 (2\theta - \frac{3}{2}\theta^2) d\theta + \int_1^2 \frac{1}{2}(2 - \theta)^2 d\theta = \frac{1}{2} + \frac{1}{6} = \frac{2}{3},$$

and hence, remembering the factor $1/k! = 1/2$,

$$e_L(f) = \frac{1}{3}f'''(\xi), \quad |e_L(f)| \leq \frac{1}{3} \|f'''\|_\infty$$

for some $\xi \in (0, 2)$.

Remark. A final subtlety. If e_L annihilates $\mathcal{P}_k$ then it also annihilates $\mathcal{P}_j$ for every $j < k$, so we get a *different* kernel $K_j(\theta) = e_L((x - \theta)_+^j)$ and a different error formula

$$e_L(f) = \frac{1}{j!} \int_a^b K_j(\theta) f^{(j+1)}(\theta) d\theta$$

valid for $f \in C^{j+1}[a, b]$. Usually taking $j = k$ is best, as it extracts the most information. But if f happens to be only C^{j+1} and not C^{k+1} – and integrands with limited smoothness are common in practice – then the lower-order kernel is the one that applies. Simpson's rule with a merely twice-differentiable integrand is a case in point.

§19.5 Ordinary Differential Equations

We now turn to what is probably the most important application of numerical analysis. We wish to approximate the solution $y : [0, \infty) \rightarrow \mathbb{R}^N$ of the initial value problem

$$y' = f(t, y), \quad y(0) = y_0,$$

where $f : \mathbb{R} \times \mathbb{R}^N \rightarrow \mathbb{R}^N$. Note that we allow y to be vector-valued, which costs us nothing notationally and buys us all higher-order scalar equations, since $y'' = g(t, y, y')$ becomes a first-order system in (y, y') .

We shall always assume that f is nice enough for the problem to make sense. In particular, we assume f is Lipschitz in its second argument, which by the Picard–Lindelöf theorem guarantees that a unique solution exists; and where we Taylor expand, we assume as much smoothness as the expansion requires. This is standard practice and is not usually where the interesting difficulties lie.

The idea is to replace the continuum of values $y(t)$ by a discrete sequence $y_0, y_1, y_2, \dots$ with $y_n \approx y(t_n)$, where $0 = t_0 < t_1 < \dots$. We shall almost always take a constant step size, $t_n = nh$. The two questions we must ask of any such scheme are: does y_n actually approach $y(t_n)$ as $h \rightarrow 0$, and how fast?

§19.5.1 One-Step Methods

Definition 19.5.1 (One-Step Method)

A **one-step method** is a recurrence of the form

$$y_{n+1} = \varphi_h(t_n, y_n),$$

in which y_{n+1} depends only on t_n, y_n, h and f .

The simplest of all is obtained by truncating the Taylor series of y after one term.

Definition 19.5.2 (Euler's Method)

Euler's method is the one-step method

$$y_{n+1} = y_n + hf(t_n, y_n).$$

The idea is transparent: from the point (t_n, y_n) , the differential equation tells us the slope of the solution curve through that point, so we follow that straight line for a time h and see where we end up. The resulting approximation is a polygon, and each segment of it is tangent to *some* solution curve of the equation – just not, in general, the one we want.

Here is Euler's method applied to $y' = y$, $y(0) = 1$, with $h = 1/4$. The true solution $y(t) = e^t$ is in blue and the Euler polygon in red.

Two things are visible in the picture. The Euler solution lags behind the true one, and the gap grows. What we need to know is whether the gap shrinks to nothing as we

shrink h .

Definition 19.5.3 (Convergence)

A method is **convergent** if, for every $t^* > 0$ and every initial value problem with sufficiently nice f ,

$$\lim_{h \rightarrow 0} \max_{n=0,1,\dots,\lfloor t^*/h \rfloor} \|y_n - y(t_n)\| = 0,$$

where y_n is the numerical solution computed with step size h .

Note what this is asking: not that a fixed number of steps become accurate, but that the error at a fixed *time* t^* , reached in $\lfloor t^*/h \rfloor$ steps, goes to zero. Since the number of steps grows like $1/h$, the errors made at each step must not be allowed to accumulate too badly. This is the whole content of the following theorem.

Theorem 19.5.4 (Convergence of Euler's Method)

Suppose f is Lipschitz in its second argument on $[0, t^*] \times \mathbb{R}^N$, that is, there is $\lambda \geq 0$ with

$$\|f(t, v) - f(t, w)\| \leq \lambda \|v - w\|$$

for all $t \in [0, t^*]$ and $v, w \in \mathbb{R}^N$. Then Euler's method converges, and indeed the error is $\mathcal{O}(h)$ uniformly on $[0, t^*]$.

Proof. The Lipschitz condition guarantees by Picard–Lindelöf that a unique solution y exists on $[0, t^*]$, so the statement makes sense. Write $e_n = y_n - y(t_n)$ for the (global) error at step n , and note $e_0 = 0$.

Taylor's theorem gives $y(t_{n+1}) = y(t_n) + hy'(t_n) + \mathcal{O}(h^2) = y(t_n) + hf(t_n, y(t_n)) + \mathcal{O}(h^2)$, where the $\mathcal{O}(h^2)$ is uniform in n because y'' is continuous on the compact interval $[0, t^*]$. Subtracting this from the Euler step,

$$\begin{aligned} \|e_{n+1}\| &= \|y_n + hf(t_n, y_n) - y(t_n) - hf(t_n, y(t_n)) - \mathcal{O}(h^2)\| \\ &\leq \|e_n\| + h \|f(t_n, y_n) - f(t_n, y(t_n))\| + ch^2 \\ &\leq (1 + h\lambda) \|e_n\| + ch^2 \end{aligned}$$

for some constant c independent of n and h . This is a linear recurrence, and unwinding it (using $e_0 = 0$) gives

$$\|e_{n+1}\| \leq ch^2 \sum_{j=0}^n (1 + h\lambda)^j = ch^2 \frac{(1 + h\lambda)^{n+1} - 1}{h\lambda} \leq \frac{ch}{\lambda} (1 + h\lambda)^{n+1}.$$

Now we use $1 + x \leq e^x$, valid for all real x , to get $(1 + h\lambda)^{n+1} \leq e^{(n+1)h\lambda} = e^{\lambda t_{n+1}} \leq e^{\lambda t^*}$. Hence

$$\|e_{n+1}\| \leq \frac{ce^{\lambda t^*}}{\lambda} h$$

for every n with $t_{n+1} \leq t^*$. The bound is independent of n and tends to 0 with h , which is convergence with $\mathcal{O}(h)$ error. $\square$

Remark. The factor $e^{\lambda t^*}$ is the price of accumulating $\mathcal{O}(1/h)$ errors of size $\mathcal{O}(h^2)$ each, with each error subsequently amplified by the flow. It is exponentially bad in t^* , which

is a genuine feature of the problem rather than an artefact of the proof: two nearby solutions of $y' = \lambda y$ really do separate exponentially. When $\lambda \rightarrow 0$ the bound looks singular, but $\frac{1}{\lambda}(e^{\lambda t^*} - 1) \rightarrow t^*$, so all is well.

The rate $\mathcal{O}(h)$ is what we mean by saying Euler's method has *order* 1. The general definition is local: we ask how much error a single step introduces, assuming that we started that step from the exact solution.

Definition 19.5.5 (Order)

A one-step method $y_{n+1} = \varphi_h(t_n, y_n)$ has **order** p if

$$y(t_{n+1}) - \varphi_h(t_n, y(t_n)) = \mathcal{O}(h^{p+1})$$

as $h \rightarrow 0$, for all sufficiently smooth f .

The exponent $p + 1$ rather than p is deliberate: as in the proof above, a *local* error of $\mathcal{O}(h^{p+1})$ made at each of $\mathcal{O}(1/h)$ steps accumulates to a *global* error of $\mathcal{O}(h^p)$. So a method of order p has global error $\mathcal{O}(h^p)$, and higher order means we can take larger steps for a given accuracy.

Example 19.5.6

For Euler's method, $y(t_{n+1}) - y(t_n) - hf(t_n, y(t_n)) = \frac{1}{2}h^2 y''(t_n) + \mathcal{O}(h^3) = \mathcal{O}(h^2)$, so $p = 1$.

§19.5.2 The Theta Method

We got Euler's method by evaluating f at the left end of the interval $[t_n, t_{n+1}]$. We could equally evaluate at the right end, or at any weighted average of the two.

Definition 19.5.7 (Theta Method)

For $\theta \in [0, 1]$, the **theta method** is

$$y_{n+1} = y_n + h \left(\theta f(t_n, y_n) + (1 - \theta) f(t_{n+1}, y_{n+1}) \right).$$

Taking $\theta = 1$ recovers Euler's method. Taking $\theta = 0$ gives the **backward Euler method**

$$y_{n+1} = y_n + hf(t_{n+1}, y_{n+1}),$$

and $\theta = \frac{1}{2}$ gives the **trapezoidal rule**

$$y_{n+1} = y_n + \frac{h}{2} (f(t_n, y_n) + f(t_{n+1}, y_{n+1})).$$

For $\theta \neq 1$ the unknown y_{n+1} appears on both sides, so the method is **implicit**: each step requires solving a (generally nonlinear) equation. That is a real cost, and one might wonder why we would pay it. There are two reasons. The first is order.

Proposition 19.5.8 (Order of the Theta Method)

The theta method has order 1, except when $\theta = \frac{1}{2}$, in which case it has order 2.

Proof. Assume $y_n = y(t_n)$ and expand everything about t_n , writing $y = y(t_n)$, $y' = y'(t_n)$ and so on. We have

$$y(t_{n+1}) = y + hy' + \frac{1}{2}h^2y'' + \frac{1}{6}h^3y''' + \mathcal{O}(h^4),$$

while $f(t_n, y(t_n)) = y'$ and, since $y'(t_{n+1}) = y' + hy'' + \frac{1}{2}h^2y''' + \mathcal{O}(h^3)$,

$$h\left(\theta y' + (1 - \theta)y'(t_{n+1})\right) = hy' + (1 - \theta)h^2y'' + \frac{1}{2}(1 - \theta)h^3y''' + \mathcal{O}(h^4).$$

Subtracting, the local error is

$$\left(\theta - \frac{1}{2}\right)h^2y'' + \left(\frac{\theta}{2} - \frac{1}{3}\right)h^3y''' + \mathcal{O}(h^4).$$

The h^2 term vanishes precisely when $\theta = \frac{1}{2}$; and when it does, the coefficient of h^3 is $\frac{1}{4} - \frac{1}{3} = -\frac{1}{12} \neq 0$. So the order is 1 in general and 2 for $\theta = \frac{1}{2}$. $\square$

The second reason for tolerating implicitness is *stability*, which will occupy us in Section 19.6. For the moment we simply record that implicit methods can be far better behaved on hard problems.

§19.5.3 Multistep Methods

Euler's method throws away everything it has computed except the most recent value. Since we have $y_0, \dots, y_n$ sitting in memory, it is natural to use several of them.

Definition 19.5.9 (Multistep Method)

An **s-step method** is a recurrence

$$\sum_{\ell=0}^s \rho_{\ell} y_{n+\ell} = h \sum_{\ell=0}^s \sigma_{\ell} f(t_{n+\ell}, y_{n+\ell}), \quad n = 0, 1, \dots,$$

normalised so that $\rho_s = 1$. The method is **explicit** if $\sigma_s = 0$ and **implicit** otherwise.

To start such a method we need s initial values $y_0, \dots, y_{s-1}$, of which the problem supplies only one; the rest are generated by some one-step method (typically a Runge–Kutta method of matching order). It is convenient to package the coefficients into two polynomials

$$\rho(w) = \sum_{\ell=0}^s \rho_{\ell} w^{\ell}, \quad \sigma(w) = \sum_{\ell=0}^s \sigma_{\ell} w^{\ell},$$

which will turn out to encode both the accuracy and the stability of the method.

Example 19.5.10

Euler's method is the one-step method with $\rho(w) = w - 1$, $\sigma(w) = 1$. Backward Euler has $\rho(w) = w - 1$, $\sigma(w) = w$. The trapezoidal rule has $\rho(w) = w - 1$, $\sigma(w) = \frac{1}{2}(w + 1)$. A genuine two-step example is the **Adams–Bashforth** method

$$y_{n+2} - y_{n+1} = h \left(\frac{3}{2}f(t_{n+1}, y_{n+1}) - \frac{1}{2}f(t_n, y_n) \right),$$

with $\rho(w) = w^2 - w$ and $\sigma(w) = \frac{3}{2}w - \frac{1}{2}$; and an implicit one is the two-step **Adams–Moulton** method

$$y_{n+2} - y_{n+1} = h \left(\frac{5}{12}f(t_{n+2}, y_{n+2}) + \frac{2}{3}f(t_{n+1}, y_{n+1}) - \frac{1}{12}f(t_n, y_n) \right).$$

Definition 19.5.11 (Order of a Multistep Method)

The multistep method above has **order** p if

$$\sum_{\ell=0}^s \rho_{\ell} y(t_{n+\ell}) - h \sum_{\ell=0}^s \sigma_{\ell} y'(t_{n+\ell}) = \mathcal{O}(h^{p+1})$$

as $h \rightarrow 0$, for all sufficiently smooth functions y .

Checking this by Taylor expansion each time would be tedious. Happily, the conditions can be packaged into a single elegant statement about ρ and σ .

Theorem 19.5.12 (Order Conditions)

The multistep method has order p if and only if

$$\rho(e^z) - z\sigma(e^z) = \mathcal{O}(z^{p+1}) \quad \text{as } z \rightarrow 0.$$

Proof. Expand everything about t_n . Writing $y^{(k)} = y^{(k)}(t_n)$ and $t_{n+\ell} = t_n + \ell h$,

$$y(t_{n+\ell}) = \sum_{k=0}^{\infty} \frac{(\ell h)^k}{k!} y^{(k)}, \quad y'(t_{n+\ell}) = \sum_{k=1}^{\infty} \frac{(\ell h)^{k-1}}{(k-1)!} y^{(k)}.$$

Substituting into the definition and collecting powers of h ,

$$\sum_{\ell} \rho_{\ell} y(t_{n+\ell}) - h \sum_{\ell} \sigma_{\ell} y'(t_{n+\ell}) = \left(\sum_{\ell} \rho_{\ell} \right) y + \sum_{k=1}^{\infty} \frac{1}{k!} \left(\sum_{\ell} \ell^k \rho_{\ell} - k \sum_{\ell} \ell^{k-1} \sigma_{\ell} \right) h^k y^{(k)}.$$

Since y is arbitrary, this is $\mathcal{O}(h^{p+1})$ precisely when

$$\sum_{\ell} \rho_{\ell} = 0 \quad \text{and} \quad \sum_{\ell} \ell^k \rho_{\ell} = k \sum_{\ell} \ell^{k-1} \sigma_{\ell} \quad \text{for } k = 1, \dots, p. \quad (*)$$

On the other hand, substituting $e^{\ell z} = \sum_k (\ell z)^k / k!$,

$$\begin{aligned} \rho(e^z) - z\sigma(e^z) &= \sum_{\ell} \rho_{\ell} e^{\ell z} - z \sum_{\ell} \sigma_{\ell} e^{\ell z} \\ &= \left(\sum_{\ell} \rho_{\ell} \right) + \sum_{k=1}^{\infty} \frac{1}{k!} \left(\sum_{\ell} \ell^k \rho_{\ell} - k \sum_{\ell} \ell^{k-1} \sigma_{\ell} \right) z^k, \end{aligned}$$

which is $\mathcal{O}(z^{p+1})$ under exactly the same conditions $(*)$. $\square$

Example 19.5.13

For the two-step Adams–Bashforth method, $\rho(w) = w^2 - w$ and $\sigma(w) = \frac{3}{2}w - \frac{1}{2}$. Then

$$\rho(e^z) = e^{2z} - e^z = z + \frac{3}{2}z^2 + \frac{7}{6}z^3 + \mathcal{O}(z^4),$$

$$z\sigma(e^z) = z\left(\frac{3}{2}e^z - \frac{1}{2}\right) = z + \frac{3}{2}z^2 + \frac{3}{4}z^3 + \mathcal{O}(z^4),$$

so $\rho(e^z) - z\sigma(e^z) = \frac{5}{12}z^3 + \mathcal{O}(z^4)$. Hence the method has order 2, and the coefficient $\frac{5}{12}$ is its *error constant*.

§19.5.4 The Root Condition and Dahlquist's Theorem

High order is not enough. Here is a cautionary example.

Example 19.5.14

Consider the two-step method $y_{n+2} - 2y_{n+1} + y_n = 0$, that is $\rho(w) = (w - 1)^2$ and $\sigma \equiv 0$. Then $\rho(e^z) - z\sigma(e^z) = (e^z - 1)^2 = z^2 + \mathcal{O}(z^3)$, so the method has order 1. But it does not involve f at all – the numerical solution is the arithmetic progression $y_n = y_0 + n(y_1 - y_0)$ regardless of the differential equation. It certainly does not converge.

What is wrong is that the recurrence itself, ignoring the right-hand side, has solutions that grow. The homogeneous recurrence $\sum_{\ell} \rho_{\ell} y_{n+\ell} = 0$ has solutions $y_n = w^n$ where $\rho(w) = 0$, and repeated roots produce solutions nw^n , n^2w^n and so on. For these to stay bounded we need the following.

Definition 19.5.15 (Root Condition)

A polynomial ρ obeys the **root condition** if all of its zeros lie in the closed unit disc $|w| \leq 1$, and every zero on the unit circle $|w| = 1$ is simple.

Note that $\rho(1) = \sum_{\ell} \rho_{\ell} = 0$ is forced by order $p \geq 1$, so $w = 1$ is always a zero; the root condition says that it must be a simple one and that no other zero may escape the disc.

The remarkable fact is that order and the root condition are not merely necessary for convergence – together they are sufficient.

Theorem 19.5.16 (Dahlquist Equivalence Theorem)

A multistep method is convergent if and only if it has order $p \geq 1$ and its polynomial ρ obeys the root condition.

We shall not prove this; the proof is long and was not given in lectures. But it is worth

appreciating what it does for us. Convergence is a statement about all initial value problems and all step sizes – an infinite amount of checking. The theorem replaces it by two finite algebraic checks on two polynomials, both of which can be done by hand in a minute.

Example 19.5.17

The two-step Adams–Bashforth method has $\rho(w) = w^2 - w = w(w - 1)$, whose roots are 0 and 1; the root condition holds, and we computed the order to be 2. So it converges.

Example 19.5.18

The method $y_{n+2} - 3y_{n+1} + 2y_n = h(f(t_{n+1}, y_{n+1}) - 2f(t_n, y_n))$ has $\rho(w) = w^2 - 3w + 2 = (w - 1)(w - 2)$. The root $w = 2$ lies outside the unit disc, so the method fails the root condition and does not converge, however good its order may be. (In fact its order is 2.)

§19.5.5 Constructing Good Multistep Methods

We would like a recipe for producing convergent methods of high order. Theorem 19.5.12 tells us to make $\rho(e^z) - z\sigma(e^z)$ vanish to high order at $z = 0$; equivalently, substituting $w = e^z$ so that $z = \log w$, we want

$$\rho(w) - \sigma(w) \log w = \mathcal{O}(|w - 1|^{p+1}) \quad \text{as } w \rightarrow 1.$$

So: choose ρ first, subject to $\rho(1) = 0$ and the root condition, and then choose σ to be the truncation of the Taylor expansion of $\rho(w)/\log w$ about $w = 1$. If $s = \deg \rho$, we truncate to degree $s - 1$ for an explicit method and degree s for an implicit one.

Method 19.5.19 (Adams Methods)

Take $\rho(w) = w^{s-1}(w - 1)$, the simplest choice satisfying the root condition (roots 0 with multiplicity $s - 1$, and a simple root at 1). The corresponding methods have the form

$$y_{n+s} - y_{n+s-1} = h \sum_{\ell=0}^s \sigma_\ell f(t_{n+\ell}, y_{n+\ell}).$$

The explicit choice ($\sigma_s = 0$) gives the **Adams–Bashforth** methods, of order s ; the implicit choice gives the **Adams–Moulton** methods, of order $s + 1$.

To see the orders claimed, note that $\rho(w)/\log w$ is analytic near $w = 1$ (the zero of $\log w$ at $w = 1$ is cancelled by the factor $w - 1$). If σ is its Taylor polynomial of degree m about $w = 1$, then $\rho(w)/\log w - \sigma(w) = \mathcal{O}(|w - 1|^{m+1})$ and hence

$$\rho(w) - \sigma(w) \log w = \mathcal{O}(|w - 1|^{m+1} |\log w|) = \mathcal{O}(|w - 1|^{m+2}),$$

giving order $m + 1$. With $m = s - 1$ we get order s , and with $m = s$ order $s + 1$.

Example 19.5.20 (Small Adams Methods)

For $s = 1$: $\rho(w) = w - 1$, and Adams–Bashforth is Euler’s method (order 1), while Adams–Moulton is the trapezoidal rule (order 2).

For $s = 2$: $\rho(w) = w^2 - w$. The expansion of $\rho(w)/\log w$ about $w = 1$ begins $1 + \frac{3}{2}(w-1) + \frac{5}{12}(w-1)^2 + \dots$. Truncating to degree 1 gives $\sigma(w) = 1 + \frac{3}{2}(w-1) = \frac{3}{2}w - \frac{1}{2}$, which is the two-step Adams–Bashforth method of order 2; keeping the quadratic term gives the two-step Adams–Moulton method of order 3, which written out is

$$y_{n+2} - y_{n+1} = h \left(\frac{5}{12}f_{n+2} + \frac{2}{3}f_{n+1} - \frac{1}{12}f_n \right),$$

where we abbreviate $f_m = f(t_m, y_m)$.

There is a second family worth knowing, obtained by fixing σ instead of ρ .

Definition 19.5.21 (Backward Differentiation Formulae)

A **BDF method** is an s -step method of the form

$$\sum_{\ell=0}^s \rho_\ell y_{n+\ell} = h \sigma_s f(t_{n+s}, y_{n+s}),$$

so that f is evaluated at one point only, at the new time level.

Theorem 19.5.22 (BDF Coefficients)

The s -step BDF method of order s has

$$\rho(w) = \sigma_s \sum_{\ell=1}^s \frac{1}{\ell} w^{s-\ell} (w-1)^\ell, \quad \sigma_s = \left(\sum_{\ell=1}^s \frac{1}{\ell} \right)^{-1}.$$

Proof. We want $\rho(w) - \sigma_s w^s \log w = \mathcal{O}(|w-1|^{s+1})$. Now

$$\log w = -\log\left(\frac{1}{w}\right) = -\log\left(1 - \frac{w-1}{w}\right) = \sum_{\ell=1}^{\infty} \frac{1}{\ell} \left(\frac{w-1}{w}\right)^\ell,$$

so that

$$\sigma_s w^s \log w = \sigma_s \sum_{\ell=1}^{\infty} \frac{1}{\ell} w^{s-\ell} (w-1)^\ell.$$

Truncating this series after $\ell = s$ commits an error $\mathcal{O}(|w-1|^{s+1})$, and the truncation is exactly the stated ρ , which is a polynomial of degree s . Finally, $\rho_s = 1$ requires the coefficient of w^s to be 1; each term contributes σ_s/ℓ , giving $\sigma_s \sum_{\ell=1}^s 1/\ell = 1$. $\square$

Example 19.5.23

For $s = 1$ we get $\sigma_1 = 1$ and $\rho(w) = w - 1$: backward Euler. For $s = 2$, $\sigma_2 = (1 + \frac{1}{2})^{-1} = \frac{2}{3}$ and

$$\rho(w) = \frac{2}{3} \left(w(w-1) + \frac{1}{2}(w-1)^2 \right) = w^2 - \frac{4}{3}w + \frac{1}{3},$$

giving the method

$$y_{n+2} - \frac{4}{3}y_{n+1} + \frac{1}{3}y_n = \frac{2}{3}h f(t_{n+2}, y_{n+2}).$$

Its ρ has roots 1 and $\frac{1}{3}$, so the root condition holds and the method converges.

Remark. The BDF construction produces a ρ that we did not get to choose, so we must check the root condition afterwards – and it can fail. In fact the s -step BDF method satisfies the root condition precisely when $s \leq 6$. Nobody uses BDF7. The reason to care about these methods at all is their exceptional stability on stiff problems, which we come to shortly.

§19.5.6 Runge–Kutta Methods

Multistep methods get high order by remembering the past. Runge–Kutta methods get it a different way: they take several trial steps *within* the current interval, and combine them. The motivation comes from quadrature. If f happened not to depend on y at all, then

$$y(t_{n+1}) = y(t_n) + \int_{t_n}^{t_{n+1}} f(t) dt,$$

and we could apply any quadrature rule we liked to the integral – Gaussian quadrature, say – to get

$$y_{n+1} = y_n + h \sum_{\ell=1}^{\nu} b_{\ell} f(t_n + c_{\ell}h),$$

where the b_{ℓ} and c_{ℓ} come from the rule rescaled to $[0, 1]$. When f does depend on y we would need $y(t_n + c_{\ell}h)$, which we do not have. The Runge–Kutta idea is to manufacture approximations to those intermediate values out of the data we do have.

Definition 19.5.24 (Runge–Kutta Method)

A ν -stage Runge–Kutta method is

$$k_{\ell} = f \left(t_n + c_{\ell}h, y_n + h \sum_{j=1}^{\nu} a_{\ell j} k_j \right), \quad \ell = 1, \dots, \nu, \quad y_{n+1} = y_n + h \sum_{\ell=1}^{\nu} b_{\ell} k_{\ell},$$

where $c_{\ell} = \sum_{j=1}^{\nu} a_{\ell j}$. The method is **explicit** if $a_{\ell j} = 0$ whenever $j \geq \ell$, so that each k_{ℓ} is computed from those before it; otherwise it is implicit.

The coefficients are conventionally displayed in a **Butcher tableau**

$$\begin{array}{c|c} c & A \\ \hline & b^{\top} \end{array} = \begin{array}{c|cccc} c_1 & a_{11} & a_{12} & \cdots & a_{1\nu} \\ c_2 & a_{21} & a_{22} & \cdots & a_{2\nu} \\ \vdots & \vdots & \vdots & & \vdots \\ c_{\nu} & a_{\nu 1} & a_{\nu 2} & \cdots & a_{\nu \nu} \\ \hline & b_1 & b_2 & \cdots & b_{\nu} \end{array}$$

in which the row sums of A are the entries of c . An explicit method has A strictly lower triangular, so its tableau has a triangle of zeros (usually left blank) on and above the diagonal.

Example 19.5.25 (Euler and the Trapezoidal Rule)

Euler's method is the one-stage explicit method with tableau

$$\begin{array}{c|c} 0 & 0 \\ \hline & 1 \end{array}$$

and the trapezoidal rule is the two-stage implicit method

$$\begin{array}{c|cc} 0 & 0 & 0 \\ 1 & \frac{1}{2} & \frac{1}{2} \\ \hline & \frac{1}{2} & \frac{1}{2} \end{array}.$$

Let us see how the order conditions arise, in the smallest interesting case.

Example 19.5.26 (Two-Stage Explicit Methods)

Take $\nu = 2$ with $a_{21} = c_2$, so that

$$k_1 = f(t_n, y_n), \quad k_2 = f(t_n + c_2 h, y_n + c_2 h k_1),$$

and $y_{n+1} = y_n + h(b_1 k_1 + b_2 k_2)$. Assume $y_n = y(t_n)$ and expand. Taylor's theorem in two variables gives

$$k_2 = f + c_2 h (f_t + f_y f) + \mathcal{O}(h^2),$$

where f and its partials are evaluated at (t_n, y_n) . On the other hand, differentiating $y' = f(t, y)$ gives $y'' = f_t + f_y f$, so

$$y_n + h(b_1 k_1 + b_2 k_2) = y + h(b_1 + b_2)y' + h^2 b_2 c_2 y'' + \mathcal{O}(h^3),$$

whereas $y(t_{n+1}) = y + h y' + \frac{1}{2} h^2 y'' + \mathcal{O}(h^3)$. Matching coefficients, the local error is

$$h(1 - b_1 - b_2)y' + \frac{h^2}{2}(1 - 2b_2 c_2)y'' + \mathcal{O}(h^3),$$

so we obtain order 2 exactly when

$$b_1 + b_2 = 1, \quad b_2 c_2 = \frac{1}{2}.$$

Two popular solutions are $b = (\frac{1}{2}, \frac{1}{2})$, $c_2 = 1$ (the *improved Euler* or Heun method) and $b = (0, 1)$, $c_2 = \frac{1}{2}$ (the *midpoint* method).

Proposition 19.5.27

No two-stage explicit Runge–Kutta method has order 3.

Proof. It suffices to exhibit one problem for which order 3 fails. Take $y' = y$, $y(0) = 1$, with exact solution $y(t) = e^t$. Then $k_1 = e^{t_n}$ and $k_2 = e^{t_n}(1 + c_2 h)$, so the local error is

$$e^{t_{n+1}} - e^{t_n} (1 + h(b_1 + b_2) + h^2 b_2 c_2) = e^{t_n} (e^h - 1 - h(b_1 + b_2) - h^2 b_2 c_2).$$

Expanding e^h , the h^3 coefficient is $\frac{1}{6}e^{t_n}$, which no choice of b_ℓ, c_ℓ can remove since they do not appear in it. So the local error is $\Theta(h^3)$ at best. $\square$

The most celebrated Runge–Kutta method of all is the four-stage, fourth-order one, which people simply call ‘RK4’.

Example 19.5.28 (The Classical RK4)

The method

$$\begin{aligned} k_1 &= f(t_n, y_n), \\ k_2 &= f(t_n + \tfrac{h}{2}, y_n + \tfrac{h}{2}k_1), \\ k_3 &= f(t_n + \tfrac{h}{2}, y_n + \tfrac{h}{2}k_2), \\ k_4 &= f(t_n + h, y_n + hk_3), \\ y_{n+1} &= y_n + \tfrac{h}{6}(k_1 + 2k_2 + 2k_3 + k_4) \end{aligned}$$

has order 4. Its Butcher tableau is

$$\begin{array}{c|ccc} 0 & & & \\ \frac{1}{2} & \frac{1}{2} & & \\ \frac{1}{2} & 0 & \frac{1}{2} & \\ 1 & 0 & 0 & 1 \\ \hline & \frac{1}{6} & \frac{1}{3} & \frac{1}{3} & \frac{1}{6} \end{array}.$$

Notice that the weights $\frac{1}{6}, \frac{1}{3}, \frac{1}{3}, \frac{1}{6}$ and the nodes $0, \frac{1}{2}, \frac{1}{2}, 1$ are exactly Simpson’s rule on $[0, 1]$ (with the midpoint counted twice). This is no accident: if f is independent of y then $k_2 = k_3$ and the method *is* Simpson’s rule.

Remark. Verifying that RK4 has order 4 by direct Taylor expansion is a genuinely unpleasant computation – one must match multivariate derivatives of f up to third order – and we shall not do it here. The systematic treatment is due to Butcher and is organised by rooted trees. What is worth knowing is the general shape of the answer: an explicit ν -stage method has order at most ν , with equality possible only for $\nu \leq 4$. To get order 5 one needs 6 stages, which is one reason RK4 remains so popular.

Remark. Implicit Runge–Kutta methods can do much better. The ν -stage *Gauss–Legendre* method, whose nodes c_ℓ are the Gaussian quadrature nodes on $[0, 1]$, has order 2ν – the maximum possible – which is precisely the exactness result of Theorem 19.3.9 reappearing in a new guise. The two-stage version, with

$$c = \left(\tfrac{1}{2} - \tfrac{\sqrt{3}}{6}, \tfrac{1}{2} + \tfrac{\sqrt{3}}{6}\right), \quad b = \left(\tfrac{1}{2}, \tfrac{1}{2}\right),$$

has order 4 using only two evaluations of f per step, at the cost of solving an implicit system.

§19.6 Stiff Equations and Stability

Everything so far has been about behaviour as $h \rightarrow 0$. In practice we do not take $h \rightarrow 0$; we take h as large as we dare, and the question is how large that is. For some problems the answer is dictated not by accuracy but by *stability*, and the discrepancy can be enormous.

Example 19.6.1

Consider the scalar problem $y' = -100y$, $y(0) = 1$, whose solution e^{-100t} has decayed to 10^{-44} by $t = 1$. Euler's method gives $y_n = (1-100h)^n$. If $h = 0.1$ then $y_n = (-9)^n$, which oscillates with wildly growing amplitude: at $t = 1$ we get $y_{10} = 3.5 \times 10^9$ instead of essentially zero. We need $|1 - 100h| < 1$, that is $h < 0.02$, purely to avoid nonsense – even though the solution itself is utterly featureless after $t = 0.05$ and any reasonable notion of accuracy would permit much larger steps.

Definition 19.6.2 (Stiffness)

An initial value problem is **stiff** if the step size of a numerical method must be kept much smaller than accuracy alone would demand, in order to keep the numerical solution bounded.

This is a deliberately informal definition, and stiffness is a property of the problem-and-method pair rather than of the problem alone. Stiffness typically arises in systems $y' = Ay$ whose eigenvalues have very different magnitudes: the fast-decaying components are numerically irrelevant after a moment, but they continue to dictate the step size forever. Such systems are the norm in chemical kinetics and in the method of lines for parabolic PDEs.

§19.6.1 Linear Stability Domains

To analyse this we use a test problem simple enough to compute with and rich enough to be informative.

Definition 19.6.3 (Linear Stability Domain)

Apply a numerical method with constant step h to the scalar test equation

$$y' = \lambda y, \quad y(0) = 1, \quad \lambda \in \mathbb{C}.$$

The **linear stability domain** of the method is

$$\mathcal{D} = \{h\lambda \in \mathbb{C} : y_n \rightarrow 0 \text{ as } n \rightarrow \infty\}.$$

The exact solution $e^{\lambda t}$ tends to 0 precisely when $\operatorname{Re} \lambda < 0$, so we would like $\mathcal{D}$ to contain the whole left half-plane.

Definition 19.6.4 (A-stability)

A method is **A-stable** if $\mathbb{C}^- = \{z \in \mathbb{C} : \operatorname{Re} z < 0\} \subseteq \mathcal{D}$.

Let us compute $\mathcal{D}$ for the theta method. Applying it to $y' = \lambda y$ gives

$$y_{n+1} = y_n + h\lambda(\theta y_n + (1-\theta)y_{n+1}) \implies y_{n+1} = \frac{1+\theta z}{1-(1-\theta)z} y_n, \quad z = h\lambda.$$

So $y_n = r(z)^n$ with $r(z) = \frac{1+\theta z}{1-(1-\theta)z}$, and $y_n \rightarrow 0$ if and only if $|r(z)| < 1$.

Example 19.6.5 (Euler's Method)

Here $\theta = 1$ and $r(z) = 1 + z$, so

$$\mathcal{D} = \{z : |1 + z| < 1\},$$

the open disc of radius 1 centred at -1 . This is a small set: it fails to contain, for instance, $z = -3$, which is exactly the instability we saw above. Euler's method is not A-stable.

Example 19.6.6 (Backward Euler)

Here $\theta = 0$ and $r(z) = (1 - z)^{-1}$, so

$$\mathcal{D} = \{z : |1 - z| > 1\},$$

the *exterior* of the open disc of radius 1 centred at $+1$. This contains the whole left half-plane, so backward Euler is A-stable. In fact $\mathcal{D}$ is much bigger than $\mathbb{C}^-$, which means backward Euler damps some components that the true solution does not damp – a form of inaccuracy, but a benign one.

Example 19.6.7 (The Trapezoidal Rule)

Here $\theta = \frac{1}{2}$ and

$$r(z) = \frac{1 + z/2}{1 - z/2} = \frac{2 + z}{2 - z},$$

so $|r(z)| < 1$ if and only if $|2 + z| < |2 - z|$, that is, if and only if z is closer to -2 than to 2 . Hence $\mathcal{D} = \mathbb{C}^-$ exactly: the trapezoidal rule is A-stable, and its stability domain is precisely right – it damps exactly what should be damped.

Here are the three domains, with the stable region shaded.

The contrast is striking. The explicit method has a bounded stability domain, so for any fixed λ with $\operatorname{Re} \lambda \ll 0$ there is a hard ceiling on h ; the two implicit methods have no such ceiling at all. This is the pay-off that justifies the extra work of solving an implicit equation at each step, and it is why stiff problems are solved with implicit methods.

Remark. The trapezoidal rule is A-stable but its $r(z)$ satisfies $|r(z)| \rightarrow 1$ as $|z| \rightarrow \infty$, so very stiff components are barely damped – they merely oscillate in sign. Backward Euler has $r(z) \rightarrow 0$, and kills them outright. A method with $r(\infty) = 0$ is called *L-stable*, and for genuinely stiff problems this is what one wants.

§19.6.2 Stability of Multistep and Runge–Kutta Methods

For a multistep method the analysis is a little different, since the recurrence is of order s . Applying the method to $y' = \lambda y$ with $z = h\lambda$ gives

$$\sum_{\ell=0}^s \rho_{\ell} y_{n+\ell} = z \sum_{\ell=0}^s \sigma_{\ell} y_{n+\ell}, \quad \text{i.e.} \quad \sum_{\ell=0}^s (\rho_{\ell} - z\sigma_{\ell}) y_{n+\ell} = 0.$$

This is a linear recurrence with characteristic polynomial $\rho(w) - z\sigma(w)$, and its solutions tend to zero exactly when all the roots of that polynomial lie strictly inside the unit disc. So

$$\mathcal{D} = \{z \in \mathbb{C} : \text{all roots } w \text{ of } \rho(w) - z\sigma(w) \text{ satisfy } |w| < 1\}.$$

Notice that $z = 0$ gives back the root condition (in its non-strict form), which is reassuring: linear stability at $z = 0$ is exactly convergence.

This is harder to work with, and the news is bad.

Theorem 19.6.8 (Second Dahlquist Barrier)

No A-stable multistep method has order greater than 2. Among the A-stable multistep methods of order 2, the trapezoidal rule has the smallest error constant.

We do not prove this. It is a genuine obstruction rather than a failure of ingenuity, and it forces a choice: either accept low order, or weaken the demand for A-stability, or leave the multistep world altogether.

The second option is what is done in practice. Many stiff systems have eigenvalues that are not merely in $\mathbb{C}^-$ but far from the imaginary axis, so it suffices to have a stability domain containing a wedge around the negative real axis. A method whose stability domain contains such a wedge $\{z : |\arg(-z)| < \alpha\}$ is called $A(\alpha)$ -stable, and the BDF methods of order up to 6 all have this property with a decent α . This is why they exist.

The third option is Runge–Kutta. Applying a Runge–Kutta method to $y' = \lambda y$ always gives $y_{n+1} = r(z)y_n$ for a rational function r , so $\mathcal{D} = \{z : |r(z)| < 1\}$; and there is no barrier theorem here.

Example 19.6.9 (An A-stable Implicit Runge–Kutta Method)

Consider the two-stage implicit method with tableau

$$\begin{array}{c|cc} 0 & \frac{1}{4} & -\frac{1}{4} \\ \frac{2}{3} & \frac{1}{4} & \frac{5}{12} \\ \hline & \frac{1}{4} & \frac{3}{4} \end{array},$$

that is,

$$k_1 = f\left(t_n, y_n + \frac{h}{4}(k_1 - k_2)\right), \quad k_2 = f\left(t_n + \frac{2h}{3}, y_n + \frac{h}{12}(3k_1 + 5k_2)\right),$$

with $y_{n+1} = y_n + \frac{h}{4}(k_1 + 3k_2)$. Applying this to $y' = \lambda y$ and eliminating k_1, k_2 gives $y_{n+1} = r(z)y_n$ with

$$r(z) = \frac{6 + 2z}{6 - 4z + z^2}.$$

We claim $\mathcal{D} \supseteq \mathbb{C}^-$. The denominator $z^2 - 4z + 6$ has roots $2 \pm i\sqrt{2}$, both in the right half-plane, so r is analytic on $\overline{\mathbb{C}^-}$; and $r(z) \rightarrow 0$ as $|z| \rightarrow \infty$. By the maximum modulus principle, $|r|$ attains its maximum over the closed left half-plane on the boundary, so it suffices to check $|r(ix)| \leq 1$ for $x \in \mathbb{R}$. Now

$$|6 + 2ix|^2 = 36 + 4x^2, \quad |6 - x^2 - 4ix|^2 = (6 - x^2)^2 + 16x^2 = 36 + 4x^2 + x^4,$$

so $|r(ix)|^2 = \frac{36+4x^2}{36+4x^2+x^4} \leq 1$, with equality only at $x = 0$. Hence $|r(z)| < 1$ throughout $\mathbb{C}^-$, and the method is A-stable. It can be shown that it also has order 3 – beating the Dahlquist barrier comfortably.

Remark. The same argument shows the ν -stage Gauss–Legendre methods are all A-stable; the two-stage one has

$$r(z) = \frac{12 + 6z + z^2}{12 - 6z + z^2},$$

for which $|r(ix)| = 1$ for all real x , so its stability domain is exactly $\mathbb{C}^-$. Order 4 and exact stability, in two stages – at the price of solving a coupled implicit system at every step.

§19.6.3 Implementation

We close the discussion of differential equations with a few words on what one actually does, since the theory above leaves two practical questions unanswered: how big should h be, and how do we solve the implicit equations?

Choosing the step size

A user of an ODE solver does not want to specify h ; they want to specify an error tolerance ε and have the solver work out h for itself, varying it as the solution demands. To do that we need a cheap estimate of the local error at each step.

Method 19.6.10 (The Milne Device)

Run two multistep methods of the same order side by side, one explicit (the *predictor*) and one implicit (the *corrector*). If the two methods have error constants c_P and c_C , then

$$y_{n+1}^P \approx y(t_{n+1}) - c_P h^{p+1} y^{(p+1)}(t_n), \quad y_{n+1}^C \approx y(t_{n+1}) - c_C h^{p+1} y^{(p+1)}(t_n).$$

Subtracting eliminates the unknown derivative,

$$h^{p+1} y^{(p+1)}(t_n) \approx \frac{y_{n+1}^P - y_{n+1}^C}{c_C - c_P},$$

and substituting back gives the estimate

$$y_{n+1}^C - y(t_{n+1}) \approx \frac{c_C}{c_C - c_P} (y_{n+1}^P - y_{n+1}^C)$$

for the local error of the corrector, computable from quantities we have already.

Example 19.6.11

With the two-step Adams–Bashforth method as predictor ($c_P = \frac{5}{12}$) and the trapezoidal rule as corrector ($c_C = -\frac{1}{12}$), the estimate is

$$y_{n+1}^C - y(t_{n+1}) \approx -\frac{1}{6} (y_{n+1}^P - y_{n+1}^C).$$

The predictor costs one extra evaluation of f , which is cheap, and it doubles as an excellent starting guess for the implicit corrector equation.

Given the estimate, the logic is straightforward: if it exceeds the tolerance ε , reject the step and retry with smaller h ; if it is comfortably below (say below $\varepsilon/10$), accept the step and increase h ; otherwise accept and carry on unchanged.

For Runge–Kutta methods there is no single error constant to exploit, and the analogous device is *embedded* Runge–Kutta: one uses two methods, of orders p and $p+1$, sharing as many stages as possible so that the extra accuracy is nearly free.

Example 19.6.12 (An Embedded Pair)

With

$$k_1 = f(t_n, y_n), \quad k_2 = f\left(t_n + \frac{h}{2}, y_n + \frac{h}{2}k_1\right), \quad k_3 = f\left(t_n + h, y_n - hk_1 + 2hk_2\right),$$

the combination $y_{n+1}^{[1]} = y_n + hk_2$ has order 2, while $y_{n+1}^{[2]} = y_n + \frac{h}{6}(k_1 + 4k_2 + k_3)$ has order 3. The difference $y_{n+1}^{[1]} - y_{n+1}^{[2]}$ estimates the error in the lower-order formula, at the cost of three function evaluations in total.

Solving the implicit equations

An implicit method requires us to solve, at each step, an equation of the form

$$y_{n+s} = h\sigma_s f(t_{n+s}, y_{n+s}) + v,$$

where v collects everything already known. The simplest approach is **functional iteration**,

$$y_{n+s}^{[j+1]} = h\sigma_s f(t_{n+s}, y_{n+s}^{[j]}) + v,$$

started from the predictor. This is a contraction provided $h|\sigma_s|\lambda < 1$, where λ is the Lipschitz constant of f – but that is precisely the sort of restriction on h we adopted an implicit method to escape. So for stiff problems functional iteration is useless, and one uses the **Newton–Raphson** method instead: setting $\psi(y) = y - h\sigma_s f(t_{n+s}, y) - v$, iterate

$$y_{n+s}^{[j+1]} = y_{n+s}^{[j]} - \left(D\psi(y_{n+s}^{[j]})\right)^{-1} \psi(y_{n+s}^{[j]}),$$

which converges quadratically from a good starting guess. Evaluating and inverting the Jacobian $D\psi = I - h\sigma_s D_y f$ at every iteration is expensive, so in practice one freezes it,

$$y_{n+s}^{[j+1]} = y_{n+s}^{[j]} - \left(D\psi(y_{n+s}^{[0]})\right)^{-1} \psi(y_{n+s}^{[j]}),$$

recomputing only when convergence deteriorates. Either way we are left with a linear system to solve at every step, usually with the same matrix many times over – which is exactly the situation the next section is designed for.

§19.7 Numerical Linear Algebra

Solving $A\mathbf{x} = \mathbf{b}$ is the single most common task in scientific computing, and one that we have already run into twice in this course – in the normal equations for least-squares fitting, and in the Newton iteration for implicit ODE methods. In pure linear algebra the problem is considered solved: $\mathbf{x} = A^{-1}\mathbf{b}$, and Cramer’s rule even gives a formula. But Cramer’s rule for a 20×20 system requires more arithmetic than has been performed in the history of the world, so we shall have to do better.

The strategy throughout is *factorisation*: write A as a product of matrices for which the system is easy, solve a sequence of easy systems, and – crucially – reuse the factorisation if the same A appears again with a different $\mathbf{b}$.

§19.7.1 Triangular Systems

The easy case is a triangular matrix.

Definition 19.7.1

A square matrix L is **lower triangular** if $L_{ij} = 0$ for $j > i$, and **unit lower triangular** if in addition $L_{ii} = 1$ for all i . Similarly U is **upper triangular** if $U_{ij} = 0$ for $j < i$.

If L is lower triangular and nonsingular, the system $L\mathbf{y} = \mathbf{b}$ is solved by *forward substitution*: the first equation gives $y_1 = b_1/L_{11}$, and having found $y_1, \dots, y_{i-1}$ the i -th equation gives

$$y_i = \frac{1}{L_{ii}} \left(b_i - \sum_{j < i} L_{ij} y_j \right).$$

This costs $\mathcal{O}(n^2)$ operations, one multiplication for each nonzero entry of L . Upper triangular systems are solved the same way from the bottom up, by *back substitution*.

§19.7.2 LU Factorisation

Definition 19.7.2 (LU Factorisation)

An **LU factorisation** of a square matrix A is a factorisation $A = LU$ in which L is unit lower triangular and U is upper triangular.

Given such a factorisation, everything becomes cheap. To solve $A\mathbf{x} = \mathbf{b}$ we solve $L\mathbf{y} = \mathbf{b}$ by forward substitution and then $U\mathbf{x} = \mathbf{y}$ by back substitution, at a cost of $\mathcal{O}(n^2)$ for each new right-hand side. The determinant is

$$\det A = \det L \det U = \prod_{i=1}^n U_{ii},$$

so A is singular precisely when some $U_{ii} = 0$.

How do we compute it? Write $\mathbf{l}_1, \dots, \mathbf{l}_n$ for the columns of L and $\mathbf{u}_1^\top, \dots, \mathbf{u}_n^\top$ for the rows of U . Then

$$A = LU = \sum_{k=1}^n \mathbf{l}_k \mathbf{u}_k^\top,$$

an expression of A as a sum of n rank-one matrices. The point is that $\mathbf{l}_k$ has zeros in its first $k-1$ entries and $\mathbf{u}_k$ has zeros in its first $k-1$ entries, so $\mathbf{l}_k \mathbf{u}_k^\top$ has zeros in its first $k-1$ rows *and* its first $k-1$ columns. Consequently the first row and column of A come entirely from the $k=1$ term, and we can read them off.

Method 19.7.3 (LU by Outer Products)

Set $A_0 = A$. For $k = 1, 2, \dots, n$:

- (i) let $\mathbf{u}_k^\top$ be the k -th row of A_{k-1} ;
- (ii) let $\mathbf{l}_k$ be the k -th column of A_{k-1} , divided by $(A_{k-1})_{kk}$ so that $(\mathbf{l}_k)_k = 1$;
- (iii) set $A_k = A_{k-1} - \mathbf{l}_k \mathbf{u}_k^\top$.

Then $A = \sum_k \mathbf{l}_k \mathbf{u}_k^\top = LU$.

At step k the dominant cost is forming the outer product, which touches an $(n-k+1) \times (n-k+1)$ block, so the total cost is $\sum_k (n-k+1)^2 \sim \frac{1}{3}n^3$ operations. This is the same $\mathcal{O}(n^3)$ as Gaussian elimination – indeed, the algorithm *is* Gaussian elimination, with the multipliers recorded in L instead of discarded. The advantage of keeping them is that a second right-hand side then costs only $\mathcal{O}(n^2)$ rather than another $\mathcal{O}(n^3)$.

Example 19.7.4

Let

$$A = \begin{pmatrix} 2 & 1 & 1 \\ 4 & 3 & 3 \\ 8 & 7 & 9 \end{pmatrix}.$$

Step 1: $\mathbf{u}_1^\top = (2, 1, 1)$ and $\mathbf{l}_1 = (1, 2, 4)^\top$, so

$$A_1 = A - \begin{pmatrix} 1 \\ 2 \\ 4 \end{pmatrix} (2, 1, 1) = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 3 & 5 \end{pmatrix}.$$

Step 2: $\mathbf{u}_2^\top = (0, 1, 1)$ and $\mathbf{l}_2 = (0, 1, 3)^\top$, giving

$$A_2 = A_1 - \begin{pmatrix} 0 \\ 1 \\ 3 \end{pmatrix} (0, 1, 1) = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 2 \end{pmatrix}.$$

Step 3: $\mathbf{u}_3^\top = (0, 0, 2)$, $\mathbf{l}_3 = (0, 0, 1)^\top$. Hence

$$L = \begin{pmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ 4 & 3 & 1 \end{pmatrix}, \quad U = \begin{pmatrix} 2 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 2 \end{pmatrix},$$

and $\det A = 2 \cdot 1 \cdot 2 = 4$.

The algorithm breaks down if $(A_{k-1})_{kk} = 0$, since we cannot divide by it. Sometimes this is unavoidable: the matrix $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ has no LU factorisation at all, as one sees immediately by multiplying out $\begin{pmatrix} 1 & 0 \\ \ell & 1 \end{pmatrix} \begin{pmatrix} u_{11} & u_{12} \\ 0 & u_{22} \end{pmatrix}$ and comparing top-left entries. The precise condition is the following.

Theorem 19.7.5 (Existence and Uniqueness of LU)

Let A be $n \times n$ and let $A^{(k)}$ denote its leading $k \times k$ principal submatrix. If $A^{(k)}$ is nonsingular for every $k = 1, \dots, n$, then A has an LU factorisation, and it is unique.

Proof. Uniqueness first, and note that it does not need the hypothesis beyond A being nonsingular. Suppose $A = LU = L'U'$ with L, L' unit lower triangular and U, U' upper triangular and nonsingular. Then $(L')^{-1}L = U'U^{-1}$. The left side is unit lower triangular (inverses and products of unit lower triangular matrices are unit lower triangular) and the right side is upper triangular. A matrix that is both is diagonal, and being unit lower triangular it must be I . Hence $L = L'$ and $U = U'$.

Existence, by induction on k , constructing the factorisation of $A^{(k)}$. For $k = 1$, take $L = (1)$ and $U = (A_{11})$, which is legitimate since $A^{(1)} \neq 0$. Suppose $A^{(k)} = L_k U_k$ with L_k unit lower triangular and U_k upper triangular; since $\det A^{(k)} = \det U_k \neq 0$, both factors are nonsingular. Write

$$A^{(k+1)} = \begin{pmatrix} A^{(k)} & \mathbf{b} \\ \mathbf{c}^\top & d \end{pmatrix},$$

and look for a factorisation

$$A^{(k+1)} = \begin{pmatrix} L_k & \mathbf{0} \\ \mathbf{x}^\top & 1 \end{pmatrix} \begin{pmatrix} U_k & \mathbf{y} \\ \mathbf{0}^\top & u \end{pmatrix} = \begin{pmatrix} L_k U_k & L_k \mathbf{y} \\ \mathbf{x}^\top U_k & \mathbf{x}^\top \mathbf{y} + u \end{pmatrix}.$$

The top-left block is already correct. The remaining equations are $L_k \mathbf{y} = \mathbf{b}$, $U_k^\top \mathbf{x} = \mathbf{c}$ and $u = d - \mathbf{x}^\top \mathbf{y}$, and each has a unique solution because L_k and U_k are nonsingular. This completes the induction, and taking $k = n$ gives the result. $\square$

Remark. The hypothesis is sufficient but not necessary: the zero matrix has an LU factorisation (many of them) while all its principal minors vanish. What the theorem really says is that if the leading minors are nonsingular, the naive algorithm never has to divide by zero – and the pivots it uses are exactly $U_{kk} = \det A^{(k)} / \det A^{(k-1)}$.

§19.7.3 Pivoting

A zero pivot is fatal, and – worse – a *small* pivot is nearly fatal, since dividing by it amplifies whatever rounding error is present. The cure for both is to reorder the rows.

Method 19.7.6 (LU with Partial Pivoting)

At step k , before doing anything else, choose $p \geq k$ maximising $|(A_{k-1})_{pk}|$ and let P_k be the permutation matrix exchanging rows k and p . Then take $\mathbf{u}_k^\top$ to be the k -th row of $P_k A_{k-1}$, take

$$\mathbf{l}_k = \frac{1}{(P_k A_{k-1})_{kk}} (k\text{-th column of } P_k A_{k-1}),$$

and set $A_k = P_k A_{k-1} - \mathbf{l}_k \mathbf{u}_k^\top$.

Choosing the largest available entry guarantees that every entry of $\mathbf{l}_k$ has modulus at

most 1, so the multipliers never magnify errors. Unwinding the algorithm, one finds

$$(P_{n-1} \cdots P_1)A = \tilde{\mathbf{l}}_1 \mathbf{u}_1^\top + \cdots + \tilde{\mathbf{l}}_n \mathbf{u}_n^\top, \quad \tilde{\mathbf{l}}_k = P_{n-1} \cdots P_{k+1} \mathbf{l}_k,$$

and since the permutations applied to $\mathbf{l}_k$ only touch entries from position $k+1$ onwards, the vectors $\tilde{\mathbf{l}}_k$ still have zeros in their first $k-1$ places. So they are the columns of a unit lower triangular matrix, and we have proved the following.

Theorem 19.7.7 (LU with Pivoting)

For any square matrix A there is a permutation matrix P such that $PA = LU$ with L unit lower triangular and U upper triangular.

Proof. Run the algorithm above, taking $P = P_{n-1} \cdots P_1$. The only remaining worry is a step at which the entire k -th column of A_{k-1} (from row k down) is zero; in that case there is nothing to eliminate, and we may simply take $P_k = I$, $\mathbf{l}_k = \mathbf{e}_k$ and $\mathbf{u}_k^\top$ the k -th row of A_{k-1} , which preserves everything we need. $\square$

To solve $A\mathbf{x} = \mathbf{b}$ we then solve $L\mathbf{y} = P\mathbf{b}$ and $U\mathbf{x} = \mathbf{y}$; permuting a vector is free.

§19.7.4 Symmetric Matrices and Cholesky

When A is symmetric it is wasteful to compute both L and U , since we ought to be able to get one from the other. The right factorisation is the following.

Definition 19.7.8

An **$LDL^\top$ factorisation** of a symmetric matrix A is a factorisation $A = LDL^\top$ with L unit lower triangular and D diagonal.

Setting $U = DL^\top$ recovers an LU factorisation, so by Theorem 19.7.5 the $LDL^\top$ factorisation is unique when it exists. It is computed by exactly the same outer-product scheme: writing $A = \sum_k D_{kk} \mathbf{l}_k \mathbf{l}_k^\top$, we set $A_0 = A$, take $D_{kk} = (A_{k-1})_{kk}$, take $\mathbf{l}_k$ to be the k -th column of A_{k-1} scaled so that $(\mathbf{l}_k)_k = 1$, and put $A_k = A_{k-1} - D_{kk} \mathbf{l}_k \mathbf{l}_k^\top$. Since we only need the lower half of each A_k , the work is halved.

Example 19.7.9

Take $A = \begin{pmatrix} 2 & 4 \\ 4 & 11 \end{pmatrix}$. Then $D_{11} = 2$ and $\mathbf{l}_1 = (1, 2)^\top$, so

$$A_1 = \begin{pmatrix} 2 & 4 \\ 4 & 11 \end{pmatrix} - 2 \begin{pmatrix} 1 \\ 2 \end{pmatrix} (1, 2) = \begin{pmatrix} 0 & 0 \\ 0 & 3 \end{pmatrix},$$

whence $D_{22} = 3$, $\mathbf{l}_2 = (0, 1)^\top$ and

$$A = \begin{pmatrix} 1 & 0 \\ 2 & 1 \end{pmatrix} \begin{pmatrix} 2 & 0 \\ 0 & 3 \end{pmatrix} \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}.$$

Definition 19.7.10

A symmetric matrix A is **positive definite** if $\mathbf{x}^\top A \mathbf{x} > 0$ for every $\mathbf{x} \neq \mathbf{0}$.

Theorem 19.7.11

A real symmetric matrix A is positive definite if and only if it has an $LDL^\top$ factorisation in which every diagonal entry of D is positive.

Proof. ($\Leftarrow$) If $A = LDL^\top$ with $D_{kk} > 0$, then for $\mathbf{x} \neq \mathbf{0}$ put $\mathbf{z} = L^\top \mathbf{x}$, which is nonzero since $L^\top$ is nonsingular. Then $\mathbf{x}^\top A \mathbf{x} = \mathbf{z}^\top D \mathbf{z} = \sum_k D_{kk} z_k^2 > 0$.

($\Rightarrow$) Suppose A is positive definite. Every leading principal submatrix $A^{(k)}$ is then positive definite (test with vectors supported on the first k coordinates), hence nonsingular, so by Theorem 19.7.5 the factorisation exists. Its diagonal entries satisfy $D_{kk} = \det A^{(k)} / \det A^{(k-1)}$, and all these determinants are positive because a positive definite matrix has positive determinant (its eigenvalues are all positive). Hence $D_{kk} > 0$. $\square$

Definition 19.7.12 (Cholesky Factorisation)

If A is symmetric positive definite, write $D^{1/2}$ for the diagonal matrix with entries $\sqrt{D_{kk}}$ and set $\tilde{L} = LD^{1/2}$. Then

$$A = \tilde{L} \tilde{L}^\top$$

with $\tilde{L}$ lower triangular with positive diagonal. This is the **Cholesky factorisation**.

Cholesky is the workhorse for symmetric positive definite systems. It needs no pivoting – the theorem guarantees the pivots are positive, and one can show they cannot grow – it uses half the storage and half the arithmetic of LU, and it fails, in a numerically detectable way, precisely when A is not positive definite. That last property makes it the standard test for positive definiteness.

§19.7.5 Banded and Sparse Matrices

Large matrices arising in practice are rarely dense. Discretising a differential equation, for instance, couples each unknown only to its neighbours, and the resulting matrix has almost all entries zero. It would be a shame to spend $\mathcal{O}(n^3)$ operations on such a matrix, and we need not.

Theorem 19.7.13 (Inheritance of Zeros)

Let $A = LU$ be an LU factorisation. If $A_{ij} = 0$ for all $j \leq m$ (that is, row i of A begins with m zeros, with $m < i$), then $L_{ij} = 0$ for $j \leq m$; and symmetrically, leading zeros in the columns of A above the diagonal are inherited by U .

Proof. We induct on j . Suppose $A_{i1} = 0$. Since $A_{i1} = \sum_k L_{ik} U_{k1} = L_{i1} U_{11}$ and $U_{11} \neq 0$, we get $L_{i1} = 0$. Now suppose $L_{i1} = \dots = L_{i,j-1} = 0$ and $A_{ij} = 0$ with

$j < i$. Then

$$0 = A_{ij} = \sum_{k \leq j} L_{ik} U_{kj} = L_{ij} U_{jj},$$

and $U_{jj} \neq 0$ gives $L_{ij} = 0$. The statement for U follows by applying this to $A^\top$. $\square$

Definition 19.7.14 (Banded Matrix)

A matrix A is **banded** with bandwidth r if $A_{ij} = 0$ whenever $|i - j| > r$.

Combining the two: if A is banded with bandwidth r , then row i of A begins with $i - r - 1$ zeros and so does row i of L ; likewise for U . So L and U are banded with the same bandwidth r , and the factorisation can be computed by touching only the band. The cost drops from $\mathcal{O}(n^3)$ to $\mathcal{O}(r^2 n)$, which for a tridiagonal matrix ($r = 1$) is $\mathcal{O}(n)$.

The picture is worth a glance: shaded cells are the ones that may be nonzero.

A (bandwidth $r = 2$)

L

U

Remark. For a general sparse matrix – one with many zeros but no particular pattern – the situation is more delicate, because elimination can create nonzeros where there were none. This is called *fill-in*, and minimising it by reordering rows and columns is a genuinely hard combinatorial problem, attacked in practice with graph-theoretic heuristics. Iterative methods, which never form a factorisation at all, are the other standard response. Both are beyond this course, and both are covered in Part II.

§19.8 QR Factorisation and Least Squares

The LU factorisation is fast, but it is not always well behaved: the factors can be much larger than A itself, and errors can grow accordingly. Orthogonal matrices, by contrast, preserve lengths exactly, and so cannot amplify anything. This makes them the tool of choice when accuracy matters more than speed – and, as we shall see, they are exactly what is needed for the least-squares problem.

Definition 19.8.1

A set of vectors $\{\mathbf{q}_i\}$ in $\mathbb{R}^m$ is **orthonormal** if $\mathbf{q}_i^\top \mathbf{q}_j = \delta_{ij}$. A square matrix Q is **orthogonal** if its columns are orthonormal, equivalently $Q^\top Q = I$, equivalently $Q^{-1} = Q^\top$.

The key property is that orthogonal matrices are isometries: $\|Q\mathbf{x}\|^2 = \mathbf{x}^\top Q^\top Q \mathbf{x} = \|\mathbf{x}\|^2$. In particular $|\det Q| = 1$, and multiplying by Q can neither magnify nor shrink an error.

Definition 19.8.2 (QR Factorisation)

Let A be $m \times n$. A **QR factorisation** of A is a factorisation $A = QR$ with Q an $m \times m$ orthogonal matrix and R an $m \times n$ upper triangular matrix. If $m \geq n$, a **reduced** (or *skinny*) QR factorisation is $A = QR$ with Q an $m \times n$ matrix with orthonormal columns and R an $n \times n$ upper triangular matrix.

If A is square and nonsingular and $A = QR$, then $A\mathbf{x} = \mathbf{b}$ becomes $R\mathbf{x} = Q^\top \mathbf{b}$, a triangular system. So QR does everything LU does; it just costs about twice as much.

To see what a reduced QR factorisation *means*, write $\mathbf{a}_1, \dots, \mathbf{a}_n$ for the columns of A and $\mathbf{q}_1, \dots, \mathbf{q}_n$ for those of Q . Comparing columns in $A = QR$ and using upper-triangularity,

$$\mathbf{a}_k = \sum_{j=1}^k R_{jk} \mathbf{q}_j.$$

So $\mathbf{q}_1, \dots, \mathbf{q}_k$ is an orthonormal basis for the span of $\mathbf{a}_1, \dots, \mathbf{a}_k$, for every k . A reduced QR factorisation is nothing other than an orthonormalisation of the columns of A , carried out one column at a time. That immediately suggests an algorithm.

§19.8.1 Gram–Schmidt**Method 19.8.3 (Gram–Schmidt)**

Assume $m \geq n$ and that the columns of A are linearly independent. Set

$$R_{11} = \|\mathbf{a}_1\|, \quad \mathbf{q}_1 = \mathbf{a}_1 / R_{11},$$

and having found $\mathbf{q}_1, \dots, \mathbf{q}_{j-1}$, set

$$R_{ij} = \mathbf{q}_i^\top \mathbf{a}_j \quad (i < j), \quad \mathbf{b}_j = \mathbf{a}_j - \sum_{i=1}^{j-1} R_{ij} \mathbf{q}_i, \quad R_{jj} = \|\mathbf{b}_j\|, \quad \mathbf{q}_j = \mathbf{b}_j / R_{jj}.$$

The vector $\mathbf{b}_j$ is $\mathbf{a}_j$ with its components along $\mathbf{q}_1, \dots, \mathbf{q}_{j-1}$ removed, so it is orthogonal to all of them; and it is nonzero because the columns of A are independent. The cost is $\mathcal{O}(mn^2)$.

This is the algorithm one meets in a first linear algebra course, and it is perfectly correct. Numerically, however, it is disappointing: the computed $\mathbf{q}_j$ drift out of orthogonality, because each is built from all its predecessors and their small errors compound. (Rearranging the arithmetic gives the ‘modified’ Gram–Schmidt process, which is noticeably better, but still not ideal.) The trouble is philosophical as much as practical – we are building an orthogonal matrix by a procedure that is not itself orthogonal.

The alternative is *orthogonal triangularisation*: rather than orthogonalising the columns of A , multiply A on the left by a sequence of orthogonal matrices, chosen to introduce zeros, until what is left is upper triangular. If

$$\Omega_k \cdots \Omega_1 A = R$$

with each Ω_i orthogonal, then $A = QR$ with $Q = (\Omega_k \cdots \Omega_1)^\top$, which is orthogonal by construction. We need a supply of orthogonal matrices that create zeros, and there are two standard choices.

§19.8.2 Givens Rotations

Definition 19.8.4 (Givens Rotation)

For $1 \leq p < q \leq m$ and $\theta \in (-\pi, \pi]$, the **Givens rotation** $\Omega^{[p,q]}(\theta)$ is the $m \times m$ matrix equal to the identity except that

$$\Omega_{pp} = \Omega_{qq} = \cos \theta, \quad \Omega_{pq} = \sin \theta, \quad \Omega_{qp} = -\sin \theta.$$

Geometrically this is a rotation of the plane spanned by $\mathbf{e}_p$ and $\mathbf{e}_q$, leaving everything else fixed; it is clearly orthogonal. For $m = 4$, say,

$$\Omega^{[1,2]} = \begin{pmatrix} \cos \theta & \sin \theta & 0 & 0 \\ -\sin \theta & \cos \theta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad \Omega^{[2,4]} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos \theta & 0 & \sin \theta \\ 0 & 0 & 1 & 0 \\ 0 & -\sin \theta & 0 & \cos \theta \end{pmatrix}.$$

Proposition 19.8.5

Let A be $m \times n$, let $1 \leq p < q \leq m$ and $1 \leq j \leq n$. Then there is θ such that $(\Omega^{[p,q]}A)_{qj} = 0$. Moreover $\Omega^{[p,q]}A$ agrees with A in every row except the p -th and q -th, and those two rows are linear combinations of the p -th and q -th rows of A .

Proof. The second and third statements hold for every θ , directly from the definition. For the first, if $A_{pj} = A_{qj} = 0$ then any θ works. Otherwise take

$$\cos \theta = \frac{A_{pj}}{\sqrt{A_{pj}^2 + A_{qj}^2}}, \quad \sin \theta = \frac{A_{qj}}{\sqrt{A_{pj}^2 + A_{qj}^2}},$$

which is a legitimate choice since the two squares sum to 1. Then

$$(\Omega^{[p,q]}A)_{qj} = -\sin \theta A_{pj} + \cos \theta A_{qj} = \frac{-A_{qj}A_{pj} + A_{pj}A_{qj}}{\sqrt{A_{pj}^2 + A_{qj}^2}} = 0. \quad \square$$

To triangularise A we apply rotations that zero the subdiagonal entries one at a time, in an order that does not destroy the zeros already made. Because $\Omega^{[p,q]}$ only alters rows p and q , taking the pairs $[p, q]$ in lexicographic order works: we clear column 1 using $\Omega^{[1,2]}, \Omega^{[1,3]}, \dots, \Omega^{[1,m]}$, then column 2 using $\Omega^{[2,3]}, \dots$, and so on.

Example 19.8.6

For a 3×3 matrix, $\Omega^{[2,3]}\Omega^{[1,3]}\Omega^{[1,2]}A$ is upper triangular for suitable choices of the three angles.

The cost is again $\mathcal{O}(mn^2)$, so on a general matrix Givens has no advantage. Its virtue is *selectivity*: each rotation touches only two rows, so if A already has many zeros we need only a few rotations. For an $n \times n$ upper Hessenberg matrix (zero below the first subdiagonal) just $n - 1$ rotations suffice, giving a QR factorisation in $\mathcal{O}(n^2)$ operations. This is exactly the situation inside the QR algorithm for eigenvalues, which is why Givens rotations are not merely of historical interest.

§19.8.3 Householder Reflections

For a dense matrix, we would rather clear a whole column at once. Reflections do this.

Definition 19.8.7 (Householder Reflection)

For $\mathbf{u} \in \mathbb{R}^m \setminus \{\mathbf{0}\}$, the **Householder reflection** associated with $\mathbf{u}$ is

$$H = I - \frac{2\mathbf{u}\mathbf{u}^\top}{\mathbf{u}^\top\mathbf{u}}.$$

Proposition 19.8.8

H is symmetric and orthogonal, with $H\mathbf{u} = -\mathbf{u}$ and $H\mathbf{v} = \mathbf{v}$ for every $\mathbf{v}$ orthogonal to $\mathbf{u}$. Moreover, if $\mathbf{a}, \mathbf{b} \in \mathbb{R}^m$ satisfy $\|\mathbf{a}\| = \|\mathbf{b}\|$ and $\mathbf{u} = \mathbf{a} - \mathbf{b}$ is nonzero, then $H\mathbf{a} = \mathbf{b}$.

Proof. Symmetry is clear. For orthogonality, writing $\alpha = \mathbf{u}^\top\mathbf{u}$,

$$H^\top H = H^2 = I - \frac{4\mathbf{u}\mathbf{u}^\top}{\alpha} + \frac{4\mathbf{u}(\mathbf{u}^\top\mathbf{u})\mathbf{u}^\top}{\alpha^2} = I.$$

The formulas $H\mathbf{u} = -\mathbf{u}$ and $H\mathbf{v} = \mathbf{v}$ are immediate. For the last claim, put $\mathbf{u} = \mathbf{a} - \mathbf{b}$ and compute

$$\mathbf{u}^\top\mathbf{a} = \|\mathbf{a}\|^2 - \mathbf{b}^\top\mathbf{a}, \quad \mathbf{u}^\top\mathbf{u} = \|\mathbf{a}\|^2 - 2\mathbf{b}^\top\mathbf{a} + \|\mathbf{b}\|^2 = 2(\|\mathbf{a}\|^2 - \mathbf{b}^\top\mathbf{a}),$$

using $\|\mathbf{a}\| = \|\mathbf{b}\|$. Hence $2\mathbf{u}^\top\mathbf{a}/\mathbf{u}^\top\mathbf{u} = 1$ and

$$H\mathbf{a} = \mathbf{a} - \mathbf{u} = \mathbf{b}. \quad \square$$

So H is the reflection of $\mathbb{R}^m$ in the hyperplane $\mathbf{u}^\perp$, and the last part says that any two vectors of equal length are reflections of each other in the hyperplane bisecting them. That is precisely what we need: taking $\mathbf{b} = \pm \|\mathbf{a}\| \mathbf{e}_1$ turns any vector into a multiple of $\mathbf{e}_1$.

Method 19.8.9 (Householder QR)

At the first step, let $\mathbf{a}_1$ be the first column of A and take

$$\mathbf{u} = \mathbf{a}_1 + \text{sign}(A_{11}) \|\mathbf{a}_1\| \mathbf{e}_1,$$

so that $H\mathbf{a}_1 = -\text{sign}(A_{11}) \|\mathbf{a}_1\| \mathbf{e}_1$ and HA has zeros below the diagonal in its first column.

In general, suppose columns $1, \dots, k-1$ have been dealt with. Let $\tilde{\mathbf{a}}_k \in \mathbb{R}^{m-k+1}$ consist of the entries $A_{kk}, \dots, A_{mk}$ of the current k -th column, put

$$\tilde{\mathbf{u}} = \tilde{\mathbf{a}}_k + \text{sign}(A_{kk}) \|\tilde{\mathbf{a}}_k\| \mathbf{e}_1 \in \mathbb{R}^{m-k+1},$$

and apply the block-diagonal orthogonal matrix

$$\begin{pmatrix} I_{k-1} & 0 \\ 0 & \tilde{H} \end{pmatrix}, \quad \tilde{H} = I - \frac{2\tilde{\mathbf{u}}\tilde{\mathbf{u}}^\top}{\tilde{\mathbf{u}}^\top\tilde{\mathbf{u}}}.$$

The leading I_{k-1} leaves the first $k-1$ rows – and hence the zeros already created – untouched.

The choice of sign deserves comment. Either sign gives a valid reflection, but if A_{kk} and $\|\tilde{\mathbf{a}}_k\|$ nearly cancel then $\tilde{\mathbf{u}}$ is tiny and computed inaccurately. Choosing the sign of A_{kk} makes the two terms reinforce rather than cancel, which is the numerically safe option.

In practice one never forms $\tilde{H}$ explicitly. Applying it to a vector $\mathbf{v}$ is just

$$\tilde{H}\mathbf{v} = \mathbf{v} - \frac{2(\tilde{\mathbf{u}}^\top\mathbf{v})}{\tilde{\mathbf{u}}^\top\tilde{\mathbf{u}}}\tilde{\mathbf{u}},$$

an inner product and an axpy, costing $\mathcal{O}(m)$ rather than $\mathcal{O}(m^2)$. Similarly Q itself is normally stored as the list of vectors $\tilde{\mathbf{u}}$, and one computes $Q^\top\mathbf{b}$ by applying the reflections in turn. The total cost is $\mathcal{O}(mn^2)$.

Example 19.8.10

Suppose we have reached

$$A = \begin{pmatrix} 2 & 4 & 7 \\ 0 & 3 & -1 \\ 0 & 0 & 2 \\ 0 & 0 & 1 \\ 0 & 0 & -2 \end{pmatrix},$$

with the first two columns already processed, and we wish to clear the third. Here

$$\tilde{\mathbf{a}}_3 = \begin{pmatrix} 2 \\ 1 \\ -2 \end{pmatrix}, \quad \|\tilde{\mathbf{a}}_3\| = 3, \quad \tilde{\mathbf{u}} = \tilde{\mathbf{a}}_3 + 3\mathbf{e}_1 = \begin{pmatrix} 5 \\ 1 \\ -2 \end{pmatrix},$$

and $\tilde{\mathbf{u}}^\top\tilde{\mathbf{u}} = 30$, $\tilde{\mathbf{u}}^\top\tilde{\mathbf{a}}_3 = 10 + 1 + 4 = 15$. Hence

$$\tilde{H}\tilde{\mathbf{a}}_3 = \tilde{\mathbf{a}}_3 - \frac{2 \cdot 15}{30}\tilde{\mathbf{u}} = \begin{pmatrix} 2 \\ 1 \\ -2 \end{pmatrix} - \begin{pmatrix} 5 \\ 1 \\ -2 \end{pmatrix} = \begin{pmatrix} -3 \\ 0 \\ 0 \end{pmatrix},$$

and the result is

$$R = \begin{pmatrix} 2 & 4 & 7 \\ 0 & 3 & -1 \\ 0 & 0 & -3 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Remark. So which should one use? For a dense matrix, Householder: it clears an entire column with one reflection and is beautifully stable. For a matrix that is already nearly triangular, Givens: each rotation is cheap and touches only the rows that need touching. Gram–Schmidt survives mainly because it produces the columns of Q one at a time, which is occasionally what one wants – and because it generalises to infinite dimensions, where reflections do not obviously help.

§19.8.4 Linear Least Squares

We finish with the problem that motivated all of this. Let A be $m \times n$ with $m > n$ and let $\mathbf{b} \in \mathbb{R}^m$. The system $A\mathbf{x} = \mathbf{b}$ has more equations than unknowns and generically has no solution at all; this is the situation of fitting n parameters to m measurements. The sensible thing to ask for instead is the $\mathbf{x}$ minimising the residual.

Definition 19.8.11 (Least Squares Problem)

Given $A \in \mathbb{R}^{m \times n}$ and $\mathbf{b} \in \mathbb{R}^m$, the **linear least squares problem** is to find $\mathbf{x} \in \mathbb{R}^n$ minimising $\|A\mathbf{x} - \mathbf{b}\|_2$.

Theorem 19.8.12 (Normal Equations)

A vector $\mathbf{x} \in \mathbb{R}^n$ solves the least squares problem if and only if

$$A^\top(A\mathbf{x} - \mathbf{b}) = \mathbf{0}, \quad \text{equivalently} \quad A^\top A\mathbf{x} = A^\top \mathbf{b}.$$

Proof. ($\Leftarrow$) Suppose $A^\top(A\mathbf{x} - \mathbf{b}) = \mathbf{0}$ and let $\mathbf{v} \in \mathbb{R}^n$ be arbitrary. Writing $\mathbf{v} = \mathbf{x} + (\mathbf{v} - \mathbf{x})$ and expanding,

$$\begin{aligned} \|A\mathbf{v} - \mathbf{b}\|^2 &= \|(A\mathbf{x} - \mathbf{b}) + A(\mathbf{v} - \mathbf{x})\|^2 \\ &= \|A\mathbf{x} - \mathbf{b}\|^2 + 2(\mathbf{v} - \mathbf{x})^\top A^\top(A\mathbf{x} - \mathbf{b}) + \|A(\mathbf{v} - \mathbf{x})\|^2 \\ &= \|A\mathbf{x} - \mathbf{b}\|^2 + \|A(\mathbf{v} - \mathbf{x})\|^2 \geq \|A\mathbf{x} - \mathbf{b}\|^2. \end{aligned}$$

($\Rightarrow$) Conversely, if $\mathbf{x}$ is a minimiser then for every $\mathbf{v}$ the scalar function $t \mapsto \|A(\mathbf{x} + t\mathbf{v}) - \mathbf{b}\|^2$ has a minimum at $t = 0$. Differentiating,

$$0 = \left. \frac{d}{dt} \right|_{t=0} (\|A\mathbf{x} - \mathbf{b}\|^2 + 2t\mathbf{v}^\top A^\top(A\mathbf{x} - \mathbf{b}) + t^2 \|A\mathbf{v}\|^2) = 2\mathbf{v}^\top A^\top(A\mathbf{x} - \mathbf{b}),$$

and as $\mathbf{v}$ was arbitrary, $A^\top(A\mathbf{x} - \mathbf{b}) = \mathbf{0}$. □

The geometric content is that the residual must be orthogonal to the column space of A : the best approximation $A\mathbf{x}$ is the orthogonal projection of $\mathbf{b}$ onto $\text{range } A$. This is Pythagoras again, exactly as in Section 2.

So one could simply solve the $n \times n$ system $A^\top A \mathbf{x} = A^\top \mathbf{b}$, say by Cholesky, since $A^\top A$ is symmetric and (if A has full column rank) positive definite. This is what statisticians did for a century, and it is not wrong. But it has three defects that a numerical analyst notices immediately.

- (i) Forming $A^\top A$ costs $\mathcal{O}(mn^2)$ operations and, more importantly, destroys any sparsity that A possessed – a sparse A can easily have a dense $A^\top A$.
- (ii) The entries of $A^\top A$ are sums of products, so if the entries of A vary greatly in magnitude, forming them loses accuracy through cancellation.
- (iii) Most seriously, the conditioning of $A^\top A$ is the *square* of that of A . Squaring an already-large condition number is an excellent way to lose every digit one has.

The remedy is to use the QR factorisation, which lets us minimise the residual without ever forming $A^\top A$.

Theorem 19.8.13 (Least Squares via QR)

Let A be $m \times n$ with $m \geq n$ and linearly independent columns, and let $A = QR$ be a reduced QR factorisation, with Q of size $m \times n$ having orthonormal columns and R upper triangular and nonsingular. Then the least squares problem is solved by the unique solution of

$$R\mathbf{x} = Q^\top \mathbf{b}.$$

Proof. By Theorem 19.8.12, $\mathbf{x}$ is a solution if and only if $A^\top(A\mathbf{x} - \mathbf{b}) = \mathbf{0}$. Substituting $A = QR$ and using $Q^\top Q = I$,

$$A^\top(A\mathbf{x} - \mathbf{b}) = R^\top Q^\top(QR\mathbf{x} - \mathbf{b}) = R^\top(R\mathbf{x} - Q^\top \mathbf{b}).$$

As R is nonsingular, so is $R^\top$, and the above vanishes precisely when $R\mathbf{x} = Q^\top \mathbf{b}$. That triangular system has a unique solution, found by back substitution. $\square$

Remark. Using the full QR factorisation gives the same conclusion in a way that also exhibits the residual. If $A = QR$ with Q orthogonal $m \times m$ and $R = \begin{pmatrix} R_1 \\ 0 \end{pmatrix}$ with R_1 upper triangular $n \times n$, then since $Q^\top$ preserves norms,

$$\|A\mathbf{x} - \mathbf{b}\|^2 = \|Q^\top A\mathbf{x} - Q^\top \mathbf{b}\|^2 = \|R_1\mathbf{x} - \mathbf{c}_1\|^2 + \|\mathbf{c}_2\|^2,$$

where $Q^\top \mathbf{b} = \begin{pmatrix} \mathbf{c}_1 \\ \mathbf{c}_2 \end{pmatrix}$ is split after n entries. The second term does not involve $\mathbf{x}$ at all, so the minimum is attained by solving $R_1\mathbf{x} = \mathbf{c}_1$, and the minimum value of the residual is exactly $\|\mathbf{c}_2\|$. This is perhaps the cleanest way to see the whole result: an orthogonal change of coordinates turns an unsolvable system into a solvable one plus an irreducible remainder.

Example 19.8.14 (Fitting a Straight Line)

Suppose we wish to fit $y = c_0 + c_1 t$ to the four data points $(0, 1)$, $(1, 3)$, $(2, 4)$, $(3, 4)$. Then

$$A = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 1 & 2 \\ 1 & 3 \end{pmatrix}, \quad \mathbf{b} = \begin{pmatrix} 1 \\ 3 \\ 4 \\ 4 \end{pmatrix},$$

and the normal equations read

$$\begin{pmatrix} 4 & 6 \\ 6 & 14 \end{pmatrix} \begin{pmatrix} c_0 \\ c_1 \end{pmatrix} = \begin{pmatrix} 12 \\ 23 \end{pmatrix},$$

with solution $c_1 = 1$, $c_0 = \frac{3}{2}$. So the best-fitting line is $y = \frac{3}{2} + t$, and the residual vector is $(-\frac{1}{2}, \frac{1}{2}, \frac{1}{2}, -\frac{1}{2})^\top$, whose components sum to zero and which is orthogonal to $(0, 1, 2, 3)^\top$ – exactly the two normal equations, read backwards.

Remark. It is worth stepping back at the end. The least squares problem we have just solved is the same problem we solved in Section 2 with orthogonal polynomials, in a different costume: there the vector space was $C[a, b]$ or $\mathcal{P}_n$ and the orthogonal basis was $p_0, \dots, p_n$; here it is $\mathbb{R}^m$ and the orthogonal basis consists of the columns of Q . In both cases the answer is an orthogonal projection, in both cases the good algorithm is the one that builds an orthogonal basis first, and in both cases the reason is the same – orthogonality decouples the problem and refuses to amplify error. If there is one idea to take away from this course, it is probably that one.

20 Optimization

Optimization is the art of doing the best you can with what you have got. Almost every quantitative question you might ask about the world – how should a factory allocate its raw materials, how should goods be routed through a road network, how should two adversaries play a game – can be phrased as the problem of making some function as small (or as large) as possible, subject to a list of constraints on what you are allowed to do. The subject is about turning that vague desire into a precise mathematical problem, and then actually *solving* it.

Two themes run through everything we do. The first is *convexity*: for a convex problem, local information is global information, and this is what makes optimization tractable at all. The second is *duality*: every optimization problem casts a shadow, a second problem whose solution certifies the optimality of the first. Duality is what lets us know when we are done, and it appears in different disguises as complementary slackness, as shadow prices, as the max-flow min-cut theorem and as the minimax theorem of game theory. Along the way we will develop honest algorithms – gradient descent, the simplex method, the transportation algorithm, Ford–Fulkerson – that can be run by hand or by machine.

This article constitutes my notes for the ‘Optimization’ course, held in Easter 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§20.1 Convex Optimization

§20.1.1 Optimization Problems

In this course, we care about problems that look like ‘minimize $f(x)$ subject to $x \in X$ ’, or problems with constraints that look like ‘minimize¹ $f(x)$ subject to $x \in X$ where $h(x) = b$ ’.

In such problems, we call f the **objective function**, and if $x \in \mathbb{R}^n$, we call the components **decision variables**. Constraints such as the one above can be given as a **functional constraint** $h(x) = b$ and a **regional constraint** $x \in X$. If both of the constraints hold for a given x , we say it is in the **feasible set** $X(b)$. A problem is feasible if the feasible set is non-empty, and bounded if the minimum over this set is bounded.

A point $x^* \in X(b)$ is **optimal** if it minimizes f over $X(b)$. The value $f(x^*)$ is the **optimal cost**.

It is worth setting up some notation for all of this, since we are going to be writing down an awful lot of optimization problems. We will write a problem in the form

$$\begin{array}{ll}\text{minimize} & f(x) \\ \text{subject to} & h(x) = b, \\ & x \in X,\end{array}$$

¹We will almost always talk about minimizing, since maximizing is basically the same thing: to maximize f we can minimize $-f$.

where $f : \mathbb{R}^n \rightarrow \mathbb{R}$, $h : \mathbb{R}^n \rightarrow \mathbb{R}^m$, $b \in \mathbb{R}^m$ and $X \subseteq \mathbb{R}^n$. So the feasible set is

$$X(b) = \{x \in X : h(x) = b\}.$$

Remark. The split between ‘functional’ and ‘regional’ constraints is not intrinsic to the problem – it is a choice that we make. The same set of feasible points can very often be described in several ways, and a large part of the skill in this course lies in choosing the description that makes the problem easiest to attack. Typically the regional constraint $x \in X$ will be something simple like $x \geq 0$ or $x \in \mathbb{Z}^n$, and the functional constraints will be the interesting ones that we handle with Lagrange multipliers.

At first glance it looks as though we have restricted ourselves to *equality* constraints, which would be a serious limitation. In fact we have not: an inequality constraint can always be converted into an equality constraint at the cost of introducing a new variable. If we want $h(x) \leq b$, we introduce a **slack variable** s and write

$$h(x) \leq b \quad \longleftrightarrow \quad h(x) + s = b, \quad s \geq 0.$$

The new variable s measures exactly how much ‘slack’ there is in the constraint, and the sign condition $s \geq 0$ is pushed into the regional constraint. This trick will be used constantly.

Example 20.1.1

Consider the problem of minimizing $x_1^2 + x_2^2$ subject to $x_1 + x_2 \geq 1$. Here $f(x) = x_1^2 + x_2^2$, and we can take $X = \mathbb{R}^2$ with the single functional constraint $x_1 + x_2 \geq 1$. Introducing a slack variable, this becomes: minimize $x_1^2 + x_2^2$ subject to $x_1 + x_2 - s = 1$ and $(x_1, x_2, s) \in \mathbb{R}^2 \times [0, \infty)$. The feasible set is a closed half-plane, and the optimum is at $x = (1/2, 1/2)$ with optimal cost $1/2$ – the point of the half plane closest to the origin.

§20.1.2 Convex Functions

We will first study optimization problems involving convex functions without constraints. In particular, we are going to study the problem:

Minimize $f(x)$, where $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is a convex function.

The reason we will care specifically about convex functions is, as you will see, that local information about the function gives us global information about the function.

It is likely that you are already familiar with the notions of convex sets and convex functions.

Definition 20.1.2 (Convex Set)

A set $S \subseteq \mathbb{R}^n$ is **convex** if for all $x, y \in S$ and all $\lambda \in [0, 1]$ we have $\lambda x + (1 - \lambda)y \in S$.

Informally, a set is convex if the line segment between any two points is totally contained in the set.

convex

not convex

We can also define convexity for functions.

Definition 20.1.3 (Convex Function)

A function $f : S \rightarrow \mathbb{R}$ is **convex** if S is convex and for all $x, y \in S$ and $\lambda \in [0, 1]$ we have

$$f(\lambda x + (1 - \lambda)y) \leq \lambda f(x) + (1 - \lambda)f(y).$$

If this inequality is strict (for $x \neq y$ and $\lambda \in (0, 1)$) then the function is **strictly convex**. A function is called **concave** if $-f$ is convex.

Again informally, this says that if we consider the graph of the function then the chord between two points will always lie above the function.

Note that a linear function $f(x) = c \cdot x$ is both convex and concave, since the defining inequality holds with equality. So linear programming, which we will spend a lot of time on later, is a special case of convex optimization.

In general, checking the definition by hand is hard, and we typically use some other conditions to check for convexity.

Proposition 20.1.4 (First-Order Conditions for Convexity)

A differentiable function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is convex if and only if for all $x, y \in \mathbb{R}^n$ we have

$$f(y) \geq f(x) + (y - x) \cdot \nabla f(x).$$

Proof. We will first check that convexity implies that this condition holds by showing it holds for $n = 1$ and using that for the general case.

If $f : \mathbb{R} \rightarrow \mathbb{R}$ is convex, and $x, y \in \mathbb{R}$ then for any $t \in (0, 1]$ we have

$$\begin{aligned} f((1 - t)x + ty) &= f(x + t(y - x)) \\ &\leq (1 - t)f(x) + tf(y) \\ \implies f(y) &\geq f(x) + \frac{f(x + t(y - x)) - f(x)}{t}. \end{aligned}$$

Taking the limit as $t \rightarrow 0$, the quotient tends to $f'(x)(y - x)$, and so $f(y) \geq f(x) + f'(x)(y - x)$.

Now for $f : \mathbb{R}^n \rightarrow \mathbb{R}$, taking any $x, y \in \mathbb{R}^n$ we can define the restricted function $g(t) = f((1 - t)x + ty)$. Since f is convex, g is also convex. We can then compute

$$g'(t) = (y - x) \cdot \nabla f((1 - t)x + ty).$$

So using the $n = 1$ case, we have $g(1) \geq g(0) + g'(0)(1 - 0)$, that is, $f(y) \geq f(x) + (y - x) \cdot \nabla f(x)$, so the condition holds as required.

Now we will show that the first-order conditions imply convexity. For some $t \in [0, 1]$, we define $x_t = (1 - t)x + ty$. Then we know that

$$\begin{aligned} f(x) &\geq f(x_t) + (x - x_t) \cdot \nabla f(x_t), \\ f(y) &\geq f(x_t) + (y - x_t) \cdot \nabla f(x_t). \end{aligned}$$

Multiplying the first by $(1 - t)$ and the second by t and summing, the gradient terms combine to give

$$(1 - t)(x - x_t) + t(y - x_t) = (1 - t)x + ty - x_t = 0,$$

so we are left with

$$(1 - t)f(x) + tf(y) \geq f(x_t),$$

as required. $\square$

This condition has a very clean geometric meaning: the tangent plane to the graph of f at any point lies entirely *below* the graph.

This picture makes the key fact about convex minimization obvious. If $\nabla f(x) = 0$ at some point x , then the first-order condition reads $f(y) \geq f(x)$ for *all* y , so x is a global minimum. In other words, for a convex function there is no such thing as a bad local minimum: every stationary point is a global minimum. This is exactly the promised phenomenon of local information giving global information, and it is the reason we can hope to minimize convex functions by walking downhill.

A possibly more familiar condition for convexity is the second-order condition. This involves the *Hessian*, the generalization of the second derivative to $\mathbb{R}^n$.

Definition 20.1.5 (Hessian)

If $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is a twice differentiable function, then the **Hessian matrix** $\nabla^2 f$ is

the symmetric matrix of second derivatives given by

$$(\nabla^2 f)_{ij} = \frac{\partial^2 f}{\partial x_i \partial x_j}.$$

In particular, we care about a specific property of the Hessian matrix.

Definition 20.1.6 (Positive Semidefinite)

A symmetric matrix $A \in \mathbb{R}^{n \times n}$ is **positive semidefinite** if for all $x \in \mathbb{R}^n$ we have $x \cdot Ax \geq 0$; equivalently, if all of the eigenvalues of A are non-negative. We write $A \succeq 0$. We write $A \succeq B$ to mean $A - B \succeq 0$.

Proposition 20.1.7 (Second-Order Conditions for Convexity)

A twice differentiable function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is convex if $\nabla^2 f(x)$ is positive semidefinite at all $x \in \mathbb{R}^n$.

Proof. Using the Taylor expansion of f , we have

$$f(y) = f(x) + (y - x) \cdot \nabla f(x) + \frac{1}{2}(y - x) \cdot (\nabla^2 f(z)(y - x)),$$

where $z = (1 - \lambda)x + \lambda y$ for some $\lambda \in [0, 1]$. Since $\nabla^2 f(z) \succeq 0$, the final term is non-negative, and so

$$f(y) \geq f(x) + (y - x) \cdot \nabla f(x).$$

Then by the first-order conditions, f is convex. □

The converse also holds, but we will not need it.

Example 20.1.8

Let us see the conditions in action.

- (i) $f(x) = x \cdot Ax$ for a symmetric matrix A has $\nabla^2 f = 2A$, so f is convex exactly when $A \succeq 0$.
- (ii) $f(x_1, x_2) = x_1^2 + 100x_2^2$ has Hessian $\text{diag}(2, 200) \succeq 0$, so is convex.
- (iii) $f(x) = e^{c \cdot x}$ has $\nabla^2 f = (cc^T)e^{c \cdot x}$, and $y \cdot (cc^T)y = (c \cdot y)^2 \geq 0$, so f is convex for any c .
- (iv) $f(x_1, x_2) = x_1x_2$ has Hessian $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, whose eigenvalues are ± 1 . So this function is neither convex nor concave.

§20.1.3 Gradient Descent

To solve our problem of minimizing $f(x)$ where $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is a convex function, we can begin by noting that convexity implies that a local minimum is a global minimum. So if we find a point where the gradient of the function is 0, then we would be finished. This suggests an extremely simple ‘greedy’ strategy: start somewhere, look around for a nearby point with a smaller value of f , move there, and repeat.

To make this concrete we need to know which direction to move in. Taking a small step of size ε in the direction v and Taylor expanding,

$$f(x + \varepsilon v) \approx f(x) + \varepsilon v \cdot \nabla f(x),$$

so any v with $v \cdot \nabla f(x) < 0$ will decrease f , at least for small enough ε . We call such a v a **descent direction**. The most natural choice is $v = -\nabla f(x)$, which gives

$$f(x - \varepsilon \nabla f(x)) \approx f(x) - \varepsilon \|\nabla f(x)\|^2 \leq f(x).$$

Definition 20.1.9 (Gradient Descent)

The **gradient descent** algorithm for minimizing f is as follows.

- (1) Choose a starting point x_0 and set $t = 0$.
- (2) If $\nabla f(x_t) = 0$ (or we have run out of patience), stop and return x_t .
- (3) Choose a step size $\eta_t > 0$ and set $x_{t+1} = x_t - \eta_t \nabla f(x_t)$.
- (4) Increment t and go to (2).

The whole art is in the choice of η_t . If it is too small we crawl; if it is too large we overshoot and oscillate. To say anything precise we need to control how fast the gradient can change.

Definition 20.1.10 (Smoothness)

A continuously differentiable $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is **β -smooth** if ∇f is β -Lipschitz, that is

$$\|\nabla f(x) - \nabla f(y)\| \leq \beta \|x - y\|$$

for all x, y . If f is twice differentiable this is equivalent to $\nabla^2 f(x) \preceq \beta I$ for all x .

Smoothness says that the linear approximation to f cannot be too badly wrong.

Lemma 20.1.11 (Quadratic Upper Bound)

If f is β -smooth then for all x, y ,

$$f(y) \leq f(x) + (y - x) \cdot \nabla f(x) + \frac{\beta}{2} \|y - x\|^2.$$

Proof. By Taylor's theorem there is a point z on the segment from x to y with

$$f(y) = f(x) + (y - x) \cdot \nabla f(x) + \frac{1}{2} (y - x) \cdot (\nabla^2 f(z)(y - x)),$$

and since $\nabla^2 f(z) \preceq \beta I$ we have $(y - x) \cdot (\nabla^2 f(z)(y - x)) \leq \beta \|y - x\|^2$. □

Together with convexity this sandwiches f between two functions that agree to first order at x : a linear lower bound and a quadratic upper bound. The quadratic upper bound is the useful one, because we can minimize it exactly.

Corollary 20.1.12

If f is β -smooth and we take a step of size $1/\beta$, then

$$f\left(x - \frac{1}{\beta} \nabla f(x)\right) \leq f(x) - \frac{1}{2\beta} \|\nabla f(x)\|^2.$$

Proof. Minimizing the right-hand side of the quadratic upper bound over y , we differentiate to get $\nabla f(x) + \beta(y - x) = 0$, so the minimizer is $y = x - \frac{1}{\beta} \nabla f(x)$. Substituting this in,

$$\begin{aligned} f(y) &\leq f(x) - \frac{1}{\beta} \|\nabla f(x)\|^2 + \frac{\beta}{2} \cdot \frac{1}{\beta^2} \|\nabla f(x)\|^2 \\ &= f(x) - \frac{1}{2\beta} \|\nabla f(x)\|^2. \square \end{aligned}$$

So each step makes definite progress, provided the gradient is not small. But a small gradient does not by itself mean we are near the optimum – think of a function with a long, almost flat valley. To rule this out we need a lower bound on the curvature as well.

Definition 20.1.13 (Strong Convexity)

A function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is **α -strongly convex** if for all x, y ,

$$f(y) \geq f(x) + (y - x) \cdot \nabla f(x) + \frac{\alpha}{2} \|y - x\|^2.$$

For twice differentiable f this is equivalent to $\nabla^2 f(x) \succeq \alpha I$ for all x .

Lemma 20.1.14

Let f be α -strongly convex with minimum value p^* . Then for any x ,

$$p^* \geq f(x) - \frac{1}{2\alpha} \|\nabla f(x)\|^2.$$

Proof. Take the minimum over y of both sides of the strong convexity inequality. The left-hand side becomes p^* . The right-hand side is a quadratic in y , minimized where $\nabla f(x) + \alpha(y - x) = 0$, that is at $y = x - \frac{1}{\alpha} \nabla f(x)$, giving

$$p^* \geq f(x) - \frac{1}{\alpha} \|\nabla f(x)\|^2 + \frac{1}{2\alpha} \|\nabla f(x)\|^2 = f(x) - \frac{1}{2\alpha} \|\nabla f(x)\|^2. \quad \square$$

In other words, if $\|\nabla f(x)\| \leq \sqrt{2\alpha\varepsilon}$ then $f(x) \leq p^* + \varepsilon$: for a strongly convex function, a small gradient really does mean we are nearly done. Putting the two bounds together gives a genuine convergence guarantee.

Theorem 20.1.15 (Convergence of Gradient Descent)

Let f be β -smooth and α -strongly convex with $0 < \alpha \leq \beta$, and let x^* be its

minimizer. Then gradient descent with step size $1/\beta$ satisfies

$$f(x_T) - f(x^*) \leq \left(1 - \frac{\alpha}{\beta}\right)^T (f(x_0) - f(x^*)) \leq e^{-\alpha T/\beta} \cdot \frac{\beta}{2} \|x_0 - x^*\|^2.$$

Proof. Write $\delta_t = f(x_t) - f(x^*)$. By the corollary above and then the lemma above (applied at x_t , with $p^* = f(x^*)$),

$$\delta_{t+1} \leq \delta_t - \frac{1}{2\beta} \|\nabla f(x_t)\|^2 \leq \delta_t - \frac{\alpha}{\beta} \delta_t = \left(1 - \frac{\alpha}{\beta}\right) \delta_t,$$

where the middle step used $\|\nabla f(x_t)\|^2 \geq 2\alpha\delta_t$. Induction gives the first inequality, and $1 - u \leq e^{-u}$ gives the second. Finally, β -smoothness applied at x^* (where $\nabla f(x^*) = 0$) gives $\delta_0 \leq \frac{\beta}{2} \|x_0 - x^*\|^2$. $\square$

The quantity $\kappa = \beta/\alpha \geq 1$ is called the **condition number** of f . To get $f(x_T) - f(x^*) \leq \varepsilon$ we need about $\kappa \log(1/\varepsilon)$ steps; each extra decimal place of accuracy costs a constant number of extra steps, which is called *linear convergence* and is very fast indeed. But the constant is κ , and if κ is huge then convergence is slow.

Example 20.1.16

Consider $f(x_1, x_2) = \frac{1}{2}(x_1^2 + 100x_2^2)$, whose Hessian is $\text{diag}(1, 100)$, so $\alpha = 1$, $\beta = 100$ and $\kappa = 100$. The level sets are extremely elongated ellipses, and the gradient at a typical point points almost straight at the long axis rather than at the origin. Gradient descent therefore zig-zags across the valley making very slow progress along it.

§20.1.4 Newton's Method and Barrier Methods

The problem in the example above is that gradient descent treats all coordinates the same way, whereas the function does not. The fix is to rescale by the Hessian. Recall that the second-order approximation to f near x_t is

$$f(x) \approx f(x_t) + (x - x_t) \cdot \nabla f(x_t) + \frac{1}{2}(x - x_t) \cdot (\nabla^2 f(x_t)(x - x_t)),$$

and minimizing the right-hand side over x gives $x = x_t - (\nabla^2 f(x_t))^{-1} \nabla f(x_t)$.

Definition 20.1.17 (Newton's Method)

Newton's method is the iteration

$$x_{t+1} = x_t - (\nabla^2 f(x_t))^{-1} \nabla f(x_t).$$

So instead of approximating f by a linear function and stepping a fixed distance, we approximate it by a paraboloid and jump straight to the bottom of that paraboloid.

Near the optimum this converges quadratically: one can show that

$$\|x_{t+1} - x^*\| \leq c \|x_t - x^*\|^2$$

once x_t is close enough to x^* , so the number of correct digits roughly doubles each step. The price is that we have to compute and invert an $n \times n$ matrix at every step.

Remark. In one dimension, Newton's method reads $x_{t+1} = x_t - f'(x_t)/f''(x_t)$, which is exactly the familiar Newton–Raphson iteration for finding a root of $g = f'$. Minimizing f and finding a zero of its derivative are of course the same problem.

Finally, a word about constraints. Suppose we want to minimize $f(x)$ subject to $f_i(x) \leq 0$ for $i = 1, \dots, m$. We would love to reduce this to an unconstrained problem, and the obvious way is to minimize

$$f(x) + \sum_{i=1}^m \phi(f_i(x)),$$

where $\phi(y) = 0$ for $y \leq 0$ and $\phi(y) = +\infty$ for $y > 0$. This is exactly the original problem, but ϕ is not remotely differentiable and so all of our machinery fails. Instead we use a smooth approximation.

Definition 20.1.18 (Logarithmic Barrier)

The **logarithmic barrier method** solves the unconstrained problem

$$\text{minimize } tf(x) - \sum_{i=1}^m \log(-f_i(x))$$

for a sequence of increasing values of $t > 0$, using the previous solution as the starting point for the next.

The function $-\log(-y)$ is $+\infty$ for $y \geq 0$ and finite for $y < 0$, rising steeply as $y \rightarrow 0^-$; it fences the iterates inside the feasible region. As $t \rightarrow \infty$ the objective f dominates the barrier, and the minimizer converges to the solution of the constrained problem. Each subproblem is solved by Newton's method. This is the basic idea behind *interior point methods*, which are what modern solvers actually use.

§20.2 Lagrangian Methods

Everything in the previous section was about *unconstrained* problems. Real problems come with constraints, and the central idea for handling them – one of the great ideas in the subject – is to not handle them at all. Instead we build the constraints into the objective function with a price attached, and then solve an unconstrained problem. If we get the prices right, the solution of the unconstrained problem automatically satisfies the constraints.

§20.2.1 The Lagrangian

Throughout this section we consider the problem

$$\begin{aligned} &\text{minimize} && f(x) \\ &\text{subject to} && h(x) = b, \end{aligned}$$

$$x \in X,$$

where $h : \mathbb{R}^n \rightarrow \mathbb{R}^m$. We will refer to this as the **primal problem**, denoted (P) .

Definition 20.2.1 (Lagrangian)

The **Lagrangian** of the problem (P) is the function

$$L(x, \lambda) = f(x) - \lambda \cdot (h(x) - b),$$

where $\lambda \in \mathbb{R}^m$ is the vector of **Lagrange multipliers**.

The point is this. If x satisfies the functional constraint $h(x) = b$, then the second term vanishes and $L(x, \lambda) = f(x)$, whatever λ is. So on the feasible set the Lagrangian *is* the objective function. Off the feasible set, the term $-\lambda \cdot (h(x) - b)$ acts as a penalty (or a reward, depending on signs) for violating the constraints, and if we choose λ well then the penalty is enough to keep the unconstrained minimizer of L inside the feasible set. Making this precise gives the following theorem, which will be our main tool.

Theorem 20.2.2 (Lagrangian Sufficiency)

Suppose we can find $\lambda^* \in \mathbb{R}^m$ and $x^* \in X$ such that

- (i) x^* minimizes $L(\cdot, \lambda^*)$ over all of X , that is, $L(x^*, \lambda^*) = \min_{x \in X} L(x, \lambda^*)$; and
- (ii) x^* is feasible, that is, $x^* \in X(b)$.

Then x^* is optimal for (P) .

Proof. Since x^* is feasible we certainly have $f(x^*) \geq \min_{x \in X(b)} f(x)$, so we only need the reverse inequality. For this, note that if $x \in X(b)$ then $h(x) - b = 0$, so subtracting $\lambda^* \cdot (h(x) - b)$ changes nothing:

$$\begin{aligned} \min_{x \in X(b)} f(x) &= \min_{x \in X(b)} (f(x) - \lambda^* \cdot (h(x) - b)) \\ &\geq \min_{x \in X} (f(x) - \lambda^* \cdot (h(x) - b)) \\ &= \min_{x \in X} L(x, \lambda^*) \\ &= L(x^*, \lambda^*) \\ &= f(x^*) - \lambda^* \cdot (h(x^*) - b) = f(x^*). \end{aligned}$$

Here the inequality is because we are minimizing over a larger set $X \supseteq X(b)$, the next-to-last line is hypothesis (i), and the last line is hypothesis (ii). So $f(x^*) = \min_{x \in X(b)} f(x)$ as claimed. $\square$

This gives us a recipe. Rather than minimize over the awkward set $X(b)$, we minimize over the nice set X for each fixed λ , obtaining a candidate $x^*(\lambda)$, and then hunt for the value of λ making $x^*(\lambda)$ feasible. Notice that we have to be careful: for some λ the Lagrangian will not have a finite minimum at all. So we define

$$\Lambda = \left\{ \lambda \in \mathbb{R}^m : \inf_{x \in X} L(x, \lambda) > -\infty \right\},$$

and only consider $\lambda \in \Lambda$.

Example 20.2.3

Consider the problem

$$\begin{aligned} & \text{minimize} && -x_1 - x_2 + x_3 \\ & \text{subject to} && x_1^2 + x_2^2 = 4, \\ & && x_1 + x_2 + x_3 = 1, \end{aligned}$$

over $x \in \mathbb{R}^3$. So $X = \mathbb{R}^3$ and $b = (4, 1)$. The Lagrangian is

$$\begin{aligned} L(x, \lambda) &= -x_1 - x_2 + x_3 - \lambda_1(x_1^2 + x_2^2 - 4) - \lambda_2(x_1 + x_2 + x_3 - 1) \\ &= (-(1 + \lambda_2)x_1 - \lambda_1 x_1^2) + (-(1 + \lambda_2)x_2 - \lambda_1 x_2^2) + (1 - \lambda_2)x_3 + 4\lambda_1 + \lambda_2. \end{aligned}$$

We have arranged the terms so that each variable appears in exactly one bracket, and so we can minimize each bracket separately.

First, which λ lie in Λ ? The x_3 term is linear, so unless $\lambda_2 = 1$ we can send it to $-\infty$. The x_1 term is a quadratic with leading coefficient $-\lambda_1$, so we need $\lambda_1 \leq 0$; and if $\lambda_1 = 0$ then the remaining linear term $-(1 + \lambda_2)x_1 = -2x_1$ is unbounded below. So $\Lambda = \{\lambda : \lambda_1 < 0, \lambda_2 = 1\}$.

For such λ , minimizing each bracket by differentiating,

$$-(1 + \lambda_2) - 2\lambda_1 x_1 = 0 \implies x_1 = \frac{-2}{2\lambda_1} = \frac{-1}{\lambda_1},$$

and identically $x_2 = -1/\lambda_1$. Note x_3 is completely free (its coefficient is zero), which is exactly what we want – it leaves us room to satisfy the second constraint.

Now we impose feasibility. From $x_1^2 + x_2^2 = 4$ we get $2/\lambda_1^2 = 2$, so $\lambda_1 = -1/\sqrt{2}$ (taking the negative root as required) and $x_1 = x_2 = \sqrt{2}$. Then the second constraint gives $x_3 = 1 - 2\sqrt{2}$.

By Lagrangian sufficiency, $x^* = (\sqrt{2}, \sqrt{2}, 1 - 2\sqrt{2})$ is optimal, with optimal cost $-1 - 2\sqrt{2}$.

§20.2.2 Inequality Constraints and Complementary Slackness

Now suppose the constraints are inequalities:

$$\begin{aligned} & \text{minimize} && f(x) \\ & \text{subject to} && h(x) \leq b, \\ & && x \in X. \end{aligned}$$

We already know how to deal with this – add a slack variable $s \geq 0$ and write $h(x) + s = b$. The Lagrangian becomes

$$L(x, s, \lambda) = f(x) - \lambda \cdot (h(x) + s - b),$$

and we now minimize over $x \in X$ and $s \geq 0$. Writing the Lagrangian as

$$L(x, s, \lambda) = \underbrace{f(x) - \lambda \cdot (h(x) - b)}_{\text{does not involve } s} - \lambda \cdot s,$$

we can read off two things immediately.

Firstly, since s ranges over all of $[0, \infty)^m$, the term $-\lambda \cdot s$ is bounded below only if $\lambda \leq 0$. So $\lambda \in \Lambda$ forces $\lambda \leq 0$: with the sign convention above, *Lagrange multipliers for $\leq$ constraints are non-positive*.

Secondly, given $\lambda \leq 0$, the minimum over $s \geq 0$ of $-\lambda \cdot s$ is attained by taking $s_i = 0$ whenever $\lambda_i < 0$ (and s_i arbitrary when $\lambda_i = 0$). In either case the minimizing s satisfies $\lambda_i s_i = 0$ for every i . This is important enough to have a name.

Theorem 20.2.4 (Complementary Slackness)

At an optimum obtained by the Lagrangian method, for each i we have

$$\lambda_i s_i = 0, \quad \text{equivalently} \quad \lambda_i (h_i(x) - b_i) = 0.$$

So for each i , either the constraint is **tight** ($h_i(x) = b_i$) or the multiplier vanishes ($\lambda_i = 0$) – or both.

In words: a constraint that is not binding has zero multiplier. If we are not up against a constraint, then it is not costing us anything, so its price should be zero. We will see this interpretation made precise in a moment, and we will meet the same phenomenon again and again – in linear programming, in the transportation algorithm, and in game theory.

Complementary slackness is enormously useful in practice, because it lets us split into cases: for each constraint, either $s_i = 0$ or $\lambda_i = 0$, and often most of the cases can be eliminated quickly.

Example 20.2.5

Consider

$$\begin{aligned} &\text{minimize} && x_1 - 3x_2 \\ &\text{subject to} && x_1^2 + x_2^2 \leq 4, \\ &&& x_1 + x_2 \leq 2, \end{aligned}$$

over $x \in \mathbb{R}^2$. Adding slack variables $s_1, s_2 \geq 0$, the Lagrangian is

$$\begin{aligned} L &= (x_1 - 3x_2) - \lambda_1(x_1^2 + x_2^2 + s_1 - 4) - \lambda_2(x_1 + x_2 + s_2 - 2) \\ &= ((1 - \lambda_2)x_1 - \lambda_1 x_1^2) + ((-3 - \lambda_2)x_2 - \lambda_1 x_2^2) - \lambda_1 s_1 - \lambda_2 s_2 + 4\lambda_1 + 2\lambda_2. \end{aligned}$$

As discussed, $\lambda_1, \lambda_2 \leq 0$. Minimizing the two brackets,

$$(1 - \lambda_2) - 2\lambda_1 x_1 = 0, \quad (-3 - \lambda_2) - 2\lambda_1 x_2 = 0.$$

If $\lambda_1 = 0$ these read $\lambda_2 = 1$ and $\lambda_2 = -3$, which is a contradiction. So $\lambda_1 < 0$, and complementary slackness gives $s_1 = 0$, i.e. the first constraint is tight: $x_1^2 + x_2^2 = 4$.

Now suppose $\lambda_2 < 0$. Then $s_2 = 0$ too, so $x_1 + x_2 = 2$ as well. Combined with $x_1^2 + x_2^2 = 4$ this gives $(x_1, x_2) = (0, 2)$ or $(2, 0)$. Substituting into the two stationarity equations, the first case gives $(\lambda_1, \lambda_2) = (1, -3)$ and the second gives $(\lambda_1, \lambda_2) = (-1, 1)$; both have a positive multiplier, so both are impossible.

Hence $\lambda_2 = 0$, and the stationarity equations become $x_1 = 1/(2\lambda_1)$ and $x_2 = -3/(2\lambda_1)$. Substituting into $x_1^2 + x_2^2 = 4$,

$$\frac{1+9}{4\lambda_1^2} = 4 \implies \lambda_1^2 = \frac{5}{8} \implies \lambda_1 = -\sqrt{5/8},$$

giving

$$(x_1, x_2) = \left(-\sqrt{2/5}, 3\sqrt{2/5} \right).$$

Finally we check that this is feasible for the second constraint: $x_1 + x_2 = 2\sqrt{2/5} \approx 1.26 \leq 2$, so $s_2 = 2 - 2\sqrt{2/5} \geq 0$. By Lagrangian sufficiency this is optimal, with cost $-10\sqrt{2/5} = -2\sqrt{10}$.

Let us record the general procedure, since it is what we will do every time.

Remark (The Lagrangian Recipe). To solve ‘minimize $f(x)$ subject to $h(x) \leq b, x \in X$ ’:

- (1) Introduce slack variables to get equality constraints $h(x) + s = b, s \geq 0$.
- (2) Form the Lagrangian $L(x, s, \lambda) = f(x) - \lambda \cdot (h(x) + s - b)$.
- (3) Find Λ , the set of λ for which $\inf_{x \in X, s \geq 0} L$ is finite.
- (4) For each $\lambda \in \Lambda$, find the minimizers $x^*(\lambda), s^*(\lambda)$.
- (5) Find $\lambda^* \in \Lambda$ for which $x^*(\lambda^*), s^*(\lambda^*)$ is feasible. Then $x^*(\lambda^*)$ is optimal.

§20.2.3 Lagrangian Duality

The Lagrangian recipe raises an obvious worry: what if there is no λ^* that makes the minimizer feasible? Then the method fails, and we would like to understand when and why. The answer is the theory of duality, which is much more than a diagnostic tool – it is arguably the most important structure in the whole subject.

Definition 20.2.6 (Dual Function and Dual Problem)

The **dual function** associated with (P) is

$$g(\lambda) = \inf_{x \in X} L(x, \lambda),$$

defined for $\lambda \in \Lambda$. The **dual problem** (D) is

$$\begin{array}{ll} \text{maximize} & g(\lambda) \\ \text{subject to} & \lambda \in \Lambda. \end{array}$$

Note that g is an infimum of *affine* functions of λ (one for each x), and an infimum of affine functions is always concave. So the dual problem is always the maximization of a concave function over a convex set, i.e. always a convex problem, no matter how horrible the primal problem was. This is remarkable and is one reason duality is so useful.

Theorem 20.2.7 (Weak Duality)

If $x \in X(b)$ and $\lambda \in \Lambda$, then $f(x) \geq g(\lambda)$. In particular

$$\inf_{x \in X(b)} f(x) \geq \sup_{\lambda \in \Lambda} g(\lambda).$$

Proof. This is the first two lines of the proof of Lagrangian sufficiency. For $x \in X(b)$ we have $h(x) = b$, so

$$f(x) = f(x) - \lambda \cdot (h(x) - b) = L(x, \lambda) \geq \inf_{x' \in X} L(x', \lambda) = g(\lambda). \quad \square$$

So every feasible λ gives a *lower bound* on the optimal cost, and every feasible x gives an *upper bound*. This is already valuable: if we find x and λ with $f(x) = g(\lambda)$, we have proved that both are optimal without any further work. In general, though, there may be a gap.

Definition 20.2.8 (Duality Gap)

The **duality gap** is

$$\inf_{x \in X(b)} f(x) - \sup_{\lambda \in \Lambda} g(\lambda) \geq 0.$$

If the duality gap is zero we say that **strong duality** holds.

The relationship with the Lagrangian method is exactly what one would hope.

Proposition 20.2.9

The Lagrangian method succeeds – that is, there is a λ^* whose associated minimizer is feasible – if and only if strong duality holds.

Proof. If the method succeeds with multiplier λ^* and minimizer x^* , then by the proof of Lagrangian sufficiency, $g(\lambda^*) = L(x^*, \lambda^*) = f(x^*) = \min_{x \in X(b)} f(x)$, so the gap is zero.

Conversely if the gap is zero then there is λ^* (or a sequence approaching it) with $g(\lambda^*) = \inf_{x \in X(b)} f(x)$, and the chain of inequalities in the sufficiency proof collapses to equalities, so the minimizer of $L(\cdot, \lambda^*)$ is feasible and optimal. $\square$

So we should ask: when does strong duality hold? The answer is beautifully geometric.

§20.2.4 Supporting Hyperplanes

The key object is the following.

Definition 20.2.10 (Value Function)

The **value function** of the problem (P) is $\phi : \mathbb{R}^m \rightarrow \mathbb{R} \cup \{\pm\infty\}$ given by

$$\phi(c) = \inf_{x \in X(c)} f(x),$$

the optimal cost when the right-hand side of the functional constraint is changed from b to c .

So $\phi(b)$ is the number we are trying to compute, and ϕ tells us how that number responds to perturbing the constraints. Now here is the definition that makes everything work.

Definition 20.2.11 (Supporting Hyperplane)

A function $\phi : \mathbb{R}^m \rightarrow \mathbb{R}$ has a **supporting hyperplane** at b if there is some $\lambda \in \mathbb{R}^m$ such that

$$\phi(c) \geq \phi(b) + \lambda \cdot (c - b) \quad \text{for all } c \in \mathbb{R}^m.$$

That is, there is a hyperplane through the point $(b, \phi(b))$ which lies entirely below the graph of ϕ . Compare this with the first-order condition for convexity, where the tangent plane at every point lies below the graph. Indeed one can show (we will not prove it) that ϕ is convex if and only if ϕ has a supporting hyperplane at every point.

Theorem 20.2.12 (Strong Duality)

Strong duality holds for (P) if and only if the value function ϕ has a supporting hyperplane at b .

Proof. Suppose first that ϕ has a supporting hyperplane at b , with normal given by λ . The trick is to compute $g(\lambda)$ by splitting the minimization over $x \in X$ into a minimization over the possible values $c = h(x)$, and then over the x achieving each value:

$$\begin{aligned} g(\lambda) &= \inf_{x \in X} (f(x) - \lambda \cdot (h(x) - b)) \\ &= \inf_{c \in \mathbb{R}^m} \inf_{x \in X(c)} (f(x) - \lambda \cdot (h(x) - c) - \lambda \cdot (c - b)) \\ &= \inf_{c \in \mathbb{R}^m} \left(\inf_{x \in X(c)} f(x) - \lambda \cdot (c - b) \right) \\ &= \inf_{c \in \mathbb{R}^m} (\phi(c) - \lambda \cdot (c - b)) \\ &\geq \phi(b), \end{aligned}$$

where in the third line we used that $h(x) = c$ for $x \in X(c)$, and the final inequality is precisely the supporting hyperplane property. But weak duality says $g(\lambda) \leq \phi(b)$, so $g(\lambda) = \phi(b)$ and the duality gap is zero.

Conversely, suppose strong duality holds, so there is λ with $g(\lambda) = \phi(b)$. Then for any c ,

$$\phi(b) = g(\lambda) = \inf_{x \in X} (f(x) - \lambda \cdot (h(x) - c) - \lambda \cdot (c - b))$$

$$\begin{aligned} &\leq \inf_{x \in X(c)} (f(x) - \lambda \cdot (h(x) - c)) - \lambda \cdot (c - b) \\ &= \phi(c) - \lambda \cdot (c - b), \end{aligned}$$

which rearranges to the supporting hyperplane condition. $\square$

This is a clean answer, but it is stated in terms of ϕ , which is the thing we do not know. Fortunately there is a checkable sufficient condition.

Theorem 20.2.13

Consider the problem ‘minimize $f(x)$ subject to $h(x) \leq b$, $x \in X$ ’, and suppose that X is convex, f is convex and h is convex (componentwise). Then the value function ϕ is convex, and hence strong duality holds.

Proof. Let $b_1, b_2 \in \mathbb{R}^m$ and $\delta \in [0, 1]$, and set $b_\delta = \delta b_1 + (1 - \delta)b_2$. Take any feasible $x_1 \in X(b_1)$ and $x_2 \in X(b_2)$, and let $x_\delta = \delta x_1 + (1 - \delta)x_2$, which lies in X by convexity of X . By convexity of h ,

$$h(x_\delta) \leq \delta h(x_1) + (1 - \delta)h(x_2) \leq \delta b_1 + (1 - \delta)b_2 = b_\delta,$$

so $x_\delta \in X(b_\delta)$. Hence by convexity of f ,

$$\phi(b_\delta) \leq f(x_\delta) \leq \delta f(x_1) + (1 - \delta)f(x_2).$$

Taking the infimum over $x_1 \in X(b_1)$ and $x_2 \in X(b_2)$ gives $\phi(b_\delta) \leq \delta\phi(b_1) + (1 - \delta)\phi(b_2)$, so ϕ is convex. $\square$

Remark. It is worth stressing where convexity was used. We needed $h(x) \leq b$ rather than $h(x) = b$: with an equality constraint, $h(x_\delta) \leq b_\delta$ does not tell us $h(x_\delta) = b_\delta$, and the argument breaks. This is why in practice one always tries to write constraints as inequalities when hoping for strong duality.

Here, incidentally, is what failure looks like: if ϕ is not convex, there may be a ‘dent’ at b and no hyperplane through $(b, \phi(b))$ can stay below the graph. The best any hyperplane can do is to support the convex hull of the graph from below, and the vertical distance between $\phi(b)$ and that best hyperplane is exactly the duality gap.

§20.2.5 Shadow Prices

We finish this section with the interpretation of Lagrange multipliers that gives them their name in economics, and which explains the strange sign conventions.

Imagine a factory that makes n products out of m raw materials. If it makes quantities

$x = (x_1, \dots, x_n)$ then it makes profit $f(x)$ (we will minimize $-f$, but let us think in terms of maximizing profit), and producing x consumes $h_j(x)$ units of raw material j . The factory has b_j units of material j available. So the factory owner solves ‘maximize $f(x)$ subject to $h(x) \leq b$ ’.

Now a supplier turns up and offers a small extra quantity $\varepsilon = (\varepsilon_1, \dots, \varepsilon_m)$ of raw materials. How much should the owner be willing to pay? The new optimal profit is $\phi(b + \varepsilon)$, so the increase is

$$\phi(b + \varepsilon) - \phi(b) \approx \sum_{j=1}^m \frac{\partial \phi}{\partial b_j}(b) \varepsilon_j.$$

The quantity $\partial \phi / \partial b_j$ is the marginal value to this factory of one more unit of material j : it is called the **shadow price** of material j . It is a ‘shadow’ price because it is invisible from outside – it depends entirely on the internal state of the factory, not on the market.

Theorem 20.2.14

If ϕ is differentiable at b and has a supporting hyperplane at b with normal λ , then $\lambda = \nabla \phi(b)$.

Proof. Let $a \in \mathbb{R}^m$ be arbitrary and $\delta > 0$. The supporting hyperplane condition at $c = b + \delta a$ gives

$$\phi(b + \delta a) - \phi(b) \geq \delta \lambda \cdot a, \quad \text{so} \quad \frac{\phi(b + \delta a) - \phi(b)}{\delta} \geq \lambda \cdot a.$$

Letting $\delta \rightarrow 0$ and using differentiability, $\nabla \phi(b) \cdot a \geq \lambda \cdot a$. Since a was arbitrary we may also apply this with $-a$, giving $\nabla \phi(b) \cdot a = \lambda \cdot a$ for all a , and hence $\lambda = \nabla \phi(b)$. $\square$

Example 20.2.15

Let us verify this in a case where we can compute everything. Consider

$$\text{minimize } \frac{1}{2}(x_1^2 + x_2^2) \text{ subject to } x_1 + x_2 = b,$$

over $x \in \mathbb{R}^2$. The Lagrangian is

$$L(x, \lambda) = \frac{1}{2}(x_1^2 + x_2^2) - \lambda(x_1 + x_2 - b) = \left(\frac{1}{2}x_1^2 - \lambda x_1\right) + \left(\frac{1}{2}x_2^2 - \lambda x_2\right) + \lambda b,$$

which is bounded below for every λ , so $\Lambda = \mathbb{R}$. Minimizing each bracket gives $x_1 = x_2 = \lambda$, and feasibility then forces $2\lambda = b$, so

$$\lambda^* = \frac{b}{2}, \quad x^* = \left(\frac{b}{2}, \frac{b}{2}\right), \quad \phi(b) = \frac{b^2}{4}.$$

And indeed $\phi'(b) = b/2 = \lambda^*$, exactly as the theorem promises. Concretely: relaxing the constraint from b to $b + \varepsilon$ increases the optimal cost by about $\lambda^* \varepsilon$.

So the Lagrange multipliers *are* the shadow prices. This makes complementary slackness completely intuitive: if a raw material is not fully used up ($s_j > 0$, the constraint is slack) then an extra unit of it is worth nothing, so its shadow price λ_j is zero. Conversely, if it

has a nonzero price then we must be using every last unit of it.

There is a matching interpretation of the dual problem. Think of it from the supplier's point of view. The supplier posts prices λ for the raw materials and offers to buy the finished products. Given prices λ , the factory owner will choose x to maximize

$$\underbrace{f(x)}_{\text{revenue}} - \underbrace{\lambda \cdot (h(x) - b)}_{\text{cost of materials}},$$

which is exactly the Lagrangian. The supplier, knowing this, chooses λ to make the factory owner's best achievable profit as small as possible – that is, the supplier solves the dual problem. Weak duality says the supplier can never squeeze the owner below the true optimum, and strong duality says that with the right prices the two coincide: at equilibrium there is no advantage to either party.

§20.3 Linear Programming

We now specialize to the case where everything in sight is linear. This may sound like a drastic restriction, and in a sense it is, but linear programs are astonishingly expressive – an enormous fraction of the optimization problems that actually arise in industry are linear programs, or are usefully approximated by them. More importantly for us, in this setting the general theory of the previous section becomes completely explicit and computable, and we will be able to write down an algorithm that solves any linear program by hand.

§20.3.1 Linear Programs

Definition 20.3.1 (Linear Program)

A **linear program** is an optimization problem in which the objective function and all of the constraints are linear (more precisely, affine) functions of the decision variables.

A general linear program might look something like

$$\begin{aligned} \text{minimize} \quad & 2x_1 - x_2 + 4x_3 \\ \text{subject to} \quad & x_1 + x_2 + x_4 \leq 2, \\ & 3x_2 - x_3 = 5, \\ & x_3 + x_4 \geq 3, \\ & x_1 \geq 0, \ x_3 \leq 0, \end{aligned}$$

with x_2 and x_4 unconstrained in sign. This is a mess of different constraint types, and before doing anything we would like to tidy it up. Happily, all of the constraint types are interchangeable.

Definition 20.3.2 (Equivalent Problems)

Two optimization problems are **equivalent** if from a feasible solution to either one we can construct a feasible solution to the other with the same cost. Rewriting a problem as an equivalent one is called **reduction**.

The reductions we need are all elementary:

- $a \cdot x \leq b$ becomes $-a \cdot x \geq -b$;
- $a \cdot x \geq b$ becomes $a \cdot x - s = b$ with $s \geq 0$ (a *surplus* variable), and $a \cdot x \leq b$ becomes $a \cdot x + s = b$ with $s \geq 0$ (a *slack* variable);
- $a \cdot x = b$ becomes the pair $a \cdot x \geq b$ and $-a \cdot x \geq -b$;
- a variable $x_j \leq 0$ is replaced by $-x_j \geq 0$;
- a variable x_j of unrestricted sign is replaced by $x_j^+ - x_j^-$ with $x_j^+, x_j^- \geq 0$.

Applying these as needed, we can put any linear program into either of two standard shapes.

Definition 20.3.3 (General and Standard Form)

A linear program is in **general form** if it is written

$$\begin{array}{ll} \text{minimize} & c \cdot x \\ \text{subject to} & Ax \geq b, \end{array}$$

and in **standard form** if it is written

$$\begin{array}{ll} \text{minimize} & c \cdot x \\ \text{subject to} & Ax = b, \\ & x \geq 0, \end{array}$$

where in both cases $A \in \mathbb{R}^{m \times n}$, $b \in \mathbb{R}^m$ and $c \in \mathbb{R}^n$.

Standard form is what we will use for computation, since the constraint $Ax = b$ is just a linear system; general form is convenient for stating duality. Both are fully general: to get from general to standard form, first introduce surplus variables to turn $Ax \geq b$ into $Ax - s = b$ with $s \geq 0$, then split each unrestricted x_j as $x_j^+ - x_j^-$, giving

$$\begin{array}{ll} \text{minimize} & c \cdot x^+ - c \cdot x^- \\ \text{subject to} & Ax^+ - Ax^- - s = b, \\ & x^+, x^-, s \geq 0, \end{array}$$

which is in standard form in the variables $(x^+, x^-, s) \in \mathbb{R}_{\geq 0}^{2n+m}$.

Notice that reduction to standard form typically increases the number of variables. That is fine: what matters is that the constraint matrix stays sparse and the structure stays linear.

§20.3.2 A Two-Dimensional Example

Before doing any theory, it is worth solving a small linear program by drawing a picture, because the picture explains everything that follows.

Example 20.3.4

Consider the problem

$$\text{maximize} \quad x_1 + x_2$$

$$\begin{aligned} \text{subject to } & x_1 + 2x_2 \leq 6, \\ & x_1 - x_2 \leq 3, \\ & x_1, x_2 \geq 0. \end{aligned}$$

The feasible set is the shaded polygon below: the intersection of four half-planes. The dashed lines are the level sets $x_1 + x_2 = \text{const}$ of the objective, which all have gradient $(1, 1)$. To maximize the objective, we slide the dashed line in the direction $(1, 1)$ as far as we can while still touching the feasible set.

The optimum is at $x^* = (4, 1)$, where the two constraint lines meet, with optimal value 5. Two features of this picture are completely general, and are the theoretical backbone of linear programming:

- (i) the feasible set is a *polyhedron* – an intersection of finitely many half-spaces; and
- (ii) the optimum is attained at a *corner* of that polyhedron.

If the objective happens to be parallel to one of the edges, then a whole edge is optimal – but even then, a corner is among the optimal points. So to solve a linear program, it suffices to search the (finitely many!) corners. Our next job is to say precisely what a corner is, algebraically.

§20.3.3 Extreme Points

Definition 20.3.5 (Extreme Point)

A point x in a convex set C is an **extreme point** if it cannot be written as $x = \delta y + (1 - \delta)z$ for $y, z \in C$ with $y \neq z$ and $\delta \in (0, 1)$. That is, x does not lie strictly inside any line segment contained in C .

extreme points

x is not extreme

The relevance is the following general fact, which explains observation (ii) above.

Proposition 20.3.6

Let f be a convex function on a convex set C , and let $y, z \in C$. Then f attains its maximum over the segment $[y, z]$ at an endpoint. Consequently, if C is a bounded polyhedron then $\max_{x \in C} f(x)$ is attained at an extreme point of C .

Proof. For the first part, if $x = \delta y + (1 - \delta)z$ then by convexity

$$f(x) \leq \delta f(y) + (1 - \delta)f(z) \leq \max\{f(y), f(z)\}.$$

For the second, every point of a bounded polyhedron C can be written as a convex combination $x = \sum_{i=1}^k \delta_i x^{(i)}$ of extreme points $x^{(i)}$, with $\delta_i \geq 0$ and $\sum \delta_i = 1$. By convexity again,

$$f(x) \leq \sum_{i=1}^k \delta_i f(x^{(i)}) \leq \max_i f(x^{(i)}),$$

so no interior point beats the best extreme point. $\square$

Since a linear function is convex (and concave), the maximum *and* the minimum of a linear function on a bounded polyhedron are both attained at extreme points. So the corners really are all we need to look at. What we lack is a way of finding them without drawing a picture, which is hopeless in $\mathbb{R}^{100}$.

§20.3.4 Basic Solutions

Consider now a linear program in standard form,

$$\begin{aligned} &\text{minimize} && c \cdot x \\ &\text{subject to} && Ax = b, \\ &&& x \geq 0, \end{aligned}$$

with $A \in \mathbb{R}^{m \times n}$ and typically $n > m$, so that $Ax = b$ is an underdetermined system with a whole affine space of solutions. Intuitively, a corner of the feasible set is a point where as many constraints as possible are tight; since the only inequality constraints are $x_j \geq 0$, this means a point with as many zero coordinates as possible.

Definition 20.3.7 (Basic Solution)

A vector $x \in \mathbb{R}^n$ is a **basic solution** of $Ax = b$ if $Ax = b$ and x has at most m nonzero entries. If in addition $x \geq 0$, it is a **basic feasible solution** (bfs).

To construct basic solutions, we choose which m coordinates are allowed to be nonzero. We make two standing assumptions on A , both harmless.

- (A) The m rows of A are linearly independent. (Otherwise some constraint is redundant or inconsistent, and we can delete it.)
- (B) Every set of m columns of A is linearly independent. (This is a genericity assumption; we can always perturb b slightly to arrange it.)

Given a choice of indices $B = \{B(1), \dots, B(m)\} \subseteq \{1, \dots, n\}$, write A_j for the j th column of A and let

$$A_B = (A_{B(1)} \quad \cdots \quad A_{B(m)}) \in \mathbb{R}^{m \times m}$$

be the corresponding **basis matrix**. Setting $x_j = 0$ for $j \notin B$, the equation $Ax = b$ reduces to $A_B x_B = b$, where $x_B = (x_{B(1)}, \dots, x_{B(m)})$. By assumption (B), A_B is invertible, and so

$$x_B = A_B^{-1}b.$$

The indices in B are the **basic indices**, the corresponding variables are the **basic variables**, and the rest are the **non-basic variables** (all set to zero). If moreover $A_B^{-1}b \geq 0$, we have found a basic feasible solution.

(C) (**Non-degeneracy**) Every basic solution has *exactly* m nonzero entries.

This last assumption is not without loss of generality, and we will discuss what goes wrong without it in Section 20.4.3. Until then we assume it.

Now we can connect the algebra to the geometry.

Theorem 20.3.8 (Basic Feasible Solutions are Extreme Points)

Let $P = \{x : Ax = b, x \geq 0\}$. Then x is an extreme point of P if and only if x is a basic feasible solution.

Proof. Suppose first that x is a bfs, with basis B , and suppose $x = \delta y + (1 - \delta)z$ with $y, z \in P$ and $\delta \in (0, 1)$. For $j \notin B$ we have $x_j = 0$, so $\delta y_j + (1 - \delta)z_j = 0$; but $y_j, z_j \geq 0$ and $\delta \in (0, 1)$, so $y_j = z_j = 0$. Hence y and z are also supported on B , and $A_B y_B = b = A_B z_B$. As A_B is invertible, $y_B = z_B = A_B^{-1}b = x_B$, and so $y = z = x$. Thus x is extreme.

Conversely suppose $x \in P$ is not a bfs, so x has $r > m$ nonzero entries, say in positions $i_1, \dots, i_r$. The columns $A_{i_1}, \dots, A_{i_r}$ are $r > m$ vectors in $\mathbb{R}^m$, hence linearly dependent: there are weights $w_{i_1}, \dots, w_{i_r}$, not all zero, with

$$w_{i_1}A_{i_1} + \dots + w_{i_r}A_{i_r} = 0.$$

Extend w to a vector in $\mathbb{R}^n$ by setting $w_i = 0$ for $i \notin \{i_1, \dots, i_r\}$. Then $w \neq 0$ and $Aw = 0$, so $A(x \pm \varepsilon w) = b$ for every ε . Moreover w is supported where x is strictly positive, so for small enough $\varepsilon > 0$ we have $x \pm \varepsilon w \geq 0$, i.e. $x \pm \varepsilon w \in P$. But then x is the midpoint of these two distinct points of P , so x is not extreme. $\square$

Corollary 20.3.9

There are at most $\binom{n}{m}$ basic solutions, and hence at most $\binom{n}{m}$ extreme points of P .

Example 20.3.10

Let us see this explicitly on the example of Section 3.2. Writing it as a minimization and adding slack variables x_3, x_4 , the standard form is: minimize $-x_1 - x_2$ subject to

$$x_1 + 2x_2 + x_3 = 6, \quad x_1 - x_2 + x_4 = 3, \quad x \geq 0,$$

so $m = 2$, $n = 4$ and there are at most $\binom{4}{2} = 6$ basic solutions. Let us list them all.

basis	$x = (x_1, x_2, x_3, x_4)$	feasible?	cost
$\{3, 4\}$	$(0, 0, 6, 3)$	yes	0
$\{1, 3\}$	$(3, 0, 3, 0)$	yes	-3
$\{1, 4\}$	$(6, 0, 0, -3)$	no	—
$\{2, 3\}$	$(0, -3, 12, 0)$	no	—
$\{2, 4\}$	$(0, 3, 0, 6)$	yes	-3
$\{1, 2\}$	$(4, 1, 0, 0)$	yes	-5

For instance, for the basis $\{1, 2\}$ we set $x_3 = x_4 = 0$ and solve $x_1 + 2x_2 = 6$, $x_1 - x_2 = 3$, giving $(x_1, x_2) = (4, 1)$. Comparing with the picture in Section 3.2, the four basic feasible solutions are exactly the four corners $(0, 0)$, $(3, 0)$, $(0, 3)$ and $(4, 1)$ of the polygon, and the two infeasible basic solutions are the points $(6, 0)$ and $(0, -3)$ where two constraint lines meet *outside* the feasible region. The best cost among the feasible ones is -5 at $(4, 1)$, in agreement with what we found geometrically.

Theorem 20.3.11 (Fundamental Theorem of Linear Programming)

If a linear program in standard form is feasible and bounded, then there is an optimal solution which is a basic feasible solution.

Proof. Let x be an optimal solution with as few nonzero entries as possible, say r of them. If $r \leq m$ then x is a bfs and we are done, so suppose $r > m$. By the argument in the previous proof, there is $w \neq 0$ with $Aw = 0$, supported on the positions where x is nonzero.

Consider $x_\theta = x + \theta w$, which satisfies $Ax_\theta = b$ for all $\theta \in \mathbb{R}$, and lies in P for all θ in some interval around 0. Its cost is $c \cdot x + \theta(c \cdot w)$. If $c \cdot w \neq 0$ then choosing the sign of θ appropriately strictly decreases the cost, contradicting optimality of x . So $c \cdot w = 0$ and x_θ is optimal for every feasible θ .

Now increase $|\theta|$ (in either direction) until some coordinate of x_θ first hits zero – this happens for a finite θ since w is nonzero and supported where x is. The resulting point is optimal, feasible, and has strictly fewer than r nonzero entries, contradicting minimality of r . $\square$

This is genuinely good news: it reduces an optimization over a continuum to a search over a finite set. The bad news is that $\binom{n}{m}$ is astronomically large – for $n = 100$ and $m = 50$ it exceeds 10^{29} – so brute force is out of the question. The simplex method, which we come to shortly, is a clever way of walking from one basic feasible solution to a better one.

§20.3.5 Duality for Linear Programs

Before the algorithm, let us work out what the duality theory of Section 2 says here. It says something extremely concrete.

Consider a linear program in general form, with surplus variables added:

$$\begin{aligned} &\text{minimize} && c \cdot x \\ &\text{subject to} && Ax - s = b, \\ &&& s \geq 0, \end{aligned}$$

where x is unrestricted. The Lagrangian is

$$L(x, s, \lambda) = c \cdot x - \lambda \cdot (Ax - s - b) = (c - A^T \lambda) \cdot x + \lambda \cdot s + \lambda \cdot b.$$

Since x ranges over all of $\mathbb{R}^n$, this is bounded below only if $c - A^T \lambda = 0$; and since s ranges over $[0, \infty)^m$, we need $\lambda \geq 0$. Given both, the infimum is attained at $s = 0$ and equals $\lambda \cdot b$. Hence

$$\Lambda = \{\lambda : A^T \lambda = c, \lambda \geq 0\}, \quad g(\lambda) = \lambda \cdot b,$$

and we have proved the following.

Proposition 20.3.12 (Dual of a General-Form LP)

The dual of

$$\text{minimize } c \cdot x \quad \text{subject to } Ax \geq b$$

is

$$\text{maximize } \lambda \cdot b \quad \text{subject to } A^T \lambda = c, \lambda \geq 0.$$

Notice that the dual of a general-form problem is in standard form. The same computation for a standard-form primal gives the reverse.

Proposition 20.3.13 (Dual of a Standard-Form LP)

The dual of

$$\text{minimize } c \cdot x \quad \text{subject to } Ax = b, x \geq 0$$

is

$$\text{maximize } \lambda \cdot b \quad \text{subject to } A^T \lambda \leq c.$$

Proof. Here $X = \{x : x \geq 0\}$ and $L(x, \lambda) = c \cdot x - \lambda \cdot (Ax - b) = (c - A^T \lambda) \cdot x + \lambda \cdot b$. Since x ranges over the non-negative orthant, this is bounded below exactly when $c - A^T \lambda \geq 0$, and then the infimum is attained at $x = 0$ and equals $\lambda \cdot b$. $\square$

These two facts fit together neatly.

Proposition 20.3.14

The dual of the dual is the primal.

Proof. Start with the standard-form primal and its dual ‘maximize $\lambda \cdot b$ subject to $A^T \lambda \leq c$ ’. Rewrite this as a minimization in general form: putting $\mu = -\lambda$,

$$\text{minimize } \mu \cdot b \quad \text{subject to } A^T \mu \geq -c,$$

whose optimal value is the negative of the original. Applying the general-form dual

with data $(b, A^T, -c)$ in place of (c, A, b) , the dual is

$$\text{maximize } -\theta \cdot c \text{ subject to } A\theta = b, \theta \geq 0,$$

that is, minimize $c \cdot \theta$ subject to $A\theta = b, \theta \geq 0$, which is the original primal. $\square$

For a completely general linear program, the pattern of the dual is worth recording; each of these can be derived by the reductions above.

Proposition 20.3.15 (Dual of a General Linear Program)

The dual of

$$\begin{aligned} &\text{minimize} && c \cdot x \\ &\text{subject to} && a_i \cdot x \geq b_i \quad i \in M_1, \\ & && a_i \cdot x \leq b_i \quad i \in M_2, \\ & && a_i \cdot x = b_i \quad i \in M_3, \\ & && x_j \geq 0 \quad j \in N_1, \\ & && x_j \leq 0 \quad j \in N_2, \\ & && x_j \text{ free} \quad j \in N_3, \end{aligned}$$

is

$$\begin{aligned} &\text{maximize} && \lambda \cdot b \\ &\text{subject to} && \lambda_i \geq 0 \quad i \in M_1, \\ & && \lambda_i \leq 0 \quad i \in M_2, \\ & && \lambda_i \text{ free} \quad i \in M_3, \\ & && \lambda \cdot A_j \leq c_j \quad j \in N_1, \\ & && \lambda \cdot A_j \geq c_j \quad j \in N_2, \\ & && \lambda \cdot A_j = c_j \quad j \in N_3. \end{aligned}$$

The mnemonic is that constraints in the primal correspond to variables in the dual and vice versa. It is worth having the correspondence in a table:

primal (minimize)	dual (maximize)
i th constraint $\geq$	i th variable ≥ 0
i th constraint $\leq$	i th variable ≤ 0
i th constraint $=$	i th variable free
j th variable ≥ 0	j th constraint $\leq$
j th variable ≤ 0	j th constraint $\geq$
j th variable free	j th constraint $=$
objective vector c	right-hand side c
right-hand side b	objective vector b
constraint matrix A	constraint matrix A^T

There is an easy way to remember the direction of the inequalities: whichever choice makes weak duality come out right is the correct one. For instance in the standard-form case, a primal variable $x_j \geq 0$ contributes $c_j x_j$ to the objective, and we need $(c_j - \lambda \cdot A_j)x_j \geq 0$ for the bound $c \cdot x \geq \lambda \cdot b$ to work; with $x_j \geq 0$ this forces $\lambda \cdot A_j \leq c_j$, which is a $\leq$ constraint in the dual.

Since a linear program has a convex objective, convex constraints and convex feasible region, the theorem of Section 2.4 applies immediately.

Theorem 20.3.16 (Strong Duality for Linear Programs)

If a linear program is feasible and bounded, then so is its dual, and their optimal values are equal.

Proof. The value function $\phi(d) = \inf\{c \cdot x : Ax \geq d\}$ is convex by the theorem in Section 2.4 (taking $X = \mathbb{R}^n$, and noting that $f(x) = c \cdot x$ and $h(x) = -Ax$ are linear, hence convex). Hence ϕ has a supporting hyperplane at b , and strong duality holds. $\square$

§20.3.6 Complementary Slackness for Linear Programs

Strong duality gives us a certificate of optimality, and in the linear case that certificate takes an extremely usable form.

Theorem 20.3.17 (Optimality Conditions)

Let x be feasible for the primal and λ feasible for the dual, in the general setting of the previous proposition. Then x and λ are both optimal if and only if

- (i) $\lambda_i(a_i \cdot x - b_i) = 0$ for all i , and
- (ii) $(c_j - \lambda \cdot A_j)x_j = 0$ for all j .

Proof. Set $u_i = \lambda_i(a_i \cdot x - b_i)$ and $v_j = (c_j - \lambda \cdot A_j)x_j$. Feasibility of x and λ makes each $u_i \geq 0$ and each $v_j \geq 0$: for instance if $i \in M_1$ then $a_i \cdot x - b_i \geq 0$ and $\lambda_i \geq 0$, while if $i \in M_2$ both factors flip sign, and if $i \in M_3$ the second factor is zero. The same case analysis works for v_j . Now

$$\sum_i u_i = \lambda \cdot (Ax) - \lambda \cdot b, \quad \sum_j v_j = c \cdot x - \lambda \cdot (Ax),$$

so adding,

$$0 \leq \sum_i u_i + \sum_j v_j = c \cdot x - \lambda \cdot b.$$

If (i) and (ii) hold then all u_i, v_j vanish, so $c \cdot x = \lambda \cdot b$, and by weak duality both must be optimal. Conversely if both are optimal then strong duality gives $c \cdot x = \lambda \cdot b$, so $\sum u_i + \sum v_j = 0$; as all the terms are non-negative, they must all be zero. $\square$

Conditions (i) and (ii) are the **complementary slackness** conditions for a linear program. Condition (i) says: if the dual variable λ_i is nonzero then the i th primal constraint is tight. Condition (ii) says: if the primal variable x_j is nonzero then the j th dual constraint is tight. So the whole state of the optimum is captured by:

$$\text{primal feasibility} \quad + \quad \text{dual feasibility} \quad + \quad \text{complementary slackness}.$$

These three conditions are what the simplex method will maintain and enforce, and the algorithm can be understood entirely in terms of them: it keeps the first and third true at all times, and works to make the second true.

Example 20.3.18

Return to our two-dimensional example, written as a minimization in general form. We minimize $-x_1 - x_2$ subject to

$$\begin{pmatrix} -1 & -2 \\ -1 & 1 \\ 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \geq \begin{pmatrix} -6 \\ -3 \\ 0 \\ 0 \end{pmatrix}.$$

The dual is: maximize $-6\lambda_1 - 3\lambda_2$ subject to $\lambda \geq 0$ and

$$-\lambda_1 - \lambda_2 + \lambda_3 = -1, \quad -2\lambda_1 + \lambda_2 + \lambda_4 = -1.$$

At the primal optimum $x^* = (4, 1)$ the first two constraints are tight and the last two are slack, so complementary slackness forces $\lambda_3 = \lambda_4 = 0$. The remaining equations give $\lambda_1 + \lambda_2 = 1$ and $2\lambda_1 - \lambda_2 = 1$, so $\lambda = (2/3, 1/3, 0, 0)$, which is indeed non-negative. The dual objective is $-6 \cdot \frac{2}{3} - 3 \cdot \frac{1}{3} = -5$, matching the primal optimal value of -5 . So each certifies the other.

The shadow price interpretation is now concrete: $\lambda_1 = 2/3$ says that relaxing the first constraint from $x_1 + 2x_2 \leq 6$ to ≤ 7 would increase the maximum of $x_1 + x_2$ by $2/3$.

§20.4 The Simplex Method

We know that an optimal solution can be found among the basic feasible solutions, and we know that there are far too many of these to enumerate. The **simplex method**, due to Dantzig, resolves this by moving from one basic feasible solution to an adjacent one, always decreasing the cost, until no improving move exists. Geometrically, it walks along the edges of the feasible polyhedron from corner to corner, downhill all the way.

**§20.4.1 Reduced Costs**

To turn the picture into an algorithm we need to answer two questions: when is a basic feasible solution optimal, and if it is not, which neighbouring solution should we move to? Both answers come from duality.

Suppose we are at a basic feasible solution x with basis matrix $B = A_B$ (we will write B for both the index set and the matrix, as is traditional). We have primal feasibility for free. Let us try to construct a λ making complementary slackness hold, and then check whether it is dual feasible.

For a standard-form problem, the three optimality conditions read

- (primal feasibility) $Ax = b, x \geq 0$;
- (dual feasibility) $A^T \lambda \leq c$;
- (complementary slackness) $x \cdot (c - A^T \lambda) = 0$.

Since $x_j = 0$ for non-basic j , complementary slackness only constrains the basic coordinates, where $x_B > 0$; so it forces $c_B - B^T \lambda = 0$, that is

$$\lambda = (B^T)^{-1} c_B.$$

With this choice of λ , primal feasibility and complementary slackness both hold. Only dual feasibility $A^T \lambda \leq c$ remains, and this motivates the following definition.

Definition 20.4.1 (Reduced Costs)

Given a basis B , the vector of **reduced costs** is

$$\bar{c} = c - A^T (B^T)^{-1} c_B, \quad \text{componentwise} \quad \bar{c}_j = c_j - c_B \cdot (B^{-1} A_j).$$

By construction, dual feasibility is precisely the statement $\bar{c} \geq 0$, so we have proved most of the following.

Theorem 20.4.2 (Optimality Criterion)

Let x be a basic feasible solution with basis B and reduced cost vector $\bar{c}$. If $\bar{c} \geq 0$ then x is optimal.

Note that $\bar{c}_j = 0$ for every basic j , since $B^{-1} A_{B(i)} = e_i$ and $c_B \cdot e_i = c_{B(i)}$. So we only need to inspect the non-basic reduced costs.

The reduced costs have a direct meaning too, which tells us what to do when some of them are negative. Suppose j is non-basic and we try to increase x_j from 0 while keeping $Ax = b$. Formally, define the j th **basic direction** d by $d_j = 1$, $d_i = 0$ for all other non-basic i , and d_B determined by the requirement $Ad = 0$:

$$Bd_B + A_j = 0 \implies d_B = -B^{-1} A_j.$$

Then $A(x + \theta d) = b$ for all θ , and since $x_B > 0$ (non-degeneracy!) we have $x + \theta d \geq 0$ for all small enough $\theta > 0$. So d is a feasible direction. Its effect on the cost is

$$c \cdot (x + \theta d) = c \cdot x + \theta (c_j - c_B \cdot (B^{-1} A_j)) = c \cdot x + \theta \bar{c}_j.$$

So $\bar{c}_j$ is exactly the rate of change of the cost as we bring x_j into the solution. If $\bar{c}_j < 0$, moving in the j th basic direction reduces the cost, and we should do so as far as possible.

How far can we go? We need $x + \theta d \geq 0$. The non-basic coordinates are fine (x_j increases from 0, the others stay at 0). For the basic coordinates, writing $u = -d_B = B^{-1} A_j$, we need $x_{B(i)} - \theta u_i \geq 0$ for each i . If $u \leq 0$ this holds for all $\theta > 0$, and the cost is unbounded below. Otherwise the largest permissible step is

$$\theta^* = \min_{\{i: u_i > 0\}} \frac{x_{B(i)}}{u_i},$$

the so-called **ratio test**. Let ℓ attain the minimum. At $\theta = \theta^*$ the basic variable $x_{B(\ell)}$ becomes zero, so we have arrived at a new point with (again) m nonzero entries: x_j has entered the basis and $x_{B(\ell)}$ has left it.

Theorem 20.4.3

With the notation above, $y = x + \theta^* d$ is a basic feasible solution with basis obtained from B by replacing $A_{B(\ell)}$ with A_j , and $c \cdot y = c \cdot x + \theta^* \bar{c}_j < c \cdot x$.

Proof. We have $Ay = b$ and $y \geq 0$ by the choice of θ^* , and $y_{B(\ell)} = 0$ while $y_j = \theta^* > 0$, so exactly m entries are nonzero and they sit in the claimed positions. The cost formula was computed above, and $\theta^* > 0$, $\bar{c}_j < 0$ give the strict decrease. $\square$

Putting this together gives the algorithm.

Definition 20.4.4 (The Simplex Method)

To minimize $c \cdot x$ subject to $Ax = b$, $x \geq 0$:

- (1) Start at a basic feasible solution x with basis B .
- (2) Compute the reduced costs $\bar{c}$. If $\bar{c} \geq 0$, stop: x is optimal.
- (3) Otherwise choose j with $\bar{c}_j < 0$, and set $u = B^{-1}A_j$.
- (4) If $u \leq 0$, stop: the problem is unbounded.
- (5) Otherwise compute $\theta^* = \min\{x_{B(i)}/u_i : u_i > 0\}$, attained at $i = \ell$.
- (6) Replace $B(\ell)$ by j in the basis, update $x \mapsto x + \theta^* d$, and go to (2).

Since the cost strictly decreases at each step (under the non-degeneracy assumption) we never revisit a basis, and there are finitely many bases, so the algorithm terminates.

§20.4.2 The Simplex Tableau

Executing the algorithm as stated would require inverting B at every step, which is intolerable by hand. The **tableau** is a bookkeeping device that maintains all of the required quantities automatically using row operations.

Definition 20.4.5 (Simplex Tableau)

The **simplex tableau** for the basis B is the array

$-c_B \cdot x_B$	$\bar{c}^T$
$B^{-1}b$	$B^{-1}A$

or in more detail

$-c_B \cdot x_B$	$\bar{c}_1$	$\bar{c}_2$	$\cdots$	$\bar{c}_n$
$x_{B(1)}$	$\vdots$	$\vdots$		$\vdots$
$\vdots$	$B^{-1}A_1$	$B^{-1}A_2$	$\cdots$	$B^{-1}A_n$
$x_{B(m)}$	$\vdots$	$\vdots$		$\vdots$

So the top-left entry is minus the current cost, the top row holds the reduced costs, the

left column holds the current basic feasible solution, and the body holds $B^{-1}A$ – which is what the ratio test and basic directions need. Note that the basic columns of $B^{-1}A$ form an identity matrix, and the corresponding entries of the top row are zero; this is how we recognize the basis by looking at the tableau.

The remarkable fact – and it really is worth pausing over – is that the update in step (6) of the algorithm is achieved by pure Gaussian elimination on the tableau. The recipe is:

- (i) Choose a **pivot column** j with $\bar{c}_j < 0$.
- (ii) Choose the **pivot row** ℓ minimizing $x_{B(i)}/u_i$ among rows with $u_i > 0$, where u_i is the entry in row i of column j . The entry at (ℓ, j) is the **pivot**.
- (iii) Divide row ℓ by the pivot, then add multiples of row ℓ to every other row (including row 0) so that column j becomes the standard basis vector e_ℓ .

Why this works is not hard to see: multiplying on the left by $\bar{B}^{-1}B$ is exactly a sequence of row operations, and the row operations that turn column j into e_ℓ are precisely those which implement the change of basis.

Example 20.4.6

We solve

$$\begin{aligned} \text{minimize} \quad & -x_1 - x_2 - x_3 \\ \text{subject to} \quad & x_1 + 2x_2 + 2x_3 \leq 10, \\ & 2x_1 + x_2 + 2x_3 \leq 10, \\ & 2x_1 + 2x_2 + x_3 \leq 20, \\ & x_1, x_2, x_3 \geq 0. \end{aligned}$$

Adding slack variables $x_4, x_5, x_6 \geq 0$ puts this in standard form with

$$A = \begin{pmatrix} 1 & 2 & 2 & 1 & 0 & 0 \\ 2 & 1 & 2 & 0 & 1 & 0 \\ 2 & 2 & 1 & 0 & 0 & 1 \end{pmatrix}, \quad b = \begin{pmatrix} 10 \\ 10 \\ 20 \end{pmatrix}, \quad c = (-1, -1, -1, 0, 0, 0).$$

The slack variables give us a basic feasible solution for free: take $B = \{4, 5, 6\}$, so B is the identity matrix and $x = (0, 0, 0, 10, 10, 20)$. Since $c_B = 0$ we have $\bar{c} = c$ and cost 0, and the initial tableau is

0	-1	-1	-1	0	0	0
10	1	2	2	1	0	0
10	2	1	2	0	1	0
20	2	2	1	0	0	1

Since $\bar{c}_1 = -1 < 0$ we pivot in column 1. The ratios are $10/1 = 10$, $10/2 = 5$ and $20/2 = 10$, so the smallest is in row 2 and the pivot is the boxed 2. We perform

$$R_2 \mapsto \frac{1}{2}R_2, \quad R_0 \mapsto R_0 + \frac{1}{2}R_2^{\text{old}}, \quad R_1 \mapsto R_1 - \frac{1}{2}R_2^{\text{old}}, \quad R_3 \mapsto R_3 - R_2^{\text{old}},$$

obtaining

5	0	$-\frac{1}{2}$	0	0	$\frac{1}{2}$	0
5	0	$\frac{3}{2}$	1	1	$-\frac{1}{2}$	0
5	1	$\frac{1}{2}$	1	0	$\frac{1}{2}$	0
10	0	1	-1	0	-1	1

The basis is now $\{4, 1, 6\}$ and the current solution is $x = (5, 0, 0, 5, 0, 10)$ with cost -5 (remember the top-left entry is *minus* the cost).

Now $\bar{c}_2 = -\frac{1}{2} < 0$, so we pivot in column 2. The ratios are $5/\frac{3}{2} = \frac{10}{3}$, $5/\frac{1}{2} = 10$ and $10/1 = 10$, so we pivot on the boxed $\frac{3}{2}$ in row 1. We perform

$$R_1 \mapsto \frac{2}{3}R_1, \quad R_0 \mapsto R_0 + \frac{1}{3}R_1^{\text{old}}, \quad R_2 \mapsto R_2 - \frac{1}{3}R_1^{\text{old}}, \quad R_3 \mapsto R_3 - \frac{2}{3}R_1^{\text{old}},$$

giving

$\frac{20}{3}$	0	0	$\frac{1}{3}$	$\frac{1}{3}$	$\frac{1}{3}$	0
$\frac{10}{3}$	0	1	$\frac{2}{3}$	$\frac{2}{3}$	$-\frac{1}{3}$	0
$\frac{10}{3}$	1	0	$\frac{2}{3}$	$-\frac{1}{3}$	$\frac{2}{3}$	0
$\frac{20}{3}$	0	0	$-\frac{5}{3}$	$-\frac{2}{3}$	$-\frac{2}{3}$	1

Every reduced cost is now non-negative, so we are optimal. Reading off the basis $\{2, 1, 6\}$ and the left-hand column, the optimal solution is

$$x^* = \left(\frac{10}{3}, \frac{10}{3}, 0, 0, 0, \frac{20}{3}\right)$$

with optimal cost $-\frac{20}{3}$.

We get the dual solution for free as well: the reduced costs of the slack variables are $\bar{c}_4 = \bar{c}_5 = \frac{1}{3}$, $\bar{c}_6 = 0$, and since $\bar{c}_{n+i} = -\lambda_i$ for slack variable i when the slack columns start as the identity, we read off $\lambda = (-\frac{1}{3}, -\frac{1}{3}, 0)$. The third constraint has zero multiplier, which is consistent with the fact that $x_6 = \frac{20}{3} > 0$ – that constraint is slack at the optimum.

Example 20.4.7 (An Unbounded Problem)

Consider the problem: minimize $-x_1 - x_2$ subject to $x_1 - x_2 \leq 1$ and $x_1, x_2 \geq 0$. Adding a slack variable, the standard form has

$$A = \begin{pmatrix} 1 & -1 & 1 \end{pmatrix}, \quad b = (1), \quad c = (-1, -1, 0),$$

and the basis $B = \{3\}$ gives the initial tableau

0	-1	-1	0
1	1	-1	1

Both $\bar{c}_1$ and $\bar{c}_2$ are negative. If we choose the pivot column $j = 2$, then $u = B^{-1}A_2 = (-1) \leq 0$, so no ratio test is possible and the problem is unbounded. Sure enough, $x = (t, t, 1)$ is feasible for every $t \geq 0$ and has cost $-2t \rightarrow -\infty$: the feasible region contains the ray in the direction $(1, 1)$, along which the objective decreases forever.

Note that had we chosen the pivot column $j = 1$ instead, we would have pivoted (with $\theta^* = 1$) to the basis $\{1\}$ and only discovered the unboundedness at the next step. Unboundedness is a property of the problem, not of the pivoting rule; the algorithm will always find it eventually.

§20.4.3 Degeneracy and Bland's Rule

We have been assuming non-degeneracy throughout, and it is time to see what it was doing.

Definition 20.4.8 (Degeneracy)

A basic feasible solution is **degenerate** if it has fewer than m nonzero entries, so that some basic variable takes the value zero.

Geometrically, degeneracy happens when more than $n-m$ of the constraints pass through the same vertex, so that the vertex is described by more than one basis. In the tableau, degeneracy is visible as a zero in the left-hand column, or as a tie in the ratio test.

three constraints meeting at one vertex

If the ratio test is a tie, then θ^* may be zero: the pivot changes the basis but does *not* move the point. The cost then does not decrease, and it becomes possible in principle for the algorithm to return to a basis it has already visited, and loop forever. This is called **cycling**. It is rare in practice but it genuinely happens, and there are small explicit examples.

The fix is to break ties in a way that provably cannot cycle.

Definition 20.4.9 (Bland's Rule)

Bland's rule is to resolve both choices in the simplex method by smallest index:

- (i) among all j with $\bar{c}_j < 0$, choose the pivot column with the smallest index j ;
- (ii) among all rows attaining the minimum in the ratio test, choose the one whose *basic variable* $B(\ell)$ has the smallest index.

Theorem 20.4.10 (Bland)

The simplex method with Bland's rule terminates.

Proof sketch. Suppose the algorithm cycles. During a cycle the cost never changes, so every pivot has $\theta^* = 0$ and the point x is fixed throughout; let D be the set of

variables that enter and leave the basis during the cycle, and let q be the largest index in D . Consider the iteration at which q leaves the basis, say with entering variable $p \in D$ (so $p < q$), and the (later) iteration at which q enters. One shows by comparing the reduced costs at these two iterations that the choice of p at the first iteration and the choice of q at the second are inconsistent with the smallest-index rule: at the second iteration the variable p would still have had negative reduced cost, and $p < q$, so p would have been chosen instead of q . This contradiction shows no cycle can occur, and since there are finitely many bases the algorithm terminates. $\square$

An alternative and more common fix in practice is *lexicographic* pivoting, which amounts to perturbing b to $b + (\varepsilon, \varepsilon^2, \dots, \varepsilon^m)$ for a formal infinitesimal ε , thereby making every basic solution non-degenerate.

Remark (How fast is the simplex method?). We have shown that the simplex method terminates, but the bound we get is terrible: there are $\binom{n}{m}$ bases and in principle we might visit a large fraction of them. In fact Klee and Minty constructed, for each n , a linear program on a slightly squashed n -dimensional cube for which Dantzig's original pivoting rule visits all 2^n vertices. So the simplex method is not a polynomial-time algorithm, at least for that rule, and no pivoting rule is known to be polynomial.

Nevertheless the simplex method is superb in practice: on real problems it typically takes a number of pivots linear in m , and this behaviour can be made precise in various average-case and smoothed-analysis models. Meanwhile there *are* provably polynomial-time algorithms for linear programming – the ellipsoid method of Khachiyan and the interior point methods descended from Karmarkar's algorithm, which are essentially the barrier methods of Section 1.4 applied to linear constraints. Modern solvers implement both families and choose between them.

§20.4.4 The Two-Phase Simplex Method

There is one loose end: the simplex method has to start at a basic feasible solution, and in the example above we were handed one by the slack variables. That is a piece of luck peculiar to problems of the form $Ax \leq b$ with $b \geq 0$. In general – for instance with $\geq$ constraints, where the surplus variables would need to be negative – finding an initial bfs is itself a non-trivial problem.

The trick is that finding a feasible point is itself a linear program that we can solve by the simplex method, and *that* problem always has an obvious starting point. We introduce **artificial variables**.

Given the standard-form problem ‘minimize $c \cdot x$ subject to $Ax = b$, $x \geq 0$ ’, where without loss of generality $b \geq 0$ (multiply rows by -1 if needed), consider the auxiliary problem

$$\begin{aligned} \text{minimize} \quad & y_1 + \dots + y_m \\ \text{subject to} \quad & Ax + y = b, \\ & x, y \geq 0. \end{aligned}$$

This has the obvious basic feasible solution $x = 0$, $y = b$. Moreover its optimal value is 0 if and only if the original problem is feasible, and any solution with $y = 0$ gives a feasible x . So:

- **Phase I:** solve the auxiliary problem by the simplex method. If the optimal value is positive, the original problem is infeasible and we stop. Otherwise we finish with a basic feasible solution in which all the artificial variables are zero.
- **Phase II:** drop the artificial variables and the Phase I objective row, and run the simplex method on the original objective starting from the basis just found.

In practice we carry both objective rows through Phase I, so that the original objective row is correctly updated and ready for Phase II.

Example 20.4.11

Consider

$$\begin{aligned} &\text{minimize} && 6x_1 + 3x_2 \\ &\text{subject to} && x_1 + x_2 \geq 1, \\ &&& 2x_1 - x_2 \geq 1, \\ &&& 3x_2 \leq 2, \\ &&& x_1, x_2 \geq 0. \end{aligned}$$

Adding surplus variables z_1, z_2 and a slack z_3 ,

$$x_1 + x_2 - z_1 = 1, \quad 2x_1 - x_2 - z_2 = 1, \quad 3x_2 + z_3 = 2.$$

Setting $x = 0$ would force $z_1 = z_2 = -1$, which is infeasible, so we add artificial variables y_1, y_2 to the first two rows and minimize $y_1 + y_2$. The starting basis is $\{y_1, y_2, z_3\}$, giving the tableau (with the original objective in row 0 and the Phase I objective in row 0'):

	x_1	x_2	z_1	z_2	z_3	y_1	y_2
0	6	3	0	0	0	0	0
0	0	0	0	0	0	1	1
1	1	1	-1	0	0	1	0
1	2	-1	0	-1	0	0	1
2	0	3	0	0	1	0	0

This is not yet a valid tableau, because the reduced costs in the basic columns y_1, y_2 must be zero. Subtracting rows 1 and 2 from row 0' fixes this:

	x_1	x_2	z_1	z_2	z_3	y_1	y_2
0	6	3	0	0	0	0	0
-2	-3	0	1	1	0	0	0
1	1	1	-1	0	0	1	0
1	2	-1	0	-1	0	0	1
2	0	3	0	0	1	0	0

The Phase I cost is 2 (top-left of row 0' is -2). Pivoting on the boxed entry in

column x_1 (ratios $1/1 = 1$ and $1/2 = \frac{1}{2}$, the latter smaller):

	x_1	x_2	z_1	z_2	z_3	y_1	y_2
-3	0	6	0	3	0	0	-3
$-\frac{1}{2}$	0	$-\frac{3}{2}$	1	$-\frac{1}{2}$	0	0	$\frac{3}{2}$
$\frac{1}{2}$	0	$\frac{3}{2}$	-1	$\frac{1}{2}$	0	1	$-\frac{1}{2}$
$\frac{1}{2}$	1	$-\frac{1}{2}$	0	$-\frac{1}{2}$	0	0	$\frac{1}{2}$
2	0	3	0	0	1	0	0

Now $\bar{c}_{x_2} = -\frac{3}{2} < 0$ in the Phase I row. The ratios are $\frac{1/2}{3/2} = \frac{1}{3}$ and $2/3$, so we pivot on the boxed $\frac{3}{2}$:

	x_1	x_2	z_1	z_2	z_3	y_1	y_2
-5	0	0	4	1	0	-4	-1
0	0	0	0	0	0	1	1
$\frac{1}{3}$	0	1	$-\frac{2}{3}$	$\frac{1}{3}$	0	$\frac{2}{3}$	$-\frac{1}{3}$
$\frac{2}{3}$	1	0	$-\frac{1}{3}$	$-\frac{1}{3}$	0	$\frac{1}{3}$	$\frac{1}{3}$
1	0	0	2	-1	1	-2	1

The Phase I objective is now 0 and the artificial variables have left the basis, so Phase I is complete. Deleting the artificial columns and the Phase I row leaves

	x_1	x_2	z_1	z_2	z_3
-5	0	0	4	1	0
$\frac{1}{3}$	0	1	$-\frac{2}{3}$	$\frac{1}{3}$	0
$\frac{2}{3}$	1	0	$-\frac{1}{3}$	$-\frac{1}{3}$	0
1	0	0	2	-1	1

All reduced costs in row 0 are non-negative, so we are already optimal – Phase II has nothing to do. The optimal solution is $x_1 = \frac{2}{3}$, $x_2 = \frac{1}{3}$, $z_3 = 1$, with optimal cost $6 \cdot \frac{2}{3} + 3 \cdot \frac{1}{3} = 5$, which is consistent with the top-left entry -5 .

Remark. It can happen that Phase I terminates with optimal value 0 but with an artificial variable still in the basis (at value zero). This is a degenerate situation; one can always pivot it out on any nonzero entry in a non-artificial column, or if the whole row is zero, delete the row as redundant.

§20.4.5 The Dual Simplex Method

The simplex method as described maintains primal feasibility and complementary slackness at every step, and works towards dual feasibility. There is a mirror-image algorithm, the **dual simplex method**, which maintains *dual* feasibility and complementary slackness and works towards primal feasibility. In tableau terms: we start with a tableau whose row 0 is non-negative but whose left-hand column has some negative entries, and we pivot to remove the negative entries while keeping row 0 non-negative.

Definition 20.4.12 (Dual Simplex Method)

Given a tableau with $\bar{c} \geq 0$:

- (1) If $B^{-1}b \geq 0$, stop: the solution is primal feasible, and hence optimal.
- (2) Otherwise choose a **pivot row** ℓ with $(B^{-1}b)_\ell < 0$.
- (3) If every entry of row ℓ (in the body) is non-negative, stop: the primal is infeasible.
- (4) Otherwise choose the **pivot column** j minimizing $|\bar{c}_j/a_{\ell j}|$ over all j with $a_{\ell j} < 0$.
- (5) Pivot on the entry $a_{\ell j}$ as usual, and go to (1).

The ratio test in step (4) is exactly what is needed to keep row 0 non-negative: after pivoting, $\bar{c}_k$ becomes $\bar{c}_k - (\bar{c}_j/a_{\ell j})a_{\ell k}$, and one checks that the minimizing choice keeps all of these non-negative. Notice that the roles of rows and columns, and of the two feasibility conditions, have swapped relative to the primal simplex method – which is precisely what one would expect from the fact that the dual of the dual is the primal.

The dual simplex method is extremely useful when we have already solved a problem and then change b (for instance by adding a new constraint). The old solution stays dual feasible but may become primal infeasible, so we can restart from it with the dual simplex method rather than solving from scratch.

Example 20.4.13

Consider

$$\begin{aligned} \text{minimize} \quad & 2x_1 + 3x_2 \\ \text{subject to} \quad & x_1 + x_2 \geq 2, \\ & x_1 + 3x_2 \geq 3, \\ & x_1, x_2 \geq 0. \end{aligned}$$

Subtracting surplus variables and then multiplying both constraint rows by -1 to make the slack variables basic, we get $-x_1 - x_2 + z_1 = -2$ and $-x_1 - 3x_2 + z_2 = -3$ with $z_1, z_2 \geq 0$, and the basis $\{z_1, z_2\}$ gives the tableau

	x_1	x_2	z_1	z_2
0	2	3	0	0
-2	-1	-1	1	0
-3	-1	-3	0	1

Row 0 is non-negative (dual feasible) but the left column is not (primal infeasible), so we use the dual simplex method. The most negative entry is -3 in row 2, so we take $\ell = 2$. The ratios $|\bar{c}_j/a_{2j}|$ for the negative entries of that row are $|2/(-1)| = 2$

and $|3/(-3)| = 1$, so we pivot on the boxed -3 in column x_2 :

	x_1	x_2	z_1	z_2
-3	1	0	0	1
-1	$-\frac{2}{3}$	0	1	$-\frac{1}{3}$
1	$\frac{1}{3}$	1	0	$-\frac{1}{3}$

Still one negative entry in the left column, so $\ell = 1$. The negative entries in that row are $-\frac{2}{3}$ in column x_1 and $-\frac{1}{3}$ in column z_2 , with ratios $|1/(-\frac{2}{3})| = \frac{3}{2}$ and $|1/(-\frac{1}{3})| = 3$; so we pivot on the boxed $-\frac{2}{3}$:

	x_1	x_2	z_1	z_2
$-\frac{9}{2}$	0	0	$\frac{3}{2}$	$\frac{1}{2}$
$\frac{3}{2}$	1	0	$-\frac{3}{2}$	$\frac{1}{2}$
$\frac{1}{2}$	0	1	$\frac{1}{2}$	$-\frac{1}{2}$

Now both the left column and row 0 are non-negative, so we have an optimal solution $x^* = (\frac{3}{2}, \frac{1}{2})$ with optimal cost $\frac{9}{2}$. Note that we never needed a Phase I.

§20.5 Network Problems

A great many of the linear programs that arise in practice have a very particular shape: the variables are indexed by the edges of a graph, and the constraints say that whatever flows into a vertex must flow out of it again. These are the **network flow** problems. They are important both because they model an enormous range of real situations – shipping goods, routing traffic, scheduling, matching – and because their special structure lets us solve them far more efficiently than by general-purpose simplex.

§20.5.1 Flows in Networks

Definition 20.5.1 (Directed Graph)

A **directed graph** (or **digraph**) is a pair $G = (V, E)$ where V is a finite set of **vertices** and $E \subseteq V \times V$ is a set of **edges**. We think of $(i, j) \in E$ as an arrow from i to j .

Definition 20.5.2 (Flow)

Let $G = (V, E)$ be a digraph on n vertices. A **flow** on G is an assignment of a real number x_{ij} to each edge $(i, j) \in E$, thought of as the amount of some commodity travelling along that edge. The flow is subject to:

- a vector $b \in \mathbb{R}^n$, where b_i is the amount injected into the network at vertex i from outside. If $b_i > 0$ we call i a **source** and if $b_i < 0$ a **sink**;
- a **cost** c_{ij} per unit of flow along (i, j) ;
- capacities $\underline{m}_{ij} \leq x_{ij} \leq \overline{m}_{ij}$ on each edge.

Definition 20.5.3 (Minimum Cost Flow)

The **minimum cost flow problem** is the linear program

$$\begin{aligned} & \text{minimize} && \sum_{(i,j) \in E} c_{ij} x_{ij} \\ & \text{subject to} && b_i + \sum_{j: (j,i) \in E} x_{ji} = \sum_{j: (i,j) \in E} x_{ij} \quad \text{for all } i \in V, \\ & && \underline{m}_{ij} \leq x_{ij} \leq \overline{m}_{ij} \quad \text{for all } (i,j) \in E. \end{aligned}$$

The first family of constraints is **conservation of flow**: what goes in must come out.

Summing the conservation equations over all i , every x_{ij} appears once on each side, so we get $\sum_i b_i = 0$. This is a necessary condition for feasibility, and it is obvious: the network has no storage, so the total injected must equal the total removed.

The conservation constraints can be written compactly.

Definition 20.5.4 (Incidence Matrix)

The **incidence matrix** of G is the matrix $A \in \mathbb{R}^{|V| \times |E|}$ whose column indexed by the edge (i,j) has $+1$ in row i , -1 in row j , and zeros elsewhere.

With this notation the conservation constraints are exactly $Ax = b$, and the minimum cost flow problem is a linear program in the (almost) standard form we have been studying. What makes network problems special is that A is a very sparse matrix with entries in $\{0, \pm 1\}$, and this has strong consequences – notably, if b and the capacities are integers then there is an integral optimal solution.

§20.5.2 The Transportation Problem

The most important special case is when the graph is bipartite.

Definition 20.5.5 (Transportation Problem)

Suppose we have n suppliers, where supplier i has s_i units available, and m consumers, where consumer j demands d_j units, with $\sum_i s_i = \sum_j d_j$. Shipping one unit from i to j costs c_{ij} . The **transportation problem** is

$$\begin{aligned} & \text{minimize} && \sum_{i=1}^n \sum_{j=1}^m c_{ij} x_{ij} \\ & \text{subject to} && \sum_{j=1}^m x_{ij} = s_i \quad \text{for } i = 1, \dots, n, \\ & && \sum_{i=1}^n x_{ij} = d_j \quad \text{for } j = 1, \dots, m, \\ & && x \geq 0. \end{aligned}$$

This looks like a special case, but it is in fact completely general.

Theorem 20.5.6

Every minimum cost flow problem with finite capacities, or with non-negative costs, is equivalent to a transportation problem.

Proof. First we normalize. We may assume $\underline{m}_{ij} = 0$ for all edges: substituting $x_{ij} = \underline{m}_{ij} + \tilde{x}_{ij}$ turns the constraint into $0 \leq \tilde{x}_{ij} \leq \overline{m}_{ij} - \underline{m}_{ij}$ and the conservation equations into the same equations with

$$\tilde{b}_i = b_i + \sum_{j: (j,i) \in E} \underline{m}_{ji} - \sum_{j: (i,j) \in E} \underline{m}_{ij}.$$

(We are just secretly shipping the minimum amount along each edge before we start.) Next, if some capacity is infinite but all costs are non-negative, we may replace it by $\sum_i |b_i|$, since no optimal solution ever ships more than this along any edge (it would have to run round a cycle, and cycles cost nothing to remove when costs are non-negative). So assume all capacities are finite.

Now build a transportation problem. For each *vertex* i of the original graph, create a consumer with demand

$$\sum_{k: (i,k) \in E} \overline{m}_{ik} - b_i.$$

For each *edge* (i, j) of the original graph, create a supplier with supply $\overline{m}_{ij}$, joined to consumer i at cost 0 and to consumer j at cost c_{ij} .

Total supply is $\sum_{(i,j)} \overline{m}_{ij}$, and total demand is $\sum_i (\sum_k \overline{m}_{ik} - b_i) = \sum_{(i,j)} \overline{m}_{ij}$ since $\sum_i b_i = 0$; so the transportation problem is balanced.

Given a flow x in the original network, ship x_{ij} from supplier (i, j) to consumer j and the remaining $\overline{m}_{ij} - x_{ij}$ to consumer i . Then supplier (i, j) 's supply is exactly used up, and $0 \leq x_{ij} \leq \overline{m}_{ij}$ is exactly the requirement that both shipments are

non-negative. The total received by consumer i is

$$\sum_{k: (i,k) \in E} (\bar{m}_{ik} - x_{ik}) + \sum_{k: (k,i) \in E} x_{ki},$$

and setting this equal to the demand $\sum_k \bar{m}_{ik} - b_i$ rearranges precisely to the conservation equation at i . Finally, the cost of the transportation solution is $\sum_{(i,j)} c_{ij} x_{ij}$, since the edges into consumer i are free. So the two problems are equivalent. $\square$

§20.5.3 Optimality for the Transportation Problem

The transportation problem is a linear program, so we know exactly what optimality means: primal feasibility, dual feasibility and complementary slackness. Let us compute what these say. Since there are two families of constraints, we take two families of multipliers: $\lambda \in \mathbb{R}^n$ for the suppliers and $\mu \in \mathbb{R}^m$ for the consumers. The Lagrangian is

$$\begin{aligned} L(x, \lambda, \mu) &= \sum_{i,j} c_{ij} x_{ij} - \sum_i \lambda_i \left(\sum_j x_{ij} - s_i \right) - \sum_j \mu_j \left(\sum_i x_{ij} - d_j \right) \\ &= \sum_{i,j} (c_{ij} - \lambda_i - \mu_j) x_{ij} + \sum_i \lambda_i s_i + \sum_j \mu_j d_j. \end{aligned}$$

Since $x \geq 0$, this has a finite infimum exactly when $c_{ij} - \lambda_i - \mu_j \geq 0$ for all i, j .

Theorem 20.5.7 (Optimality Conditions)

A feasible x is optimal for the transportation problem if there exist $\lambda \in \mathbb{R}^n$, $\mu \in \mathbb{R}^m$ with

- (i) $\lambda_i + \mu_j \leq c_{ij}$ for all (i, j) (dual feasibility)
- (ii) $(c_{ij} - \lambda_i - \mu_j) x_{ij} = 0$ for all (i, j) (complementary slackness)

Proof. Immediate from the general optimality conditions for a linear program, applied to the Lagrangian above. $\square$

Condition (ii) says: wherever we actually ship something, the dual constraint is tight. Note that the multipliers are not unique – adding a constant k to every λ_i and subtracting it from every μ_j changes nothing. We therefore normalize by setting $\lambda_1 = 0$, which leaves $m + n - 1$ unknowns.

To get started we need an initial basic feasible solution, and here there is a very simple recipe: the **north-west corner rule**. Start at the top-left cell of the table, ship as much as possible (the smaller of the remaining supply and remaining demand), cross off whichever of the row or column is exhausted, and repeat.

Theorem 20.5.8

The set of cells with $x_{ij} > 0$ in a basic feasible solution of the transportation problem forms a spanning tree of the bipartite graph, and hence contains exactly $m + n - 1$ cells.

We will not prove this, but it is easy to believe: there are $m + n$ constraints of which

one is redundant (because $\sum s_i = \sum d_j$), so a basis has $m + n - 1$ elements; and a set of edges with no cycle and $m + n - 1$ elements on $m + n$ vertices is a spanning tree. The practical consequence is that the equations $\lambda_i + \mu_j = c_{ij}$ over the basic cells, together with $\lambda_1 = 0$, always have a unique solution – we can propagate along the tree.

§20.5.4 The Transportation Algorithm

We record the data in a **transportation tableau**, one cell per (i, j) , showing the current flow x_{ij} , the cost c_{ij} and the quantity $\lambda_i + \mu_j$, with the supplies down the right, the demands along the bottom, and λ, μ in the margins. The algorithm is then:

- (1) Find an initial basic feasible solution (e.g. by the north-west corner rule).
- (2) Solve $\lambda_i + \mu_j = c_{ij}$ over the basic cells, with $\lambda_1 = 0$.
- (3) If $\lambda_i + \mu_j \leq c_{ij}$ for every cell, stop – the solution is optimal.
- (4) Otherwise pick a cell (i, j) with $\lambda_i + \mu_j > c_{ij}$. Adding (i, j) to the spanning tree creates a unique cycle. Send θ units around this cycle (alternately $+\theta$ and $-\theta$), increasing θ until some basic cell is driven to zero. That cell leaves the basis and (i, j) enters.
- (5) Go to (2).

This is exactly the simplex method in disguise: step (3) is the check $\bar{c} \geq 0$, and step (4) is the ratio test.

Example 20.5.9

Take three suppliers with $s = (14, 10, 9)$ and four consumers with $d = (12, 5, 8, 8)$, and costs

$$C = \begin{pmatrix} 5 & 3 & 4 & 6 \\ 2 & 7 & 4 & 1 \\ 5 & 6 & 2 & 4 \end{pmatrix}.$$

The north-west corner rule gives

$$x = \begin{pmatrix} 12 & 2 & 0 & 0 \\ 0 & 3 & 7 & 0 \\ 0 & 0 & 1 & 8 \end{pmatrix},$$

with basic cells $(1, 1), (1, 2), (2, 2), (2, 3), (3, 3), (3, 4)$ – six of them, as promised. Complementary slackness gives

$$\lambda_1 + \mu_1 = 5, \quad \lambda_1 + \mu_2 = 3, \quad \lambda_2 + \mu_2 = 7, \quad \lambda_2 + \mu_3 = 4, \quad \lambda_3 + \mu_3 = 2, \quad \lambda_3 + \mu_4 = 4,$$

which with $\lambda_1 = 0$ solves to

$$\lambda = (0, 4, 2), \quad \mu = (5, 3, 0, 2).$$

It is convenient to record all of this in a single tableau, with the multipliers in the margins and each cell showing the current flow and the cost, written $x_{ij} | c_{ij}$:

	$\mu_1 = 5$	$\mu_2 = 3$	$\mu_3 = 0$	$\mu_4 = 2$	s_i
$\lambda_1 = 0$	12 5	2 3	0 4	0 6	14
$\lambda_2 = 4$	0 2	3 7	7 4	0 1	10
$\lambda_3 = 2$	0 5	0 6	1 2	8 4	9
d_j	12	5	8	8	

One checks at a glance that the rows sum to the supplies and the columns to the demands. Now we tabulate $\lambda_i + \mu_j$ against c_{ij} :

$\lambda_i + \mu_j$	$\mu_1 = 5$	$\mu_2 = 3$	$\mu_3 = 0$	$\mu_4 = 2$
$\lambda_1 = 0$	5 (5)	3 (3)	0 (4)	2 (6)
$\lambda_2 = 4$	9 (2)	7 (7)	4 (4)	6 (1)
$\lambda_3 = 2$	7 (5)	5 (6)	2 (2)	4 (4)

(costs c_{ij} in brackets). Cell (2, 1) violates the condition badly: $9 > 2$. Cell (2, 4) also violates it, as does (3, 1); we pick (2, 1).

Adding (2, 1) to the tree creates the cycle $(2, 1) \rightarrow (1, 1) \rightarrow (1, 2) \rightarrow (2, 2) \rightarrow (2, 1)$. Putting θ into (2, 1) forces $x_{11} \mapsto 12 - \theta$, $x_{12} \mapsto 2 + \theta$ and $x_{22} \mapsto 3 - \theta$. The binding constraint is $x_{22} \geq 0$, so $\theta = 3$ and cell (2, 2) leaves. The new solution is

$$x = \begin{pmatrix} 9 & 5 & 0 & 0 \\ 3 & 0 & 7 & 0 \\ 0 & 0 & 1 & 8 \end{pmatrix},$$

with basic cells (1, 1), (1, 2), (2, 1), (2, 3), (3, 3), (3, 4). Re-solving for the multipliers,

$$\lambda_1 + \mu_1 = 5, \lambda_1 + \mu_2 = 3, \lambda_2 + \mu_1 = 2, \lambda_2 + \mu_3 = 4, \lambda_3 + \mu_3 = 2, \lambda_3 + \mu_4 = 4,$$

giving $\lambda = (0, -3, -5)$ and $\mu = (5, 3, 7, 9)$. Checking again:

$\lambda_i + \mu_j$	$\mu_1 = 5$	$\mu_2 = 3$	$\mu_3 = 7$	$\mu_4 = 9$
$\lambda_1 = 0$	5 (5)	3 (3)	7 (4)	9 (6)
$\lambda_2 = -3$	2 (2)	0 (7)	4 (4)	6 (1)
$\lambda_3 = -5$	0 (5)	-2 (6)	2 (2)	4 (4)

Now (2, 4) violates: $6 > 1$. (So does (1, 3) and (1, 4).) Taking (2, 4), the cycle is $(2, 4) \rightarrow (2, 3) \rightarrow (3, 3) \rightarrow (3, 4) \rightarrow (2, 4)$, so $x_{23} \mapsto 7 - \theta$, $x_{33} \mapsto 1 + \theta$, $x_{34} \mapsto 8 - \theta$. The binding constraint is $x_{23} \geq 0$ at $\theta = 7$, giving

$$x = \begin{pmatrix} 9 & 5 & 0 & 0 \\ 3 & 0 & 0 & 7 \\ 0 & 0 & 8 & 1 \end{pmatrix}.$$

The new multipliers solve to $\lambda = (0, -3, 0)$ and $\mu = (5, 3, 2, 4)$, and now

$\lambda_i + \mu_j$	$\mu_1 = 5$	$\mu_2 = 3$	$\mu_3 = 2$	$\mu_4 = 4$
$\lambda_1 = 0$	5 (5)	3 (3)	2 (4)	4 (6)
$\lambda_2 = -3$	2 (2)	0 (7)	-1 (4)	1 (1)
$\lambda_3 = 0$	5 (5)	3 (6)	2 (2)	4 (4)

Every entry satisfies $\lambda_i + \mu_j \leq c_{ij}$, so we are optimal. The cost is

$$9 \cdot 5 + 5 \cdot 3 + 3 \cdot 2 + 7 \cdot 1 + 8 \cdot 2 + 1 \cdot 4 = 45 + 15 + 6 + 7 + 16 + 4 = 93.$$

Remark (Transshipment). A variant that often occurs is the **transshipment problem**, in which goods may pass through intermediate depots rather than going directly from supplier to consumer. Formally this is just a minimum cost flow problem on a graph with some vertices having $b_i = 0$, and by the reduction theorem above it can be converted into a transportation problem. In practice a slicker route is available: replace each cost c_{ij} by the cost $\hat{c}_{ij}$ of the *cheapest path* from i to j in the network (computable by any shortest-path algorithm), and then solve the resulting transportation problem with costs $\hat{c}$. Any optimal solution of that problem is realized by routing each shipment along its cheapest path.

§20.5.5 The Assignment Problem

A further special case, and one of the classics, is the following.

Definition 20.5.10 (Assignment Problem)

Given n workers and n jobs, and a cost c_{ij} of assigning worker i to job j , the **assignment problem** is to find a bijection σ from workers to jobs minimizing $\sum_i c_{i\sigma(i)}$.

Written as an optimization over $\{0, 1\}$ -matrices this is a combinatorial problem with $n!$ candidates, which sounds hopeless. But it is exactly a transportation problem with $s_i = d_j = 1$ for all i, j :

$$\begin{aligned} &\text{minimize} && \sum_{i,j} c_{ij} x_{ij} \\ &\text{subject to} && \sum_j x_{ij} = 1 \text{ for each } i, \quad \sum_i x_{ij} = 1 \text{ for each } j, \quad x \geq 0. \end{aligned}$$

The feasible set of this linear program consists of the *doubly stochastic* matrices, and the corresponding combinatorial problem is recovered by the following classical fact, which we quote.

Theorem 20.5.11 (Birkhoff–von Neumann)

The extreme points of the set of doubly stochastic $n \times n$ matrices are exactly the permutation matrices.

Combining this with the fundamental theorem of linear programming, some optimal solution of the linear program is an extreme point, hence a permutation matrix, hence

an honest assignment. So we may simply solve the transportation problem and read off the answer – an $n!$ -sized search has been replaced by a polynomial-time algorithm. This phenomenon, where the linear relaxation of an integer problem automatically has integral optima, is exactly what makes network problems so tractable, and it recurs in the maximum flow problem below.

§20.5.6 The Maximum Flow Problem

We now turn to a different, and in some ways more fundamental, network problem. There are no costs; instead every edge has a capacity, there is a single source (vertex 1) and a single sink (vertex n), and we want to push as much as possible from source to sink.

Definition 20.5.12 (Maximum Flow Problem)

Given a digraph $G = (V, E)$ on vertices $\{1, \dots, n\}$ with capacities $c_{ij} \geq 0$, the **maximum flow problem** is

$$\begin{aligned} & \text{maximize} && \delta \\ & \text{subject to} && \sum_{j: (i,j) \in E} x_{ij} - \sum_{j: (j,i) \in E} x_{ji} = \begin{cases} \delta & i = 1 \\ -\delta & i = n \\ 0 & \text{otherwise,} \end{cases} \\ & && 0 \leq x_{ij} \leq c_{ij} \quad \text{for all } (i,j) \in E. \end{aligned}$$

We call δ the **value** of the flow.

This is a minimum cost flow problem in disguise: add an edge from n back to 1 with cost -1 and infinite capacity, and set all $b_i = 0$; then minimizing the cost is the same as maximizing the flow round the added edge, which is δ . But there is a much better way to think about it.

Definition 20.5.13 (Cut)

A **cut** of G is a partition of V into two sets $(S, V \setminus S)$. Its **capacity** is

$$C(S) = \sum_{\substack{(i,j) \in E \\ i \in S, j \in V \setminus S}} c_{ij},$$

the total capacity of the edges crossing from S to $V \setminus S$.

The following inequality is the easy half of the story: no flow can beat any cut.

Proposition 20.5.14

Let x be a feasible flow with value δ , and let $(S, V \setminus S)$ be any cut with $1 \in S$ and $n \in V \setminus S$. Then $\delta \leq C(S)$.

Proof. For $X, Y \subseteq V$ write $f_x(X, Y) = \sum_{(i,j) \in E, i \in X, j \in Y} x_{ij}$ for the total flow from X to Y . Summing the conservation equations over $i \in S$, all terms vanish except the one at $i = 1$, so

$$\delta = \sum_{i \in S} \left(\sum_{j: (i,j) \in E} x_{ij} - \sum_{j: (j,i) \in E} x_{ji} \right) = f_x(S, V) - f_x(V, S).$$

Splitting V as $S \cup (V \setminus S)$ in both terms, the $f_x(S, S)$ contributions cancel, leaving

$$\delta = f_x(S, V \setminus S) - f_x(V \setminus S, S) \leq f_x(S, V \setminus S) \leq C(S),$$

using $f_x(V \setminus S, S) \geq 0$ and $x_{ij} \leq c_{ij}$. $\square$

The remarkable fact is that this bound is always attained: some cut is exactly as good as the best flow. This is a theorem of Ford and Fulkerson, and it is a beautiful example of strong duality in a combinatorial setting – the maximum flow problem and the minimum cut problem are dual to each other.

Definition 20.5.15 (Augmenting Path)

Let x be a feasible flow. A path $v_0, v_1, \dots, v_k$ in the *undirected* sense – so consecutive vertices are joined by an edge in one direction or the other – is an **augmenting path** if

- $x_{v_i v_{i+1}} < c_{v_i v_{i+1}}$ for every edge traversed forwards, and
- $x_{v_{i+1} v_i} > 0$ for every edge traversed backwards.

The point is that along such a path we can increase the flow by some $\varepsilon > 0$ on the forward edges and decrease it by ε on the backward edges, and conservation still holds at every intermediate vertex. So if there is an augmenting path from 1 to n , the flow value can be increased and x was not optimal.

augmenting path 1, a, d, n

Theorem 20.5.16 (Max-Flow Min-Cut)

The maximum value of a feasible flow equals the minimum capacity of a cut separating 1 from n :

$$\delta^* = \min\{C(S) : S \subseteq V, 1 \in S, n \in V \setminus S\}.$$

Proof. By the proposition, $\delta^* \leq C(S)$ for every such cut, so it is enough to exhibit a cut with $C(S) = \delta^*$.

Let x be an optimal flow, and define

$$S = \{1\} \cup \{i \in V : \text{there is an augmenting path from 1 to } i\}.$$

Since x is optimal there is no augmenting path from 1 to n , so $n \notin S$ and $(S, V \setminus S)$ is a cut separating 1 from n . From the proof of the proposition,

$$\delta^* = f_x(S, V \setminus S) - f_x(V \setminus S, S),$$

and we claim both terms take their extreme values.

First, $f_x(V \setminus S, S) = 0$. Indeed, suppose $(v, u) \in E$ with $v \in V \setminus S$, $u \in S$ and $x_{vu} > 0$. Then we may extend an augmenting path from 1 to u by traversing (v, u) backwards, obtaining an augmenting path from 1 to v ; so $v \in S$, a contradiction.

Second, $f_x(S, V \setminus S) = C(S)$. Indeed, suppose $(u, v) \in E$ with $u \in S$, $v \in V \setminus S$ and $x_{uv} < c_{uv}$. Then we may extend an augmenting path from 1 to u by traversing (u, v) forwards, so $v \in S$, again a contradiction. Hence every edge from S to $V \setminus S$ is saturated.

Therefore $\delta^* = C(S) - 0 = C(S)$, as required. $\square$

Notice that the proof is constructive: it tells us that if we cannot find an augmenting path, we are done, and it even hands us the certifying cut. This is the algorithm.

Definition 20.5.17 (Ford–Fulkerson Algorithm)

To find a maximum flow:

- (1) Start from any feasible flow, e.g. $x = 0$.
- (2) Search for an augmenting path from 1 to n . If there is none, stop – x is optimal.
- (3) Increase the flow along the path by as much as possible (the smallest of $c_{ij} - x_{ij}$ over forward edges and x_{ji} over backward edges), and go to (2).

The bookkeeping is easiest with the **residual network**: for each edge (i, j) we record a forward residual capacity $c_{ij} - x_{ij}$ and a backward residual capacity x_{ij} . An augmenting path is then just an ordinary directed path in the residual network, and the amount we can push is the smallest residual capacity along it.

**Example 20.5.18**

Consider the network drawn above, with capacities

$$c_{1a} = 5, \quad c_{ab} = 1, \quad c_{bn} = 5, \quad c_{1c} = 5, \quad c_{cd} = 2, \quad c_{dn} = 5, \quad c_{ad} = 4,$$

and start with $x = 0$.

- (i) The path $1, a, b, n$ is augmenting; the bottleneck is $c_{ab} = 1$, so we send 1 unit. Now $x_{1a} = x_{ab} = x_{bn} = 1$ and $\delta = 1$.
- (ii) The path $1, a, d, n$ is augmenting; the bottleneck is $c_{1a} - x_{1a} = 4$, so we send 4 units. Now $x_{1a} = 5$, $x_{ad} = 4$, $x_{dn} = 4$ and $\delta = 5$.
- (iii) The path $1, c, d, n$ is augmenting; the bottleneck is $c_{dn} - x_{dn} = 1$, so we send 1 unit. Now $x_{1c} = x_{cd} = 1$, $x_{dn} = 5$ and $\delta = 6$.

The final flow is $x_{1a} = 5$, $x_{ab} = 1$, $x_{bn} = 1$, $x_{ad} = 4$, $x_{1c} = 1$, $x_{cd} = 1$, $x_{dn} = 5$.

To see that this is optimal we compute the set S of vertices reachable from 1 by an augmenting path. The edge $1a$ is saturated, so a is not reachable that way; but $x_{1c} = 1 < 5$, so $c \in S$. From c , $x_{cd} = 1 < 2$, so $d \in S$. From d , the edge dn is saturated, but the edge ad carries flow $4 > 0$, so traversing it *backwards* puts $a \in S$. From a , the edge ab is saturated, so we get nothing new. Hence

$$S = \{1, a, c, d\},$$

and $n \notin S$, so this is a genuine cut. Its capacity is the total capacity of edges leaving S , namely ab and dn :

$$C(S) = c_{ab} + c_{dn} = 1 + 5 = 6 = \delta^*,$$

confirming optimality.

Remark. Finding the cut requires a little care: S consists of everything reachable by an augmenting path, and augmenting paths may traverse edges backwards, so one must chase the reachability to the end. When Ford–Fulkerson stops, the set of reachable vertices is automatically a minimum cut – that is exactly what the proof of the max-flow min-cut theorem showed.

Example 20.5.19

Here is a larger example in which a backward edge is genuinely needed. Take vertices $1, a, b, c, d, n$ with capacities

$$c_{1a} = 10, \quad c_{1c} = 10, \quad c_{ab} = 4, \quad c_{ac} = 2, \quad c_{ad} = 8, \quad c_{bn} = 10, \quad c_{cd} = 9, \quad c_{db} = 6, \quad c_{dn} = 10,$$

starting from $x = 0$.

- (i) Augment along $1, a, d, n$ by $\min(10, 8, 10) = 8$. Now $\delta = 8$, with $x_{1a} = 8$, $x_{ad} = 8$ (saturated) and $x_{dn} = 8$.
- (ii) Augment along $1, c, d, n$ by $\min(10, 9, 2) = 2$. Now $\delta = 10$, with $x_{1c} = 2$, $x_{cd} = 2$ and $x_{dn} = 10$ (saturated).
- (iii) Augment along $1, c, d, b, n$ by $\min(8, 7, 6, 10) = 6$. Now $\delta = 16$, with $x_{1c} = 8$, $x_{cd} = 8$, $x_{db} = 6$ (saturated) and $x_{bn} = 6$.
- (iv) Augment along $1, a, b, n$ by $\min(2, 4, 4) = 2$, the bottleneck being $c_{1a} - x_{1a} = 2$. Now $\delta = 18$, with $x_{1a} = 10$ (saturated), $x_{ab} = 2$ and $x_{bn} = 8$.

At this stage the only unsaturated edge out of 1 is $1c$, so $c \in S$; from c we have $x_{cd} = 8 < 9$, so $d \in S$; from d both dn and db are saturated, but $x_{ad} = 8 > 0$ so traversing ad backwards gives $a \in S$; from a we have $x_{ab} = 2 < 4$, so $b \in S$; and from b we have $x_{bn} = 8 < 10$, so $n \in S$. So we have found an augmenting path,

$$1 \rightarrow c \rightarrow d \xrightarrow{\text{backwards}} a \rightarrow b \rightarrow n,$$

with bottleneck $\min(2, 1, 8, 2, 2) = 1$, coming from the edge cd . Augmenting by 1 (and remembering to *decrease* x_{ad}) gives $\delta = 19$ and

$$x_{1a} = 10, x_{1c} = 9, x_{ab} = 3, x_{ac} = 0, x_{ad} = 7, x_{cd} = 9, x_{db} = 6, x_{bn} = 9, x_{dn} = 10.$$

Now $1a$ is saturated and $x_{1c} = 9 < 10$, so $c \in S$; but from c the edge cd is saturated and the only other edge at c is ac , which carries no flow. So $S = \{1, c\}$, and

$$C(S) = c_{1a} + c_{cd} = 10 + 9 = 19 = \delta^*.$$

So the flow of 19 is optimal, certified by the cut $\{1, c\}$. Notice that without the backward step in the fifth augmentation we would have stopped at $\delta = 18$: the flow of 8 units sent from a to d in step (i) was, with hindsight, a mistake, and the backward edge is precisely the mechanism by which the algorithm undoes it.

Theorem 20.5.20 (Termination)

If all capacities are integers, then the Ford–Fulkerson algorithm terminates in finitely many steps, and the maximum flow is integral.

Proof. If x is integral, then the bottleneck along any augmenting path is a positive integer, so the augmented flow is integral and the value increases by at least 1. Since δ is bounded above by the capacity of any cut, only finitely many augmentations can occur. Starting from $x = 0$, which is integral, the result follows. $\square$

The same argument works for rational capacities (clear denominators). For irrational capacities, the algorithm can in principle fail to terminate if the augmenting paths are chosen badly – choosing shortest augmenting paths always works, and gives the Edmonds–Karp algorithm.

§20.5.7 An Application: Bipartite Matching

The integrality in the theorem above is what makes max-flow such a powerful combinatorial tool: it turns questions about $\{0, 1\}$ -valued combinatorial objects into questions about flows.

Theorem 20.5.21

Every k -regular bipartite graph has a perfect matching.

Proof. Let G be a bipartite graph with parts L and R each of size N , with every vertex having degree k . (The parts have equal size because counting edges gives $k|L| = |E| = k|R|$.) Build a flow network: add a source 1 joined to every vertex of L with capacity 1 , add a sink n joined from every vertex of R with capacity 1 , and direct every edge of G from L to R with capacity 1 .

The cut $S = \{1\}$ has capacity N , so $\delta^* \leq N$. On the other hand, sending $1/k$ along every edge of G and 1 along every edge from the source and to the sink gives a feasible flow of value N (each vertex of L receives 1 and sends out $k \cdot \frac{1}{k} = 1$). So $\delta^* = N$.

By the previous theorem, since all capacities are integers, there is an *integral* flow of value N . Every edge then carries flow 0 or 1 , and every vertex of L has exactly one outgoing edge with flow 1 (it receives exactly 1 from the source), and similarly every vertex of R has exactly one incoming edge with flow 1 . The edges carrying flow 1 therefore form a perfect matching. $\square$

Remark. The same technique proves Hall's marriage theorem: a bipartite graph with parts L, R has a matching saturating L if and only if $|N(A)| \geq |A|$ for every $A \subseteq L$. One shows that a cut of capacity less than $|L|$ in the network above corresponds exactly to a violating set A , and then applies max-flow min-cut.

§20.6 Game Theory

We close with a topic that at first sight has nothing to do with optimization: what should you do when the thing you are optimizing against is another person, who is optimizing against you? The answer, remarkably, is that a two-player zero-sum game is exactly a pair of dual linear programs, and the fundamental theorem of such games – the minimax theorem – is exactly strong duality. This is one of the most satisfying appearances of the theory we have built.

§20.6.1 Two-Player Zero-Sum Games

Definition 20.6.1 (Zero-Sum Game)

A **two-person zero-sum game** consists of two players, P_1 and P_2 , with m and n available actions respectively, and a **payoff matrix** $A \in \mathbb{R}^{m \times n}$. If P_1 plays i and P_2 plays j , then P_1 wins the amount a_{ij} and P_2 loses the same amount.

So P_1 chooses a row and wants the entry to be large; P_2 chooses a column and wants it to be small. 'Zero-sum' means that one player's gain is exactly the other's loss – there is nothing to cooperate over.

Suppose first that the players move in sequence, and P_1 must move first. If P_1 plays row i then P_2 , seeing this, will respond with the column minimizing a_{ij} . So P_1 should solve

$$\max_i \min_j a_{ij}.$$

Symmetrically, if P_2 moves first then P_2 should solve

$$\min_j \max_i a_{ij}.$$

It is always the case that

$$\max_i \min_j a_{ij} \leq \min_j \max_i a_{ij},$$

since $\min_{j'} a_{ij'} \leq a_{ij} \leq \max_{i'} a_{i'j}$ for every i, j ; taking the max over i on the left and the min over j on the right preserves this. Moving second is (weakly) an advantage: you get to see what your opponent did.

Definition 20.6.2 (Saddle Point)

An entry $a_{i^*j^*}$ is a **saddle point** if it is simultaneously the minimum of its row and the maximum of its column, that is

$$a_{i^*j} \geq a_{i^*j^*} \geq a_{ij^*} \quad \text{for all } i, j.$$

Equivalently, $\max_i \min_j a_{ij} = a_{i^*j^*} = \min_j \max_i a_{ij}$. In this case $a_{i^*j^*}$ is called the **value** of the game.

The name comes from the geometry: at a saddle point the payoff surface curves up in one direction and down in the other, like a mountain pass.

Example 20.6.3

Take

$$A = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}.$$

Row minima are 1 and 3, so $\max_i \min_j a_{ij} = 3$. Column maxima are 3 and 4, so $\min_j \max_i a_{ij} = 3$. These agree, so $(2, 1)$ is a saddle point and the value of the game is 3. Both players should play their part of the saddle point regardless of who moves first, and neither can do better by deviating.

Example 20.6.4

Take

$$A = \begin{pmatrix} 4 & 2 \\ 1 & 3 \end{pmatrix}.$$

Row minima are 2 and 1, so $\max_i \min_j a_{ij} = 2$. Column maxima are 4 and 3, so $\min_j \max_i a_{ij} = 3$. These do not agree, and there is no saddle point.

In this game there is no stable pair of choices. If P_1 plays row 1 then P_2 prefers column 2; but against column 2, P_1 prefers row 2; against row 2, P_2 prefers column 1; against column 1, P_1 prefers row 1 – and we are back where we started. Whatever either player does, if the other knows it they can exploit it.

§20.6.2 Mixed Strategies

The resolution of the second example is one of the great ideas of game theory: the players should randomize. If P_1 picks a row at random according to a probability distribution, then P_2 cannot know which row will be played, only the distribution, and so cannot exploit the choice exactly.

Definition 20.6.5 (Mixed Strategy)

A **mixed strategy** for P_1 is a vector $p \in \mathbb{R}^m$ with $p \geq 0$ and $\sum_i p_i = 1$, where p_i is the probability of playing action i . Similarly a mixed strategy for P_2 is $q \in \mathbb{R}^n$ with $q \geq 0$, $\sum_j q_j = 1$. A strategy which plays one action with probability 1 is called **pure**.

If P_1 plays p and P_2 plays q , the expected payoff to P_1 is

$$\sum_{i,j} p_i a_{ij} q_j = p \cdot (Aq) = p^T Aq.$$

If P_1 plays p and P_2 responds with a pure strategy j , the expected payoff is $\sum_i a_{ij} p_i = (A^T p)_j$; and since a mixed strategy is an average of pure ones, P_2 can do no better than the best pure response. So P_1 wants to solve

$$\begin{aligned} & \text{maximize} && \min_j (A^T p)_j \\ & \text{subject to} && \sum_i p_i = 1, \quad p \geq 0. \end{aligned}$$

This is not yet a linear program, but the standard trick of introducing a variable for the minimum makes it one. Writing $e = (1, 1, \dots, 1)^T$ (of whatever length is needed),

$$\begin{aligned} (P_1) \quad & \text{maximize} && v \\ & \text{subject to} && A^T p \geq ve, \\ & && e \cdot p = 1, \quad p \geq 0. \end{aligned}$$

Similarly, P_2 wants to minimize the maximum expected loss, giving

$$\begin{aligned} (P_2) \quad & \text{minimize} && w \\ & \text{subject to} && Aq \leq we, \\ & && e \cdot q = 1, \quad q \geq 0. \end{aligned}$$

Both are honest linear programs, in the variables (p, v) and (q, w) respectively. And now the punchline.

Theorem 20.6.6

The problems (P_1) and (P_2) are dual to each other.

Proof. Introduce a slack variable $s \geq 0$ to write P_2 's constraints as $Aq + s = we$, and take multipliers $\lambda_1 \in \mathbb{R}^m$ for these and $\lambda_2 \in \mathbb{R}$ for the normalization $e \cdot q = 1$. The Lagrangian is

$$\begin{aligned} L(w, q, s, \lambda) &= w + \lambda_1 \cdot (Aq + s - we) - \lambda_2(e \cdot q - 1) \\ &= w(1 - \lambda_1 \cdot e) + (A^T \lambda_1 - \lambda_2 e) \cdot q + \lambda_1 \cdot s + \lambda_2. \end{aligned}$$

Now: w is unrestricted, so we need $\lambda_1 \cdot e = 1$; $q \geq 0$, so we need $A^T \lambda_1 - \lambda_2 e \geq 0$; and $s \geq 0$, so we need $\lambda_1 \geq 0$. Given all of these the infimum is λ_2 . Hence the dual problem is

$$\begin{aligned} &\text{maximize} && \lambda_2 \\ &\text{subject to} && A^T \lambda_1 \geq \lambda_2 e, \\ &&& e \cdot \lambda_1 = 1, \lambda_1 \geq 0, \end{aligned}$$

which is exactly (P_1) under the identification $\lambda_1 = p$, $\lambda_2 = v$. $\square$

Theorem 20.6.7 (Minimax Theorem)

For any payoff matrix A ,

$$\max_p \min_q p^T A q = \min_q \max_p p^T A q,$$

where the maximum and minimum are over mixed strategies. The common value v is called the **value** of the game.

Proof. The left-hand side is the optimal value of (P_1) and the right-hand side is the optimal value of (P_2) , and we have just shown these are dual linear programs. Both are feasible – take p and q uniform, and v, w suitably extreme – and both are bounded, since $\min_{i,j} a_{ij} \leq p^T A q \leq \max_{i,j} a_{ij}$ always. So strong duality applies and the optimal values agree. $\square$

This is a genuinely surprising theorem. It says that in a zero-sum game, once we allow randomization, there is no advantage to moving second: P_1 can guarantee an expected payoff of at least v no matter what P_2 does, and P_2 can guarantee losing at most v no matter what P_1 does. The game has a well-defined value, and there is no secret to keep.

The complementary slackness conditions for this dual pair are worth recording, since they are what we use to compute.

Theorem 20.6.8 (Optimality Conditions for Games)

Mixed strategies p, q are optimal for P_1 and P_2 respectively, with value v , if and only if

- (i) $A^T p \geq ve$, $e \cdot p = 1$, $p \geq 0$; (primal feasibility)
- (ii) $Aq \leq ve$, $e \cdot q = 1$, $q \geq 0$; (dual feasibility)
- (iii) $v = p^T A q$. (complementary slackness)

Proof. Complementary slackness for the dual pair above reads $p \cdot (Aq - we) = 0$ and $q \cdot (A^T p - ve) = 0$. Since $e \cdot p = e \cdot q = 1$, these say $p^T Aq = w$ and $p^T Aq = v$ respectively, so at an optimum $v = w = p^T Aq$. $\square$

The practical content of (iii) is the following pair of statements, which we will use in a moment:

- if $p_i > 0$ then the i th constraint of P_2 's problem is tight, i.e. $(Aq)_i = v$;
- if $q_j > 0$ then the j th constraint of P_1 's problem is tight, i.e. $(A^T p)_j = v$.

In words: every action that a player actually uses with positive probability must give exactly the value of the game against the opponent's optimal strategy. If some action gave strictly less, the player would drop it.

§20.6.3 Finding Optimal Strategies

In principle we can always solve the linear program by the simplex method, but for small games there are shortcuts.

- (1) **Look for a saddle point.** If the payoff matrix has one, the corresponding pure strategies are optimal for both players and we are done.
- (2) **Eliminate dominated actions.** If $a_{ij} \geq a_{i'j}$ for every j , then row i **dominates** row i' : P_1 can never do worse by playing i instead of i' , so there is an optimal strategy with $p_{i'} = 0$, and we may delete row i' . Similarly, if $a_{ij} \leq a_{ij'}$ for every i then column j dominates column j' (from P_2 's point of view, smaller is better), and we may delete column j' .
- (3) **Reduce to a small linear program.** A $2 \times n$ or $m \times 2$ game reduces to a one-dimensional problem that can be solved graphically.
- (4) **Use complementary slackness** to recover the other player's strategy once you have one of them.

Example 20.6.9

Let us return to the game with no saddle point,

$$A = \begin{pmatrix} 4 & 2 \\ 1 & 3 \end{pmatrix},$$

and solve it properly. Write P_1 's mixed strategy as $p = (p, 1 - p)$. Against P_2 's two pure strategies the expected payoffs are

$$(A^T p)_1 = 4p + (1 - p) = 1 + 3p, \quad (A^T p)_2 = 2p + 3(1 - p) = 3 - p,$$

and P_1 wants to maximize the smaller of these. The first is increasing in p and the second decreasing, so the maximum of the minimum is where they cross:

$$1 + 3p = 3 - p \implies p = \frac{1}{2}, \quad v = \frac{5}{2}.$$

Similarly, writing $q = (q, 1 - q)$ for P_2 ,

$$(Aq)_1 = 4q + 2(1 - q) = 2 + 2q, \quad (Aq)_2 = q + 3(1 - q) = 3 - 2q,$$

and P_2 minimizes the larger of these, which happens where $2 + 2q = 3 - 2q$, that is $q = \frac{1}{4}$, again with value $\frac{5}{2}$.

So the value of the game is $\frac{5}{2}$, with $p^* = (\frac{1}{2}, \frac{1}{2})$ and $q^* = (\frac{1}{4}, \frac{3}{4})$. Notice that $\frac{5}{2}$ lies strictly between $\max_i \min_j a_{ij} = 2$ and $\min_j \max_i a_{ij} = 3$: randomizing has genuinely bought P_1 something over any pure strategy, and it has cost P_2 less than any pure strategy would have.

Notice also the structure of the answer: at the optimum, *both* of P_2 's pure strategies give P_1 the same expected payoff. This is complementary slackness at work – since $q_1, q_2 > 0$, both of P_1 's constraints must be tight. Equivalently, P_1 chooses p precisely so as to make P_2 indifferent between their options; if P_2 were not indifferent, they would have a strictly better reply and could exploit P_1 .

Example 20.6.10

Consider the game with payoff matrix

$$A = \begin{pmatrix} 2 & 3 & 4 \\ 3 & 1 & \frac{1}{2} \\ 1 & 3 & 2 \end{pmatrix}.$$

First, is there a saddle point? The row minima are $2, \frac{1}{2}, 1$, so $\max_i \min_j = 2$; the column maxima are $3, 3, 4$, so $\min_j \max_i = 3$. These differ, so there is no saddle point and we will need mixed strategies.

Next, look for domination. Row 1 is $(2, 3, 4)$ and row 3 is $(1, 3, 2)$; since $2 \geq 1$, $3 \geq 3$ and $4 \geq 2$, row 1 dominates row 3, so we may take $p_3 = 0$ and work with

$$\tilde{A} = \begin{pmatrix} 2 & 3 & 4 \\ 3 & 1 & \frac{1}{2} \end{pmatrix}.$$

Write P_1 's strategy as $p = (p, 1 - p, 0)$. Then P_1 's problem becomes

$$\begin{aligned} &\text{maximize} && v \\ &\text{subject to} && 2p + 3(1 - p) \geq v, \\ & && 3p + 1(1 - p) \geq v, \\ & && 4p + \frac{1}{2}(1 - p) \geq v, \\ & && 0 \leq p \leq 1, \end{aligned}$$

that is, $v \leq \min \{3 - p, 1 + 2p, \frac{1}{2} + \frac{7}{2}p\}$, and we want to choose p to make this minimum as large as possible. Since this is a one-dimensional problem we can just draw the three lines and look at their lower envelope.

The lower envelope, drawn in red, is maximized where the lines $3 - p$ and $1 + 2p$ cross, at $p = \frac{2}{3}$, giving $v = \frac{7}{3}$. (The third line, $\frac{1}{2} + \frac{7}{2}p$, takes the value $\frac{1}{2} + \frac{7}{3} = \frac{17}{6} > \frac{7}{3}$ there, so it is not binding.) So

$$p^* = \left(\frac{2}{3}, \frac{1}{3}, 0\right), \quad v = \frac{7}{3}.$$

Now we use complementary slackness to find P_2 's strategy q . Since $p_1, p_2 > 0$, the first two constraints of P_2 's problem must be tight:

$$(Aq)_1 = 2q_1 + 3q_2 + 4q_3 = \frac{7}{3}, \quad (Aq)_2 = 3q_1 + q_2 + \frac{1}{2}q_3 = \frac{7}{3}.$$

Also, the third constraint of P_1 's problem is slack (we computed $\frac{17}{6} > \frac{7}{3}$), so complementary slackness forces $q_3 = 0$. With $q_1 + q_2 = 1$, the first equation gives

$$2q_1 + 3(1 - q_1) = \frac{7}{3} \implies 3 - q_1 = \frac{7}{3} \implies q_1 = \frac{2}{3},$$

and one checks that the second equation is satisfied: $3 \cdot \frac{2}{3} + \frac{1}{3} = \frac{7}{3}$. So

$$q^* = \left(\frac{2}{3}, \frac{1}{3}, 0\right).$$

Finally we should sanity check the answer against the optimality conditions. We have $A^T p^* = \left(\frac{7}{3}, \frac{7}{3}, \frac{17}{6}\right) \geq \frac{7}{3}e$ and $Aq^* = \left(\frac{7}{3}, \frac{7}{3}, \frac{5}{3}\right) \leq \frac{7}{3}e$, and $p^{*T} Aq^* = \frac{7}{3}$. All three conditions hold, so p^* and q^* really are optimal and the value of the game is $\frac{7}{3}$.

Remark. It is worth noticing what this answer means. P_1 's value from playing the pure strategy 'always row 1' is only 2 (their opponent would always answer with column 1), and from 'always row 2' is only $\frac{1}{2}$. By mixing the two in the ratio 2 : 1, P_1 guarantees $\frac{7}{3} > 2$. Randomization is strictly better than any deterministic play. That this is possible at all, and that the resulting value is exactly matched by the opponent's best defence, is the content of the minimax theorem – which is to say, of linear programming duality.

21 Quantum Mechanics

Quantum mechanics is the mathematical framework used to describe nature at the scale of subatomic particles. These notes will primarily focus on building up this mathematical framework, and not so much on the actual applications or physical background to it.

This article constitutes my notes for the ‘Quantum Mechanics’ course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly¹ in quite a few areas (more so than some of my other notes). Still, all lectured material should be covered.

§21.1 A Quantum Prelude

Before we do any mathematics, it is worth spending a little time on the physics that forced quantum mechanics into existence. None of the material in this section is logically necessary for what follows – we could just write down the axioms and get on with it – but the axioms will look much less arbitrary if we first see the experiments they were invented to explain.

The story, compressed into a single sentence, is this: at the turn of the twentieth century it became clear that light (which everyone knew was a wave) sometimes behaves like a stream of particles, and that electrons (which everyone knew were particles) sometimes behave like waves.

§21.1.1 Light: Waves or Particles?

First, a quick reminder of the vocabulary of waves, which we will use constantly. A wave with period T in time has frequency $\nu = 1/T$ and **angular frequency** $\omega = 2\pi/T$; a wave with period λ in space (the **wavelength**) has **wavenumber** $k = 2\pi/\lambda$. The basic travelling wave in one dimension is $f(x, t) = Ae^{i(kx - \omega t)}$, with amplitude A , moving at speed ω/k ; in three dimensions this becomes the **plane wave** $Ae^{i(\mathbf{k} \cdot \mathbf{x} - \omega t)}$, with **wavevector** $\mathbf{k}$ and $\lambda = 2\pi/|\mathbf{k}|$. A governing wave equation imposes a relation $\omega = \omega(\mathbf{k})$ between the two – the **dispersion relation** – and for any *linear* wave equation, solutions superpose: the sum of two solutions is a solution. All of the interference phenomena below, and indeed quantum mechanics itself, flow from this superposition property.

By 1900 the wave theory of light looked untouchable. Young’s double slit experiment (1801–03) showed that light passing through two narrow slits produces an interference pattern – alternating bright and dark fringes, from the two paths adding in or out of phase – exactly as water waves do, and Maxwell’s theory of electromagnetism (1862–64) identified light as an electromagnetic wave, predicting its speed from the constants of electricity and magnetism.

¹In particular, these notes are influenced by the ‘Principles of Quantum Mechanics’ course, along with numerous books.

The first cracks appeared with *black-body radiation*. A body heated to temperature T emits radiation, and the simplest system to study is a black body – a perfectly absorbing surface. Classical physics predicted that the intensity of emitted radiation should grow without bound as the frequency increases, which is plainly wrong (this is the ‘ultraviolet catastrophe’). The observed spectrum instead has a clear maximum, and Planck (1900) found that this curve could be derived exactly if one assumed that radiation of angular frequency ω is exchanged only in discrete lumps of energy

$$E = \hbar\omega,$$

where $\hbar \approx 1.05 \times 10^{-34}$ J s is the **reduced Planck constant**².

Einstein (1905) took this quantisation seriously in his analysis of the **photoelectric effect**. Take a metal surface in a vacuum and shine light of angular frequency ω on it; for suitable frequencies, electrons are emitted. If light were purely a wave, we would expect:

- (i) the energy of the emitted electrons to grow with the *intensity* of the light, since a more intense wave carries more energy;
- (ii) light of any frequency to eventually eject electrons, provided the intensity is high enough;
- (iii) a delay at low intensities, while enough energy is absorbed.

Every one of these expectations fails. What is actually observed is that the maximum kinetic energy of the emitted electrons depends only on the frequency,

$$E_{\max} = \hbar\omega - \phi,$$

where ϕ is a constant depending on the metal, that no electrons at all are emitted below the threshold frequency $\omega_{\min} = \phi/\hbar$ no matter how intense the light, and that emission is immediate but the *rate* of emission grows with intensity.

²One often also sees the ordinary Planck constant $h = 2\pi\hbar$. Quantum mechanics is much more pleasant when written in terms of $\hbar$, so that is what we will use throughout. Note that $\hbar$ has dimensions of energy $\times$ time, or equivalently position $\times$ momentum – the dimensions of *action*, and also of angular momentum.

Einstein's explanation is that light of angular frequency ω arrives in quanta – **photons** – each carrying energy $E = \hbar\omega$, and each photon can liberate at most one electron. An electron bound to the metal with binding energy ϕ then escapes with energy at most $\hbar\omega - \phi$, and increasing the intensity increases the number of photons (and hence the emission rate) but not the energy of each one.

Further confirmation came from *Compton scattering* (1923): X-rays scattered off electrons change frequency by an amount depending on the scattering angle, exactly as if each X-ray photon were a relativistic particle with energy $E = \hbar\omega$ and momentum

$$\mathbf{p} = \hbar\mathbf{k},$$

where $\mathbf{k}$ is the wavevector of the light. Indeed, treating the collision as relativistic two-particle scattering (a nice exercise with the kinematics of IA Dynamics and Relativity) and inserting these relations, one predicts the frequency shift

$$\frac{1}{\omega'} = \frac{1}{\omega} + \frac{\hbar}{m_e c^2} (1 - \cos \theta)$$

for X-rays scattered through an angle θ – which is exactly what Compton measured. So light carries energy and momentum in particle-like packets, while still interfering like a wave. Remarkably, G. I. Taylor (1909) repeated the double slit experiment with light so faint that only one photon was in the apparatus at a time – and the interference pattern still built up, photon by photon. Whatever a photon is, it is not simply a classical particle following one path or the other.

§21.1.2 Atoms and Their Spectra

A second, independent crisis was brewing inside the atom. Rutherford's scattering experiment (1911) – firing α particles at gold foil, and finding that most passed straight through while a few bounced almost straight back – showed that an atom is mostly empty space, with its positive charge concentrated in a tiny nucleus, orbited by electrons.

This 'solar system' picture has two fatal problems.

- (i) An orbiting electron is accelerating, and by classical electromagnetism an accelerating charge radiates. The electron should lose energy continuously and spiral into the nucleus in a fraction of a second. Atoms should not exist.
- (ii) Atoms absorb and emit light only at certain discrete frequencies – the *spectral lines*. For hydrogen these frequencies fit the remarkably simple empirical formula

$$\omega_{mn} = 2\pi c R_0 \left(\frac{1}{n^2} - \frac{1}{m^2} \right), \quad m > n,$$

where m, n are positive integers and $R_0 \approx 1.1 \times 10^7 \text{ m}^{-1}$ is the *Rydberg constant*. Nothing in classical mechanics singles out these frequencies.

(A word on how spectra are seen. Pass a current through a tube of hydrogen and the emitted light, split by a prism, is not a rainbow but a handful of sharp bright lines – the *emission spectrum*. Shine white light *through* cold hydrogen and the same frequencies appear as dark absorption lines cut out of the continuum. The frequencies are fingerprints of the element – this is how helium was discovered in the Sun before it was found on Earth – and any theory of the atom lives or dies by predicting them.)

Bohr (1913) proposed a fix that was as effective as it was unjustified: he postulated that the electron's orbital angular momentum is *quantised*,

$$L = m_e v r = n \hbar, \quad n = 1, 2, 3, \dots,$$

so that only certain orbits are allowed, and that radiation is emitted only when the electron jumps between them. Let's see what this gives us. For a circular orbit of radius r , the Coulomb force provides the centripetal acceleration:

$$\frac{e^2}{4\pi\epsilon_0 r^2} = \frac{m_e v^2}{r}.$$

Combining this with $v = n\hbar/m_e r$, we can solve for the allowed radii:

$$r_n = \frac{4\pi\epsilon_0 \hbar^2}{m_e e^2} n^2 = a_0 n^2,$$

where $a_0 \approx 5.3 \times 10^{-11} \text{ m}$ is the **Bohr radius**. The energy of the n th orbit is then

$$E_n = \frac{1}{2} m_e v^2 - \frac{e^2}{4\pi\epsilon_0 r} = -\frac{e^2}{8\pi\epsilon_0 a_0} \cdot \frac{1}{n^2} = -\frac{e^4 m_e}{32\pi^2 \epsilon_0^2 \hbar^2} \cdot \frac{1}{n^2}.$$

The lowest energy state, $n = 1$, has $E_1 \approx -13.6 \text{ eV}$, and the energy released in a jump from level m down to level n is carried away by a photon with $\hbar\omega = E_m - E_n$, which reproduces the Rydberg formula exactly, with the right value of R_0 in terms of fundamental constants.

This is a genuinely impressive result, and also clearly not the whole story – nothing explains *why* angular momentum should come in units of $\hbar$, and the model fails completely for atoms with more than one electron. We will return to hydrogen at the very end of these notes, and derive its energy levels honestly.

§21.1.3 Matter Waves

The missing idea came from de Broglie (1923–24), who proposed a striking symmetry: if light waves behave like particles, then particles should behave like waves. Specifically, associated to any particle with energy E and momentum $\mathbf{p}$ there is a wave with

$$\omega = \frac{E}{\hbar}, \quad \mathbf{k} = \frac{\mathbf{p}}{\hbar},$$

that is, with wavelength $\lambda = 2\pi/|\mathbf{k}| = 2\pi\hbar/|\mathbf{p}|$.

This immediately demystifies Bohr's quantisation rule. If the electron is a wave running around a circular orbit of radius r , then for the wave to join up with itself we need a whole number of wavelengths to fit around the circumference: $2\pi r = n\lambda$. But then

$$L = pr = \hbar k \cdot \frac{n\lambda}{2\pi} = \hbar \cdot \frac{2\pi}{\lambda} \cdot \frac{n\lambda}{2\pi} = n\hbar,$$

which is exactly Bohr's condition – quantisation appears as a standing wave condition.

Is any of this true? Davisson and Germer, and independently G. P. Thomson (1927–28), fired electrons at crystals and observed diffraction patterns – interference fringes – with exactly the wavelength $\lambda = 2\pi\hbar/|\mathbf{p}|$ predicted by de Broglie³. Matter genuinely does interfere with itself.

So by the mid 1920s the experimental picture was clear: both light and matter propagate like waves but are detected like particles, energies and angular momenta of bound systems are quantised, and the classical description fails at atomic scales. Between 1925 and 1930, Heisenberg, Schrödinger, Born, Dirac, Pauli and others assembled these fragments into a coherent mathematical theory. Building up (the wave-mechanical formulation of) that theory is the business of the rest of these notes.

§21.2 Wavefunctions and States

§21.2.1 States in Classical Mechanics

Before setting out the framework of quantum mechanics, it is worth being clear about the abstract structure of the theory it replaces.

In classical mechanics, particle motion is described by Newton's laws. These are a set of second order differential equations, which when coupled with two initial conditions then specify the future motion of the particle for all time. These initial conditions are typically taken to be position and momentum $(x(t_0), p(t_0))$. So Newton's laws really say that the entire state of a particle is encoded by a vector $(x(t), p(t))$ in the *phase space* M of position and momentum. As time passes, the particle's state traces out a path in phase space, but the whole path is determined by the initial vector (along with the differential equation given by Newton's laws).

There is a way of packaging Newton's laws that makes the parallel with quantum mechanics especially close: Hamilton's formulation, in which the dynamics is generated by the total energy $H(x, p) = \frac{p^2}{2m} + U(x)$ through

$$\frac{dx}{dt} = \frac{\partial H}{\partial p} \quad \text{and} \quad \frac{dp}{dt} = -\frac{\partial H}{\partial x}.$$

Keep this in mind – in quantum mechanics too, it will be the energy that generates time evolution (and Ehrenfest's theorem in Section 6 will make the correspondence exact, at the level of averages).

But of course a particle really corresponds to something physical – it's not really an element of an abstract vector space M . We need some way to go from this framework of

³There is a pleasing irony here: J. J. Thomson won a Nobel prize for showing the electron is a particle, and his son G. P. Thomson won one for showing it is a wave.

phase space to physical quantities. This is done by introducing *observables*, which are functions $O : M \rightarrow \mathbb{R}$.

Observables can be all sorts of things – position, kinetic energy, angular momentum, and everything else. These observables are defined for vectors in M , but we typically want to evaluate them at the vector corresponding to our particle’s state at some time t . Still, we don’t factor time into our definition of observables, it’s just baked into the point at which we evaluate them.

Classical mechanics is a game of juggling initial conditions, inputs to Newton’s laws (such as forces and potentials), and observables. We will see that in the abstract, quantum and classical mechanics are similar in this way: there will be a space of states, a notion of observables, and an equation of motion. What changes – completely – is what these things *are*.

One warning before we begin. Classical mechanics and quantum mechanics are fundamentally different – you can’t derive quantum mechanics from classical mechanics, and attempts to introduce it like that will fail. In reality, you should look at the mathematical framework of quantum mechanics and use that to build intuition. To help with this, looking at the *mathematical* framework of classical mechanics may also help, but it shouldn’t be where you derive your intuition.

§21.2.2 The Wavefunction and the Born Rule

So how do we describe a point particle? In classical mechanics we had the pair of vectors $(\mathbf{x}, \mathbf{p})$. The corresponding description in quantum mechanics is the *state* of the particle, which is described by a complex-valued *wavefunction*.

Definition 21.2.1 (Wavefunction)

A **wavefunction** is a complex-valued function $\psi(\mathbf{x}, t) : \mathbb{R}^3 \times \mathbb{R} \rightarrow \mathbb{C}$, satisfying certain mathematical properties dictated by its physical interpretation (described below). At each fixed time t , we think of $\psi(\cdot, t)$ as a function of position alone, with t an external parameter.

At first sight this is a strange object – we have replaced six real numbers with an entire complex function. The connection between the wavefunction and the underlying physical particle is given by the *Born rule*, and it is probabilistic.

Axiom 21.2.2 (The Born Rule)

The probability density for a particle in the state ψ to be found at position $\mathbf{x}$ at time t is

$$\rho(\mathbf{x}, t) = |\psi(\mathbf{x}, t)|^2.$$

That is, the probability of finding the particle in a small volume δV about $\mathbf{x}$ is $\rho(\mathbf{x}, t) \delta V$.

The Born rule immediately imposes a restriction on which functions can be wavefunctions. Because the particle has to be *somewhere* with probability 1, we need

$$\int_{\mathbb{R}^3} |\psi(\mathbf{x}, t)|^2 dV = 1,$$

in which case we say ψ is **normalised**. It is frequently useful to work with unnormalised wavefunctions, for which we only demand that the above integral is finite and non-zero – such ψ are called **normalisable**, or *square-integrable*. Given a normalisable wavefunction with

$$\int_{\mathbb{R}^3} |\psi(\mathbf{x}, t)|^2 dV = N,$$

the rescaled wavefunction $\psi/\sqrt{N}$ is then normalised, and it is this rescaled function that the Born rule speaks about.

Example 21.2.3 (Normalising a Gaussian)

Let's normalise the (one-dimensional, time-independent) wavefunction

$$\psi(x) = Ce^{-x^2/2\sigma^2}, \quad \sigma > 0.$$

We need $\int_{-\infty}^{\infty} |\psi|^2 dx = |C|^2 \int_{-\infty}^{\infty} e^{-x^2/\sigma^2} dx = |C|^2 \sigma \sqrt{\pi} = 1$, using the Gaussian integral $\int_{-\infty}^{\infty} e^{-u^2} du = \sqrt{\pi}$. So we may take

$$C = \frac{1}{(\pi\sigma^2)^{1/4}},$$

(or this multiplied by any phase). The particle is then found within $[-\sigma, \sigma]$ with probability $\int_{-\sigma}^{\sigma} |\psi|^2 dx \approx 0.84$, and the tails, while never exactly zero, are negligible beyond a few multiples of σ . Wavefunctions of exactly this shape will keep appearing throughout these notes – as wavepackets, as oscillator ground states, and as the states of minimal uncertainty.

Remark (For Pedants). If we have two wavefunctions which differ by a complex phase, $\tilde{\psi}(\mathbf{x}, t) = e^{i\theta} \psi(\mathbf{x}, t)$ for some constant $\theta \in \mathbb{R}$, then this does not change the probability density $\rho(\mathbf{x}, t)$ – or indeed anything else physically measurable. Because of this, we treat the two wavefunctions ψ and $\tilde{\psi}$ as corresponding to the same state. So states really correspond to rays in the vector space of wavefunctions. We will not fuss about this distinction, but it is worth keeping in mind that overall phases are unphysical, while *relative* phases in a superposition very much are physical, as we are about to see.

§21.2.3 Hilbert Space and Inner Products

The natural language of quantum mechanics is linear algebra. In a finite dimensional vector space, we have abstract vectors v , which can be represented concretely by considering some basis and writing say $v = (v_1, v_2, \dots, v_n)$. In quantum mechanics, we deal with the abstract object of a *state*, and it too can be represented concretely – the wavefunction $\psi(\mathbf{x}, t)$ should be thought of as the (continuous) collection of coefficients of the state in the ‘basis’ of positions⁴.

The set of states we work with is the following.

Definition 21.2.4 (Hilbert Space)

⁴This point of view is developed properly in the ‘Principles of Quantum Mechanics’ course, where states are vectors $|\psi\rangle$ in an abstract Hilbert space, and the wavefunction is the collection of components $\psi(\mathbf{x}) = \langle \mathbf{x} | \psi \rangle$. In this course we always work directly with the wavefunction.

The **Hilbert space** $\mathcal{H}$ is the vector space of normalisable (square-integrable) functions on $\mathbb{R}^3$,

$$\mathcal{H} = \left\{ \psi : \mathbb{R}^3 \rightarrow \mathbb{C} \mid 0 < \int_{\mathbb{R}^3} |\psi|^2 dV < \infty \right\} \cup \{0\}.$$

Calling this a vector space is a claim, albeit a small one: we need linear combinations of normalisable functions to be normalisable.

Proposition 21.2.5 (Superposition Principle)

If $\psi_1, \psi_2 \in \mathcal{H}$ and $\lambda_1, \lambda_2 \in \mathbb{C}$, then $\lambda_1\psi_1 + \lambda_2\psi_2 \in \mathcal{H}$.

Proof. For any complex numbers z_1, z_2 we have $2|z_1||z_2| \leq |z_1|^2 + |z_2|^2$, and so

$$|z_1 + z_2|^2 \leq |z_1|^2 + 2|z_1||z_2| + |z_2|^2 \leq 2|z_1|^2 + 2|z_2|^2.$$

Applying this pointwise with $z_i = \lambda_i\psi_i(\mathbf{x})$ and integrating,

$$\int_{\mathbb{R}^3} |\lambda_1\psi_1 + \lambda_2\psi_2|^2 dV \leq 2|\lambda_1|^2 \int_{\mathbb{R}^3} |\psi_1|^2 dV + 2|\lambda_2|^2 \int_{\mathbb{R}^3} |\psi_2|^2 dV < \infty,$$

as required. $\square$

This innocent-looking closure property is where quantum mechanics departs from everything classical: *the superposition of two states is a state*. If ψ_1 is ‘particle here’ and ψ_2 is ‘particle there’, then $(\psi_1 + \psi_2)/\sqrt{2}$ is a perfectly legitimate physical state, and it is not ‘here’, nor ‘there’, nor ‘here or there with 50/50 ignorance’ – as interference experiments show, it is something genuinely new. Nothing analogous holds for solutions of Newton’s equations.

The Hilbert space also carries an inner product, which will be the central computational tool of the whole course.

Definition 21.2.6 (Inner Product)

For wavefunctions $\psi, \phi \in \mathcal{H}$, we define

$$\langle \psi, \phi \rangle = \int_{\mathbb{R}^3} \psi^*(\mathbf{x}) \phi(\mathbf{x}) dV.$$

Note carefully the complex conjugate on the first argument. This inner product has the properties you would hope for.

Proposition 21.2.7 (Properties of the Inner Product)

For $\psi, \phi \in \mathcal{H}$ and $\lambda_1, \lambda_2 \in \mathbb{C}$:

- (i) $\langle \psi, \phi \rangle$ is well defined (the integral converges);
- (ii) $\langle \psi, \phi \rangle^* = \langle \phi, \psi \rangle$;
- (iii) the inner product is linear in the second argument, $\langle \psi, \lambda_1\phi_1 + \lambda_2\phi_2 \rangle = \lambda_1\langle \psi, \phi_1 \rangle + \lambda_2\langle \psi, \phi_2 \rangle$, and antilinear in the first, $\langle \lambda_1\psi_1 + \lambda_2\psi_2, \phi \rangle = \lambda_1^*\langle \psi_1, \phi \rangle + \lambda_2^*\langle \psi_2, \phi \rangle$;

(iv) $\langle \psi, \psi \rangle \geq 0$, with equality (for continuous ψ) if and only if $\psi = 0$.

Proof. Properties (ii)–(iv) follow directly from the definition. For (i), we use $2|\psi^* \phi| \leq |\psi|^2 + |\phi|^2$ pointwise, so

$$\int_{\mathbb{R}^3} |\psi^* \phi| dV \leq \frac{1}{2} \int_{\mathbb{R}^3} |\psi|^2 dV + \frac{1}{2} \int_{\mathbb{R}^3} |\phi|^2 dV < \infty,$$

and the integral converges absolutely. $\square$

We write $\|\psi\|^2 = \langle \psi, \psi \rangle$, so that ψ is normalised exactly when $\|\psi\| = 1$. Two useful pieces of terminology, imported straight from linear algebra:

Definition 21.2.8 (Orthonormality and Completeness)

A set of wavefunctions $\{\psi_n\}$ is **orthonormal** if $\langle \psi_m, \psi_n \rangle = \delta_{mn}$. It is **complete** if every $\psi \in \mathcal{H}$ can be expanded as

$$\psi = \sum_n \lambda_n \psi_n$$

for some constants $\lambda_n \in \mathbb{C}$.

For a complete orthonormal set, the expansion coefficients can be extracted with the inner product, just as Fourier coefficients are.

Proposition 21.2.9 (Extracting Coefficients)

If $\{\psi_n\}$ is a complete orthonormal set and $\psi = \sum_n \lambda_n \psi_n$, then $\lambda_n = \langle \psi_n, \psi \rangle$.

Proof. Using linearity and orthonormality,

$$\langle \psi_n, \psi \rangle = \left\langle \psi_n, \sum_m \lambda_m \psi_m \right\rangle = \sum_m \lambda_m \langle \psi_n, \psi_m \rangle = \sum_m \lambda_m \delta_{nm} = \lambda_n. \quad \square$$

This should feel exactly like Fourier series – and indeed Fourier series will literally appear when we solve the particle in a box.

Example 21.2.10 (A Complete Orthonormal Set)

On the interval $[-a, a]$ (which will be the home of the ‘infinite square well’ later), the functions

$$\psi_n(x) = \frac{1}{\sqrt{a}} \begin{cases} \cos \frac{n\pi x}{2a} & n \text{ odd,} \\ \sin \frac{n\pi x}{2a} & n \text{ even,} \end{cases} \quad n = 1, 2, 3, \dots$$

form an orthonormal set: for instance, for $m \neq n$ both odd,

$$\frac{1}{a} \int_{-a}^a \cos \frac{m\pi x}{2a} \cos \frac{n\pi x}{2a} dx = \frac{1}{2a} \int_{-a}^a \left(\cos \frac{(m-n)\pi x}{2a} + \cos \frac{(m+n)\pi x}{2a} \right) dx = 0,$$

with the mixed sine-cosine integrals vanishing by parity. Completeness (for functions

vanishing at $\pm a$) is exactly the convergence of Fourier series, which we take on trust from Analysis. This set will turn out to be the set of energy eigenfunctions of a particle in a box, and the expansion coefficients will carry direct physical meaning.

§21.2.4 The Postulates of Quantum Mechanics

We can now clearly set out the mathematical framework that quantum mechanics uses. It's natural to think about answering the following questions: How is a quantum state represented mathematically? How do we take this representation and calculate physical quantities? Given the state at some time t_1 , how do we find the state at some time t_2 ? With answers to these we are well on our way.

The truth is that you have to start somewhere, and these postulates are where it's going to be. They cannot be derived – they are justified by the (superb) agreement of their consequences with experiment.

Axiom 21.2.11 (States)

The state of a quantum mechanical system at time t is given by a non-zero wavefunction $\psi(\cdot, t)$ in the Hilbert space $\mathcal{H}$, with ψ and $\tilde{\psi} = \lambda\psi$ (for $\lambda \in \mathbb{C} \setminus \{0\}$) describing the same state.

Axiom 21.2.12 (Observables)

Every observable quantity O of the system corresponds to a Hermitian linear operator $\hat{O} : \mathcal{H} \rightarrow \mathcal{H}$.

Here an **operator** is a linear map $\hat{O} : \mathcal{H} \rightarrow \mathcal{H}$, that is

$$\hat{O}(\lambda_1\psi_1 + \lambda_2\psi_2) = \lambda_1\hat{O}\psi_1 + \lambda_2\hat{O}\psi_2,$$

and *Hermitian* is a symmetry condition with respect to the inner product whose statement and consequences we will develop properly in Section 6 – for now, think ‘real eigenvalues guaranteed’. The observables we will meet most often are built from position and momentum:

$$\begin{aligned} \text{position} \quad \hat{x}_i\psi &= x_i\psi, \\ \text{momentum} \quad \hat{p}_i\psi &= -i\hbar\frac{\partial\psi}{\partial x_i}, \\ \text{energy} \quad \hat{H}\psi &= -\frac{\hbar^2}{2m}\nabla^2\psi + U(\mathbf{x})\psi, \end{aligned}$$

where the **Hamiltonian** $\hat{H}$ is the operator version of the classical energy $\frac{\mathbf{p}^2}{2m} + U(\mathbf{x})$ of a particle of mass m moving in a potential U – notice it is exactly what you get by substituting $\hat{p}_i$ for p_i . The momentum operator looks like a logical leap right now; we will motivate it when we discuss the Schrödinger equation, and again (better) when we compute expectation values.

Next, measurement. You'll notice that in classical mechanics, an observable is a function that takes a state and produces some numerical value – something that can be thought of as reading out a value from some measurement device. For quantum mechanics we work with states in a vector space, so if we had two different states with two different

values of an observable, then since the sum of states is also a state – what would the observable read on the sum? There is no consistent classical answer. The way quantum mechanics deals with this is as follows.

Axiom 21.2.13 (Measurement)

The possible outcomes of a measurement of the observable O are the eigenvalues of the operator $\hat{O}$. The states in which O has a definite, well-defined value are exactly the eigenfunctions of $\hat{O}$: if $\hat{O}\psi = \lambda\psi$, then measuring O in the state ψ returns λ with certainty.

Axiom 21.2.14 (The Born Rule, Amplitude Form)

Suppose ψ_1 and ψ_2 are normalised eigenfunctions of $\hat{O}$ with distinct eigenvalues $\lambda_1 \neq \lambda_2$, and consider the superposition

$$\psi = \alpha_1\psi_1 + \alpha_2\psi_2, \quad \alpha_1, \alpha_2 \in \mathbb{C}.$$

Then ψ does not have a well-defined value of O . If O is measured in this state, the result is λ_1 or λ_2 , with probabilities

$$\mathbb{P}(\lambda_1) = \frac{|\alpha_1|^2}{|\alpha_1|^2 + |\alpha_2|^2}, \quad \mathbb{P}(\lambda_2) = \frac{|\alpha_2|^2}{|\alpha_1|^2 + |\alpha_2|^2},$$

and immediately after a measurement returning λ_i , the state of the system is ψ_i .

The general form of this rule (for arbitrarily many eigenfunctions, and with degenerate eigenvalues) will be given in Section 6, once we have established that eigenfunctions of Hermitian operators really do form complete orthonormal sets. Note that this axiom implies that a global phase on a state makes no difference to any probability – but relative phases between the α_i *can* make a difference to the probabilities of other observables, which is precisely the interference we saw in the double slit experiment. Note also the final sentence – the notorious ‘collapse of the wavefunction’. Measurement changes the state, discontinuously.

Finally, dynamics.

Axiom 21.2.15 (Time Evolution)

Between measurements, the wavefunction evolves according to the **time-dependent Schrödinger equation**

$$i\hbar \frac{\partial \psi}{\partial t} = \hat{H}\psi,$$

where $\hat{H}$ is the Hamiltonian operator of the system.

The Hamiltonian is the distinguished observable of the theory: the energy determines the dynamics. The whole of the next section is devoted to this equation.

A final word on the shape of the framework. Where classical mechanics had (phase space, observable functions, Newton/Hamilton’s equations), quantum mechanics has (Hilbert space, Hermitian operators, the Schrödinger equation) – the parallel we promised. But the measurement axioms have no classical counterpart at all: they are the genuinely new

– and genuinely strange – ingredient, and interpreting what they ‘really mean’ (what counts as a measurement? what happens during collapse?) remains contested a century on. Mercifully, using the rules requires no philosophy, and their predictions have never once failed an experimental test. We shall calculate.

§21.3 The Schrödinger Equation

§21.3.1 The Time-Dependent Schrödinger Equation

For a particle of mass m moving in a potential $U(\mathbf{x})$, the time evolution axiom reads explicitly

$$i\hbar \frac{\partial \psi}{\partial t}(\mathbf{x}, t) = -\frac{\hbar^2}{2m} \nabla^2 \psi(\mathbf{x}, t) + U(\mathbf{x})\psi(\mathbf{x}, t).$$

This equation is a postulate – it is not derived from anything – but we can at least see that it is a *sensible* postulate, by checking it against de Broglie’s matter waves.

Consider a free particle, $U = 0$, and try the plane wave

$$\psi(\mathbf{x}, t) = \exp(i(\mathbf{k} \cdot \mathbf{x} - \omega t)).$$

Substituting into the Schrödinger equation, the left hand side gives $\hbar\omega\psi$ and the right hand side gives $\frac{\hbar^2|\mathbf{k}|^2}{2m}\psi$, so the plane wave is a solution precisely when

$$\hbar\omega = \frac{\hbar^2|\mathbf{k}|^2}{2m}.$$

Using the de Broglie relations $E = \hbar\omega$ and $\mathbf{p} = \hbar\mathbf{k}$, this dispersion relation is exactly

$$E = \frac{|\mathbf{p}|^2}{2m},$$

the correct energy-momentum relation for a free non-relativistic particle. So the Schrödinger equation is precisely the wave equation whose dispersion relation encodes Newtonian kinematics via de Broglie’s dictionary. This also motivates the momentum operator: acting on the plane wave,

$$-i\hbar\nabla\psi = \hbar\mathbf{k}\psi = \mathbf{p}\psi,$$

so plane waves are eigenfunctions of $\hat{\mathbf{p}} = -i\hbar\nabla$ with eigenvalue exactly their de Broglie momentum.

Remark. Two structural features are worth noting immediately.

- (i) The equation is *first order in time*. Contrast Newton’s second law, which is second order: there, we needed both position and momentum as initial data. Here a single initial condition – the wavefunction $\psi(\mathbf{x}, t_0)$ – determines the entire future evolution. The wavefunction really is the whole state.
- (ii) Time and space appear asymmetrically (first derivative against second derivative). This is how it must be for a non-relativistic theory, but it means the Schrödinger equation cannot be compatible with special relativity, where space and time must be treated on an equal footing. The relativistic story (the Dirac equation, quantum field theory) is well beyond this course.

Remark. The equation is also *linear*: any complex linear combination of solutions is a solution. This is forced on us by the superposition principle, and it is what makes the linear algebra of the previous section the right toolkit.

Remark (What the Wavefunction is Not). It is tempting – and was tempting historically, to Schrödinger himself – to picture ψ as a physical wave rippling through space, like an electromagnetic field. The Born rule already strains this picture (the wave would have to ‘collapse’ instantaneously everywhere upon measurement), but the decisive objection is that for *two* particles the wavefunction is a function $\psi(\mathbf{x}_1, \mathbf{x}_2, t)$ on six-dimensional configuration space, not two waves in ordinary space – and it need not factorise as $\psi_1(\mathbf{x}_1)\psi_2(\mathbf{x}_2)$. (When it doesn’t, the particles are said to be *entangled*, which is the doorway to the strangest and most fertile parts of the subject – but multi-particle systems are beyond this course.) The wavefunction is best regarded as what it is: the mathematical repository of everything knowable about the system.

§21.3.2 Conservation of Probability

There is a consistency check we had better perform. The Born rule requires the total probability $\int |\psi|^2 dV$ to equal 1 at all times, but the Schrödinger equation tells the wavefunction how to evolve – these had better be compatible, i.e. the normalisation of the wavefunction had better be preserved by time evolution. It is, and the proof reveals a conserved current, in close analogy with the conservation of charge in electromagnetism or mass in fluid dynamics.

Theorem 21.3.1 (Conservation of Probability)

Let ψ solve the time-dependent Schrödinger equation with real potential U , and suppose $\psi \rightarrow 0$ suitably fast as $|\mathbf{x}| \rightarrow \infty$. Define the **probability current**

$$\mathbf{J}(\mathbf{x}, t) = -\frac{i\hbar}{2m} (\psi^* \nabla \psi - \psi \nabla \psi^*).$$

Then the probability density $\rho = |\psi|^2$ satisfies the continuity equation

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J} = 0,$$

and consequently $\int_{\mathbb{R}^3} |\psi(\mathbf{x}, t)|^2 dV$ is constant in time.

Proof. The Schrödinger equation and its complex conjugate give

$$\frac{\partial \psi}{\partial t} = \frac{i\hbar}{2m} \nabla^2 \psi - \frac{i}{\hbar} U \psi, \quad \frac{\partial \psi^*}{\partial t} = -\frac{i\hbar}{2m} \nabla^2 \psi^* + \frac{i}{\hbar} U \psi^*,$$

where we used that U is real. Then

$$\begin{aligned} \frac{\partial \rho}{\partial t} &= \frac{\partial}{\partial t} (\psi^* \psi) = \psi^* \frac{\partial \psi}{\partial t} + \psi \frac{\partial \psi^*}{\partial t} \\ &= \frac{i\hbar}{2m} (\psi^* \nabla^2 \psi - \psi \nabla^2 \psi^*) + \frac{i}{\hbar} (-U \psi^* \psi + U \psi \psi^*) \\ &= \frac{i\hbar}{2m} \nabla \cdot (\psi^* \nabla \psi - \psi \nabla \psi^*) = -\nabla \cdot \mathbf{J}, \end{aligned}$$

where in the second-to-last step we used $\nabla \cdot (\psi^* \nabla \psi) = \psi^* \nabla^2 \psi + \nabla \psi^* \cdot \nabla \psi$, the cross terms cancelling. This is the continuity equation. Integrating over a large ball B_R

and applying the divergence theorem,

$$\frac{d}{dt} \int_{B_R} |\psi|^2 dV = - \int_{\partial B_R} \mathbf{J} \cdot d\mathbf{S} \rightarrow 0 \text{ as } R \rightarrow \infty,$$

since ψ (and hence $\mathbf{J}$) vanishes at infinity. So the total integral is conserved. $\square$

The continuity equation is a stronger statement than mere conservation of the total: it says probability is conserved *locally*. Probability cannot teleport from one region to another; it must flow through the intervening space, with flux $\mathbf{J}$. We will use the current $\mathbf{J}$ quantitatively when we study scattering.

Example 21.3.2 (Currents of Basic States)

Two instructive special cases (in one dimension, where $J = -\frac{i\hbar}{2m}(\psi^*\psi' - \psi\psi'^*)$):

- (i) *Real wavefunctions carry no current.* If $\psi = \psi^*$ then the two terms cancel and $J = 0$ – and more generally the same holds if ψ is real up to a constant phase. All our bound states below can be taken real, so they carry no flux anywhere: they really are ‘stationary’ in the strongest sense.

- (ii) *Plane waves carry uniform current.* For $\psi = Ae^{i(kx - \omega t)}$,

$$J = -\frac{i\hbar}{2m} (|A|^2(ik) - |A|^2(-ik)) = |A|^2 \frac{\hbar k}{m},$$

which is (density) $\times$ (velocity), with the velocity $p/m = \hbar k/m$. Probability flows steadily to the right (for $k > 0$), consistent with ρ being constant: inflow balances outflow everywhere.

Complexity of the wavefunction, in both senses of the word, is where motion lives.

§21.3.3 Stationary States and the Time-Independent Schrödinger Equation

Faced with a linear PDE, we separate variables. Try a solution of the form

$$\psi(\mathbf{x}, t) = \chi(\mathbf{x}) T(t).$$

Substituting into the time-dependent Schrödinger equation and dividing through by χT ,

$$i\hbar \frac{T'(t)}{T(t)} = \frac{\hat{H}\chi(\mathbf{x})}{\chi(\mathbf{x})}.$$

The left hand side depends only on t and the right hand side only on $\mathbf{x}$, so both are equal to a constant, E say. The time equation $i\hbar T' = ET$ immediately gives

$$T(t) = e^{-iEt/\hbar},$$

while the spatial equation is the following.

Definition 21.3.3 (Time-Independent Schrödinger Equation)

The **time-independent Schrödinger equation** is the eigenvalue equation

$$\hat{H}\chi = E\chi, \quad \text{i.e.} \quad -\frac{\hbar^2}{2m}\nabla^2\chi(\mathbf{x}) + U(\mathbf{x})\chi(\mathbf{x}) = E\chi(\mathbf{x}).$$

That is, χ is an eigenfunction of the Hamiltonian with eigenvalue E – by the measurement axiom, a state of definite energy E . (Since $\hat{H}$ is Hermitian, E is guaranteed to be real; a complex E would also make $|T(t)|$ blow up either forwards or backwards in time, destroying normalisation.)

Definition 21.3.4 (Stationary State)

A **stationary state** of energy E is a solution of the time-dependent Schrödinger equation of the form

$$\psi(\mathbf{x}, t) = \chi(\mathbf{x}) e^{-iEt/\hbar},$$

where χ satisfies the time-independent Schrödinger equation with eigenvalue E .

The name is explained by computing the probability density:

$$\rho(\mathbf{x}, t) = |\psi(\mathbf{x}, t)|^2 = |\chi(\mathbf{x})|^2 \left| e^{-iEt/\hbar} \right|^2 = |\chi(\mathbf{x})|^2,$$

which is independent of time. Nothing observable about a stationary state ever changes – the time dependence is a pure phase. This, incidentally, resolves the stability problem of the atom: an electron in a stationary state has literally nothing about it that evolves, so there is nothing to radiate.

Why do we care so much about this special class of solutions? Because of linearity, and a completeness fact we will establish in Section 6: *every* solution of the time-dependent Schrödinger equation is a superposition of stationary states. If the Hamiltonian has (say, discrete) eigenfunctions χ_n with eigenvalues E_n , the general solution is

$$\psi(\mathbf{x}, t) = \sum_n a_n \chi_n(\mathbf{x}) e^{-iE_n t/\hbar}, \quad a_n \in \mathbb{C},$$

and the coefficients are fixed by the initial data: $a_n = \langle \chi_n, \psi(\cdot, 0) \rangle$. Solving the time-independent equation is therefore not a warm-up problem – it is the whole problem. Once you know the spectrum of $\hat{H}$, time evolution is just attaching phases.

In general the Hamiltonian can also have a continuous family of eigenfunctions χ_α with energies E_α (we will meet this for the free particle), in which case sums are replaced by integrals:

$$\psi(\mathbf{x}, t) = \int A(\alpha) \chi_\alpha(\mathbf{x}) e^{-iE_\alpha t/\hbar} d\alpha.$$

It is worth seeing explicitly how superposition brings back genuine time dependence, given that each individual stationary state has none.

Example 21.3.5 (A Two-State Superposition)

Suppose χ_1, χ_2 are orthonormal (real) stationary states with distinct energies $E_1 \neq E_2$, and consider

$$\psi(\mathbf{x}, t) = \frac{1}{\sqrt{2}} \left(\chi_1(\mathbf{x}) e^{-iE_1 t/\hbar} + \chi_2(\mathbf{x}) e^{-iE_2 t/\hbar} \right).$$

The probability density is

$$|\psi|^2 = \frac{1}{2} \left(\chi_1^2 + \chi_2^2 + 2\chi_1\chi_2 \cos \left(\frac{(E_2 - E_1)t}{\hbar} \right) \right),$$

which *oscillates* in time, at the single angular frequency

$$\omega_{21} = \frac{E_2 - E_1}{\hbar}.$$

The probability sloshes back and forth between the regions where $\chi_1\chi_2 > 0$ and those where $\chi_1\chi_2 < 0$. Notice that this is precisely the Bohr transition frequency between the two levels – it is superpositions like this, driven by a coupling to the electromagnetic field, that radiate at the observed spectral frequencies. Note also that the *relative phase* between the two terms is doing real physical work here, as promised in Section 2: replacing $\chi_2 \mapsto e^{i\theta}\chi_2$ shifts the phase of the oscillation.

A large portion of these notes – all of the next two sections – consists of solving the time-independent Schrödinger equation for various potentials U , and interpreting the answers. It is remarkable how much physics is contained in a single ordinary differential equation.

§21.4 One-Dimensional Systems

We now restrict to one spatial dimension, where the time-independent Schrödinger equation

$$-\frac{\hbar^2}{2m}\chi''(x) + U(x)\chi(x) = E\chi(x)$$

is an ordinary differential equation, and everything can be computed explicitly. This is not just a pedagogical simplification – the one-dimensional problems in this section are the hydrogen atoms of quantum mechanics, and (as we will see in Section 7) genuinely three-dimensional problems often reduce to one-dimensional ones.

§21.4.1 The Free Particle and Wavepackets

Let's start with the simplest possible potential: $U = 0$. The time-independent Schrödinger equation is $-\frac{\hbar^2}{2m}\chi'' = E\chi$, with solutions

$$\chi_k(x) = e^{ikx}, \quad E = \frac{\hbar^2 k^2}{2m},$$

for any $k \in \mathbb{R}$. Attaching the time dependence, we get the **de Broglie plane waves**

$$\psi_k(x, t) = \exp \left(ikx - \frac{i\hbar k^2}{2m}t \right),$$

which are momentum eigenstates: $\hat{p}\psi_k = \hbar k\psi_k$. Notice that the energy spectrum is *continuous* – any $E \geq 0$ occurs – in sharp contrast with the bound systems we study later.

There is, however, an embarrassment:

$$\int_{-\infty}^{\infty} |\psi_k(x, t)|^2 dx = \int_{-\infty}^{\infty} 1 dx = \infty,$$

so plane waves are not normalisable, and strictly speaking are not states in $\mathcal{H}$ at all⁵. There are two standard ways of dealing with this, and both are physically illuminating:

- (i) build normalisable solutions as superpositions of plane waves – *wavepackets*;
- (ii) keep the plane waves but reinterpret them as describing steady *beams* of particles rather than single particles (we will do this when we study scattering).

Let's carry out the first honestly. By the superposition principle, for any (reasonable) amplitude function $A(k)$,

$$\psi(x, t) = \int_{-\infty}^{\infty} A(k) \exp\left(ikx - \frac{i\hbar k^2}{2m}t\right) dk$$

solves the time-dependent Schrödinger equation. Choose a Gaussian profile peaked around a wavenumber k_0 :

$$A(k) = \exp\left(-\frac{\sigma}{2}(k - k_0)^2\right), \quad \sigma > 0.$$

The resulting solution is called the **Gaussian wavepacket**. The integral is doable by hand: the exponent is

$$F(k) = -\frac{\sigma}{2}(k - k_0)^2 + ikx - \frac{i\hbar k^2}{2m}t = -\frac{\alpha}{2}k^2 + \beta k + \delta,$$

where

$$\alpha = \sigma + \frac{i\hbar t}{m}, \quad \beta = \sigma k_0 + ix, \quad \delta = -\frac{\sigma}{2}k_0^2.$$

Completing the square, $F(k) = -\frac{\alpha}{2}\left(k - \frac{\beta}{\alpha}\right)^2 + \frac{\beta^2}{2\alpha} + \delta$, and shifting the contour of integration (justified since the integrand is entire and decays), we are left with a standard Gaussian integral $\int_{-\infty}^{\infty} e^{-\alpha u^2/2} du = \sqrt{2\pi/\alpha}$, giving

$$\psi(x, t) = \sqrt{\frac{2\pi}{\alpha}} \exp\left(\frac{\beta^2}{2\alpha} + \delta\right).$$

This looks opaque, but taking the modulus squared and simplifying (a worthwhile exercise in complex bookkeeping),

$$\rho(x, t) = |\bar{\psi}(x, t)|^2 = \sqrt{\frac{\sigma}{\pi\left(\sigma^2 + \frac{\hbar^2 t^2}{m^2}\right)}} \exp\left(-\frac{\sigma\left(x - \frac{\hbar k_0}{m}t\right)^2}{\sigma^2 + \frac{\hbar^2 t^2}{m^2}}\right),$$

where $\bar{\psi}$ is the normalised wavepacket. This is a Gaussian bump, and we can read off the physics directly.

⁵This is a general feature: normalisability requires $\chi \rightarrow 0$ at infinity, so any eigenfunction that remains oscillatory out to infinity – any ‘unbound’ state – fails to be normalisable. The plane wave is the extreme case.

The peak of the bump is at

$$\langle x \rangle = \int_{-\infty}^{\infty} x \rho(x, t) dx = \frac{\hbar k_0}{m} t,$$

so the packet moves with constant velocity $\hbar k_0/m = p_0/m$, exactly the classical velocity of a particle of momentum $p_0 = \hbar k_0$. The width of the bump,

$$\Delta x = \sqrt{\langle x^2 \rangle - \langle x \rangle^2} = \sqrt{\frac{1}{2} \left(\sigma + \frac{\hbar^2 t^2}{m^2 \sigma} \right)},$$

grows with time: wavepackets spread. This is dispersion – the different plane-wave components travel at different speeds, so the packet cannot hold itself together. One can similarly compute (using the momentum operator $\hat{p} = -i\hbar \frac{\partial}{\partial x}$)

$$\langle p \rangle = \int_{-\infty}^{\infty} \bar{\psi}^* \left(-i\hbar \frac{\partial}{\partial x} \right) \bar{\psi} dx = \hbar k_0, \quad \Delta p = \frac{\hbar}{\sqrt{2 \left(\sigma + \frac{\hbar^2 t^2}{m^2 \sigma} \right)}},$$

so momentum is sharp to precision Δp , which *shrinks* as the packet spreads. At $t = 0$ we find the tidy relation

$$\Delta x \Delta p = \frac{\hbar}{2}.$$

A tightly localised packet (small σ) has a wildly uncertain momentum, and vice versa – with the product bounded below. Compare the two extremes: a plane wave has $\Delta p = 0$ but $\Delta x = \infty$. This trade-off is not an artefact of the Gaussian: it is the *uncertainty principle*, which we will state and prove in general in Section 6 – and we will see there that the Gaussian is precisely the minimising shape.

§21.4.2 The Infinite Square Well

Our first genuinely quantum system is a particle trapped in a box: the **infinite square well**

$$U(x) = \begin{cases} 0 & |x| \leq a, \\ \infty & |x| > a. \end{cases}$$

The infinite potential should be understood as a limit (of the finite well of the next-but-one subsection, say): its effect is that the wavefunction must vanish wherever $U = \infty$, since otherwise the term $U\chi$ in the Schrödinger equation is infinite. So $\chi(x) = 0$ for $|x| > a$, and by continuity we get boundary conditions

$$\chi(\pm a) = 0.$$

(At an infinite jump in U we insist only that χ is continuous; χ' is allowed to jump. At any finite discontinuity of U , both χ and χ' must be continuous – we will use this repeatedly.)

Inside the well the equation is free:

$$\chi'' + k^2 \chi = 0, \quad k = \sqrt{\frac{2mE}{\hbar^2}},$$

with general solution $\chi(x) = A \sin kx + B \cos kx$. (One can check directly that $E \leq 0$ gives only the zero solution.) The boundary conditions read

$$A \sin ka + B \cos ka = 0, \quad -A \sin ka + B \cos ka = 0,$$

adding and subtracting: $B \cos ka = 0$ and $A \sin ka = 0$. We cannot have both $A = B = 0$, and $\sin ka, \cos ka$ never vanish together, so exactly one of the following holds:

- (i) $A = 0$ and $\cos ka = 0$, giving $k = \frac{n\pi}{2a}$ with n odd, and even eigenfunctions $\chi \propto \cos kx$;
- (ii) $B = 0$ and $\sin ka = 0$, giving $k = \frac{n\pi}{2a}$ with n even, and odd eigenfunctions $\chi \propto \sin kx$.

Fixing the constants by normalisation, $\int_{-a}^a |\chi_n|^2 dx = 1$, we obtain a discrete family of stationary states, one for each positive integer n :

$$\chi_n(x) = \frac{1}{\sqrt{a}} \begin{cases} \cos \frac{n\pi x}{2a} & n \text{ odd,} \\ \sin \frac{n\pi x}{2a} & n \text{ even,} \end{cases} \quad E_n = \frac{\hbar^2 k_n^2}{2m} = \frac{\hbar^2 \pi^2 n^2}{8ma^2}.$$

This small computation displays most of the characteristic features of bound quantum systems, so let's pause and stare at it.

- (i) *The energy is quantised.* Only the discrete values $E_n \propto n^2$ occur – the boundary conditions act exactly like the ‘standing wave’ condition in de Broglie’s picture: an integer number of half-wavelengths must fit in the box.
- (ii) *The ground state energy is not zero.* The lowest possible energy is $E_1 = \hbar^2 \pi^2 / 8ma^2 > 0$: a confined quantum particle cannot sit still. This is forced by the uncertainty principle – confinement to $\Delta x \sim a$ requires $\Delta p \gtrsim \hbar/a$, and hence kinetic energy of order $\hbar^2/ma^2$.
- (iii) *Nodes.* The n th eigenfunction has $n - 1$ interior zeros, at which the particle is never found. It is genuinely strange that a particle can be found on both sides of a point it can never be found at; resist the temptation to think of the particle as ‘moving’ – the state is stationary.
- (iv) *The classical limit.* For large n , the density $|\chi_n|^2$ oscillates so rapidly that any realistic position measurement averages it out to the constant $1/2a$ – the uniform distribution a classical bouncing particle would give.

Remark. The eigenfunctions $\{\chi_n\}$ are precisely a Fourier basis for $[-a, a]$, so completeness of eigenfunctions of $\hat{H}$ is, in this example, exactly the classical statement that Fourier series converge. The general solution of the time-dependent problem in the box,

$$\psi(x, t) = \sum_{n=1}^{\infty} a_n \chi_n(x) e^{-iE_n t/\hbar},$$

is a Fourier series with rotating coefficients.

Example 21.4.1 (Position Statistics in the Ground State)

Let's compute the position statistics of the ground state $\chi_1 = \frac{1}{\sqrt{a}} \cos \frac{\pi x}{2a}$. By symmetry $\langle x \rangle = 0$ (the density is even), and

$$\langle x^2 \rangle = \frac{1}{a} \int_{-a}^a x^2 \cos^2 \frac{\pi x}{2a} dx = \frac{1}{2a} \int_{-a}^a x^2 \left(1 + \cos \frac{\pi x}{a}\right) dx = \frac{a^2}{3} - \frac{2a^2}{\pi^2},$$

where the second integral is done by integrating by parts twice. So

$$\Delta x = a \sqrt{\frac{1}{3} - \frac{2}{\pi^2}} \approx 0.36 a,$$

somewhat less than the value $a/\sqrt{3} \approx 0.58 a$ for a uniform distribution – the ground state huddles towards the middle of the box. For the momentum, $\langle p \rangle = 0$ (again by symmetry – or note χ_1 is real, so its current J vanishes), while $\langle p^2 \rangle = 2mE_1 = \hbar^2 \pi^2 / 4a^2$, since χ_1 is an eigenfunction of $\hat{p}^2 = 2m\hat{H}$ inside the well. Multiplying,

$$\Delta x \Delta p = \frac{\pi \hbar}{2} \sqrt{\frac{1}{3} - \frac{2}{\pi^2}} \approx 0.57 \hbar > \frac{\hbar}{2},$$

comfortably (but not extravagantly) consistent with the uncertainty principle we will prove in Section 6.

Exercise 21.4.2. Show that in the n th eigenstate, $\Delta x \Delta p = \frac{n\pi\hbar}{2} \sqrt{\frac{1}{3} - \frac{2}{n^2\pi^2}}$, which grows linearly in n – highly excited states are far from minimal uncertainty.

§21.4.3 Parity

You will have noticed that every eigenfunction of the infinite well was either even or odd. This is not a coincidence, and it is worth isolating the mechanism, since we will use it as a labour-saving device repeatedly.

Proposition 21.4.3 (Parity of Eigenfunctions)

Suppose the potential is even, $U(-x) = U(x)$, and that χ is an eigenfunction of $\hat{H}$ whose eigenvalue E is *non-degenerate* (no other linearly independent eigenfunction has the same eigenvalue). Then χ is either even or odd.

Proof. If U is even then the map $x \mapsto -x$ leaves the time-independent Schrödinger equation unchanged, so if $\chi(x)$ is a solution with eigenvalue E , so is $\tilde{\chi}(x) = \chi(-x)$. By non-degeneracy, $\tilde{\chi}$ must be proportional to χ , say $\chi(-x) = \alpha\chi(x)$. Applying this twice,

$$\chi(x) = \chi(-(-x)) = \alpha\chi(-x) = \alpha^2\chi(x),$$

so $\alpha^2 = 1$, i.e. $\alpha = \pm 1$. Then $\alpha = 1$ makes χ even and $\alpha = -1$ makes it odd. $\square$

Even when eigenvalues are degenerate, we can always *choose* a basis of even and odd eigenfunctions (take $\chi(x) \pm \chi(-x)$). The upshot for computations: for a symmetric potential we may search for even solutions and odd solutions separately, which roughly halves the work. In the language of operators, the **parity operator** $\hat{P}\chi(x) = \chi(-x)$ commutes with $\hat{H}$, and we are choosing simultaneous eigenfunctions of both – a point

we will return to in Section 6.

In fact, in one dimension the non-degeneracy hypothesis comes for free, which is why every bound state we compute in this section is automatically even or odd.

Proposition 21.4.4 (No Degeneracy in One Dimension)

Bound state energy levels of the one-dimensional Schrödinger equation are non-degenerate.

Proof. Suppose χ_1 and χ_2 are both normalisable eigenfunctions with the same eigenvalue E . Consider the Wronskian

$$W(x) = \chi_1 \chi_2' - \chi_2 \chi_1'.$$

Differentiating and using the Schrödinger equation for each ($\chi_i'' = \frac{2m}{\hbar^2}(U - E)\chi_i$),

$$W' = \chi_1 \chi_2'' - \chi_2 \chi_1'' = \frac{2m}{\hbar^2}(U - E)(\chi_1 \chi_2 - \chi_2 \chi_1) = 0,$$

so W is constant. Since bound states (and their derivatives) decay at infinity, $W \rightarrow 0$, so $W \equiv 0$. Then wherever the functions are non-zero,

$$\frac{\chi_1'}{\chi_1} = \frac{\chi_2'}{\chi_2},$$

and integrating gives $\ln \chi_1 = \ln \chi_2 + \text{const}$, i.e. $\chi_1 \propto \chi_2$. So the two eigenfunctions represent the same state. $\square$

(In three dimensions this argument collapses – there is no Wronskian – and degeneracy returns with a vengeance, as we will see: it is one of the main new phenomena of Section 7.)

Exercise 21.4.5. Show that the parity operator $\hat{P}$ is Hermitian, that $\hat{P}^2 = \hat{I}$, and deduce that its eigenvalues are ± 1 with the eigenfunctions being exactly the even and odd functions. Show also that $[\hat{H}, \hat{P}] = 0$ if and only if the potential is even.

§21.4.4 The Finite Square Well

Now let's make the walls finite: consider

$$U(x) = \begin{cases} 0 & |x| \leq a, \\ U_0 & |x| > a, \end{cases}$$

with $U_0 > 0$. We look for **bound states**: normalisable eigenfunctions, which requires $0 < E < U_0$ (for $E > U_0$ solutions oscillate at infinity, giving the scattering states of the next section). Classically a particle with $E < U_0$ is imprisoned in $|x| \leq a$ forever. Quantum mechanically, something more interesting happens.

By parity, we may look for even and odd solutions separately; we will do the even case in detail. Write

$$k = \sqrt{\frac{2mE}{\hbar^2}}, \quad \kappa = \sqrt{\frac{2m(U_0 - E)}{\hbar^2}},$$

both real and positive. Inside the well, $\chi'' = -k^2\chi$, and the even solution is $\chi = B \cos kx$. Outside, $\chi'' = \kappa^2\chi$, with solutions $e^{\pm\kappa x}$; normalisability kills the growing exponential on each side, and evenness ties the two coefficients together, leaving

$$\chi(x) = \begin{cases} Ce^{\kappa x} & x < -a, \\ B \cos kx & |x| \leq a, \\ Ce^{-\kappa x} & x > a. \end{cases}$$

Since U has only a finite jump at $x = \pm a$, both χ and χ' must be continuous there. At $x = a$:

$$B \cos ka = Ce^{-\kappa a}, \quad -kB \sin ka = -\kappa Ce^{-\kappa a}.$$

Dividing the second equation by the first (both sides are non-zero for a non-trivial solution),

$$k \tan ka = \kappa.$$

This, together with the defining relation

$$k^2 + \kappa^2 = \frac{2mU_0}{\hbar^2},$$

determines the allowed energies. These are transcendental equations, so we solve them graphically. Introduce the dimensionless variables $\xi = ka$ and $\eta = \kappa a$; then we need the intersections of

$$\eta = \xi \tan \xi \quad \text{and} \quad \xi^2 + \eta^2 = r_0^2, \quad r_0 = a\sqrt{\frac{2mU_0}{\hbar^2}},$$

in the quadrant $\xi, \eta > 0$: the branches of $\xi \tan \xi$ against a circle whose radius r_0 measures how ‘big’ the well is (in depth and width together).

Each intersection (ξ_n, η_n) gives a bound state with energy

$$E_n = \frac{\hbar^2 \xi_n^2}{2ma^2}.$$

Reading off the picture:

- (i) There is *always* at least one even bound state, no matter how small r_0 (i.e. how shallow or narrow the well): the first branch of $\xi \tan \xi$ starts at the origin, so the circle always crosses it.

- (ii) There are only ever *finitely many* bound states: the circle has finite radius, and the branches of $\xi \tan \xi$ are spaced π apart. Deeper and wider wells (larger r_0) support more bound states – in the figure, $r_0 = 2$ gives one even bound state, while $r_0 = 5$ gives two.
- (iii) As $U_0 \rightarrow \infty$, $r_0 \rightarrow \infty$ and the intersections approach the asymptotes $\xi_n \rightarrow \frac{n\pi}{2}$ (n odd) – exactly the even levels of the infinite well, as they had better.

The odd solutions run identically: inside the well $\chi = A \sin kx$, outside the same decaying exponentials but now with opposite signs on the two sides, and the matching at $x = a$ gives

$$-k \cot ka = \kappa, \quad \text{i.e.} \quad -\xi \cot \xi = \eta.$$

The branches of $-\xi \cot \xi$ interleave with those of $\xi \tan \xi$ (the first becomes positive only for $\xi > \pi/2$), so the even and odd levels alternate up the spectrum, just as in the infinite well – and an odd bound state exists only once $r_0 > \pi/2$, i.e. only if the well is deep enough. This condition will return with new significance in the three-dimensional theory (§7.2).

Here is what the ground state actually looks like:

The striking feature is the exponential tails: $\chi \neq 0$ in the region $|x| > a$, which a classical particle of this energy can never enter. The particle has positive probability of being found in the *classically forbidden region*. The tails decay over the length scale $1/\kappa$; note that the closer E is to the top of the well, the smaller κ and the further the state leaks out. This leakage is the seed of *quantum tunnelling*, which we will meet properly in the next section.

§21.4.5 The Harmonic Oscillator

The final – and most important – one-dimensional system is the **harmonic oscillator**:

$$U(x) = \frac{1}{2}m\omega^2 x^2.$$

Its importance comes from a Taylor expansion: near a generic stable equilibrium x_0 of *any* potential, $U(x) \approx U(x_0) + \frac{1}{2}U''(x_0)(x - x_0)^2$, so every small oscillation in nature – molecular vibrations, phonons in crystals, modes of the electromagnetic field – is approximately a harmonic oscillator. Classically the particle oscillates as $x = A \cos(\omega t + \phi)$ with any amplitude, so any energy $E \geq 0$ is possible.

The time-independent Schrödinger equation is

$$-\frac{\hbar^2}{2m}\chi''(x) + \frac{1}{2}m\omega^2 x^2 \chi(x) = E\chi(x).$$

First we tidy up: the natural length scale is $\sqrt{\hbar/m\omega}$, so substitute

$$\xi = \sqrt{\frac{m\omega}{\hbar}} x, \quad \varepsilon = \frac{2E}{\hbar\omega},$$

which reduces the equation to the dimensionless form

$$-\frac{d^2\chi}{d\xi^2} + \xi^2\chi = \varepsilon\chi.$$

Let's think about how solutions must behave for large $|\xi|$: there $\chi'' \approx \xi^2\chi$, which has solutions behaving like $e^{\pm\xi^2/2}$, and normalisability forces the decaying one. Indeed, we can spot one exact solution immediately: $\chi = e^{-\xi^2/2}$ satisfies $\chi'' = (\xi^2 - 1)\chi$, so it is an eigenfunction with $\varepsilon = 1$, that is

$$\chi_0(x) = \left(\frac{m\omega}{\pi\hbar}\right)^{1/4} \exp\left(-\frac{m\omega}{2\hbar}x^2\right), \quad E_0 = \frac{\hbar\omega}{2}.$$

A Gaussian! (And in fact this is the ground state, as the count of nodes will confirm.)

Guided by the asymptotics, for the general solution we make the ansatz

$$\chi(\xi) = f(\xi) e^{-\xi^2/2}.$$

Substituting in, f must satisfy **Hermite's equation**:

$$f'' - 2\xi f' + (\varepsilon - 1)f = 0.$$

The point $\xi = 0$ is regular, so we look for a power series solution $f(\xi) = \sum_{n \geq 0} a_n \xi^n$. Substituting and comparing coefficients of ξ^n :

$$(n+2)(n+1)a_{n+2} - 2na_n + (\varepsilon - 1)a_n = 0,$$

which gives the recurrence

$$a_{n+2} = \frac{2n+1-\varepsilon}{(n+1)(n+2)} a_n.$$

The even coefficients are determined by a_0 and the odd ones by a_1 ; by parity (the potential is even!) we may take exactly one of a_0, a_1 to be non-zero.

Now, the crucial question: does the series terminate? Here is why it must.

Proposition 21.4.6

If the series for f does not terminate, then $\chi = f e^{-\xi^2/2}$ is not normalisable.

Proof. Suppose the series is infinite. For large n the recurrence gives

$$\frac{a_{n+2}}{a_n} = \frac{2n+1-\varepsilon}{(n+1)(n+2)} \sim \frac{2}{n}.$$

Compare with the function $g(\xi) = e^{\xi^2} = \sum_m \frac{\xi^{2m}}{m!} = \sum_n b_n \xi^n$, whose coefficients satisfy

$$\frac{b_{n+2}}{b_n} = \frac{(n/2)!}{(n/2+1)!} = \frac{2}{n+2} \sim \frac{2}{n}.$$

So the tails of the two series agree asymptotically, and $f(\xi)$ grows like e^{ξ^2} as $|\xi| \rightarrow \infty$ (this comparison can be made rigorous). But then

$$\chi(\xi) = f(\xi) e^{-\xi^2/2} \sim e^{\xi^2/2},$$

which blows up, and is certainly not normalisable. $\square$

So f must be a polynomial: the series must terminate. Looking at the recurrence, the coefficient a_{N+2} vanishes (with $a_N \neq 0$) exactly when

$$\varepsilon = 2N + 1, \quad N = 0, 1, 2, \dots,$$

and undoing the substitution $\varepsilon = 2E/\hbar\omega$, we have proven the following famous result.

Theorem 21.4.7 (Spectrum of the Harmonic Oscillator)

The energy levels of the quantum harmonic oscillator are

$$E_N = \left(N + \frac{1}{2}\right) \hbar\omega, \quad N = 0, 1, 2, \dots$$

The energy levels form an exactly evenly-spaced ladder, with spacing $\hbar\omega$ – precisely the quantum of energy $\hbar\omega$ that Planck and Einstein needed for radiation of frequency ω . The ground state energy $\frac{1}{2}\hbar\omega$ is again non-zero (the ‘zero-point energy’).

The corresponding polynomials $f_N =: H_N$, normalised conventionally, are the **Hermite polynomials**, the first few being

$$H_0(\xi) = 1, \quad H_1(\xi) = 2\xi, \quad H_2(\xi) = 4\xi^2 - 2, \quad H_3(\xi) = 8\xi^3 - 12\xi,$$

and the eigenfunctions – the *Hermite functions* – are

$$\chi_N(\xi) = C_N H_N(\xi) e^{-\xi^2/2}, \quad C_N = \left(\frac{m\omega}{\pi\hbar}\right)^{1/4} \frac{1}{\sqrt{2^N N!}},$$

each a polynomial oscillation inside a Gaussian envelope, with χ_N having exactly N nodes and parity $(-1)^N$. (Orthogonality of the χ_N , i.e. $\int H_M H_N e^{-\xi^2} d\xi = 2^N N! \sqrt{\pi} \delta_{MN}$, is automatic from the general theory of the next section: they are eigenfunctions of a Hermitian operator with distinct eigenvalues.)

Note that each χ_N leaks past the classical turning points (where the dashed level meets the parabola) into the classically forbidden region, just as in the finite well. And the classical limit works as it did in the box: a classical oscillator of amplitude A spends most time near the turning points (where it moves slowest), with position distribution $1/\pi\sqrt{A^2 - x^2}$, and for large N the rapidly-oscillating $|\chi_N|^2$ locally averages to exactly this – largest near the turning points, smallest in the middle – the opposite of the ground state, which piles up in the centre. The Hermite functions form a complete orthonormal set for $\mathcal{H}$ – another instance of the completeness of Hamiltonian eigenfunctions that we keep running into, and will address head-on in Section 6.

Example 21.4.8 (Half-Oscillator)

As a quick test of understanding, consider the potential $U(x) = \frac{1}{2}m\omega^2 x^2$ for $x > 0$ and $U(x) = \infty$ for $x \leq 0$. An eigenfunction must vanish at $x = 0$ and solve the oscillator equation for $x > 0$ – so the eigenfunctions are exactly the *odd* oscillator eigenfunctions restricted to $x > 0$, and the spectrum is

$$E = \left(2j + 1 + \frac{1}{2}\right) \hbar\omega, \quad j = 0, 1, 2, \dots,$$

i.e. every other level of the full oscillator, starting at $\frac{3}{2}\hbar\omega$.

Before moving on, it is worth collecting the qualitative features that all our bound state problems have shared, since they hold for essentially any one-dimensional potential well.

- (i) In the *classically allowed* region ($E > U(x)$), the Schrödinger equation reads $\chi'' = -k(x)^2\chi$: the eigenfunction oscillates, faster where $E - U$ is larger.
- (ii) In the *classically forbidden* region ($E < U(x)$), $\chi'' = \kappa(x)^2\chi$: the eigenfunction grows or decays roughly exponentially, and normalisability selects decay – giving the tunnelling tails we keep seeing.
- (iii) Matching an oscillation smoothly onto decaying tails at both ends is only possible for special values of E – this is, at bottom, *why* bound state energies are quantised.
- (iv) The n th bound state (ordering by energy) has $n - 1$ nodes: higher energy means faster oscillation means more sign changes. Together with non-degeneracy and parity, this gives a reliable sanity check on any claimed spectrum.

§21.5 Scattering in One Dimension

So far we have studied bound states – normalisable eigenfunctions with discrete energies. We now turn to the complementary situation: a particle fired *at* a potential from far away, which may bounce back or pass through. This is a scattering problem, and it is where the non-normalisable solutions we discarded earlier earn their keep.

§21.5.1 Beams and Probability Flux

The physically honest way to describe a localised incoming particle is a wavepacket, say a Gaussian wavepacket centred far to the left of the potential and moving right. At late times, the packet splits into a reflected packet moving left and a transmitted packet moving right, and we would define the **reflection and transmission coefficients**

$$R = \lim_{t \rightarrow \infty} \int_{-\infty}^0 |\psi(x, t)|^2 dx, \quad T = \lim_{t \rightarrow \infty} \int_0^{\infty} |\psi(x, t)|^2 dx,$$

the probabilities of each outcome, with $R + T = 1$ automatic from conservation of probability. This is doable but computationally painful. Happily, there is a much slicker approach: the **beam interpretation**.

Take the plane wave stationary state

$$\psi_k(x, t) = A e^{ikx} e^{-iE_k t/\hbar}, \quad E_k = \frac{\hbar^2 k^2}{2m},$$

and instead of apologising for $\rho_k = |A|^2$ being constant (non-normalisable), *reinterpret* it: ψ_k describes not one particle but a steady beam of independent particles, each with momentum $\hbar k$, with constant average density $|A|^2$ per unit length. The probability current of Section 3 becomes the particle flux of the beam:

$$J_k = -\frac{i\hbar}{2m} \left(\psi_k^* \frac{\partial \psi_k}{\partial x} - \psi_k \frac{\partial \psi_k^*}{\partial x} \right) = |A|^2 \frac{\hbar k}{m},$$

which is just (density) $\times$ (velocity p/m), exactly as for a classical beam. Reflection and transmission coefficients are then *ratios of fluxes*:

$$R = \frac{|J_{\text{ref}}|}{|J_{\text{inc}}|}, \quad T = \frac{|J_{\text{trans}}|}{|J_{\text{inc}}|}.$$

One can show (by building wavepackets out of these stationary states) that the two approaches agree, so we will happily use the easier one.

One structural fact makes flux bookkeeping in one dimension especially clean.

Proposition 21.5.1 (Flux is Constant in Stationary States)

For a stationary state in one dimension, the probability current $J(x)$ is independent of x .

Proof. For a stationary state, $\rho = |\chi|^2$ is independent of t , so the continuity equation $\partial_t \rho + \partial_x J = 0$ reduces to $\partial_x J = 0$. $\square$

So in any scattering problem, whatever flux flows in must flow out: evaluating J far to the left and far to the right of the potential and equating them will give us $R + T = 1$ automatically, whatever the shape of the obstacle in between.

§21.5.2 The Potential Step

Our first scattering problem is the **potential step**

$$U(x) = \begin{cases} 0 & x \leq 0, \\ U_0 & x > 0, \end{cases}$$

with a beam of particles of energy E incident from the left. There are two regimes, depending on whether the beam has enough energy to climb the step.

Case 1: $E > U_0$. Write

$$k = \sqrt{\frac{2mE}{\hbar^2}}, \quad \bar{k} = \sqrt{\frac{2m(E - U_0)}{\hbar^2}},$$

both real. The stationary Schrödinger equation solves separately on each side:

$$\chi(x) = \begin{cases} e^{ikx} + Be^{-ikx} & x \leq 0, \\ Ce^{i\bar{k}x} & x > 0. \end{cases}$$

We have already inserted the physics here, so let's spell it out. On the left, e^{ikx} is the incident beam (normalised to unit amplitude, which we may do) and Be^{-ikx} is

the reflected beam. On the right, $Ce^{i\bar{k}x}$ is the transmitted beam; a term $De^{-i\bar{k}x}$ would describe a beam coming in from $x = +\infty$, which our experimental setup does not contain, so $D = 0$.

U has a finite jump, so χ and χ' are continuous at $x = 0$:

$$1 + B = C, \quad ik(1 - B) = i\bar{k}C,$$

giving

$$B = \frac{k - \bar{k}}{k + \bar{k}}, \quad C = \frac{2k}{k + \bar{k}}.$$

Now compute fluxes. On the left the current splits into incident and reflected parts, $J_{\text{inc}} = \frac{\hbar k}{m}$ and $J_{\text{ref}} = -\frac{\hbar k}{m}|B|^2$; on the right $J_{\text{trans}} = \frac{\hbar \bar{k}}{m}|C|^2$. So

$$R = |B|^2 = \left(\frac{k - \bar{k}}{k + \bar{k}} \right)^2, \quad T = \frac{\bar{k}}{k}|C|^2 = \frac{4k\bar{k}}{(k + \bar{k})^2}.$$

Note the extra factor of $\bar{k}/k$ in T – transmission compares *fluxes*, not amplitudes, and the transmitted beam moves more slowly. You can check directly that

$$R + T = \frac{(k - \bar{k})^2 + 4k\bar{k}}{(k + \bar{k})^2} = 1,$$

as conservation of probability demands. Sanity checks: as $E \rightarrow U_0$ (so $\bar{k} \rightarrow 0$) we get $R \rightarrow 1$ – a barely-clearing beam is entirely reflected – and as $E \rightarrow \infty$ we get $T \rightarrow 1$. But notice that for any finite energy $R > 0$: *a quantum particle can be reflected by a step it has enough energy to climb*. This has no classical analogue.

Case 2: $E < U_0$. Now $\bar{k} = i\kappa$ is purely imaginary, with $\kappa = \sqrt{2m(U_0 - E)/\hbar^2} > 0$, and the solution for $x > 0$ becomes

$$\chi(x) = Ce^{-\kappa x},$$

where we discarded the growing exponential. The matching gives the same formulae with $\bar{k} = i\kappa$:

$$B = \frac{k - i\kappa}{k + i\kappa},$$

which has $|B| = 1$, so $R = 1$: total reflection, as a classical particle would do. But the wavefunction is *not* zero beyond the step – it decays exponentially, penetrating the forbidden region to depth $\sim 1/\kappa$, just like the tails of the finite-well bound states. There is no transmitted flux (χ real up to phase for $x > 0$ gives $J = 0$), so nothing is ‘getting through’ in steady state – but the non-zero amplitude in the wall is about to become very important.

Example 21.5.2 (Reflection by a Cliff)

Here is a variant that classical intuition gets badly wrong. Take a *downward* step, $U = 0$ for $x \leq 0$ and $U = -U_0 < 0$ for $x > 0$, with a beam incident from the left with energy $E > 0$. A classical particle simply speeds up over the edge, with certainty. Quantum mechanically the algebra of Case 1 applies verbatim with $\bar{k} = \sqrt{2m(E + U_0)}/\hbar > k$, so

$$R = \left(\frac{k - \bar{k}}{k + \bar{k}} \right)^2 > 0,$$

and in the low energy limit $E \ll U_0$ we have $\bar{k} \gg k$ and $R \rightarrow 1$: a slow particle is almost certainly *reflected by the attractive drop*. Reflection is caused by any sharp change in the potential – in either direction – because it is a wave phenomenon (an impedance mismatch), not a matter of insufficient energy. This is why cold neutrons bounce off material surfaces, which is quantitatively the basis of neutron mirrors and the storage of ultracold neutrons in bottles.

§21.5.3 The Potential Barrier and Tunnelling

Now make the wall thin: consider the **potential barrier**

$$U(x) = \begin{cases} U_0 & 0 < x < a, \\ 0 & \text{otherwise,} \end{cases}$$

with a beam incident from the left with energy $0 < E < U_0$ – classically, guaranteed to bounce off. Write as usual

$$k = \sqrt{\frac{2mE}{\hbar^2}}, \quad \kappa = \sqrt{\frac{2m(U_0 - E)}{\hbar^2}}.$$

The solution has three pieces:

$$\chi(x) = \begin{cases} e^{ikx} + Ae^{-ikx} & x \leq 0, \\ Be^{-\kappa x} + Ce^{\kappa x} & 0 < x < a, \\ De^{ikx} & x \geq a. \end{cases}$$

Note that inside the barrier we must keep *both* exponentials – the barrier is finite, so neither blows up – and on the right we keep only the outgoing beam. Continuity of χ and χ' at $x = 0$ and $x = a$ gives four equations:

$$\begin{aligned} 1 + A &= B + C, & ik(1 - A) &= \kappa(C - B), \\ Be^{-\kappa a} + Ce^{\kappa a} &= De^{ika}, & \kappa(Be^{\kappa a} - Ce^{-\kappa a}) &= ikDe^{ika}, \end{aligned}$$

four linear equations in the four unknowns A, B, C, D . Solving (eliminate B and C first), one finds

$$D = \frac{-4i\kappa k e^{-ika}}{(\kappa - ik)^2 e^{\kappa a} - (\kappa + ik)^2 e^{-\kappa a}},$$

and the transmission coefficient $T = |D|^2$ (the incident and transmitted beams travel at the same speed) simplifies, after some algebra with $\sinh$, to

$$T = \frac{4k^2 \kappa^2}{(k^2 + \kappa^2)^2 \sinh^2(\kappa a) + 4k^2 \kappa^2}.$$

The key point: $T > 0$. The beam has energy strictly less than the barrier, and some of it gets through anyway. This is **quantum tunnelling**.

The figure shows $\text{Re } \chi$: an incident-plus-reflected standing wave pattern on the left, exponential decay through the barrier, and a small transmitted wave – of the same wavelength as the incident one, but much smaller amplitude – emerging on the right.

For a tall or wide barrier, $\kappa a \gg 1$, we have $\sinh(\kappa a) \approx \frac{1}{2}e^{\kappa a}$ and so

$$T \approx \frac{16k^2\kappa^2}{(k^2 + \kappa^2)^2} e^{-2\kappa a} \propto \exp\left(-\frac{2a}{\hbar} \sqrt{2m(U_0 - E)}\right).$$

The transmission probability decays *exponentially* with the barrier width and with the square root of its height. This exponential sensitivity is why tunnelling is invisible for everyday objects but ubiquitous at atomic scales, and it is quantitatively responsible for, among other things, α -decay of nuclei (the decay rate spans some twenty orders of magnitude across nuclei, tracking the exponential above), nuclear fusion in the Sun (protons tunnel through their Coulomb repulsion), and the scanning tunnelling microscope (where the exponential dependence of the tunnelling current on the tip–surface distance gives sub-atomic resolution).

Exercise 21.5.3. Put numbers in: for an electron tunnelling through a vacuum gap with $U_0 - E \approx 4$ eV (a typical metal work function), show that $2\kappa \approx 2 \text{ \AA}^{-1}$, so that increasing a scanning tunnelling microscope’s tip–surface gap by a single ångström suppresses the current by a factor of $e^2 \approx 7$. This is why the STM can resolve individual atoms.

Remark (Scattering Above the Barrier). The case $E > U_0$ is obtained from our formulae by the replacement $\kappa \mapsto i\bar{k}$ with $\bar{k} = \sqrt{2m(E - U_0)}/\hbar$, which turns $\sinh$ into $\sin$:

$$T = \frac{4k^2\bar{k}^2}{(k^2 - \bar{k}^2)^2 \sin^2(\bar{k}a) + 4k^2\bar{k}^2}.$$

Classically T would be 1; quantum mechanically $T < 1$ in general (reflection by a barrier you can clear, just as at the step) – *except* at the special energies where $\sin \bar{k}a = 0$, i.e. $\bar{k}a = n\pi$, where $T = 1$ exactly. These perfect transmissions are **resonances**: a whole number of half-wavelengths fits across the barrier, and the reflected waves from its two edges interfere destructively. The same effect for a potential *well* explains the Ramsauer–Townsend effect, in which noble gases are bizarrely transparent to electrons of one particular energy.

§21.6 Operators, Measurement and Uncertainty

We now pay our debts. Several times we have leaned on properties of Hermitian operators – real eigenvalues, orthogonal eigenfunctions, completeness – and on a still-unproven uncertainty principle. This section develops the operator theory of quantum mechanics properly, and it is here that the structure of the subject really lives.

§21.6.1 Expectation Values

The Born rule makes the outcome of a measurement a random variable, so the natural first question is: what is its mean? For position this needs no new ideas – the probability density is $|\psi|^2$, so (working in one dimension, with ψ normalised)

$$\langle \hat{x} \rangle_\psi = \int_{-\infty}^{\infty} x |\psi(x, t)|^2 dx = \int_{-\infty}^{\infty} \psi^* x \psi dx = \langle \psi, \hat{x} \psi \rangle.$$

The final expression is the one that generalises. For any observable with operator $\hat{A}$, we define the **expectation value** of $\hat{A}$ in the (normalised) state ψ as

$$\langle \hat{A} \rangle_\psi = \langle \psi, \hat{A} \psi \rangle = \int \psi^* (\hat{A} \psi) dx.$$

We will justify, in §6.3 below, that this really is the mean of the measurement distribution given by the Born rule. But first, let's use it to close a gap from Section 2: why is momentum represented by $-i\hbar\partial_x$? Here is a satisfying consistency check: *the expectation of momentum is the mass times the velocity of the expectation of position*. Assume ψ solves the Schrödinger equation. Then using the continuity equation $\partial_t |\psi|^2 = -\partial_x J$,

$$\begin{aligned} m \frac{d}{dt} \langle \hat{x} \rangle_\psi &= m \int_{-\infty}^{\infty} x \frac{\partial |\psi|^2}{\partial t} dx = -m \int_{-\infty}^{\infty} x \frac{\partial J}{\partial x} dx = m \int_{-\infty}^{\infty} J dx \\ &= -\frac{i\hbar}{2} \int_{-\infty}^{\infty} \left(\psi^* \frac{\partial \psi}{\partial x} - \psi \frac{\partial \psi^*}{\partial x} \right) dx = -i\hbar \int_{-\infty}^{\infty} \psi^* \frac{\partial \psi}{\partial x} dx = \langle \hat{p} \rangle_\psi, \end{aligned}$$

integrating by parts twice (boundary terms vanish for normalisable states). So with $\hat{p} = -i\hbar\partial_x$, the quantum expectations obey the classical kinematic relation $\langle p \rangle = m \frac{d}{dt} \langle x \rangle$ – this is the first instalment of Ehrenfest's theorem, coming shortly.

§21.6.2 Hermitian Operators

Definition 21.6.1 (Hermitian Conjugate)

The **Hermitian conjugate** (or adjoint) of an operator $\hat{A}$ is the operator $\hat{A}^\dagger$ defined by

$$\langle \hat{A}^\dagger \psi, \phi \rangle = \langle \psi, \hat{A} \phi \rangle \quad \text{for all } \psi, \phi \in \mathcal{H}.$$

Directly from the definition one checks the algebraic rules

$$(\lambda_1 \hat{A}_1 + \lambda_2 \hat{A}_2)^\dagger = \lambda_1^* \hat{A}_1^\dagger + \lambda_2^* \hat{A}_2^\dagger, \quad (\hat{A} \hat{B})^\dagger = \hat{B}^\dagger \hat{A}^\dagger.$$

Definition 21.6.2 (Hermitian Operator)

An operator $\hat{A}$ is **Hermitian** (self-adjoint) if $\hat{A}^\dagger = \hat{A}$, that is if

$$\langle \hat{A} \psi, \phi \rangle = \langle \psi, \hat{A} \phi \rangle \quad \text{for all } \psi, \phi \in \mathcal{H}.$$

Example 21.6.3 (The Basic Observables are Hermitian)

The position operator is Hermitian, essentially because x is real:

$$\langle \hat{x} \psi, \phi \rangle = \int (x\psi)^* \phi dx = \int \psi^* (x\phi) dx = \langle \psi, \hat{x} \phi \rangle.$$

The momentum operator is Hermitian, by integration by parts – and note how the factor of i is essential, absorbing the minus sign that integration by parts produces:

$$\langle \hat{p}\psi, \phi \rangle = \int \left(-i\hbar \frac{\partial \psi}{\partial x} \right)^* \phi dx = i\hbar \int \frac{\partial \psi^*}{\partial x} \phi dx = -i\hbar \int \psi^* \frac{\partial \phi}{\partial x} dx = \langle \psi, \hat{p}\phi \rangle,$$

the boundary terms vanishing since states decay at infinity. (So ∂_x alone is *anti*-Hermitian; the $-i\hbar$ fixes it.) Similarly, integrating by parts twice shows $\hat{p}^2$ (and hence the kinetic energy) is Hermitian, and multiplication by a real potential $U(x)$ is Hermitian just like $\hat{x}$ – so the Hamiltonian $\hat{H} = \frac{\hat{p}^2}{2m} + U(\hat{x})$ is Hermitian.

While we have the machinery out, here is a small but structurally important observation.

Proposition 21.6.4 (Energies are Bounded Below)

For any normalised state ψ , the kinetic energy has $\langle \hat{T} \rangle_\psi \geq 0$, and consequently every energy eigenvalue satisfies $E \geq \min U$.

Proof. Integrating by parts (boundary terms vanishing as usual),

$$\langle \hat{T} \rangle_\psi = -\frac{\hbar^2}{2m} \int \psi^* \frac{\partial^2 \psi}{\partial x^2} dx = \frac{\hbar^2}{2m} \int \left| \frac{\partial \psi}{\partial x} \right|^2 dx \geq 0.$$

If $\hat{H}\chi = E\chi$ with χ normalised, then $E = \langle \hat{T} \rangle_\chi + \langle U \rangle_\chi \geq 0 + \min U$. $\square$

This is the promise, made when we stated the axioms, that the Hamiltonian's spectrum is bounded below – there is a stable state of least energy, and matter cannot cascade down through an endless ladder of ever-lower energies. (It also confirms little facts we used along the way, e.g. that the infinite well has no eigenvalues with $E \leq 0$.)

Now the two fundamental structural facts, both with proofs that are one-line applications of Hermiticity.

Proposition 21.6.5 (Real Eigenvalues)

The eigenvalues of a Hermitian operator are real.

Proof. Let $\hat{A}\psi = a\psi$ with ψ normalised. Then

$$a = \langle \psi, \hat{A}\psi \rangle = \langle \hat{A}\psi, \psi \rangle = a^* \langle \psi, \psi \rangle = a^*,$$

using Hermiticity in the middle step. So $a \in \mathbb{R}$. $\square$

Proposition 21.6.6 (Orthogonal Eigenfunctions)

Eigenfunctions of a Hermitian operator with distinct eigenvalues are orthogonal.

Proof. Let $\hat{A}\psi_1 = a_1\psi_1$ and $\hat{A}\psi_2 = a_2\psi_2$ with $a_1 \neq a_2$. Then

$$a_1 \langle \psi_1, \psi_2 \rangle = \langle \hat{A}\psi_1, \psi_2 \rangle = \langle \psi_1, \hat{A}\psi_2 \rangle = a_2 \langle \psi_1, \psi_2 \rangle,$$

(using $a_1 \in \mathbb{R}$ for the first equality), so $(a_1 - a_2)\langle\psi_1, \psi_2\rangle = 0$, and since $a_1 \neq a_2$ we get $\langle\psi_1, \psi_2\rangle = 0$. $\square$

These are exactly the statements you know for real symmetric (or complex Hermitian) matrices, transplanted to infinite dimensions – along with their proofs. The remaining matrix fact, diagonalisability, is also what we want, but its infinite-dimensional proof is genuinely beyond this course, so we record it as an article of faith.

Fact 21.6.7 (Completeness of Eigenfunctions)

The eigenfunctions (discrete and continuous together) of a Hermitian operator form a complete basis of $\mathcal{H}$: every state can be expanded in them.

For every operator in this course, completeness can be checked concretely (e.g. Fourier series for the infinite well, Hermite functions for the oscillator), so nothing we do rests on an unproved generality.

Remark (Continuous Spectra and Improper Eigenfunctions). The caveat ‘discrete and continuous together’ is doing real work. The momentum operator has *no* normalisable eigenfunctions at all – its would-be eigenfunctions are the plane waves e^{ikx} , with a continuum of eigenvalues $\hbar k$ – and the position operator is even worse: $\hat{x}\psi = x_0\psi$ forces ψ to vanish everywhere except at the point x_0 , so its ‘eigenfunctions’ are the Dirac delta functions $\delta(x - x_0)$. Neither family lives in $\mathcal{H}$, but both are complete in the integral sense: the expansion of a state in position eigenfunctions is the tautology $\psi(x) = \int \psi(x_0)\delta(x - x_0)dx_0$, and the expansion in momentum eigenfunctions is precisely the *Fourier transform*,

$$\psi(x) = \frac{1}{\sqrt{2\pi\hbar}} \int_{-\infty}^{\infty} \tilde{\psi}(p) e^{ipx/\hbar} dp.$$

The measurement rules extend with sums replaced by integrals: $|\psi(x_0)|^2$ is the probability density for position measurements – so the Born rule of Section 2 is exactly the continuous-spectrum case of the general measurement axioms – and $|\tilde{\psi}(p)|^2$ is the probability density for momentum measurements. Making all this rigorous takes functional analysis beyond this course, but using it takes only care.

Applied to the Hamiltonian, this fact is what justifies the claim of Section 3 that stationary states suffice:

Corollary 21.6.8 (General Solution of the Schrödinger Equation)

Every solution of the time-dependent Schrödinger equation may be written

$$\psi(x, t) = \sum_n a_n \chi_n(x) e^{-iE_n t/\hbar}, \quad a_n = \langle \chi_n, \psi(\cdot, 0) \rangle,$$

where $\{\chi_n\}$ is a complete orthonormal set of eigenfunctions of $\hat{H}$ (with integrals over any continuous part of the spectrum understood).

§21.6.3 Measurement

We can now state the measurement rules in their final form, generalising the two-state Born rule of Section 2. Let $\hat{O}$ be an observable with a complete orthonormal set of

eigenfunctions $\{\psi_n\}$ and eigenvalues $\{\lambda_n\}$, and let $\psi = \sum_n a_n \psi_n$ be a normalised state.

- (i) A measurement of O returns some eigenvalue of $\hat{O}$.
- (ii) If the eigenvalues are non-degenerate, the probability of the outcome λ_n is

$$\mathbb{P}(O = \lambda_n) = |a_n|^2 = |\langle \psi_n, \psi \rangle|^2.$$

- (iii) If an eigenvalue λ is degenerate, with orthonormal eigenfunctions $\{\psi_i\}_{i \in I}$ spanning its eigenspace, then $\mathbb{P}(O = \lambda) = \sum_{i \in I} |a_i|^2$.
- (iv) (*The projection postulate.*) If the measurement returns λ , the state immediately afterwards is the normalised projection of ψ onto the λ -eigenspace:

$$\psi \mapsto \frac{1}{\sqrt{\sum_{i \in I} |a_i|^2}} \sum_{i \in I} a_i \psi_i,$$

which for a non-degenerate eigenvalue is simply ψ_n . An immediately repeated measurement therefore returns λ again with certainty.

Let us sanity-check this. The probabilities sum to one:

$$\sum_n |a_n|^2 = \sum_{n,m} a_n^* a_m \langle \psi_n, \psi_m \rangle = \left\langle \sum_n a_n \psi_n, \sum_m a_m \psi_m \right\rangle = \langle \psi, \psi \rangle = 1,$$

using orthonormality – this is just Parseval's theorem. And the mean of the distribution is

$$\sum_n \lambda_n |a_n|^2 = \sum_{n,m} a_n^* \lambda_m a_m \delta_{nm} = \left\langle \sum_n a_n \psi_n, \sum_m a_m \lambda_m \psi_m \right\rangle = \langle \psi, \hat{O} \psi \rangle = \langle \hat{O} \rangle_\psi,$$

confirming that the expectation value defined in §6.1 is indeed the statistical mean of measurement outcomes. Notice how tightly the mathematics interlocks with the physics here: Hermiticity guarantees the outcomes (eigenvalues) are real numbers, orthogonality makes the probabilities well defined and additive, and completeness guarantees every state can actually be measured.

Let's do a full worked example, in the system where we can compute everything.

Example 21.6.9 (Measuring the Energy of a Particle in a Box)

Take the infinite square well of §4.2 (width $2a$, eigenfunctions χ_n , energies $E_n = \hbar^2 \pi^2 n^2 / 8ma^2$), and suppose the particle is prepared in the state

$$\psi = \frac{1}{\sqrt{6}} \chi_1 + \sqrt{\frac{2}{3}} \chi_2 + \frac{1}{\sqrt{6}} \chi_3.$$

(This is normalised: $\frac{1}{6} + \frac{2}{3} + \frac{1}{6} = 1$.) Measuring the energy:

- (i) The possible outcomes are E_1 , E_2 , E_3 only – no other value can ever occur, however many times we repeat the experiment on identically prepared systems.
- (ii) Their probabilities are $|a_n|^2$: we get E_1 with probability $\frac{1}{6}$, E_2 with probability $\frac{2}{3}$, and E_3 with probability $\frac{1}{6}$.

(iii) The mean outcome is

$$\langle \hat{H} \rangle_\psi = \frac{1}{6}E_1 + \frac{2}{3}E_2 + \frac{1}{6}E_3 = \left(\frac{1}{6} + \frac{8}{3} + \frac{3}{2} \right) E_1 = \frac{13}{3}E_1,$$

which – note well – is not itself an allowed outcome of any single measurement.

(iv) If the measurement returns E_2 , the state collapses to χ_2 , and all subsequent energy measurements return E_2 with certainty. The information about the original coefficients is irretrievably gone.

Suppose instead we had measured *position* first, getting some value near x_0 , and then energy. The position measurement collapses ψ to a state sharply peaked at x_0 , which is *not* an energy eigenstate but a fresh superposition of all the χ_n – so the subsequent energy measurement can now return values other than E_1, E_2, E_3 with non-zero probability. Measurements of incompatible observables interfere with each other's statistics; this is the operational meaning of non-commutation, made quantitative by the uncertainty principle below.

Example 21.6.10 (A Flat Start)

For a slightly less rigged example, prepare the particle in the box in the *uniform* state $\psi(x, 0) = 1/\sqrt{2a}$ (constant across the well). The expansion coefficients are genuine Fourier integrals: for n even, $a_n = 0$ by parity, while for n odd,

$$a_n = \langle \chi_n, \psi \rangle = \frac{1}{\sqrt{2a}} \cdot \frac{1}{\sqrt{a}} \int_{-a}^a \cos \frac{n\pi x}{2a} dx = \frac{\sqrt{2}}{a} \cdot \frac{2a}{n\pi} \sin \frac{n\pi}{2} = \pm \frac{2\sqrt{2}}{n\pi}.$$

So an energy measurement returns E_1 with probability $|a_1|^2 = 8/\pi^2 \approx 0.81$, E_3 with probability $8/9\pi^2 \approx 0.09$, and so on – one can check $\sum_{n \text{ odd}} 8/n^2\pi^2 = 1$ using $\sum_{n \text{ odd}} 1/n^2 = \pi^2/8$. Every possible outcome is an odd level, with rapidly decaying probabilities; and since the state is not an eigenstate, $\psi(x, t)$ genuinely evolves, sloshing around the box forever (with, pleasingly, exact revivals: all the phases $e^{-iE_n t/\hbar}$ realign at $t = 16ma^2/\pi\hbar$, since each $E_n/E_1 = n^2$ is an integer).

Remark (The Measurement Problem). It would be dishonest not to flag the elephant in the room. We have given the theory *two* rules of evolution: the Schrödinger equation (deterministic, linear, continuous) between measurements, and collapse (probabilistic, nonlinear, discontinuous) during them – without ever saying what physically counts as a ‘measurement’. A measuring device is itself made of atoms; applying the Schrödinger equation to the device plus particle produces a superposition of ‘pointer states’, not a definite outcome – this is the content of Schrödinger’s famous cat. How (or whether) collapse really happens is called the *measurement problem*, and proposed resolutions (decoherence, many-worlds, hidden variables, objective collapse, ...) remain genuinely contested. None of this ambiguity infects the predictions: for every experiment anyone has devised, the rules above say what the statistics will be, and they have always been right. We take the pragmatic road, as does the course.

§21.6.4 Commutators

Operators, unlike numbers, need not commute – and essentially all distinctively quantum phenomena trace back to this. The failure to commute is measured by the following bracket.

Definition 21.6.11 (Commutator)

The **commutator** of operators $\hat{A}$ and $\hat{B}$ is

$$[\hat{A}, \hat{B}] = \hat{A}\hat{B} - \hat{B}\hat{A}.$$

The commutator is antisymmetric, $[\hat{A}, \hat{B}] = -[\hat{B}, \hat{A}]$, linear in each slot, and satisfies the Leibniz-type rules

$$[\hat{A}, \hat{B}\hat{C}] = [\hat{A}, \hat{B}]\hat{C} + \hat{B}[\hat{A}, \hat{C}], \quad [\hat{A}\hat{B}, \hat{C}] = \hat{A}[\hat{B}, \hat{C}] + [\hat{A}, \hat{C}]\hat{B},$$

which are checked by expanding everything out (and are worth internalising – they let you avoid ever expanding everything out again).

Example 21.6.12 (The Canonical Commutation Relation)

The most important commutator in quantum mechanics is between position and momentum. Apply the operators to a test wavefunction (never manipulate bare operators when unsure!):

$$\begin{aligned} \hat{x}\hat{p}\psi &= x \left(-i\hbar \frac{\partial \psi}{\partial x} \right) = -i\hbar x \frac{\partial \psi}{\partial x}, \\ \hat{p}\hat{x}\psi &= -i\hbar \frac{\partial}{\partial x}(x\psi) = -i\hbar\psi - i\hbar x \frac{\partial \psi}{\partial x}. \end{aligned}$$

Subtracting, $[\hat{x}, \hat{p}]\psi = i\hbar\psi$ for every ψ , so

$$[\hat{x}, \hat{p}] = i\hbar,$$

(times the identity operator). This is the **canonical commutation relation**, and one can regard it as the mathematical core of quantum mechanics – everything in this section flows from it.

Commuting observables are exactly the simultaneously measurable ones, in the following sense.

Definition 21.6.13 (Simultaneously Diagonalisable)

Hermitian operators $\hat{A}$, $\hat{B}$ are **simultaneously diagonalisable** if there is a complete basis $\{\psi_i\}$ of joint eigenfunctions: $\hat{A}\psi_i = \lambda_i\psi_i$ and $\hat{B}\psi_i = \mu_i\psi_i$.

Theorem 21.6.14 (Compatibility Criterion)

Hermitian operators $\hat{A}$ and $\hat{B}$ are simultaneously diagonalisable if and only if $[\hat{A}, \hat{B}] = 0$.

Proof. ($\Rightarrow$) Given a complete joint eigenbasis, for each basis element

$$[\hat{A}, \hat{B}]\psi_i = \hat{A}(\mu_i\psi_i) - \hat{B}(\lambda_i\psi_i) = (\lambda_i\mu_i - \mu_i\lambda_i)\psi_i = 0,$$

and by linearity and completeness $[\hat{A}, \hat{B}]\psi = 0$ for every ψ .

($\Leftarrow$) Suppose $[\hat{A}, \hat{B}] = 0$, and let V_λ be the eigenspace of $\hat{A}$ for eigenvalue λ . For $\psi \in V_\lambda$,

$$\hat{A}(\hat{B}\psi) = \hat{B}(\hat{A}\psi) = \lambda(\hat{B}\psi),$$

so $\hat{B}$ maps V_λ into itself. The restriction of $\hat{B}$ to each V_λ is still Hermitian, so (by completeness applied within V_λ) we may pick a basis of each V_λ consisting of eigenfunctions of $\hat{B}$. These are joint eigenfunctions, and running over all λ they form a complete basis of $\mathcal{H}$. $\square$

If $[\hat{A}, \hat{B}] = 0$ we call the observables **compatible**: in a joint eigenstate both have definite values, so both can be known simultaneously with perfect precision, and measuring one does not disturb the (collapsed) eigenstate of the other. By contrast $[\hat{x}, \hat{p}] = i\hbar \neq 0$: position and momentum are incompatible, and no state whatsoever has definite values of both. The uncertainty principle below is the quantitative version of this statement. We have also already used this circle of ideas twice without saying so: parity commutes with a symmetric Hamiltonian (§4.3), and in Section 7 the set $\{\hat{H}, \hat{L}^2, \hat{L}_z\}$ of mutually commuting operators will organise the whole three-dimensional theory.

Remark (Labelling States). Compatibility also solves a bookkeeping problem that degeneracy creates. If an eigenvalue of $\hat{A}$ is degenerate, the outcome of measuring A does not pin down the state – we need more information. The fix is to find further observables commuting with $\hat{A}$ (and each other), and keep adding them until the joint eigenspaces are one-dimensional; such a maximal collection is called a *complete set of commuting observables*, and the corresponding eigenvalues (‘quantum numbers’) then label a basis of states unambiguously. For the hydrogen atom the set will be $\{\hat{H}, \hat{L}^2, \hat{L}_z\}$ with quantum numbers (N, ℓ, m) – this is precisely why atomic states are labelled by three quantum numbers, and the scheme survives (with spin added) into the periodic table.

§21.6.5 Ehrenfest’s Theorem

If quantum mechanics is right, it is right about tennis balls too, so classical mechanics must be hiding inside it somewhere. The precise statement is that *expectation values obey classical-looking equations of motion*, and the commutator controls the dynamics.

Theorem 21.6.15 (Ehrenfest’s Theorem)

Let ψ evolve by the Schrödinger equation, and let $\hat{A}$ be an observable with no explicit time dependence. Then

$$\frac{d}{dt}\langle \hat{A} \rangle_\psi = \frac{i}{\hbar} \langle [\hat{H}, \hat{A}] \rangle_\psi.$$

Proof. Differentiating under the integral,

$$\frac{d}{dt}\langle \psi, \hat{A}\psi \rangle = \left\langle \frac{\partial \psi}{\partial t}, \hat{A}\psi \right\rangle + \left\langle \psi, \hat{A} \frac{\partial \psi}{\partial t} \right\rangle.$$

The Schrödinger equation gives $\frac{\partial \psi}{\partial t} = \frac{1}{i\hbar} \hat{H} \psi$, so, using antilinearity in the first argument and Hermiticity of $\hat{H}$,

$$\frac{d}{dt} \langle \hat{A} \rangle_\psi = -\frac{1}{i\hbar} \langle \hat{H} \psi, \hat{A} \psi \rangle + \frac{1}{i\hbar} \langle \psi, \hat{A} \hat{H} \psi \rangle = \frac{i}{\hbar} \left(\langle \psi, \hat{H} \hat{A} \psi \rangle - \langle \psi, \hat{A} \hat{H} \psi \rangle \right) = \frac{i}{\hbar} \langle [\hat{H}, \hat{A}] \rangle_\psi. \quad \square$$

(If $\hat{A}$ does depend explicitly on time, one simply adds $\langle \partial \hat{A} / \partial t \rangle_\psi$ to the right hand side; we will never need this.) Let's harvest the consequences, for a particle with $\hat{H} = \frac{\hat{p}^2}{2m} + U(\hat{x})$.

(i) *Energy conservation*: taking $\hat{A} = \hat{H}$, since $[\hat{H}, \hat{H}] = 0$,

$$\frac{d}{dt} \langle \hat{H} \rangle_\psi = 0.$$

(ii) *Velocity*: taking $\hat{A} = \hat{x}$, we need $[\hat{H}, \hat{x}] = \frac{1}{2m} [\hat{p}^2, \hat{x}]$. By the Leibniz rule and the canonical commutation relation,

$$[\hat{p}^2, \hat{x}] = \hat{p}[\hat{p}, \hat{x}] + [\hat{p}, \hat{x}]\hat{p} = -2i\hbar\hat{p},$$

so

$$\frac{d}{dt} \langle \hat{x} \rangle_\psi = \frac{i}{\hbar} \cdot \left(\frac{-2i\hbar}{2m} \right) \langle \hat{p} \rangle_\psi = \frac{\langle \hat{p} \rangle_\psi}{m},$$

recovering (now effortlessly) the relation we derived by hand in §6.1.

(iii) *Newton's second law*: taking $\hat{A} = \hat{p}$, only the potential contributes, and on a test function

$$[U(\hat{x}), \hat{p}] \psi = U(-i\hbar \psi') + i\hbar (U\psi)' = i\hbar U'(x) \psi,$$

so

$$\frac{d}{dt} \langle \hat{p} \rangle_\psi = -\langle U'(\hat{x}) \rangle_\psi.$$

Example 21.6.16 (The Oscillator Swings Classically)

For the harmonic oscillator, $U'(x) = m\omega^2 x$ is *linear*, so $\langle U'(\hat{x}) \rangle = m\omega^2 \langle \hat{x} \rangle$ exactly, and Ehrenfest's equations close up:

$$\frac{d}{dt} \langle \hat{x} \rangle = \frac{\langle \hat{p} \rangle}{m}, \quad \frac{d}{dt} \langle \hat{p} \rangle = -m\omega^2 \langle \hat{x} \rangle \implies \frac{d^2}{dt^2} \langle \hat{x} \rangle = -\omega^2 \langle \hat{x} \rangle.$$

So for *any* state whatsoever – however spread out, however wildly non-classical – the mean position of an oscillator swings sinusoidally at exactly the classical frequency ω . (In a stationary state, of course, $\langle \hat{x} \rangle = 0$ for all time: the oscillation only shows up in superpositions of neighbouring levels, which oscillate at frequency $(E_{N+1} - E_N)/\hbar = \omega$ – everything is consistent.)

Together, (ii) and (iii) say that $\langle \hat{x} \rangle$ and $\langle \hat{p} \rangle$ obey exactly Newton's equations, with the force averaged over the state⁶. Classical mechanics is the story of the means; quantum mechanics is the story of the whole distribution.

⁶Note the subtlety: the classical trajectory would require $\frac{d}{dt} \langle p \rangle = -U'(\langle x \rangle)$, but what we actually get is $-\langle U'(x) \rangle$. These agree when U' is linear (free particle, uniform force, harmonic oscillator) or when the state is sharply peaked – which is exactly the classical limit.

§21.6.6 The Uncertainty Principle

Having discussed the means of measurement distributions, we turn to their spreads.

Definition 21.6.17 (Uncertainty)

The **uncertainty** of the observable A in the (normalised) state ψ is $\Delta_\psi A \geq 0$, where

$$(\Delta_\psi A)^2 = \langle (\hat{A} - \langle \hat{A} \rangle_\psi)^2 \rangle_\psi = \langle \hat{A}^2 \rangle_\psi - \langle \hat{A} \rangle_\psi^2.$$

This is precisely the variance of the measurement distribution (the second equality is the usual expand-the-square manipulation, using linearity of expectation values). The uncertainty vanishes exactly on states where the observable has a definite value:

Lemma 21.6.18

$(\Delta_\psi A)^2 \geq 0$, with equality if and only if ψ is an eigenfunction of $\hat{A}$.

Proof. Write $\hat{A}' = \hat{A} - \langle \hat{A} \rangle_\psi$ (a Hermitian operator, since $\langle \hat{A} \rangle_\psi$ is real). By Hermiticity,

$$(\Delta_\psi A)^2 = \langle \psi, \hat{A}'^2 \psi \rangle = \langle \hat{A}' \psi, \hat{A}' \psi \rangle = \|\hat{A}' \psi\|^2 \geq 0,$$

with equality iff $\hat{A}' \psi = 0$, i.e. iff $\hat{A} \psi = \langle \hat{A} \rangle_\psi \psi$. $\square$

The engine of the uncertainty principle is the Cauchy–Schwarz inequality, which holds in any inner product space.

Theorem 21.6.19 (Cauchy–Schwarz Inequality)

For $\psi, \phi \in \mathcal{H}$,

$$|\langle \psi, \phi \rangle|^2 \leq \langle \psi, \psi \rangle \langle \phi, \phi \rangle,$$

with equality if and only if $\phi = \lambda \psi$ for some $\lambda \in \mathbb{C}$ (or $\psi = 0$).

Proof. We may assume $\psi \neq 0$. For any $\lambda \in \mathbb{C}$,

$$0 \leq \langle \phi - \lambda \psi, \phi - \lambda \psi \rangle = \langle \phi, \phi \rangle - \lambda \langle \phi, \psi \rangle - \lambda^* \langle \psi, \phi \rangle + |\lambda|^2 \langle \psi, \psi \rangle.$$

Choose the minimising value $\lambda = \langle \psi, \phi \rangle / \langle \psi, \psi \rangle$; the right hand side becomes

$$\langle \phi, \phi \rangle - \frac{|\langle \psi, \phi \rangle|^2}{\langle \psi, \psi \rangle} \geq 0,$$

which rearranges to the claim. Equality forces $\langle \phi - \lambda \psi, \phi - \lambda \psi \rangle = 0$, i.e. $\phi = \lambda \psi$. $\square$

Theorem 21.6.20 (Generalised Uncertainty Principle)

For observables A, B and any normalised state ψ ,

$$\Delta_\psi A \Delta_\psi B \geq \frac{1}{2} \left| \langle [\hat{A}, \hat{B}] \rangle_\psi \right|.$$

Proof. Let $\hat{A}' = \hat{A} - \langle \hat{A} \rangle_\psi$ and $\hat{B}' = \hat{B} - \langle \hat{B} \rangle_\psi$, both Hermitian, and note $[\hat{A}', \hat{B}'] = [\hat{A}, \hat{B}]$ (the subtracted constants commute with everything). By the lemma above and Cauchy–Schwarz,

$$(\Delta_\psi A)^2 (\Delta_\psi B)^2 = \|\hat{A}'\psi\|^2 \|\hat{B}'\psi\|^2 \geq |\langle \hat{A}'\psi, \hat{B}'\psi \rangle|^2 = |\langle \psi, \hat{A}'\hat{B}'\psi \rangle|^2,$$

using Hermiticity of $\hat{A}'$ at the last step. Now split the product into commutator and anticommutator parts:

$$\hat{A}'\hat{B}' = \frac{1}{2}[\hat{A}', \hat{B}'] + \frac{1}{2}\{\hat{A}', \hat{B}'\}, \quad \{\hat{A}', \hat{B}'\} = \hat{A}'\hat{B}' + \hat{B}'\hat{A}'.$$

The anticommutator of Hermitian operators is Hermitian, so $\langle \{\hat{A}', \hat{B}'\} \rangle_\psi$ is *real*; the commutator is anti-Hermitian ($[\hat{A}', \hat{B}']^\dagger = -[\hat{A}', \hat{B}']$), so $\langle [\hat{A}', \hat{B}'] \rangle_\psi$ is purely *imaginary* (both by the argument in the proof that Hermitian operators have real expectations). Hence the two contributions are the real and imaginary parts of $\langle \psi, \hat{A}'\hat{B}'\psi \rangle$, and

$$|\langle \psi, \hat{A}'\hat{B}'\psi \rangle|^2 = \frac{1}{4}|\langle [\hat{A}, \hat{B}] \rangle_\psi|^2 + \frac{1}{4}|\langle \{\hat{A}', \hat{B}'\} \rangle_\psi|^2 \geq \frac{1}{4}|\langle [\hat{A}, \hat{B}] \rangle_\psi|^2.$$

Taking square roots gives the theorem. $\square$

Corollary 21.6.21 (Heisenberg's Uncertainty Principle)

For any normalised state ψ ,

$$\Delta_\psi x \Delta_\psi p \geq \frac{\hbar}{2}.$$

Proof. Take $\hat{A} = \hat{x}$, $\hat{B} = \hat{p}$ in the theorem: $[\hat{x}, \hat{p}] = i\hbar$, so the right hand side is $\frac{1}{2}|i\hbar| = \frac{\hbar}{2}$, independent of the state. $\square$

Let us be clear about what this does and does not say. It is a statement about *states*, not about clumsy measuring devices: no quantum state, however cleverly prepared, has both a sharp position and a sharp momentum. It underlies phenomena we have already met – zero-point energies (confinement forces momentum spread, hence kinetic energy), the stability of atoms (an electron squashed into the nucleus would have enormous momentum uncertainty), and the spreading of wavepackets.

Remark (Energy-Time Uncertainty). You will often see a companion relation $\Delta E \Delta t \gtrsim \hbar$ quoted. Beware: time is *not* an observable in quantum mechanics (there is no operator $\hat{t}$), so this cannot be an instance of the theorem above. The honest statement comes from Ehrenfest: for any observable A ,

$$\Delta_\psi H \cdot \Delta_\psi A \geq \frac{1}{2} |\langle [\hat{H}, \hat{A}] \rangle_\psi| = \frac{\hbar}{2} \left| \frac{d}{dt} \langle \hat{A} \rangle_\psi \right|,$$

so defining $\tau_A = \Delta_\psi A / \left| \frac{d}{dt} \langle \hat{A} \rangle_\psi \right|$ – the time it takes the statistics of A to change noticeably – we get $\Delta_\psi H \cdot \tau_A \geq \hbar/2$. States with sharp energy change slowly (a stationary state, with $\Delta H = 0$, never changes at all); fast dynamics requires energy spread. This is the sense in which short-lived excited states have broad spectral lines.

The uncertainty principle is not only a prohibition – used with a little courage, it is a computational tool.

Example 21.6.22 (Estimating the Ground State Energy of the Oscillator)

For the harmonic oscillator, the ground state must balance two competing costs: potential energy grows if the state spreads out, kinetic energy grows (via the uncertainty principle) if it is squeezed. Let's estimate the minimum. For a state centred at the origin with $\langle \hat{x} \rangle = \langle \hat{p} \rangle = 0$ (as holds for the ground state, by parity), we have $\langle \hat{x}^2 \rangle = (\Delta x)^2$ and $\langle \hat{p}^2 \rangle = (\Delta p)^2$, so

$$\langle \hat{H} \rangle = \frac{(\Delta p)^2}{2m} + \frac{1}{2}m\omega^2(\Delta x)^2 \geq \frac{\hbar^2}{8m(\Delta x)^2} + \frac{1}{2}m\omega^2(\Delta x)^2,$$

using $\Delta p \geq \hbar/2\Delta x$. Minimising over Δx (by calculus, or AM–GM), the minimum of the right hand side is at $(\Delta x)^2 = \hbar/2m\omega$, giving

$$\langle \hat{H} \rangle \geq \frac{\hbar\omega}{4} + \frac{\hbar\omega}{4} = \frac{\hbar\omega}{2}.$$

This lower bound is exactly the true ground state energy $E_0 = \frac{1}{2}\hbar\omega$ – the bound is achieved because the true ground state is a Gaussian, i.e. a minimal uncertainty state (see below). The same crude argument applied to hydrogen (balancing $\hbar^2/2m_e r^2$ against $-e^2/4\pi\epsilon_0 r$) predicts both the Bohr radius and the -13.6 eV ground state energy up to factors of order one: the sizes and energies of atoms are set by the uncertainty principle.

Which states are the most classical, saturating the bound? Tracing through the proof, equality requires equality in Cauchy–Schwarz, $\hat{B}'\psi = \lambda\hat{A}'\psi$, and vanishing of the anticommutator term, which together force λ to be purely imaginary: $(\hat{p} - \langle p \rangle)\psi = ic(\hat{x} - \langle x \rangle)\psi$ for some real c . Centering things at the origin for simplicity, this is the ODE

$$-i\hbar\psi' = icx\psi \implies \psi(x) = C \exp\left(-\frac{cx^2}{2\hbar}\right),$$

a *Gaussian* (with $c > 0$ for normalisability). So the minimal-uncertainty states are exactly the Gaussian wavepackets of §4.1 – which is why the Gaussian packet computation gave $\Delta x \Delta p = \hbar/2$ exactly at $t = 0$ – and, pleasingly, why the oscillator ground state (a Gaussian!) is the physical state that comes closest to sitting classically still at the bottom of the well.

§21.7 Quantum Mechanics in Three Dimensions

Real particles live in three dimensions, so it is time to go back to the full Schrödinger equation

$$i\hbar \frac{\partial \psi}{\partial t} = -\frac{\hbar^2}{2m} \nabla^2 \psi + U(\mathbf{x})\psi,$$

with wavefunctions normalised over $\mathbb{R}^3$. Everything from Sections 2, 3 and 6 – inner products, Hermitian operators, measurement, stationary states – was set up in $\mathbb{R}^3$ from the start, so carries over verbatim. What is genuinely new in three dimensions is *angular momentum*, and the associated richness of degeneracy.

The observables now come in triples: $\hat{x}_i\psi = x_i\psi$ and $\hat{p}_i = -i\hbar\frac{\partial}{\partial x_i}$ for $i = 1, 2, 3$, with canonical commutation relations

$$[\hat{x}_i, \hat{p}_j] = i\hbar\delta_{ij}, \quad [\hat{x}_i, \hat{x}_j] = [\hat{p}_i, \hat{p}_j] = 0.$$

Different coordinate directions are compatible: it is x_i and p_i *in the same direction* that refuse to commute.

§21.7.1 Separable Solutions

When the potential splits as a sum $U(\mathbf{x}) = U_1(x_1) + U_2(x_2) + U_3(x_3)$, the time-independent Schrödinger equation separates in Cartesian coordinates: substituting $\chi(\mathbf{x}) = \chi_1(x_1)\chi_2(x_2)\chi_3(x_3)$, each factor satisfies a one-dimensional Schrödinger equation with potential U_i , and the energies add. All our one-dimensional work is thus immediately recycled.

Example 21.7.1 (The Three-Dimensional Harmonic Oscillator)

For $U = \frac{1}{2}m\omega^2|\mathbf{x}|^2 = \sum_i \frac{1}{2}m\omega^2x_i^2$, the separable eigenfunctions are products of Hermite functions, with

$$E_{n_1n_2n_3} = (n_1 + n_2 + n_3 + \frac{3}{2})\hbar\omega, \quad n_i \in \{0, 1, 2, \dots\}.$$

The energy depends only on $n = n_1 + n_2 + n_3$, so the level $E = (n + \frac{3}{2})\hbar\omega$ has degeneracy equal to the number of ways of writing n as an ordered sum of three non-negative integers, namely $\binom{n+2}{2} = \frac{1}{2}(n+1)(n+2)$. This is our first meeting with large degeneracies – a symptom of the symmetry of the potential, as we are about to understand properly.

Example 21.7.2 (Particle in a Cubical Box)

Similarly, for a particle confined to a cube of side L (infinite walls, one corner at the origin), the eigenfunctions are products of one-dimensional box modes $\sin(n_i\pi x_i/L)$, with

$$E = \frac{\hbar^2\pi^2}{2mL^2} (n_1^2 + n_2^2 + n_3^2), \quad n_i \in \{1, 2, 3, \dots\}.$$

The ground state $(1, 1, 1)$ is unique, but the first excited level, $(2, 1, 1), (1, 2, 1), (1, 1, 2)$, is three-fold degenerate – the three states are related by rotating the box, so the degeneracy is again symmetry in action. (Higher up, ‘accidental’ coincidences like $1^2 + 1^2 + 5^2 = 3^2 + 3^2 + 3^2 = 27$ appear as well.) Counting the number of lattice points with $n_1^2 + n_2^2 + n_3^2 \leq 2mEL^2/\hbar^2\pi^2$ gives the *density of states* for a quantum gas – the starting point of statistical mechanics.

§21.7.2 Spherically Symmetric Potentials and the Radial Equation

The potentials nature actually likes – above all the Coulomb potential – are not sums but are **spherically symmetric**: $U = U(r)$ where $r = |\mathbf{x}|$. The right coordinates are spherical polars (r, θ, ϕ) ,

$$x = r \sin \theta \cos \phi, \quad y = r \sin \theta \sin \phi, \quad z = r \cos \theta,$$

in which the Laplacian takes the form

$$\nabla^2 = \frac{1}{r} \frac{\partial^2}{\partial r^2} r + \frac{1}{r^2} \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \phi^2} \right].$$

As a first pass, let's look for eigenfunctions that share the symmetry of the potential: $\chi = \chi(r)$ only. Then only the radial part of the Laplacian acts,

$$\nabla^2 \chi(r) = \frac{1}{r} \frac{d^2}{dr^2} (r\chi(r)) = \chi'' + \frac{2}{r} \chi',$$

and the time-independent Schrödinger equation becomes

$$-\frac{\hbar^2}{2m} \left(\chi'' + \frac{2}{r} \chi' \right) + U(r)\chi = E\chi.$$

There is a substitution that makes this look one-dimensional: let

$$\sigma(r) = r\chi(r).$$

Then the equation collapses to

$$-\frac{\hbar^2}{2m} \sigma''(r) + U(r)\sigma(r) = E\sigma(r),$$

which is *exactly* the one-dimensional Schrödinger equation – but on the half-line $r \geq 0$. The boundary conditions carry the memory of three dimensions: normalisability now reads

$$\int_{\mathbb{R}^3} |\chi|^2 dV = 4\pi \int_0^\infty |\chi(r)|^2 r^2 dr = 4\pi \int_0^\infty |\sigma(r)|^2 dr < \infty,$$

and for $\chi = \sigma/r$ to be well behaved at the origin we need

$$\sigma(0) = 0.$$

So: radial problems are one-dimensional problems on $r > 0$ with a hard wall at $r = 0$ – precisely the setting of the half-oscillator example of §4.5. A useful slogan: *the s-wave states of a 3D well are the odd states of the corresponding 1D well.*

Example 21.7.3 (The Spherical Potential Well)

Take $U(r) = 0$ for $r \leq a$ and $U(r) = U_0$ for $r > a$, and look for bound states $0 < E < U_0$. With the usual $k = \sqrt{2mE}/\hbar$ and $\kappa = \sqrt{2m(U_0 - E)}/\hbar$, the equation for σ is the finite-well equation, and the condition $\sigma(0) = 0$ selects the *odd* solutions:

$$\sigma(r) = \begin{cases} A \sin kr & r \leq a, \\ B e^{-\kappa r} & r > a. \end{cases}$$

Matching σ and σ' at $r = a$ gives

$$-k \cot ka = \kappa,$$

to be solved against $k^2 + \kappa^2 = 2mU_0/\hbar^2$, i.e. in the dimensionless variables of §4.4, the intersections of $\eta = -\xi \cot \xi$ with the circle of radius r_0 . The first branch of $-\xi \cot \xi$ only becomes positive for $\xi > \pi/2$, so there is *no bound state at all* unless $r_0 > \pi/2$, i.e. unless

$$U_0 a^2 > \frac{\pi^2 \hbar^2}{8m}.$$

Contrast the one-dimensional finite well, which always had a bound state: in three dimensions, a well must be deep or wide enough to trap a particle. (This is physically relevant: the deuteron – the proton-neutron bound state – is only just bound, and

this criterion is essentially the estimate nuclear physicists use for the strength of the nuclear force.)

To go beyond spherically symmetric *states*, we need to understand the angular part of the Laplacian – and that operator turns out to be precisely the angular momentum.

§21.7.3 Angular Momentum

Classically, angular momentum $\mathbf{L} = \mathbf{x} \times \mathbf{p}$ is the conserved quantity associated with rotational symmetry, and conservation of $\mathbf{L}$ is what reduces classical central-force motion to a one-dimensional radial problem. We now build the quantum analogue, by direct substitution.

Definition 21.7.4 (Angular Momentum Operators)

The **angular momentum operators** are

$$\hat{\mathbf{L}} = \hat{\mathbf{x}} \times \hat{\mathbf{p}} = -i\hbar \mathbf{x} \times \nabla, \quad \text{i.e.} \quad \hat{L}_i = -i\hbar \epsilon_{ijk} x_j \frac{\partial}{\partial x_k},$$

together with the **total angular momentum**

$$\hat{L}^2 = \hat{L}_1^2 + \hat{L}_2^2 + \hat{L}_3^2.$$

(There is no ordering ambiguity in the definition: $\hat{L}_i$ involves only products like $\hat{x}_2 \hat{p}_3$ with different indices, which commute.) Each $\hat{L}_i$ is Hermitian, being built from commuting Hermitian factors, and so is $\hat{L}^2$.

The central computation is the commutator of two components. Let's do one honestly, acting on a test function and using $[\hat{x}_i, \hat{p}_j] = i\hbar \delta_{ij}$:

$$\begin{aligned} [\hat{L}_1, \hat{L}_2] &= [\hat{x}_2 \hat{p}_3 - \hat{x}_3 \hat{p}_2, \hat{x}_3 \hat{p}_1 - \hat{x}_1 \hat{p}_3] \\ &= [\hat{x}_2 \hat{p}_3, \hat{x}_3 \hat{p}_1] + [\hat{x}_3 \hat{p}_2, \hat{x}_1 \hat{p}_3] \\ &= \hat{x}_2 [\hat{p}_3, \hat{x}_3] \hat{p}_1 + \hat{x}_1 [\hat{x}_3, \hat{p}_3] \hat{p}_2 = i\hbar (\hat{x}_1 \hat{p}_2 - \hat{x}_2 \hat{p}_1) = i\hbar \hat{L}_3, \end{aligned}$$

where the two dropped commutators vanish because all their factors commute. The same computation with indices cycled gives the full set of **angular momentum commutation relations**:

$$[\hat{L}_i, \hat{L}_j] = i\hbar \epsilon_{ijk} \hat{L}_k.$$

So the three components of angular momentum are mutually *incompatible*: no state has definite values of two different components (except the states with $\hat{\mathbf{L}}\psi = 0$). We cannot know the angular momentum vector; the best we can hope for is one component, plus the total length. And indeed:

Proposition 21.7.5

$[\hat{L}^2, \hat{L}_i] = 0$ for each i .

Proof. Using the Leibniz rule and the commutation relations (take $i = 3$, the others

being identical):

$$\begin{aligned} [\hat{L}^2, \hat{L}_3] &= \sum_{j=1}^3 (\hat{L}_j [\hat{L}_j, \hat{L}_3] + [\hat{L}_j, \hat{L}_3] \hat{L}_j) \\ &= i\hbar (-\hat{L}_1 \hat{L}_2 - \hat{L}_2 \hat{L}_1 + \hat{L}_2 \hat{L}_1 + \hat{L}_1 \hat{L}_2) = 0, \end{aligned}$$

the $j = 3$ terms vanishing outright. $\square$

By convention we choose the compatible pair to be $\hat{L}^2$ and $\hat{L}_3 = \hat{L}_z$. Moreover, angular momentum is compatible with any spherically symmetric Hamiltonian.

Proposition 21.7.6

For $\hat{H} = \frac{\hat{p}^2}{2m} + U(r)$ with U spherically symmetric,

$$[\hat{H}, \hat{L}_i] = 0 \quad \text{and} \quad [\hat{H}, \hat{L}^2] = 0.$$

Proof (Sketch). First, using the Leibniz rules and the canonical commutation relations, one computes

$$[\hat{L}_i, \hat{x}_j] = i\hbar \epsilon_{ijk} \hat{x}_k, \quad [\hat{L}_i, \hat{p}_j] = i\hbar \epsilon_{ijk} \hat{p}_k$$

– both position and momentum transform as vectors. From these,

$$[\hat{L}_i, \hat{p}^2] = \sum_j (\hat{p}_j [\hat{L}_i, \hat{p}_j] + [\hat{L}_i, \hat{p}_j] \hat{p}_j) = i\hbar \epsilon_{ijk} (\hat{p}_j \hat{p}_k + \hat{p}_k \hat{p}_j) = 0,$$

since a symmetric expression is contracted against the antisymmetric ϵ_{ijk} . Identically $[\hat{L}_i, \hat{x}^2] = 0$, and more generally $\hat{L}_i$ commutes with any function of r alone (e.g. by noting $\hat{L}_i$ involves only angular derivatives, as the spherical coordinate expressions below make manifest). Hence $[\hat{H}, \hat{L}_i] = 0$, and then $[\hat{H}, \hat{L}^2] = 0$ follows by the Leibniz rule. $\square$

So rotations are symmetries, and angular momentum is conserved (by Ehrenfest's theorem, $\frac{d}{dt} \langle \hat{L}_i \rangle = 0$), exactly as classically. So for a central potential we have a triple of mutually commuting observables

$$\{\hat{H}, \hat{L}^2, \hat{L}_z\},$$

and by the compatibility theorem of §6.4 we can look for a complete set of *joint* eigenfunctions of all three at once. (This set is in fact maximal – there is no further independent operator commuting with all of them – so these three quantum numbers are a complete label for the states.) This is the quantum version of ‘use conservation of $\mathbf{L}$ to reduce to a radial problem’, and it is exactly how we will crack the hydrogen atom.

§21.7.4 Spherical Harmonics

To find the joint eigenfunctions, we express the angular momentum operators in spherical polar coordinates. For $\hat{L}_z$ the computation is short enough to do in full: holding r and θ fixed and varying ϕ , we have $\partial x / \partial \phi = -r \sin \theta \sin \phi = -y$ and $\partial y / \partial \phi = r \sin \theta \cos \phi = x$

(and $\partial z/\partial\phi = 0$), so by the chain rule

$$\frac{\partial}{\partial\phi} = x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x},$$

which is exactly $\hat{L}_z/(-i\hbar)$. That is, we get the beautifully simple

$$\hat{L}_z = -i\hbar \frac{\partial}{\partial\phi},$$

(rotation about the z -axis is translation in ϕ – compare $\hat{p} = -i\hbar\partial_x$!) and, by a longer but entirely similar computation,

$$\hat{L}^2 = -\hbar^2 \left[\frac{1}{\sin\theta} \frac{\partial}{\partial\theta} \left(\sin\theta \frac{\partial}{\partial\theta} \right) + \frac{1}{\sin^2\theta} \frac{\partial^2}{\partial\phi^2} \right].$$

Comparing with the Laplacian in spherical polars, we discover the identity

$$-\hbar^2 \nabla^2 = -\frac{\hbar^2}{r} \frac{\partial^2}{\partial r^2} r + \frac{\hat{L}^2}{r^2},$$

i.e. the angular part of the kinetic energy is $\hat{L}^2/2mr^2$ – exactly the centrifugal term of classical mechanics.

The operators $\hat{L}_z, \hat{L}^2$ act only on angles, so we look for their joint eigenfunctions as functions $Y(\theta, \phi)$ on the unit sphere:

$$\hat{L}_z Y = \hbar m Y, \quad \hat{L}^2 Y = \lambda Y.$$

Separating $Y(\theta, \phi) = P(\theta) \Phi(\phi)$, the $\hat{L}_z$ equation gives $-i\hbar\Phi' = \hbar m\Phi$, so

$$\Phi(\phi) = e^{im\phi}.$$

Now, the point with coordinates ϕ and $\phi + 2\pi$ is the *same point of space*, so single-valuedness of the wavefunction demands $e^{2\pi im} = 1$:

$$m \in \mathbb{Z}.$$

The eigenvalues of any angular momentum component are integer multiples of $\hbar$ – quantisation of angular momentum has just fallen out of periodicity, with no extra input. (m is called the **magnetic** (or azimuthal) **quantum number**.)

Substituting into the $\hat{L}^2$ equation gives an ODE in θ alone:

$$\frac{1}{\sin\theta} \frac{d}{d\theta} \left(\sin\theta \frac{dP}{d\theta} \right) - \frac{m^2}{\sin^2\theta} P = -\frac{\lambda}{\hbar^2} P.$$

This is the *associated Legendre equation* (in the variable $u = \cos\theta$). The analysis is of the same flavour as the Hermite story – generic solutions blow up at the poles $\theta = 0, \pi$, and demanding regularity quantises the eigenvalue – so we just quote the result: regular solutions exist precisely when

$$\lambda = \hbar^2 \ell(\ell + 1), \quad \ell \in \{0, 1, 2, \dots\}, \quad |m| \leq \ell,$$

and are the *associated Legendre functions*

$$P_{\ell,m}(\cos\theta) = (\sin\theta)^{|m|} \frac{d^{|m|}}{d(\cos\theta)^{|m|}} P_{\ell}(\cos\theta),$$

where P_{ℓ} is the ℓ th Legendre polynomial. The constraint $|m| \leq \ell$ appears because P_{ℓ} has degree ℓ , so differentiating more than ℓ times gives zero – and it is the quantum counterpart of the classical triviality $|L_z| \leq |\mathbf{L}|$. We call ℓ the **total angular momentum quantum number**.

Definition 21.7.7 (Spherical Harmonics)

The joint eigenfunctions

$$Y_{\ell,m}(\theta, \phi) = P_{\ell,m}(\cos \theta) e^{im\phi}, \quad \hat{L}^2 Y_{\ell,m} = \hbar^2 \ell(\ell+1) Y_{\ell,m}, \quad \hat{L}_z Y_{\ell,m} = \hbar m Y_{\ell,m},$$

are called the **spherical harmonics**.

For each ℓ there are exactly $2\ell+1$ values of m , and the $Y_{\ell,m}$ form a complete orthogonal family on the sphere (as they must, being eigenfunctions of Hermitian operators with distinct eigenvalue pairs). The first few, normalised so that $\int_{S^2} |Y|^2 = 1$:

$$Y_{0,0} = \frac{1}{\sqrt{4\pi}}, \quad Y_{1,0} = \sqrt{\frac{3}{4\pi}} \cos \theta, \quad Y_{1,\pm 1} = \mp \sqrt{\frac{3}{8\pi}} \sin \theta e^{\pm i\phi}.$$

Example 21.7.8 (Verifying $Y_{1,0}$)

Let's check directly that $Y = \cos \theta$ does what we claim. It has no ϕ dependence, so $\hat{L}_z Y = -i\hbar \partial Y / \partial \phi = 0$: indeed $m = 0$. For $\hat{L}^2$:

$$\hat{L}^2 Y = -\frac{\hbar^2}{\sin \theta} \frac{\partial}{\partial \theta} (\sin \theta \cdot (-\sin \theta)) = \frac{\hbar^2}{\sin \theta} \cdot 2 \sin \theta \cos \theta = 2\hbar^2 \cos \theta,$$

so $\hat{L}^2 Y = \ell(\ell+1)\hbar^2 Y$ with $\ell = 1$, as claimed. A measurement of $\mathbf{L}^2$ in this state returns $2\hbar^2$ – note, *not* $\hbar^2$: the eigenvalues of $\hat{L}^2$ are $\ell(\ell+1)\hbar^2$, never a perfect square times $\hbar^2$, one of several places where the true quantum answer differs from the Bohr model's $L^2 = n^2\hbar^2$.

It is worth having a picture of these. Plotting $|Y_{\ell,m}|$ radially against direction (a cross-section through the z -axis is shown; the full shapes are these curves revolved about the vertical axis):

The state $Y_{0,0}$ is isotropic (no angular momentum, no preferred direction); $Y_{1,0}$ concentrates along the z -axis; $Y_{1,\pm 1}$ concentrate in the equatorial plane. Readers who have met atomic orbitals will recognise the s and p orbitals – chemistry's p_x, p_y, p_z are real linear combinations of $Y_{1,0}$ and $Y_{1,\pm 1}$.

Example 21.7.9 (Measuring L_z)

Suppose a particle's angular dependence is proportional to $\sin \theta \cos \phi$ (this is the ' p_x orbital' – and one can check it is orthogonal to $Y_{0,0}$ and $Y_{1,0}$ directly, e.g. $\int_{S^2} \cos \theta \sin \theta \cos \phi d\Omega = 0$ since the ϕ -integral of $\cos \phi$ vanishes). What does a measurement of L_z give? First expand in spherical harmonics: since $\cos \phi =$

$$\frac{1}{2}(e^{i\phi} + e^{-i\phi}),$$

$$\sin \theta \cos \phi = \frac{1}{2} \sin \theta e^{i\phi} + \frac{1}{2} \sin \theta e^{-i\phi} \propto Y_{1,1} - Y_{1,-1}$$

(up to the normalisation constants), an equal-weight superposition of $m = 1$ and $m = -1$. So by the measurement postulates, L_z returns $+\hbar$ or $-\hbar$, each with probability $\frac{1}{2}$ – and never 0, even though $\langle \hat{L}_z \rangle = 0$. A measurement of $\mathbf{L}^2$ on the same state returns $2\hbar^2$ with certainty, since only $\ell = 1$ appears. This is the whole apparatus of Section 6 – expansion, Born rule, compatible observables – running in its natural habitat.

Finally, let's put the pieces together for a general central potential. Since $\{\hat{H}, \hat{L}^2, \hat{L}_z\}$ commute, we may take energy eigenfunctions of the separated form

$$\chi(r, \theta, \phi) = R(r) Y_{\ell, m}(\theta, \phi),$$

and substituting into $\hat{H}\chi = E\chi$ using $-\hbar^2\nabla^2 = -\frac{\hbar^2}{r}\partial_r^2 r + \frac{\hat{L}^2}{r^2}$, the spherical harmonic passes through everything and cancels, leaving the **radial Schrödinger equation**

$$-\frac{\hbar^2}{2m} \left(R'' + \frac{2}{r} R' \right) + \underbrace{\left(U(r) + \frac{\hbar^2 \ell(\ell+1)}{2mr^2} \right)}_{U_{\text{eff}}(r)} R = ER.$$

This is a one-dimensional problem in the *effective potential* U_{eff} : the true potential plus the centrifugal barrier $\hbar^2 \ell(\ell+1)/2mr^2$, which pushes states with angular momentum away from the origin. Note two facts worth savouring:

- (i) taking $\ell = 0$ recovers exactly the spherically symmetric analysis of §7.2 – the ‘s-wave’ states;
- (ii) m does not appear in the radial equation at all, so every energy level automatically comes with degeneracy at least $2\ell+1$: rotating a state costs no energy. Degeneracy is symmetry made visible.

§21.8 The Hydrogen Atom

We have assembled everything needed for the crown jewel of the course: the quantum mechanics of the hydrogen atom, the problem whose experimental fingerprints (the spectral lines of Section 1) forced the whole theory into being.

Hydrogen is one electron bound to one proton. The proton is nearly two thousand times heavier, so we model it as fixed at the origin⁷, creating the Coulomb potential in which the electron moves:

$$U(r) = -\frac{e^2}{4\pi\epsilon_0} \cdot \frac{1}{r}.$$

Since $U \rightarrow 0$ at infinity, bound states – normalisable eigenfunctions – must have $E < 0$, and these are what we look for.

⁷More honestly, one works in the centre-of-mass frame and replaces m_e by the reduced mass $\mu = m_e m_p / (m_e + m_p) \approx 0.9995 m_e$ – a correction well below the accuracy we care about here (though spectroscopists can see it: it is how deuterium was discovered).

§21.8.1 The s-wave States

Let's warm up with the spherically symmetric states, $\ell = 0$, following §7.2 – this case already contains the entire energy spectrum. The radial equation reads

$$-\frac{\hbar^2}{2m_e} \left(\chi'' + \frac{2}{r} \chi' \right) - \frac{e^2}{4\pi\epsilon_0 r} \chi = E\chi.$$

Tidy up by defining the (positive) constants

$$\nu^2 = -\frac{2m_e E}{\hbar^2}, \quad \beta = \frac{e^2 m_e}{2\pi\epsilon_0 \hbar^2},$$

so the equation becomes

$$\chi'' + \frac{2}{r} \chi' + \left(\frac{\beta}{r} - \nu^2 \right) \chi = 0.$$

As $r \rightarrow \infty$ this is $\chi'' \approx \nu^2 \chi$, so solutions behave like $e^{\pm \nu r}$ and normalisability selects the decaying exponential. As with the harmonic oscillator, we peel off the asymptotics: substitute

$$\chi(r) = f(r) e^{-\nu r},$$

giving

$$f'' + \frac{2}{r}(1 - \nu r)f' + \frac{1}{r}(\beta - 2\nu)f = 0.$$

Try a power series $f(r) = \sum_{n \geq 0} a_n r^n$ (one checks first, by trying $f \sim r^c$, that the indicial equation $c(c+1) = 0$ forces $c = 0$; the root $c = -1$ would make $\chi \sim 1/r$, which is not acceptable at the origin). Substituting and comparing coefficients of r^{n-1} :

$$n(n+1)a_n = (2\nu n - \beta)a_{n-1},$$

that is,

$$a_n = \frac{2\nu n - \beta}{n(n+1)} a_{n-1}.$$

Once again everything hinges on whether the series terminates. If it does not, then asymptotically $a_n/a_{n-1} \sim 2\nu/n$, which is precisely the growth rate of the coefficients of $e^{2\nu r}$ – so f would grow like $e^{2\nu r}$, overwhelming the decaying factor and making $\chi \sim e^{\nu r}$ non-normalisable (the same comparison argument as for the oscillator). So the series must terminate: there is an integer $N \geq 1$ with $a_N = 0$ and $a_{N-1} \neq 0$, which by the recurrence means

$$2\nu N = \beta, \quad \text{i.e.} \quad \nu = \frac{\beta}{2N}.$$

Unwinding the definitions of ν and β , we have found the energy levels:

$$E_N = -\frac{\hbar^2 \nu^2}{2m_e} = -\frac{e^4 m_e}{32\pi^2 \epsilon_0^2 \hbar^2} \cdot \frac{1}{N^2},$$

in exact agreement with the Bohr model, and hence with the observed spectrum – but this time derived from an honest wave equation, with no orbits postulated.

The eigenfunctions are polynomials (of degree $N-1$, the *Laguerre polynomials*) times a decaying exponential. In particular the ground state, $N=1$, is a pure exponential:

$$\chi_1(r) = \frac{1}{\sqrt{\pi a_0^3}} e^{-r/a_0}, \quad a_0 = \frac{1}{\nu} \Big|_{N=1} = \frac{2}{\beta} = \frac{4\pi\epsilon_0 \hbar^2}{m_e e^2},$$

where the decay length is exactly the Bohr radius $a_0 \approx 5.3 \times 10^{-11}$ m of Section 1.

Example 21.8.1 (The Size of the Atom)

Where is the electron? Let's compute the expected radius in the ground state:

$$\langle r \rangle = \int_{\mathbb{R}^3} \chi_1^* r \chi_1 dV = \frac{4\pi}{\pi a_0^3} \int_0^\infty r^3 e^{-2r/a_0} dr = \frac{4}{a_0^3} \cdot \frac{3! a_0^4}{2^4} = \frac{3}{2} a_0,$$

using $\int_0^\infty r^3 e^{-\alpha r} dr = 3!/\alpha^4$. So the quantum atom is one and a half times larger, on average, than Bohr's orbit – a genuinely different (and experimentally correct) prediction. The electron is not on a circle of radius a_0 ; it is in a fuzzy exponential cloud.

Example 21.8.2 (Energy Bookkeeping in the Ground State)

In the same way, $\langle 1/r \rangle = 4\pi \cdot \frac{1}{\pi a_0^3} \int_0^\infty r e^{-2r/a_0} dr = 1/a_0$, so the expected potential energy in the ground state is

$$\langle U \rangle = -\frac{e^2}{4\pi\epsilon_0} \left\langle \frac{1}{r} \right\rangle = -\frac{e^2}{4\pi\epsilon_0 a_0} = 2E_1,$$

and hence the expected kinetic energy is $\langle T \rangle = E_1 - \langle U \rangle = -E_1 > 0$. So

$$\langle T \rangle = -\frac{1}{2} \langle U \rangle,$$

which is precisely the *virial theorem* for an inverse-square force law, in expectation – another classical relation surviving intact as a statement about means. Numerically: the electron has kinetic energy +13.6 eV and potential energy –27.2 eV, and it costs 13.6 eV to pull it away.

§21.8.2 The General Solution

Now the full problem, with angular momentum. By §7.4 we take

$$\chi(r, \theta, \phi) = R(r) Y_{\ell, m}(\theta, \phi),$$

where the radial function satisfies

$$R'' + \frac{2}{r} R' + \left(\frac{\beta}{r} - \nu^2 - \frac{\ell(\ell+1)}{r^2} \right) R = 0.$$

The large- r asymptotics are unchanged (the centrifugal term is subleading), so again $R = g(r)e^{-\nu r}$. Near the origin the centrifugal term dominates: trying $g \sim r^c$ gives the indicial equation

$$c(c+1) = \ell(\ell+1) \implies c = \ell \text{ or } c = -\ell - 1,$$

and regularity at the origin forces $c = \ell$ – states with angular momentum are suppressed like r^ℓ near the centre, pushed out by the centrifugal barrier. So we write

$$g(r) = r^\ell \sum_{n \geq 0} a_n r^n,$$

and the same machinery as before (substitute, compare coefficients) produces the recurrence

$$a_n = \frac{2\nu(n+\ell) - \beta}{n(n+2\ell+1)} a_{n-1}.$$

Again the series must terminate or R grows like $e^{\nu r}$; terminating at the $n_{\max}$ -th term requires

$$2\nu(n_{\max} + \ell) = \beta, \quad n_{\max} \geq 1.$$

Defining the **principal quantum number** $N = n_{\max} + \ell$, we get $\nu = \beta/2N$ exactly as before, and therefore *exactly the same energy levels*

$$E_N = -\frac{e^4 m_e}{32\pi^2 \epsilon_0^2 \hbar^2} \cdot \frac{1}{N^2} = -\frac{\hbar^2}{2m_e a_0^2} \cdot \frac{1}{N^2},$$

now with the constraint $\ell \leq N - 1$ (since $n_{\max} \geq 1$). The full set of stationary states is indexed by three quantum numbers:

$$\chi_{N,\ell,m}(r, \theta, \phi) = R_{N,\ell}(r) Y_{\ell,m}(\theta, \phi), \quad \begin{cases} N = 1, 2, 3, \dots \\ \ell = 0, 1, \dots, N - 1, \\ m = -\ell, \dots, \ell, \end{cases}$$

with $R_{N,\ell}(r) = r^\ell g_{N,\ell}(r) e^{-r/Na_0}$ and $g_{N,\ell}$ a polynomial of degree $N - \ell - 1$ (a *generalised Laguerre polynomial*). In spectroscopic notation, states with $\ell = 0, 1, 2, \dots$ are called $s, p, d, \dots$ states; the state $\chi_{2,1,m}$ is ‘ $2p$ ’, and so on.

Example 21.8.3 (The First Few Radial Functions)

The recurrence makes these easy to generate. For $N = 1$, $\ell = 0$ the polynomial is a constant, giving the ground state we already know. For $N = 2$, $\ell = 0$ we have $\nu = 1/2a_0$ and one step of the recurrence gives $a_1/a_0 = (2\nu - \beta)/2 = -\nu$, while for $N = 2$, $\ell = 1$ the polynomial is again constant. Normalising:

$$\begin{aligned} R_{1,0}(r) &= \frac{2}{a_0^{3/2}} e^{-r/a_0}, \\ R_{2,0}(r) &= \frac{1}{\sqrt{2} a_0^{3/2}} \left(1 - \frac{r}{2a_0}\right) e^{-r/2a_0}, \\ R_{2,1}(r) &= \frac{1}{2\sqrt{6} a_0^{3/2}} \cdot \frac{r}{a_0} e^{-r/2a_0}. \end{aligned}$$

Note the general features on display: $N - \ell - 1$ radial nodes ($R_{2,0}$ vanishes at $r = 2a_0$; $R_{2,1}$ has none), the r^ℓ suppression at the origin, and the decay length Na_0 growing with the principal quantum number – excited atoms are physically bigger.

The energy depends on N *alone* – not on ℓ or m . So the level E_N is highly degenerate:

$$D(N) = \sum_{\ell=0}^{N-1} (2\ell + 1) = N^2.$$

The m -degeneracy is the rotational symmetry we understood in §7.4; but the ℓ -degeneracy – states with visibly different shapes and different angular momenta sharing an energy exactly – is special to the $1/r$ potential, and is called an *accidental* degeneracy. (It is not really an accident: the Coulomb problem has a hidden extra conserved quantity, the Runge–Lenz vector, just as in the classical Kepler problem where it is responsible for orbits being closed ellipses. But that story belongs to another course.)

It is illuminating to look at the *radial probability density* $P(r) = r^2 |R_{N,\ell}(r)|^2$ (the r^2 from the volume element: $P(r)\delta r$ is the probability of finding the electron at radius between r and $r + \delta r$):

The $1s$ density peaks exactly at $r = a_0$ (differentiate $r^2 e^{-2r/a_0}$ and see) – so Bohr’s orbit survives as the *most probable* radius of the ground state. The $2s$ state shows a radial node (a spherical shell where the electron is never found), while $2p$ has none but is pushed outwards by the centrifugal barrier; both are concentrated roughly four times (N^2) further out than $1s$.

Exercise 21.8.4. Show that the radial density of the $2p$ state, $P(r) \propto r^4 e^{-r/a_0}$, peaks at exactly $r = 4a_0 = 2^2 a_0$ – the Bohr orbit for $N = 2$ – and more generally that the ‘circular’ states ($\ell = N - 1$, whose radial functions $r^{N-1} e^{-r/Na_0}$ have no nodes) peak at exactly $r = N^2 a_0$. The Bohr model lives on inside quantum mechanics as the family of maximal-angular-momentum states.

§21.8.3 The Hydrogen Spectrum

Finally, let’s close the loop with Section 1. An atom in an excited state can drop to a lower level, emitting a photon carrying the energy difference⁸: a transition from level M down to level $N < M$ produces a photon of angular frequency

$$\hbar\omega = E_M - E_N = \frac{e^4 m_e}{32\pi^2 \epsilon_0^2 \hbar^2} \left(\frac{1}{N^2} - \frac{1}{M^2} \right),$$

which is precisely the Rydberg formula, with the Rydberg constant now expressed in fundamental constants (and matching its measured value). Transitions down to $N = 1$ form the *Lyman series* (ultraviolet), those down to $N = 2$ the *Balmer series* (the visible lines that gave the game away historically), down to $N = 3$ the *Paschen series* (infrared), and so on.

Example 21.8.5 (The Red Line of Hydrogen)

The lowest Balmer transition, $3 \rightarrow 2$, releases

$$E_3 - E_2 = 13.6 \left(\frac{1}{4} - \frac{1}{9} \right) \text{ eV} = 13.6 \cdot \frac{5}{36} \text{ eV} \approx 1.89 \text{ eV},$$

corresponding to a wavelength $\lambda = 2\pi\hbar c / (E_3 - E_2) \approx 656 \text{ nm}$ – the famous red line $H\alpha$, visible in a discharge tube in any teaching lab, and responsible for the red glow of emission nebulae across the night sky. It is hard to think of another place in physics where a short power series computation connects so directly to the colour of things.

⁸The mechanism of the transition – the coupling of the atom to the electromagnetic field – is outside our theory: strictly, our stationary states never change. Getting this right requires quantum electrodynamics; the energy bookkeeping, which is all we need for the spectrum, does not.

For $E > 0$ the spectrum of $\hat{H}$ is continuous – these are the scattering states of an ionised electron flying past a proton – which is why the discrete lines accumulate at the *ionisation energy* 13.6 eV and give way to a continuum beyond.

Let's take stock of what quantum mechanics has achieved here, compared with the Bohr model it replaces.

- (i) The energy levels and spectrum come out identically – and correctly – but now as eigenvalues of a differential operator, with the quantisation forced by normalisability, not decreed.
- (ii) The angular momentum is completely different, and Bohr's was wrong: the true eigenvalues of $\hat{L}^2$ are $\hbar^2\ell(\ell+1)$ with $\ell \leq N-1$, not $\hbar^2N^2$ – so the ground state has *zero* angular momentum (it agrees with Bohr's $L = N\hbar$ only in the limit of large ℓ). The electron does not orbit.
- (iii) The model explains what Bohr could not: the degeneracies N^2 (visible in the splitting of spectral lines in electric and magnetic fields), and the relative intensities of the lines, via the shapes of the wavefunctions.

§21.8.4 Beyond Hydrogen

It is natural to ask how far this machinery reaches. For an atom of atomic number Z – a nucleus of charge $+Ze$ with Z electrons – the honest Hamiltonian acts on a wavefunction $\psi(\mathbf{x}_1, \dots, \mathbf{x}_Z)$ of all the electron positions at once:

$$\hat{H} = \sum_{j=1}^Z \left(-\frac{\hbar^2}{2m_e} \nabla_j^2 - \frac{Ze^2}{4\pi\epsilon_0|\mathbf{x}_j|} \right) + \sum_{j<k} \frac{e^2}{4\pi\epsilon_0|\mathbf{x}_j - \mathbf{x}_k|}.$$

The last sum – the electron-electron repulsion – is what ruins everything: without it, the equation would separate, and the eigenfunctions would just be products of hydrogen-like states

$$\psi = \chi_{(1)}(\mathbf{x}_1)\chi_{(2)}(\mathbf{x}_2)\cdots\chi_{(Z)}(\mathbf{x}_Z), \quad E = \sum_j E_{(j)},$$

each factor a state $\chi_{N,\ell,m}$ in the (rescaled, $a_0 \mapsto a_0/Z$) Coulomb potential. With the repulsion, no exact solution is known for any $Z \geq 2$, and one falls back on treating the product form as an approximation in which each electron sees an averaged, screened nuclear charge. This is crude but structurally right, and two extra ingredients – both beyond this course, both essential – turn it into the periodic table:

- (i) electrons carry *spin*, an internal two-valued degree of freedom with no classical analogue, doubling the count of states at each level from N^2 to $2N^2$;
- (ii) identical electrons obey the *Pauli exclusion principle*: no two may occupy the same state.

Filling the one-electron levels from the bottom, two electrons at a time per orbital, gives shells of sizes $2, 8, 18, \dots = 2N^2$, and the chemistry of an element is governed by its outermost, partially-filled shell – the periodicity of the periodic table is the level structure of the hydrogen atom, doubled and stacked. (The screening breaks the accidental ℓ -degeneracy, which is why the shells actually fill in the slightly scrambled order familiar from chemistry.)

Getting all of this right – spin, identical particles, perturbative approximations, and the deeper structure (Dirac notation, abstract Hilbert spaces, symmetries) hiding beneath the wave mechanics we have used – is the business of the sequel courses, ‘Principles of Quantum Mechanics’ above all.

And that is a fitting place to stop. From five axioms about wavefunctions we have recovered – and corrected – the atom.

22 Statistics

Statistics is the science of making informed decisions. It is an area of mathematics that is widely applicable, and covers the design of experiments, the analysis of data, statistical inference, and the communication of uncertainty and risk. In this course we will focus on formal statistical inference.

Probability, as we met it in IA, starts from a fully specified model and asks what the data will look like. Statistics runs that arrow backwards: we are handed the data, and asked what the model must have been. That inversion is what gives the subject its character – there is never a single right answer, only estimates with quantified uncertainty, and procedures whose long-run behaviour we can guarantee. Almost everything in these notes is an attempt to make one of the words ‘estimate’, ‘uncertainty’ or ‘guarantee’ precise.

This article constitutes my notes for the ‘Statistics’ course, held in Lent 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered. Note that familiarity with classical probability theory is assumed, and a full recap is not included – the reader is referred to my ‘Probability’ notes for anything in Section 1 that is unfamiliar.

§22.1 Introduction

§22.1.1 Parametric Inference

Let $X_1, \dots, X_n$ be i.i.d random variables. We will assume that the distribution of X_i belongs to some family with parameter $\theta \in \Theta$. For example, we could have $X_1 \sim \text{Poisson}(\mu)$ with $\theta = \mu \in \Theta = (0, \infty)$. We can also have a multi-dimensional parameter such as $X_1 \sim N(\mu, \sigma^2)$ with $\theta = (\mu, \sigma^2) \in \Theta = \mathbb{R} \times (0, \infty)$. We will use the observed $X = (X_1, \dots, X_n)$ to make inferences about the parameter θ . Such inferences include:

1. Point estimate of $\hat{\theta}(X)$ of θ ;
2. An interval estimate $(\hat{\theta}_1(X), \hat{\theta}_2(X))$ of θ ;
3. Testing hypothesis about θ , that is, checking whether there is evidence in the data X against a given hypothesis.

In this course we will usually assume that the distribution family of $X_1, \dots, X_n$ is known, and that the parameter is unknown. From time to time we will be able to make slightly more general statements.

This setup is called **parametric** inference, because the unknown is a finite-dimensional parameter. It is a genuine modelling assumption, and a strong one: if the family is badly chosen then no amount of clever estimation will save us. In practice one checks the family afterwards, and Section 5 gives us the tools (goodness-of-fit tests) to do exactly that.

§22.1.2 Random Samples and Statistics

We should fix some language before we start.

Definition 22.1.1 (Random Sample)

A **random sample** of size n from a distribution f is a collection $X = (X_1, \dots, X_n)$ of independent random variables, each with distribution f . We write $X_1, \dots, X_n \stackrel{\text{iid}}{\sim} f$.

Definition 22.1.2 (Statistic)

A **statistic** is any function $T(X)$ of the data alone. In particular a statistic may *not* depend on the unknown parameter θ : it must be something we can actually compute once the data are in front of us.

The distribution of a statistic $T(X)$ – which of course will in general depend on θ – is called its **sampling distribution**. Most of statistics consists of choosing a statistic whose sampling distribution we understand well enough to say something useful.

The two statistics we will use over and over are the sample mean and the sum of squared deviations from it.

Definition 22.1.3 (Sample Mean and S_{XX})

Given a sample $X_1, \dots, X_n$ we write

$$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i, \quad S_{XX} = \sum_{i=1}^n (X_i - \bar{X})^2.$$

If $\mathbb{E}[X_1] = \mu$ and $\text{Var}(X_1) = \sigma^2$ then linearity of expectation and bilinearity of variance immediately give

$$\mathbb{E}[\bar{X}] = \mu, \quad \text{Var}(\bar{X}) = \frac{\sigma^2}{n},$$

so the sample mean is ‘centred at the right place’ and gets more concentrated as n grows. It is worth recording the standardised version

$$Z_n = \frac{\sqrt{n}(\bar{X} - \mu)}{\sigma},$$

which has mean 0 and variance 1 whatever μ and σ are. The central limit theorem says Z_n is approximately $N(0, 1)$ for large n , and this single fact is responsible for a remarkable fraction of the approximations in this course.

There is one small wrinkle worth noticing now, since it will bite us later. A short computation gives

$$\begin{aligned} \mathbb{E}[S_{XX}] &= \mathbb{E} \left[\sum_i (X_i - \mu)^2 - n(\bar{X} - \mu)^2 \right] \\ &= n\sigma^2 - n \cdot \frac{\sigma^2}{n} = (n-1)\sigma^2, \end{aligned}$$

so S_{XX}/n *underestimates* σ^2 , and it is $S_{XX}/(n-1)$ that is unbiased. The intuition is that we have used up one ‘degree of freedom’ estimating the mean, and the data look slightly less spread out about $\bar{X}$ than about the true μ . This phrase ‘degrees of freedom’ will be given a precise geometric meaning in Section 7.

§22.1.3 Sampling Distributions from the Normal

Almost all the exact distribution theory in this course comes from one place: sums of squares of independent standard normals. We collect the three families here, since we will want to refer to them from the very beginning. All three are already implicitly present in IA Probability as special cases or ratios of gamma distributions.

Recall that $X \sim \text{Gamma}(\alpha, \lambda)$ has density proportional to $x^{\alpha-1}e^{-\lambda x}$ on $(0, \infty)$, and that gammas with a common rate add: $\text{Gamma}(\alpha_1, \lambda) + \text{Gamma}(\alpha_2, \lambda) = \text{Gamma}(\alpha_1 + \alpha_2, \lambda)$ for independent summands.

Definition 22.1.4 (Chi-Squared Distribution)

Let $Z_1, \dots, Z_k$ be i.i.d $N(0, 1)$. Then

$$\chi_k^2 := Z_1^2 + \dots + Z_k^2$$

is said to have the **chi-squared distribution on k degrees of freedom**.

If $Z \sim N(0, 1)$ then $Z^2 \sim \text{Gamma}(1/2, 1/2)$ (a one-line change of variables), so by the addition rule $\chi_k^2 \sim \text{Gamma}(k/2, 1/2)$, with density

$$f(x) = \frac{1}{2^{k/2}\Gamma(k/2)} x^{k/2-1} e^{-x/2}, \quad x > 0.$$

In particular $\mathbb{E}[\chi_k^2] = k$ and $\text{Var}(\chi_k^2) = 2k$. The shape changes character as k increases: for $k \leq 2$ the density is decreasing, and for $k \geq 3$ it has an interior mode at $k - 2$, drifting rightwards and flattening out.

We will write $\chi_k^2(\alpha)$ for the **upper α point** of the distribution, that is, the number with $\mathbb{P}(\chi_k^2 > \chi_k^2(\alpha)) = \alpha$. The same convention will be used for every distribution in these notes.

Definition 22.1.5 (Student's t -Distribution)

Let $Z \sim N(0, 1)$ and $V \sim \chi_k^2$ be independent. Then

$$T = \frac{Z}{\sqrt{V/k}}$$

is said to have the **t -distribution on k degrees of freedom**, written $T \sim t_k$.

The point of this definition – which looks arbitrary until you see it used – is that it describes what happens when you standardise a normal mean but have to *estimate* the standard deviation rather than knowing it. We will prove exactly this in Section 6. One can compute the density to be

$$f_T(t) = \frac{\Gamma\left(\frac{k+1}{2}\right)}{\Gamma\left(\frac{k}{2}\right) \sqrt{\pi k}} \left(1 + \frac{t^2}{k}\right)^{-(k+1)/2},$$

which is symmetric and bell-shaped, but with polynomially decaying (hence much fatter) tails than the normal. Indeed $\mathbb{P}(T > t) > \mathbb{P}(Z > t)$ for every $t > 0$: having to estimate σ costs us, and the cost shows up precisely as extra probability far from the centre.

As $k \rightarrow \infty$ we have $V/k \rightarrow 1$ by the law of large numbers, so $t_k \rightarrow N(0, 1)$; the picture above shows this happening already by $k = 10$. For small k the tails really are heavy: t_1 is the Cauchy distribution, which has no mean at all. In general $\mathbb{E}[T] = 0$ for $k > 1$ and $\text{Var}(T) = k/(k-2)$ for $k > 2$, with the variance infinite at $k = 2$ and undefined at $k = 1$.

Definition 22.1.6 (*F*-Distribution)

Let $V \sim \chi_m^2$ and $W \sim \chi_n^2$ be independent. Then

$$F = \frac{V/m}{W/n}$$

is said to have the ***F*-distribution on m and n degrees of freedom**, written $F \sim F_{m,n}$.

This is what appears when we want to compare two variances, or – much more importantly – when we want to compare the fit of two nested models by comparing two sums of squares. It is supported on $(0, \infty)$ and concentrates around 1 as both $m, n \rightarrow \infty$, which is what one would expect of a ratio of two estimates of the same quantity.

Two relations are worth remembering, both immediate from the definitions. First, if $T \sim t_n$ then $T^2 \sim F_{1,n}$, since $T^2 = Z^2/(V/n)$ and $Z^2 \sim \chi_1^2$. Second, if $F \sim F_{m,n}$ then $1/F \sim F_{n,m}$. The first of these will let us identify a two-sided t -test with an F -test in Section 7.

§22.2 Estimation

Suppose $X_1, \dots, X_n$ are i.i.d observations with a pdf (or pmf) $f_X(x \mid \theta)$ where θ is an unknown parameter in a parameter space Θ . The first and most basic inferential question is: what single value of θ do the data suggest?

§22.2.1 Estimators, Bias and Mean Squared Error

Definition 22.2.1 (Estimator)

An **estimator** is a statistic or function of the data $T(X) = \hat{\theta}$ which does *not* depend on θ , and is used to approximate the true parameter θ .

The distribution of $T(X)$ is its **sampling distribution**.

We can then go on to define the *bias* of an estimator.

Definition 22.2.2 (Bias)

The **bias** of $\hat{\theta} = T(X)$ is

$$\text{bias}(\hat{\theta}) = \mathbb{E}_\theta(\hat{\theta}) - \theta,$$

where $\mathbb{E}_\theta$ gives expectation in the model $X_i \sim f_X(\cdot \mid \theta)$.

Remark. In general the bias is a function of the true parameter θ , even though it is not explicit in the notation $\text{bias}(\hat{\theta})$.

Definition 22.2.3 (Unbiased Estimator)

We say that $\hat{\theta}$ is **unbiased** if $\text{bias}(\hat{\theta}) = 0$ for *all* values of the true parameter θ .

Example 22.2.4 (Defining an Estimator)

Consider the i.i.d random variables $X_1, \dots, X_n \sim N(\mu, 1)$. Then we can define the

estimator

$$\hat{\mu} = T(X) = \frac{1}{n} \sum_i X_i = \bar{X}.$$

The sampling distribution of $\hat{\mu}$ is $T(X) \sim N(\mu, 1/n)$.

We can see that $\hat{\mu}$ is an unbiased estimator since

$$\mathbb{E}_\theta(\hat{\mu}) = \mathbb{E}_\mu(\bar{X}) = \mu,$$

for all $\mu \in \mathbb{R}$.

Unbiasedness on its own is a very weak requirement – it says nothing about how far $\hat{\theta}$ typically is from θ , only that the errors average out. One way of measuring ‘how far’ $\hat{\theta}$ is from θ ‘on average’ is given by the *mean squared error* (mse).

Definition 22.2.5 (Mean Squared Error)

The **mean squared error** of $\hat{\theta}$ is defined to be

$$\text{mse}(\hat{\theta}) = \mathbb{E}_\theta \left[(\hat{\theta} - \theta)^2 \right].$$

Again, note that $\text{mse}(\hat{\theta})$ may depend on θ , even though this dependence is omitted from the notation.

Proposition 22.2.6 (Bias-Variance Decomposition)

For any estimator $\hat{\theta}$ with finite second moment,

$$\text{mse}(\hat{\theta}) = \text{Var}_\theta(\hat{\theta}) + \text{bias}^2(\hat{\theta}).$$

Proof. We add and subtract $\mathbb{E}_\theta \hat{\theta}$ inside the square:

$$\begin{aligned} \text{mse}(\hat{\theta}) &= \mathbb{E}_\theta \left[(\hat{\theta} - \mathbb{E}_\theta \hat{\theta} + \mathbb{E}_\theta \hat{\theta} - \theta)^2 \right] \\ &= \mathbb{E}_\theta \left[(\hat{\theta} - \mathbb{E}_\theta \hat{\theta})^2 \right] + 2(\mathbb{E}_\theta \hat{\theta} - \theta) \mathbb{E}_\theta [\hat{\theta} - \mathbb{E}_\theta \hat{\theta}] + (\mathbb{E}_\theta \hat{\theta} - \theta)^2 \\ &= \underbrace{\text{Var}_\theta(\hat{\theta})}_{\geq 0} + \underbrace{\text{bias}_\theta^2(\hat{\theta})}_{\geq 0}, \end{aligned}$$

since the cross term vanishes: $\mathbb{E}_\theta[\hat{\theta} - \mathbb{E}_\theta \hat{\theta}] = 0$. □

This decomposition is the single most useful identity in estimation theory, because it shows that there is a genuine *tradeoff*: we may be able to buy a large reduction in variance at the cost of a small bias, and come out ahead. Insisting on unbiasedness forbids that trade entirely. Let’s see this happen.

Example 22.2.7 (A Biased Estimator that Wins)

Consider the random variable $X \sim \text{Bin}(n, \theta)$, and suppose n is known, with $\theta \in [0, 1]$ being an unknown parameter.

The standard estimator for this example would be

$$T_U = \frac{X}{n},$$

which can be thought of as the ‘proportion of successes observed’. This estimator is clearly unbiased since

$$\mathbb{E}_\theta(T_U) = \frac{\mathbb{E}_\theta X}{n} = \frac{n\theta}{n} = \theta.$$

We can also compute that

$$\text{mse}(T_U) = \text{Var}_\theta(T_U) = \frac{\theta(1-\theta)}{n}.$$

Now consider another estimator

$$T_B = \frac{X+1}{n+2} = w \cdot \underbrace{\frac{X}{n}}_{T_U} + (1-w) \cdot \frac{1}{2}, \quad w = \frac{n}{n+2},$$

which shrinks the observed proportion towards $1/2$. Its bias is

$$\text{bias}(T_B) = \frac{n\theta + 1}{n+2} - \theta = \frac{1-2\theta}{n+2},$$

which vanishes only at $\theta = 1/2$, and its variance is $w^2\theta(1-\theta)/n$. So

$$\text{mse}(T_B) = w^2 \cdot \frac{\theta(1-\theta)}{n} + (1-w)^2 \left(\frac{1}{2} - \theta\right)^2.$$

Plotting these against θ for $n = 10$, we see that neither estimator dominates.

The biased estimator is better over a broad range of θ near $1/2$, and worse near the endpoints. Which one we prefer therefore depends on what we believe about θ before seeing the data – an observation which will lead us, in Section 4, straight to Bayesian inference.

It is also worth seeing that insisting on unbiasedness can produce estimators that are frankly absurd.

Example 22.2.8 (Unbiasedness Gone Wrong)

Suppose $X \sim \text{Poisson}(\lambda)$ and we wish to estimate $\theta = \mathbb{P}(X = 0)^2 = e^{-2\lambda}$. For $T(X)$ to be unbiased we need, for all $\lambda > 0$,

$$\mathbb{E}_\lambda[T(X)] = \sum_{x=0}^{\infty} T(x) \frac{\lambda^x e^{-\lambda}}{x!} = e^{-2\lambda},$$

that is, $\sum_{x \geq 0} T(x) \lambda^x / x! = e^{-\lambda}$. Comparing coefficients of λ^x with the power series for $e^{-\lambda}$ gives $T(x) = (-1)^x$.

So the *unique* unbiased estimator of θ takes only the values ± 1 , and estimates a quantity known to lie in $(0, 1)$ by -1 whenever we observe an odd number of events. Unbiasedness is clearly not, by itself, a guarantee of anything sensible.

§22.2.2 Sufficiency

The data $X = (X_1, \dots, X_n)$ typically contains far more detail than we need. If $X_1, \dots, X_n$ are i.i.d Bernoulli, it seems clear that the *order* of the successes tells us nothing about θ ; only the total number matters. Sufficiency is the notion that makes this precise.

Definition 22.2.9 (Sufficient Statistic)

A statistic $T(X)$ is **sufficient** for θ if the conditional distribution of X given $T(X)$ does not depend on θ .

In other words – once we know $T(X)$, the remaining randomness in X is pure noise, generated by a mechanism we could simulate ourselves without knowing θ . Nothing about θ is lost by throwing away X and keeping only $T(X)$. Note that θ and $T(X)$ may both be vector-valued, and need not have the same dimension.

Example 22.2.10 (Bernoulli Trials)

Let $X_1, \dots, X_n$ be i.i.d Bernoulli(θ) with $\theta \in [0, 1]$. The joint mass function is

$$f_X(x | \theta) = \prod_{i=1}^n \theta^{x_i} (1 - \theta)^{1-x_i} = \theta^{\sum x_i} (1 - \theta)^{n - \sum x_i},$$

which depends on x only through $t = \sum_i x_i$. Let $T(X) = \sum_i X_i$; since $T \sim \text{Bin}(n, \theta)$, for any x with $\sum_i x_i = t$ we get

$$\mathbb{P}_\theta(X = x | T(X) = t) = \frac{\mathbb{P}_\theta(X = x)}{\mathbb{P}_\theta(T = t)} = \frac{\theta^t (1 - \theta)^{n-t}}{\binom{n}{t} \theta^t (1 - \theta)^{n-t}} = \frac{1}{\binom{n}{t}},$$

and the probability is 0 if $\sum_i x_i \neq t$. This is free of θ , so T is sufficient: given the total, the particular arrangement of successes is uniform over all $\binom{n}{t}$ arrangements, regardless of θ .

Checking sufficiency from the definition means computing a conditional distribution, which is tedious. Happily there is a criterion that lets us read sufficiency straight off the likelihood.

Theorem 22.2.11 (Factorisation Criterion)

A statistic T is sufficient for θ if and only if we can write

$$f_X(x | \theta) = g(T(x), \theta) h(x)$$

for some functions g and h , where h does not depend on θ .

Proof. We give the proof in the discrete case; the continuous case is identical with sums replaced by integrals (and a little care about null sets).

Suppose first that the factorisation holds, and let $t = T(x)$. Then

$$\begin{aligned} \mathbb{P}_\theta(X = x | T(X) = t) &= \frac{\mathbb{P}_\theta(X = x, T(X) = t)}{\mathbb{P}_\theta(T(X) = t)} \\ &= \frac{g(T(x), \theta) h(x)}{\sum_{x': T(x') = t} g(T(x'), \theta) h(x')} \\ &= \frac{g(t, \theta) h(x)}{g(t, \theta) \sum_{x': T(x') = t} h(x')} = \frac{h(x)}{\sum_{x': T(x') = t} h(x')}, \end{aligned}$$

which does not depend on θ . (If $T(x) \neq t$ the conditional probability is 0, which certainly does not depend on θ .) So T is sufficient.

Conversely, suppose T is sufficient. Then

$$\begin{aligned} f_X(x | \theta) &= \mathbb{P}_\theta(X = x) = \mathbb{P}_\theta(X = x, T(X) = T(x)) \\ &= \underbrace{\mathbb{P}_\theta(X = x | T(X) = T(x))}_{=h(x)} \underbrace{\mathbb{P}_\theta(T(X) = T(x))}_{=g(T(x), \theta)}, \end{aligned}$$

where the first factor is free of θ precisely by sufficiency. $\square$

Let's put this to work.

Example 22.2.12 (Bernoulli, Again)

With $f_X(x | \theta) = \theta^{\sum x_i} (1-\theta)^{n-\sum x_i}$ we may take $T(x) = \sum_i x_i$, $g(t, \theta) = \theta^t (1-\theta)^{n-t}$ and $h(x) \equiv 1$. So T is sufficient, and we never had to compute a conditional distribution.

Example 22.2.13 (Uniform on $[0, \theta]$)

Let $X_1, \dots, X_n$ be i.i.d $U[0, \theta]$ with $\theta > 0$. The joint density is

$$f_X(x | \theta) = \prod_{i=1}^n \frac{1}{\theta} \mathbb{1}\{0 \leq x_i \leq \theta\} = \underbrace{\frac{1}{\theta^n} \mathbb{1}\left\{\max_i x_i \leq \theta\right\}}_{g(T(x), \theta)} \cdot \underbrace{\mathbb{1}\left\{\min_i x_i \geq 0\right\}}_{h(x)},$$

so $T(X) = \max_i X_i$ is sufficient for θ . This is a good example of a sufficient statistic that is not a sum: only the largest observation constrains θ at all.

Example 22.2.14 (Normal with Both Parameters Unknown)

Let $X_1, \dots, X_n$ be i.i.d $N(\mu, \sigma^2)$ with $\theta = (\mu, \sigma^2)$ unknown. Expanding the exponent,

$$f_X(x | \theta) = (2\pi\sigma^2)^{-n/2} \exp \left(-\frac{1}{2\sigma^2} \sum_i x_i^2 + \frac{\mu}{\sigma^2} \sum_i x_i - \frac{n\mu^2}{2\sigma^2} \right),$$

which depends on x only through $(\sum_i x_i, \sum_i x_i^2)$. Taking $h \equiv 1$, this pair is sufficient for (μ, σ^2) .

§22.2.3 Minimal Sufficiency

Sufficient statistics are far from unique. The whole data $T(X) = X$ is always sufficient, and any injective function of a sufficient statistic is again sufficient. What we actually want is a sufficient statistic that compresses as much as possible.

Definition 22.2.15 (Minimal Sufficiency)

A sufficient statistic T is **minimal sufficient** if it is a function of every other sufficient statistic; equivalently, if S is sufficient then $S(x) = S(y)$ implies $T(x) = T(y)$.

Remark. If S and T are minimal sufficient then they are in bijection, that is, $T(x) = T(y)$ if and only if $S(x) = S(y)$. So we can think of minimal sufficient statistics as being unique up to bijection.

Theorem 22.2.16 (Criterion for Minimal Sufficiency)

Suppose that $f_X(x | \theta)/f_X(y | \theta)$ is constant in θ if and only if $T(x) = T(y)$. Then T is minimal sufficient.

Before proving this, it is worth understanding what the hypothesis says. Write $x \sim_1 y$ if the likelihood ratio $f_X(x | \theta)/f_X(y | \theta)$ is free of θ , and $x \sim_2 y$ if $T(x) = T(y)$. Both are equivalence relations on the sample space, and the hypothesis is exactly that they have the same equivalence classes. Note that this also gives a *recipe*: compute the classes of $\sim_1$, and define T to be any labelling of them. So minimal sufficient statistics always exist.

Proof. We first show T is sufficient. For each value t in the range of T pick a representative z_t with $T(z_t) = t$. Then for any x ,

$$f_X(x | \theta) = \underbrace{f_X(z_{T(x)} | \theta)}_{g(T(x), \theta)} \cdot \underbrace{\frac{f_X(x | \theta)}{f_X(z_{T(x)} | \theta)}}_{h(x)}.$$

The first factor depends on x only through $T(x)$, and the second is free of θ by hypothesis, since $T(x) = T(z_{T(x)})$. By the factorisation criterion, T is sufficient.

Now let S be any other sufficient statistic, so $f_X(x | \theta) = g_S(S(x), \theta)h_S(x)$. Suppose

$S(x) = S(y)$. Then

$$\frac{f_X(x | \theta)}{f_X(y | \theta)} = \frac{g_S(S(x), \theta) h_S(x)}{g_S(S(y), \theta) h_S(y)} = \frac{h_S(x)}{h_S(y)},$$

which is constant in θ . By hypothesis this forces $T(x) = T(y)$. So T is a function of S , and as S was arbitrary, T is minimal sufficient. $\square$

Example 22.2.17 (Normal Samples)

Let $X_1, \dots, X_n$ be i.i.d $N(\mu, \sigma^2)$ with both parameters unknown. Then

$$\frac{f_X(x | \mu, \sigma^2)}{f_X(y | \mu, \sigma^2)} = \exp \left(-\frac{1}{2\sigma^2} \left(\sum_i x_i^2 - \sum_i y_i^2 \right) + \frac{\mu}{\sigma^2} \left(\sum_i x_i - \sum_i y_i \right) \right).$$

This is constant in (μ, σ^2) if and only if both bracketed differences vanish, that is, if and only if $\sum_i x_i = \sum_i y_i$ and $\sum_i x_i^2 = \sum_i y_i^2$. Hence

$$T(X) = \left(\sum_i X_i, \sum_i X_i^2 \right)$$

is minimal sufficient, as is the more familiar bijective repackaging $(\bar{X}, S_{XX})$.

Example 22.2.18 (Dimension Mismatch)

The parameter and a minimal sufficient statistic need not have the same dimension. Take $X_1, \dots, X_n \sim N(\mu, \mu^2)$, so $\Theta = \mathbb{R} \setminus \{0\}$ is one-dimensional. Running the same computation with $\sigma^2 = \mu^2$, the ratio is

$$\exp \left(-\frac{1}{2\mu^2} \left(\sum_i x_i^2 - \sum_i y_i^2 \right) + \frac{1}{\mu} \left(\sum_i x_i - \sum_i y_i \right) \right),$$

and since $1/\mu$ and $1/\mu^2$ are not proportional as functions of μ , this is constant only when both differences vanish. So $(\bar{X}, S_{XX})$ is still minimal sufficient: a two-dimensional statistic for a one-dimensional parameter.

§22.2.4 The Rao-Blackwell Theorem

We now have a notion of ‘the data, compressed without loss’. The Rao-Blackwell theorem says that this compression is not merely lossless, but actively *useful*: averaging any estimator over the discarded information can only improve it.

From now on we will usually drop the subscript θ from $\mathbb{E}_\theta$ and $\mathbb{P}_\theta$, with the understanding that all expectations are taken in the model with true parameter θ .

Theorem 22.2.19 (Rao-Blackwell)

Let T be sufficient for θ , and let $\tilde{\theta}$ be an estimator with $\mathbb{E}[\tilde{\theta}^2] < \infty$ for all θ . Define

$$\hat{\theta} = \mathbb{E}[\tilde{\theta} \mid T].$$

Then $\hat{\theta}$ is an estimator, and for all θ ,

$$\mathbb{E}[(\hat{\theta} - \theta)^2] \leq \mathbb{E}[(\tilde{\theta} - \theta)^2],$$

with equality if and only if $\tilde{\theta}$ is (almost surely) a function of T .

Remark. It is essential that T be *sufficient*, and not merely any statistic. Otherwise $\hat{\theta}$ would generally depend on θ and so fail to be an estimator at all:

$$\hat{\theta} = \mathbb{E}[\tilde{\theta} \mid T] = \int \tilde{\theta}(x) \underbrace{f_{X|T}(x \mid T)}_{\text{free of } \theta \text{ as } T \text{ is sufficient}} dx.$$

Sufficiency is exactly the condition that makes this conditional average computable from the data.

Proof. By the tower property,

$$\mathbb{E}[\hat{\theta}] = \mathbb{E}[\mathbb{E}[\tilde{\theta} \mid T]] = \mathbb{E}[\tilde{\theta}],$$

so $\hat{\theta}$ and $\tilde{\theta}$ have exactly the same bias. By the conditional variance formula,

$$\text{Var}(\tilde{\theta}) = \mathbb{E} \left[\underbrace{\text{Var}(\tilde{\theta} \mid T)}_{\geq 0} \right] + \underbrace{\text{Var}(\mathbb{E}[\tilde{\theta} \mid T])}_{=\text{Var}(\hat{\theta})} \geq \text{Var}(\hat{\theta}).$$

Now apply the bias-variance decomposition to both estimators: they have equal squared bias, and $\hat{\theta}$ has no larger variance, so $\text{mse}(\hat{\theta}) \leq \text{mse}(\tilde{\theta})$.

For the equality case, the inequality above is strict unless $\mathbb{E}[\text{Var}(\tilde{\theta} \mid T)] = 0$, that is, unless $\text{Var}(\tilde{\theta} \mid T) = 0$ almost surely, which says exactly that $\tilde{\theta}$ is a function of T . $\square$

So the recipe is: find *any* unbiased estimator, however crude, then condition it on a sufficient statistic. The result is unbiased and at least as good. Let's do this twice.

Example 22.2.20 (Rao-Blackwellising a Poisson Indicator)

Let $X_1, \dots, X_n$ be i.i.d $\text{Poisson}(\lambda)$, and suppose we wish to estimate $\theta = \mathbb{P}(X_1 = 0) = e^{-\lambda}$. The joint mass function is

$$f_X(x \mid \lambda) = \frac{e^{-n\lambda} \lambda^{\sum x_i}}{\prod_i x_i!},$$

so $T = \sum_i X_i$ is sufficient by the factorisation criterion (and note that re-parametrising by $\theta = e^{-\lambda}$ does not change this). Recall $T \sim \text{Poisson}(n\lambda)$.

A very crude unbiased estimator is

$$\tilde{\theta} = \mathbb{1}\{X_1 = 0\},$$

which throws away $X_2, \dots, X_n$ entirely, but does satisfy $\mathbb{E}[\tilde{\theta}] = \mathbb{P}(X_1 = 0) = \theta$. Conditioning on T ,

$$\begin{aligned} \hat{\theta} = \mathbb{E}[\tilde{\theta} \mid T = t] &= \mathbb{P}\left(X_1 = 0 \mid \sum_i X_i = t\right) \\ &= \frac{\mathbb{P}(X_1 = 0) \mathbb{P}\left(\sum_{i \geq 2} X_i = t\right)}{\mathbb{P}\left(\sum_{i \geq 1} X_i = t\right)} \\ &= \frac{e^{-\lambda} \cdot e^{-(n-1)\lambda} ((n-1)\lambda)^t / t!}{e^{-n\lambda} (n\lambda)^t / t!} = \left(\frac{n-1}{n}\right)^t. \end{aligned}$$

So the Rao-Blackwellised estimator is

$$\hat{\theta} = \left(1 - \frac{1}{n}\right)^{\sum_i X_i},$$

which is unbiased and has mean squared error no larger than $\tilde{\theta}$ for every θ . It is also a sensible-looking quantity: writing $\sum_i X_i = n\bar{X}$, we have $\hat{\theta} = (1 - 1/n)^{n\bar{X}} \rightarrow e^{-\bar{X}}$, and $\bar{X} \rightarrow \lambda$ almost surely by the strong law, so $\hat{\theta} \rightarrow e^{-\lambda} = \theta$.

Example 22.2.21 (Rao-Blackwellising for the Uniform)

Let $X_1, \dots, X_n$ be i.i.d $U[0, \theta]$, and recall $T = \max_i X_i$ is sufficient. Since $\mathbb{E}[X_1] = \theta/2$, the estimator $\tilde{\theta} = 2X_1$ is unbiased. Conditioning on $T = t$ and splitting on whether X_1 achieves the maximum,

$$\begin{aligned} \hat{\theta} &= 2 \mathbb{E}\left[X_1 \mid \max_i X_i = t\right] \\ &= 2t \cdot \mathbb{P}\left(X_1 = \max_i X_i \mid \max_i X_i = t\right) \\ &\quad + 2 \mathbb{E}[X_1 \mid X_1 < t] \mathbb{P}\left(X_1 \neq \max_i X_i \mid \max_i X_i = t\right). \end{aligned}$$

By symmetry X_1 is the maximum with probability $1/n$, and given that it is not, X_1 is uniform on $[0, t]$, so has mean $t/2$. Hence

$$\hat{\theta} = \frac{2t}{n} + 2 \cdot \frac{t}{2} \cdot \frac{n-1}{n} = \frac{2t + t(n-1)}{n} = \frac{n+1}{n} \max_i X_i.$$

This is a dramatic improvement. One can compute directly that $\text{Var}(\tilde{\theta}) = \theta^2/3$, while

$$\text{Var}(\hat{\theta}) = \frac{\theta^2}{n(n+2)},$$

so the mean squared error drops from order 1 to order n^{-2} . That is much better than the usual n^{-1} rate, and reflects the fact that the maximum of a uniform sample converges to θ unusually quickly.

§22.2.5 Maximum Likelihood Estimation

We now come to the workhorse of the whole subject. The idea is disarmingly simple: having observed x , prefer the value of θ under which what we saw was most probable.

Definition 22.2.22 (Likelihood)

For fixed observed data x , the **likelihood function** $L : \Theta \rightarrow \mathbb{R}$ is

$$L(\theta) = f_X(x \mid \theta) = \prod_{i=1}^n f_{X_i}(x_i \mid \theta),$$

and the **log-likelihood** is $\ell(\theta) = \log L(\theta) = \sum_i \log f_{X_i}(x_i \mid \theta)$.

Note carefully that L is a function of θ , not of x : it is the joint density read ‘sideways’. It is not a probability distribution on Θ and does not integrate to 1.

Definition 22.2.23 (Maximum Likelihood Estimator)

A **maximum likelihood estimator** (MLE) $\hat{\theta}$ is any value of $\theta \in \Theta$ maximising L , or equivalently (as log is increasing) maximising ℓ .

In well-behaved cases Θ is an open interval and ℓ is differentiable and concave, so we may find $\hat{\theta}$ by solving $\ell'(\theta) = 0$. But this is not a definition, only a technique – and it fails exactly when the likelihood has its maximum on a boundary, which happens more often than one might expect.

Example 22.2.24 (Bernoulli)

Let $X_1, \dots, X_n$ be i.i.d Bernoulli(p). Then

$$\ell(p) = \sum_i [X_i \log p + (1 - X_i) \log(1 - p)] = \left(\sum_i X_i \right) \log p + \left(n - \sum_i X_i \right) \log(1 - p),$$

so

$$\ell'(p) = \frac{\sum_i X_i}{p} - \frac{n - \sum_i X_i}{1 - p},$$

which vanishes precisely at $p = \bar{X}$. As $\ell'' < 0$ throughout $(0, 1)$ this is the unique maximum, so $\hat{p} = \bar{X}$. This estimator is unbiased.

Example 22.2.25 (Normal with Both Parameters Unknown)

Let $X_1, \dots, X_n$ be i.i.d $N(\mu, \sigma^2)$. Then

$$\ell(\mu, \sigma^2) = -\frac{n}{2} \log(2\pi) - \frac{n}{2} \log \sigma^2 - \frac{1}{2\sigma^2} \sum_i (X_i - \mu)^2.$$

Differentiating,

$$\frac{\partial \ell}{\partial \mu} = \frac{1}{\sigma^2} \sum_i (X_i - \mu),$$

which vanishes at $\mu = \bar{X}$ for any σ^2 . Substituting this and differentiating in σ^2 ,

$$\frac{\partial \ell}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{1}{2\sigma^4} \sum_i (X_i - \bar{X})^2,$$

which vanishes at $\sigma^2 = S_{XX}/n$. So

$$(\hat{\mu}, \hat{\sigma}^2) = \left(\bar{X}, \frac{S_{XX}}{n} \right).$$

We computed in Section 1 that $\mathbb{E}[S_{XX}] = (n-1)\sigma^2$, so $\hat{\sigma}^2$ is biased downwards, with

$$\mathbb{E}[\hat{\sigma}^2] = \frac{n-1}{n} \sigma^2.$$

The bias vanishes as $n \rightarrow \infty$; we say $\hat{\sigma}^2$ is **asymptotically unbiased**. This behaviour is entirely typical: maximum likelihood estimators of variance parameters are usually a little too small, because they fit the mean to the data first.

Example 22.2.26 (Uniform on $[0, \theta]$: A Boundary Maximum)

Let $X_1, \dots, X_n$ be i.i.d $U[0, \theta]$. The likelihood is

$$L(\theta) = \frac{1}{\theta^n} \mathbb{1} \left\{ \theta \geq \max_i X_i \right\},$$

which is zero for $\theta < \max_i X_i$ and then strictly decreasing. So it is maximised at

$$\hat{\theta}_{\text{MLE}} = \max_i X_i,$$

and calculus was of no use whatsoever. Comparing with the Rao-Blackwellised estimator $\frac{n+1}{n} \max_i X_i$ obtained above, we see that the MLE is biased downwards, with $\mathbb{E}[\hat{\theta}_{\text{MLE}}] = \frac{n}{n+1} \theta$ – which is obvious in hindsight, since $\max_i X_i < \theta$ always.

Example 22.2.27 (Poisson)

Let $X_1, \dots, X_n$ be i.i.d $\text{Poisson}(\lambda)$. Then $\ell(\lambda) = -n\lambda + (\sum_i X_i) \log \lambda - \sum_i \log(X_i!)$, and $\ell'(\lambda) = -n + \sum_i X_i/\lambda$ vanishes at $\hat{\lambda} = \bar{X}$. Since $\ell''(\lambda) = -\sum_i X_i/\lambda^2 < 0$ this is the maximum, and it is unbiased.

§22.2.6 Properties of the Maximum Likelihood Estimator

Maximum likelihood is not just convenient; it has several structural properties that make it the default choice.

Proposition 22.2.28 (MLEs Depend Only on Sufficient Statistics)

If T is sufficient for θ , then any maximum likelihood estimator is a function of T .

Proof. By the factorisation criterion $L(\theta) = g(T(x), \theta)h(x)$, and $h(x)$ is a positive constant as far as maximisation over θ is concerned. So the maximiser depends on x only through $T(x)$. $\square$

Proposition 22.2.29 (Invariance)

Let H be a bijection of Θ onto some set Φ , and let $\varphi = H(\theta)$. If $\hat{\theta}$ is a maximum likelihood estimator for θ , then $H(\hat{\theta})$ is a maximum likelihood estimator for φ .

Proof. The likelihood for φ is $L^*(\varphi) = L(H^{-1}(\varphi))$, and as H is a bijection, L^* is maximised at $\varphi = H(\hat{\theta})$ exactly when L is maximised at $\hat{\theta}$. $\square$

This invariance is a genuine convenience: to estimate $e^{-\lambda}$ in the Poisson model we may simply write down $e^{-\bar{X}}$. (Note the contrast with unbiasedness, which has no such invariance – $\mathbb{E}[g(\hat{\theta})] \neq g(\mathbb{E}[\hat{\theta}])$ in general.)

Finally, and most importantly, maximum likelihood estimators are asymptotically normal.

Fact 22.2.30 (Asymptotic Normality of the MLE)

Under regularity conditions on the model (which we will not state precisely here), the maximum likelihood estimator $\hat{\theta} = \hat{\theta}_n$ based on n i.i.d observations satisfies

$$\sqrt{n}(\hat{\theta} - \theta) \rightarrow N(0, \Sigma)$$

in distribution as $n \rightarrow \infty$, for a limiting covariance matrix Σ determined by the model. Precisely, for all ‘nice’ sets A ,

$$\mathbb{P}_\theta(\sqrt{n}(\hat{\theta} - \theta) \in A) \rightarrow \mathbb{P}(Z \in A), \quad Z \sim N(0, \Sigma).$$

The matrix Σ is the inverse of the *Fisher information* per observation, and one can show that no reasonable estimator can asymptotically beat it – so maximum likelihood is, in a precise sense, asymptotically optimal. We will not prove any of this in this course, but the statement matters: it tells us that for large n the MLE is approximately unbiased, approximately normal, and has a variance of order $1/n$. That is exactly the input we need to construct approximate confidence intervals, which is where we go next.

Remark. For many models ℓ cannot be maximised in closed form, and $\hat{\theta}$ is found numerically (typically by Newton-Raphson on ℓ' , which converges quickly because ℓ is asymptotically quadratic near its maximum). The asymptotic theory above applies just the same.

§22.3 Confidence Intervals

A point estimate on its own is not much of an answer. If a poll reports that 52% of voters support a proposal, we want to know whether that number is accurate to within one percentage point or ten. An interval estimate answers this, and confidence intervals are the frequentist way of producing one.

§22.3.1 Definition and Construction

Definition 22.3.1 (Confidence Interval)

A $100\gamma\%$ **confidence interval** for a parameter θ is a pair of statistics $A(X) \leq B(X)$ such that

$$\mathbb{P}_\theta(A(X) \leq \theta \leq B(X)) = \gamma \quad \text{for all } \theta \in \Theta.$$

The reader should stare at that probability statement for a moment, because everything hinges on what is random in it. The parameter θ is a fixed unknown constant; it is the *endpoints* $A(X)$ and $B(X)$ that are random. We are not saying ‘ θ falls in a fixed interval 95% of the time’; we are saying ‘a random interval catches the fixed θ 95% of the time’. Note also that the requirement is uniform in θ : the coverage must be γ whatever the truth happens to be.

Example 22.3.2 (Normal Mean, Known Variance)

Let $X_1, \dots, X_n$ be i.i.d $N(\theta, 1)$, and let us find a 95% confidence interval for θ . We know that

$$\bar{X} \sim N\left(\theta, \frac{1}{n}\right), \quad \text{so} \quad Z = \sqrt{n}(\bar{X} - \theta) \sim N(0, 1).$$

The crucial point is that the distribution of Z is *the same for every* θ . So we may pick numbers $a < b$ with $\Phi(b) - \Phi(a) = 0.95$ once and for all, and then

$$0.95 = \mathbb{P}_\theta\left(a \leq \sqrt{n}(\bar{X} - \theta) \leq b\right) = \mathbb{P}_\theta\left(\bar{X} - \frac{b}{\sqrt{n}} \leq \theta \leq \bar{X} - \frac{a}{\sqrt{n}}\right).$$

Hence $(\bar{X} - b/\sqrt{n}, \bar{X} - a/\sqrt{n})$ is a 95% confidence interval, for *any* such a, b . To make the interval as short as possible we take it symmetric, $-a = b = z_{0.025} \approx 1.96$, where in general $z_\alpha = \Phi^{-1}(1 - \alpha)$ denotes the upper α point of $N(0, 1)$. This gives the familiar

$$\bar{X} \pm \frac{1.96}{\sqrt{n}}.$$

The technique used there deserves a name.

Definition 22.3.3 (Pivot)

A **pivot** is a function $R(X, \theta)$ of both the data and the parameter whose distribution under $\mathbb{P}_\theta$ is the same for every $\theta \in \Theta$.

A pivot is not a statistic (it involves θ), and its distribution is not a sampling distribution of anything we can compute – but because it does not depend on θ , we can look up its quantiles in advance. The general recipe is then:

- (i) Find a pivot $R(X, \theta)$.
- (ii) Choose constants $c_1 < c_2$ with $\mathbb{P}(c_1 \leq R \leq c_2) = \gamma$, using the (known) distribution of R .
- (iii) Rearrange the inequalities $c_1 \leq R(X, \theta) \leq c_2$ to isolate θ , obtaining $A(X) \leq \theta \leq B(X)$.

Step (iii) is where things can get awkward – the rearrangement need not be possible in closed form, and if R is not monotone in θ the resulting set may not even be an interval. When θ is vector-valued we simply drop the pretence and speak of a **confidence set**: any $A(X) \subseteq \Theta$ with $\mathbb{P}_\theta(\theta \in A(X)) = \gamma$ for all θ .

A useful closure property, immediate from the definition, is the following.

Proposition 22.3.4

If $(A(X), B(X))$ is a $100\gamma\%$ confidence interval for θ and T is a strictly increasing function, then $(T(A(X)), T(B(X)))$ is a $100\gamma\%$ confidence interval for $T(\theta)$.

Proof. Since T is strictly increasing, $A(X) \leq \theta \leq B(X)$ if and only if $T(A(X)) \leq T(\theta) \leq T(B(X))$, so the two events are identical and have the same probability. $\square$

§22.3.2 Standard Constructions

Example 22.3.5 (Normal Variance, Known Mean)

Let $X_1, \dots, X_n$ be i.i.d $N(0, \sigma^2)$ with σ^2 unknown. Since $X_i/\sigma \sim N(0, 1)$, a natural pivot is

$$R(X, \sigma^2) = \sum_{i=1}^n \frac{X_i^2}{\sigma^2} \sim \chi_n^2,$$

whose distribution is free of σ^2 as required. (We could have used the single observation X_1/σ , but that would waste $n - 1$ of our data points and give a hopelessly wide interval.) Taking $c_1 = \chi_n^2(0.975)$ and $c_2 = \chi_n^2(0.025)$ so that $\mathbb{P}(c_1 \leq R \leq c_2) = 0.95$, and rearranging,

$$0.95 = \mathbb{P}\left(c_1 \leq \frac{\sum_i X_i^2}{\sigma^2} \leq c_2\right) = \mathbb{P}\left(\frac{\sum_i X_i^2}{c_2} \leq \sigma^2 \leq \frac{\sum_i X_i^2}{c_1}\right).$$

Note that the interval is *not* symmetric about any natural estimator, because the χ^2 distribution is skewed.

Example 22.3.6 (A Bernoulli Proportion)

Let $X_1, \dots, X_n$ be i.i.d Bernoulli(p) with n large. The MLE is $\hat{p} = \bar{X}$, and by the central limit theorem

$$\sqrt{n} \frac{\hat{p} - p}{\sqrt{p(1-p)}} \approx N(0, 1).$$

This is an approximate pivot, but rearranging the resulting inequalities for p requires solving a quadratic (since p appears in the denominator too). The standard dodge is to replace $p(1-p)$ by $\hat{p}(1-\hat{p})$ in the denominator, which is legitimate for large n since $\hat{p} \rightarrow p$. Then

$$\mathbb{P} \left(-z_{0.025} \leq \sqrt{n} \frac{\hat{p} - p}{\sqrt{\hat{p}(1-\hat{p})}} \leq z_{0.025} \right) \approx 0.95,$$

giving the approximate 95% confidence interval

$$\hat{p} \pm z_{0.025} \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}.$$

Its width is largest when $\hat{p} = 1/2$, where it is about $2 \times 1.96 \times \frac{1}{2\sqrt{n}} \approx 1/\sqrt{n}$. Replacing $\hat{p}(1-\hat{p})$ by its maximum $1/4$ gives the **conservative** interval $\hat{p} \pm 1/\sqrt{n}$, which has coverage *at least* 95% for every p – this is where the familiar ‘margin of error of 3% on a poll of 1000 people’ comes from.

Example 22.3.7 (Poisson Rate)

Let $X_1, \dots, X_n$ be i.i.d Poisson(μ) with n large. Since $\text{Var}(X_1) = \mu$, the central limit theorem gives

$$\sqrt{n} \frac{\bar{X} - \mu}{\sqrt{\mu}} \approx N(0, 1),$$

and substituting $\hat{\mu} = \bar{X}$ in the denominator as before yields the approximate 95% interval $\bar{X} \pm 1.96\sqrt{\bar{X}/n}$.

§22.3.3 Interpreting Confidence Intervals

The frequentist meaning of a confidence interval is a statement about the *procedure*, not about the particular interval we happen to have computed. If we were to repeat the experiment many times, each time constructing the interval by the same recipe, then about $100\gamma\%$ of those intervals would contain the true θ .

Twenty intervals from twenty repetitions of the same experiment are drawn above; one of them (in red) misses the true value. Before the data are seen, the probability that the interval will catch θ is 0.95. After the data are seen, the interval is a specific pair of numbers, and θ either is or is not inside it – there is no residual randomness left to have a probability about.

This is not mere pedantry. Here is an example where the naive reading is plainly absurd.

Example 22.3.8 (A 50% Interval We Sometimes Know Is Right)

Let X_1, X_2 be i.i.d uniform on $(\theta - \frac{1}{2}, \theta + \frac{1}{2})$. Then

$$\mathbb{P}\left(\min_i X_i \leq \theta \leq \max_i X_i\right) = \mathbb{P}(X_1 \leq \theta \leq X_2) + \mathbb{P}(X_2 \leq \theta \leq X_1) = \frac{1}{4} + \frac{1}{4} = \frac{1}{2},$$

since each X_i falls above or below θ with probability $1/2$, independently of the other. So the interval $(\min_i X_i, \max_i X_i)$ is a perfectly valid 50% confidence interval.

But now suppose we observe $x_1 = 0.1$ and $x_2 = 0.9$, so $|x_1 - x_2| = 0.8 > 1/2$. Since both observations lie within $1/2$ of θ , we have $\theta > 0.9 - 0.5 = 0.4$ and $\theta < 0.1 + 0.5 = 0.6$, so certainly $\theta \in (0.1, 0.9)$. We are 100% certain, not 50%! Conversely if $x_1 = 0.4$ and $x_2 = 0.45$ we have learned rather little, and 50% feels generous.

The coverage statement is still true – averaged over repetitions, half the intervals contain θ . It is simply not a statement about this particular data set.

If one genuinely wants a probability statement about θ given the data actually observed, one has to be willing to treat θ as a random variable in the first place. That is the Bayesian position, and it is where we turn next.

§22.4 Bayesian Inference

Everything so far has been **frequentist**: θ is a fixed unknown constant, and all probability statements are about the data, in the context of hypothetical repetitions of the experiment. Bayesian inference takes a different starting point. It treats θ itself as a random variable, with a distribution expressing our uncertainty about it, and then simply conditions on the data.

§22.4.1 Priors and Posteriors

Definition 22.4.1 (Prior and Posterior)

The **prior** distribution $\pi(\theta)$ on Θ represents our beliefs about θ before observing any data. Given data X with density (or mass function) $f_X(x | \theta)$, the **posterior** distribution is the conditional distribution of θ given $X = x$, written $\pi(\theta | x)$.

By Bayes' rule,

$$\pi(\theta | x) = \frac{\pi(\theta)f_X(x | \theta)}{f_X(x)}, \quad f_X(x) = \int_{\Theta} f_X(x | \theta)\pi(\theta) d\theta$$

(with the integral replaced by a sum if Θ is discrete). Since the denominator does not involve θ at all, it is nothing but a normalising constant, and in practice we almost always work with the proportionality

$$\pi(\theta | x) \propto \pi(\theta) f_X(x | \theta),$$

in words: *posterior* $\propto$ *prior* $\times$ *likelihood*. This is the entire machinery. The art lies in recognising the right-hand side as a standard distribution up to normalisation, which saves us from ever computing the integral.

Remark. If T is sufficient for θ , the posterior depends on the data only through T . Indeed by the factorisation criterion

$$\pi(\theta | x) \propto \pi(\theta)g(T(x), \theta)h(x) \propto \pi(\theta)g(T(x), \theta),$$

since $h(x)$ is constant in θ . So the Bayesian and frequentist notions of ‘the relevant information in the data’ agree exactly.

Example 22.4.2 (A Medical Test)

A patient is tested for a disease. Let $\theta = 1$ if they are infected and $\theta = 0$ otherwise, and let $X = 1$ if the test is positive. The likelihood is specified by the **sensitivity** $f_X(1 | 1)$ and the **specificity** $f_X(0 | 0)$ of the test. For the prior we might take $\pi(1)$ to be the prevalence of the disease in the population. Then

$$\pi(1 | X = 1) = \frac{\pi(1)f_X(1 | 1)}{\pi(1)f_X(1 | 1) + \pi(0)f_X(1 | 0)}.$$

If the disease is rare, so $\pi(1) \ll \pi(0)$, this can be small even for an excellent test: with sensitivity and specificity both 99% and prevalence 0.1%, a positive test gives

$$\pi(1 | X = 1) = \frac{0.001 \times 0.99}{0.001 \times 0.99 + 0.999 \times 0.01} \approx 0.09.$$

The false positives from the huge healthy population swamp the true positives. This is the classical illustration of why the prior cannot be ignored.

§22.4.2 Conjugate Priors

The computation is especially pleasant when prior and posterior belong to the same family.

Definition 22.4.3 (Conjugacy)

A family of priors is **conjugate** to a likelihood if the posterior always lies in the same family.

Example 22.4.4 (Beta-Binomial)

Let θ be the mortality rate for a particular operation, and model the number of deaths in n operations as $X \sim \text{Bin}(n, \theta)$. Suppose data from other hospitals suggest the rate lies between 3% and 20% with an average around 10%. A natural family of priors on $[0, 1]$ is the beta family,

$$\pi(\theta) \propto \theta^{a-1}(1-\theta)^{b-1}, \quad \theta \sim \text{Beta}(a, b),$$

which has mean $a/(a+b)$. Taking $a = 3$, $b = 27$ gives $\mathbb{E}[\theta] = 0.1$ and $\mathbb{P}(0.03 < \theta < 0.2) \approx 0.9$, matching our beliefs well.

Now suppose we observe x deaths in n operations. Then

$$\pi(\theta | x) \propto \theta^{a-1}(1-\theta)^{b-1} \cdot \theta^x(1-\theta)^{n-x} = \theta^{x+a-1}(1-\theta)^{n-x+b-1},$$

which we recognise immediately as $\text{Beta}(a+x, b+n-x)$. So the beta family is conjugate to the binomial likelihood, and the update rule is beautifully simple: add the successes to a , add the failures to b .

With $n = 10$ operations and $x = 0$ deaths, the posterior is $\text{Beta}(3, 37)$.

The posterior has both a smaller mean ($3/40 = 0.075$ against $3/30 = 0.1$) and a smaller variance than the prior: observing no deaths has shifted our beliefs downwards and sharpened them. Notice also how modest the shift is – ten operations is not much data against a prior worth 30 pseudo-observations, and the Bayesian machinery weights them accordingly.

Example 22.4.5 (Gamma-Poisson)

Let $X_1, \dots, X_n$ be i.i.d $\text{Poisson}(\theta)$ with prior $\theta \sim \text{Gamma}(a, b)$, so $\pi(\theta) \propto \theta^{a-1}e^{-b\theta}$. Then

$$\pi(\theta | x) \propto \theta^{a-1}e^{-b\theta} \cdot \theta^{\sum x_i} e^{-n\theta} = \theta^{a+\sum x_i-1} e^{-(b+n)\theta},$$

so the posterior is $\text{Gamma}(a + \sum_i x_i, b + n)$: the gamma family is conjugate to the Poisson.

Example 22.4.6 (Normal-Normal)

Let $X_1, \dots, X_n$ be i.i.d $N(\theta, \sigma^2)$ with σ^2 known, and give θ the prior $N(\mu_0, \tau_0^2)$. Then

$$\pi(\theta | x) \propto \exp\left(-\frac{(\theta - \mu_0)^2}{2\tau_0^2}\right) \exp\left(-\frac{\sum_i (x_i - \theta)^2}{2\sigma^2}\right).$$

The exponent is a quadratic in θ , so the posterior is normal, and completing the square gives $N(\mu_1, \tau_1^2)$ with

$$\frac{1}{\tau_1^2} = \frac{1}{\tau_0^2} + \frac{n}{\sigma^2}, \quad \mu_1 = \tau_1^2 \left(\frac{\mu_0}{\tau_0^2} + \frac{n\bar{x}}{\sigma^2} \right).$$

The interpretation is very clean if we think in terms of **precisions** (reciprocal variances): precisions add, and the posterior mean is the precision-weighted average of the prior mean and the sample mean. As $n \rightarrow \infty$ the data term dominates and $\mu_1 \rightarrow \bar{x}$, so the prior is eventually washed out – which is reassuring.

§22.4.3 Point Estimates as Optimal Decisions

The posterior is the complete Bayesian answer. But often we must actually *do* something – commit to a single number, or a single course of action. Decision theory tells us how.

We choose a decision δ from a set Δ of available actions, and specify a **loss function** $L(\theta, \delta)$ giving the penalty incurred for taking action δ when the truth is θ . Having observed x , we then choose δ to minimise the **posterior expected loss**

$$h(\delta) = \int_{\Theta} L(\theta, \delta) \pi(\theta | x) d\theta.$$

Definition 22.4.7 (Bayes Estimator)

When $\Delta = \Theta$ (so that our ‘action’ is to report an estimate of θ), the minimiser $\hat{\theta}^{(B)}$ of $h(\delta)$ is the **Bayes estimator** of θ for the loss L .

Different losses give different estimators, and pleasingly the three most natural losses give the three most natural summaries of the posterior.

Example 22.4.8 (Quadratic Loss Gives the Posterior Mean)

Take $L(\theta, \delta) = (\theta - \delta)^2$. Then

$$h(\delta) = \int_{\Theta} (\theta - \delta)^2 \pi(\theta | x) d\theta,$$

and differentiating under the integral,

$$h'(\delta) = -2 \int_{\Theta} (\theta - \delta) \pi(\theta | x) d\theta,$$

which vanishes when $\delta = \int_{\Theta} \theta \pi(\theta | x) d\theta$. As $h''(\delta) = 2 > 0$ this is the minimum. So the Bayes estimator under quadratic loss is the *posterior mean*.

Example 22.4.9 (Absolute Loss Gives the Posterior Median)

Take $L(\theta, \delta) = |\theta - \delta|$. Splitting the integral at δ ,

$$h(\delta) = \int_{-\infty}^{\delta} (\delta - \theta) \pi(\theta | x) d\theta + \int_{\delta}^{\infty} (\theta - \delta) \pi(\theta | x) d\theta,$$

and differentiating (the boundary terms cancel since the integrands vanish at $\theta = \delta$),

$$h'(\delta) = \int_{-\infty}^{\delta} \pi(\theta | x) d\theta - \int_{\delta}^{\infty} \pi(\theta | x) d\theta.$$

This vanishes when the two tails have equal mass, i.e. at the *posterior median*. Since h' is increasing, this is the minimum.

Example 22.4.10 (Zero-One Loss Gives the Posterior Mode)

For $\varepsilon > 0$ take $L(\theta, \delta) = \mathbb{1}\{|\theta - \delta| > \varepsilon\}$, which penalises us only if we miss by more than ε . Then

$$h(\delta) = 1 - \int_{\delta-\varepsilon}^{\delta+\varepsilon} \pi(\theta | x) d\theta,$$

which is minimised by centring the window on the region of highest posterior density. As $\varepsilon \rightarrow 0$ this converges to the *posterior mode*, also called the maximum a posteriori (MAP) estimate. Note that with a flat prior the posterior is proportional to the likelihood, so the MAP estimate is then exactly the maximum likelihood estimate – a satisfying point of contact between the two philosophies.

Example 22.4.11 (Beta-Binomial, Continued)

In the surgery example the posterior was $\text{Beta}(3, 37)$. Under quadratic loss the Bayes estimator is the posterior mean $3/40 = 0.075$, while the posterior mode is $(3 - 1)/(3 + 37 - 2) = 2/38 \approx 0.053$. Compare the maximum likelihood estimate $\hat{\theta} = x/n = 0$, which asserts that the operation is perfectly safe on the basis of ten cases. The prior is doing real work here, and doing it sensibly.

§22.4.4 Credible Intervals**Definition 22.4.12** (Credible Interval)

A $100\gamma\%$ **credible interval** for θ is an interval $(A(x), B(x))$ with

$$\mathbb{P}(A(x) \leq \theta \leq B(x) | X = x) = \int_{A(x)}^{B(x)} \pi(\theta | x) d\theta = \gamma.$$

Superficially this looks identical to a confidence interval, but the probability means something quite different – and much closer to what people usually want. Here θ is the random quantity and the data are fixed, so we really may say: ‘given the data I have, there is probability γ that θ lies in this interval’. That is precisely the statement that was illegitimate for confidence intervals.

The price, of course, is that the answer depends on the prior. Two statisticians with

different priors will report different credible intervals from the same data, and neither is wrong. Note also that credible intervals are not unique: any A, B capturing γ of the posterior mass will do. Common choices are the **equal-tailed** interval, running between the $\frac{1-\gamma}{2}$ and $\frac{1+\gamma}{2}$ posterior quantiles, and the **highest posterior density** interval, which is the shortest such interval and consists of the points with the largest posterior density.

Example 22.4.13

Continuing the surgery example, the equal-tailed 95% credible interval for the mortality rate under the $\text{Beta}(3, 37)$ posterior runs between the 2.5% and 97.5% points of that distribution, which are approximately 0.016 and 0.173. So having seen ten operations with no deaths, we would report a mortality rate of about 7.5%, with a credible interval of roughly (1.6%, 17.3%).

§22.5 Hypothesis Testing

Estimation asks ‘what is θ ?’. Hypothesis testing asks a cruder but often more useful question: ‘is there evidence in the data against a particular claim about θ ?’. This is the form most scientific questions actually take – does the drug work, is the coin fair, does the data fit the model – and the framework we build here is the one used, for better or worse, throughout the empirical sciences.

§22.5.1 Hypotheses, Tests and Errors

Definition 22.5.1 (Hypothesis)

A **hypothesis** is an assertion about the distribution of the data X . The **null hypothesis** H_0 is the default or baseline assertion; the **alternative hypothesis** H_1 is what we entertain if H_0 is found wanting.

A hypothesis is **simple** if it completely specifies the distribution of X , and **composite** otherwise.

Example 22.5.2

Let $X_1, \dots, X_n$ be i.i.d Bernoulli(θ). We might test $H_0 : \theta = \frac{1}{2}$ against $H_1 : \theta = \frac{3}{4}$, in which case both hypotheses are simple; or $H_0 : \theta = \frac{1}{2}$ against $H_1 : \theta \neq \frac{1}{2}$, in which case H_1 is composite.

Example 22.5.3

Suppose the X_i take values in $\{0, 1, 2, \dots\}$ and we test $H_0 : X_i \stackrel{\text{iid}}{\sim} \text{Poisson}(\lambda)$ for *some* λ , against H_1 : the X_i have some other distribution. Here H_0 is composite (because λ is unspecified), and the test is a **goodness-of-fit** test. We will return to these later in this section.

Definition 22.5.4 (Test)

A **test** of H_0 is specified by a **critical region** (or rejection region) $C \subseteq \mathcal{X}$, where

$\mathcal{X}$ is the sample space. If $X \in C$ we **reject** H_0 ; otherwise we **fail to reject** H_0 . The complement $A = \mathcal{X} \setminus C$ is the **acceptance region**.

The asymmetric language is deliberate. Failing to reject H_0 is not evidence *for* H_0 – it may simply mean we had too little data to detect a departure. There are two ways to go wrong:

Definition 22.5.5 (Type I and Type II Errors)

A **type I error** (a false positive) is rejecting H_0 when it is true; a **type II error** (a false negative) is failing to reject H_0 when it is false. When H_0 and H_1 are simple we write

$$\alpha = \mathbb{P}_{H_0}(X \in C), \quad \beta = \mathbb{P}_{H_1}(X \notin C).$$

We call α the **size** of the test and $1 - \beta = \mathbb{P}_{H_1}(X \in C)$ its **power**.

The two error probabilities trade off against each other: shrinking C reduces α and increases β . The classical resolution of this tension is to fix an acceptable type I error rate α (conventionally 0.05 or 0.01) and then, subject to that constraint, make the power as large as possible. Note the asymmetry this builds in: H_0 is protected, and we reject it only on strong evidence. Note also that computing α requires only H_0 , whereas computing β requires us to specify H_1 precisely – which is one reason simple alternatives are so much easier to handle.

§22.5.2 The Neyman-Pearson Lemma

Suppose both hypotheses are simple, with X having density (or mass function) f_i under H_i . Which critical region should we choose?

Definition 22.5.6 (Likelihood Ratio Test)

The **likelihood ratio statistic** is

$$\Lambda_x(H_0; H_1) = \frac{f_1(x)}{f_0(x)},$$

and the **likelihood ratio test** has critical region $C = \{x : \Lambda_x(H_0; H_1) > k\}$ for some constant k .

In other words – reject H_0 exactly when the data are sufficiently more probable under H_1 than under H_0 . This is an obviously reasonable thing to do, and the remarkable content of the next result is that it is *optimal*.

Lemma 22.5.7 (Neyman-Pearson)

Let H_0 and H_1 be simple hypotheses with densities f_0, f_1 that are positive on the same set. Suppose that for some $k > 0$ the likelihood ratio test with critical region $C = \{x : f_1(x)/f_0(x) > k\}$ has size α . Then among all tests of size at most α , this test has the largest power.

Proof. Write $\overline{C}$ for the complement of C , and let

$$\alpha = \int_C f_0(x) \, dx, \quad \beta = \int_{\overline{C}} f_1(x) \, dx$$

be the error probabilities of the likelihood ratio test. Let C^* be the critical region of any other test, with error probabilities α^*, β^* , and suppose $\alpha^* \leq \alpha$. We must show $\beta \leq \beta^*$.

Cancelling the contribution from $\overline{C} \cap \overline{C}^*$, which is common to both,

$$\beta - \beta^* = \int_{\overline{C}} f_1 - \int_{\overline{C}^*} f_1 = \int_{\overline{C} \cap C^*} f_1 - \int_{C \cap \overline{C}^*} f_1.$$

Now on $\overline{C}$ we have $f_1 \leq k f_0$, and on C we have $f_1 \geq k f_0$. Applying these to the two integrals respectively (the first is over a subset of $\overline{C}$, the second over a subset of C),

$$\begin{aligned} \beta - \beta^* &\leq k \int_{\overline{C} \cap C^*} f_0 - k \int_{C \cap \overline{C}^*} f_0 \\ &= k \left[\int_{\overline{C} \cap C^*} f_0 + \int_{C \cap C^*} f_0 - \int_{C \cap C^*} f_0 - \int_{C \cap \overline{C}^*} f_0 \right] \\ &= k \left[\int_{C^*} f_0 - \int_C f_0 \right] = k [\alpha^* - \alpha] \leq 0, \end{aligned}$$

where in the middle line we added and subtracted the same quantity in order to reassemble the integrals over C^* and over C . Hence $\beta \leq \beta^*$, and the likelihood ratio test has power $1 - \beta \geq 1 - \beta^*$. $\square$

Remark. The hypothesis that a likelihood ratio test of *exactly* size α exists is a real restriction, and typically fails for discrete data, where the achievable sizes form a finite set. The fix is to allow **randomised tests**, which for certain boundary values of x reject H_0 with some probability strictly between 0 and 1; every size α is then achievable, and the lemma holds in that generality.

Example 22.5.8 (The Z-Test)

Let $X_1, \dots, X_n$ be i.i.d $N(\mu, \sigma_0^2)$ with σ_0^2 known, and test $H_0 : \mu = \mu_0$ against $H_1 : \mu = \mu_1$ where $\mu_1 > \mu_0$. The likelihood ratio is

$$\begin{aligned} \Lambda_x &= \frac{(2\pi\sigma_0^2)^{-n/2} \exp\left(-\frac{1}{2\sigma_0^2} \sum_i (x_i - \mu_1)^2\right)}{(2\pi\sigma_0^2)^{-n/2} \exp\left(-\frac{1}{2\sigma_0^2} \sum_i (x_i - \mu_0)^2\right)} \\ &= \exp\left(\underbrace{\frac{\mu_1 - \mu_0}{\sigma_0^2}}_{>0} n\bar{x} + \frac{n(\mu_0^2 - \mu_1^2)}{2\sigma_0^2}\right), \end{aligned}$$

which depends on the data only through $\bar{x}$, and is strictly increasing in it. Hence

$\Lambda_x > k$ if and only if $\bar{x} > k'$, if and only if

$$Z = \frac{\sqrt{n}(\bar{X} - \mu_0)}{\sigma_0} > k''$$

for suitable constants. Under H_0 we have $Z \sim N(0, 1)$, so to achieve size α we take $k'' = z_\alpha = \Phi^{-1}(1 - \alpha)$. This is the **Z-test**, and by Neyman-Pearson it is the most powerful test of its size.

The geometry of what is going on is worth a picture. Below are the two densities of the test statistic Z under H_0 and H_1 , with the critical region $\{Z > k\}$ shaded under each.

Moving k to the right shrinks the blue shaded area (the size) but also shrinks the red one (the power). The Neyman-Pearson lemma says that among all ways of carving a region of blue area α out of the line, taking a right-hand tail of the likelihood ratio captures the most red.

§22.5.3 p -Values

Reporting only ‘reject at the 5% level’ throws away information: it does not distinguish a marginal result from an overwhelming one. The p -value records how extreme the observed data actually were.

Definition 22.5.9 (p -Value)

Suppose the critical region has the form $C = \{x : T(x) > k\}$ for a test statistic T , and let x^* be the observed data. The **p -value** is

$$p = \mathbb{P}_{H_0}(T(X) \geq T(x^*)).$$

Equivalently, the p -value is the smallest size α at which we would have rejected H_0 with these data. Small p means the observed data were surprising under H_0 .

Example 22.5.10

Continuing the Z -test with $\mu_0 = 5$, $\sigma_0 = 1$, $\alpha = 0.05$, suppose we observe $x^* = (5.1, 5.5, 4.9, 5.3)$. Then $\bar{x}^* = 5.2$ and $z^* = \sqrt{4}(5.2 - 5)/1 = 0.4$. The critical region is $\{Z > 1.645\}$, so we do not reject H_0 ; the p -value is $1 - \Phi(0.4) \approx 0.34$, so a value at least this extreme would arise about a third of the time even if H_0 were true.

Proposition 22.5.11

If the test statistic T has a continuous distribution, then under H_0 the p -value is uniformly distributed on $[0, 1]$.

Proof. Let F be the distribution function of T under H_0 , so $p = 1 - F(T)$. Then for $u \in (0, 1)$,

$$\begin{aligned}\mathbb{P}_{H_0}(p \leq u) &= \mathbb{P}_{H_0}(1 - F(T) \leq u) = \mathbb{P}_{H_0}(F(T) \geq 1 - u) \\ &= \mathbb{P}_{H_0}(T \geq F^{-1}(1 - u)) = 1 - F(F^{-1}(1 - u)) = u. \square\end{aligned}$$

This is a useful sanity check, and also a warning: under the null, p -values below 0.05 occur exactly 5% of the time by construction. If one tests twenty independent null hypotheses, one expects a ‘significant’ result by chance alone.

§22.5.4 Composite Hypotheses and Power Functions

Now let $X \sim f_X(\cdot | \theta)$ with $\theta \in \Theta$, and consider $H_0 : \theta \in \Theta_0$ against $H_1 : \theta \in \Theta_1$, where Θ_0, Θ_1 are disjoint. The error probabilities now depend on which particular θ obtains, so we need a function rather than a number.

Definition 22.5.12 (Power Function, Size, UMP)

The **power function** of a test with critical region C is

$$W(\theta) = \mathbb{P}_\theta(X \in C), \quad \theta \in \Theta.$$

Its **size** is $\alpha = \sup_{\theta \in \Theta_0} W(\theta)$, the worst-case type I error rate. A test with power function W and size at most α is **uniformly most powerful** (UMP) of size α if for every other test with power function W^* and size at most α ,

$$W(\theta) \geq W^*(\theta) \quad \text{for all } \theta \in \Theta_1.$$

The word ‘uniformly’ is doing the work: we are asking for a single test that is simultaneously best against every alternative. Such tests need not exist – and typically do not, for two-sided alternatives, since the best test against $\theta > \theta_0$ points in the wrong direction for $\theta < \theta_0$. For one-sided alternatives in simple models, however, they often do.

Example 22.5.13 (One-Sided Test for a Normal Mean)

Let $X_1, \dots, X_n$ be i.i.d $N(\mu, \sigma_0^2)$ with σ_0^2 known, and consider

$$H_0 : \mu \leq \mu_0, \quad H_1 : \mu > \mu_0.$$

We claim the Z -test with $C = \{Z > z_\alpha\}$, where $Z = \sqrt{n}(\bar{X} - \mu_0)/\sigma_0$, is UMP of size α .

First we compute the power function. Under $\mathbb{P}_\mu$ we have $\sqrt{n}(\bar{X} - \mu)/\sigma_0 \sim N(0, 1)$,

so

$$\begin{aligned}
 W(\mu) &= \mathbb{P}_\mu \left(\frac{\sqrt{n}(\bar{X} - \mu_0)}{\sigma_0} > z_\alpha \right) \\
 &= \mathbb{P}_\mu \left(\frac{\sqrt{n}(\bar{X} - \mu)}{\sigma_0} > z_\alpha + \frac{\sqrt{n}(\mu_0 - \mu)}{\sigma_0} \right) \\
 &= 1 - \Phi \left(z_\alpha + \frac{\sqrt{n}(\mu_0 - \mu)}{\sigma_0} \right).
 \end{aligned}$$

This is strictly increasing in μ , so $\sup_{\mu \leq \mu_0} W(\mu) = W(\mu_0) = 1 - \Phi(z_\alpha) = \alpha$, and the test has size α as claimed.

The picture shows what a good power function looks like: it passes through α at the boundary μ_0 , stays below α on Θ_0 , and climbs towards 1 on Θ_1 , the more steeply the more data we have.

Now for optimality. The key observation is that the critical region C does not depend on μ_1 at all – it was determined by μ_0 and α alone. So fix any $\mu_1 > \mu_0$ and consider the simple hypotheses $H'_0 : \mu = \mu_0$ and $H'_1 : \mu = \mu_1$. By the previous example, C is precisely the likelihood ratio critical region for H'_0 against H'_1 , of size α .

Let C^* be any test of H_0 against H_1 with size at most α . Regarded as a test of H'_0 against H'_1 , its size is

$$W^*(\mu_0) \leq \sup_{\mu \leq \mu_0} W^*(\mu) \leq \alpha.$$

So by the Neyman-Pearson lemma, $W(\mu_1) \geq W^*(\mu_1)$. Since $\mu_1 > \mu_0$ was arbitrary, the test is UMP.

§22.5.5 Generalised Likelihood Ratio Tests

For genuinely composite hypotheses there is no likelihood ratio to speak of, since neither hypothesis specifies a single density. The natural fix is to compare the best each hypothesis can do.

Definition 22.5.14 (Generalised Likelihood Ratio)

Suppose the hypotheses are **nested**, $H_0 : \theta \in \Theta_0$ and $H_1 : \theta \in \Theta_1$ with $\Theta_0 \subseteq \Theta_1$.

The **generalised likelihood ratio** is

$$\Lambda_x(H_0; H_1) = \frac{\sup_{\theta \in \Theta_1} f_X(x | \theta)}{\sup_{\theta \in \Theta_0} f_X(x | \theta)},$$

and the **generalised likelihood ratio test** rejects H_0 when Λ_x is large.

Since $\Theta_0 \subseteq \Theta_1$ we always have $\Lambda_x \geq 1$: the larger model can always fit at least as well. The question is whether it fits *enough* better to justify its extra parameters, and the test statistic $2 \log \Lambda_x$ measures exactly this.

Example 22.5.15 (Two-Sided Test for a Normal Mean)

Let $X_1, \dots, X_n$ be i.i.d $N(\mu, \sigma_0^2)$ with σ_0^2 known, and test $H_0 : \mu = \mu_0$ against $H_1 : \mu \in \mathbb{R}$. The numerator is maximised at the MLE $\hat{\mu} = \bar{X}$, so

$$\Lambda_x = \frac{\exp\left(-\frac{1}{2\sigma_0^2} \sum_i (x_i - \bar{x})^2\right)}{\exp\left(-\frac{1}{2\sigma_0^2} \sum_i (x_i - \mu_0)^2\right)}.$$

Expanding $\sum_i (x_i - \mu_0)^2 = \sum_i (x_i - \bar{x})^2 + n(\bar{x} - \mu_0)^2$, everything cancels except

$$2 \log \Lambda_x = \frac{n(\bar{x} - \mu_0)^2}{\sigma_0^2} = \left(\frac{\sqrt{n}(\bar{x} - \mu_0)}{\sigma_0} \right)^2.$$

Under H_0 the bracket is $N(0, 1)$, so $2 \log \Lambda_x \sim \chi_1^2$ *exactly*, and the size- α test rejects when

$$\frac{n(\bar{X} - \mu_0)^2}{\sigma_0^2} > \chi_1^2(\alpha), \quad \text{equivalently} \quad \left| \frac{\sqrt{n}(\bar{X} - \mu_0)}{\sigma_0} \right| > z_{\alpha/2}.$$

This is a **two-sided** test: the critical region consists of both tails in terms of the original statistic.

It is worth seeing the one- and two-sided critical regions side by side, since choosing between them is a modelling decision that must be made *before* looking at the data.

In the example above the exact distribution of $2 \log \Lambda$ was available. Usually it is not, and we appeal to the following remarkable theorem, whose content is that the χ_1^2 we just found was no accident.

Definition 22.5.16 (Dimension of a Hypothesis)

The **dimension** of $H_0 : \theta \in \Theta_0$ is the number of free parameters in Θ_0 .

Example 22.5.17

If $\Theta_0 = \{\theta \in \mathbb{R}^k : \theta_1 = \dots = \theta_p = 0\}$ then $\dim \Theta_0 = k - p$. More generally if $A \in \mathbb{R}^{p \times k}$ has linearly independent rows and $\Theta_0 = \{\theta \in \mathbb{R}^k : A\theta = b\}$, then $\dim \Theta_0 = k - p$: each independent linear constraint costs one dimension.

Theorem 22.5.18 (Wilks)

Suppose $\Theta_0 \subseteq \Theta_1$ with $\dim \Theta_1 - \dim \Theta_0 = p$, and let $X = (X_1, \dots, X_n)$ be i.i.d from $f_X(\cdot | \theta)$ with the true θ in the interior of Θ_0 . Then under regularity conditions, as $n \rightarrow \infty$,

$$2 \log \Lambda_X \rightarrow \chi_p^2$$

in distribution; that is, $\mathbb{P}_\theta(2 \log \Lambda_X \leq \ell) \rightarrow \mathbb{P}(\Xi \leq \ell)$ for every $\ell > 0$, where $\Xi \sim \chi_p^2$.

We will not prove this (the proof is a Taylor expansion of ℓ about the MLE, combined with asymptotic normality of the MLE). But it is enormously useful: it says that whatever the model, the price of p extra parameters is measured on the same universal χ_p^2 scale. In particular the size- α generalised likelihood ratio test rejects when $2 \log \Lambda_X > \chi_p^2(\alpha)$, and this has size approximately α for large n .

Example 22.5.19

In the two-sided normal example, $\dim \Theta_1 = 1$ and $\dim \Theta_0 = 0$, so $p = 1$ and Wilks' theorem predicts $2 \log \Lambda \approx \chi_1^2$ – which we verified exactly, for every n .

§22.5.6 Goodness of Fit

We now apply this machinery to the question of whether a model fits at all. Let $X_1, \dots, X_n$ be i.i.d taking values in $\{1, \dots, k\}$, and write $p_i = \mathbb{P}(X_1 = i)$ and

$$N_i = \#\{j : X_j = i\},$$

so $\sum_i p_i = 1$ and $\sum_i N_i = n$. Then $(N_1, \dots, N_k) \sim \text{Multinomial}(n; p_1, \dots, p_k)$, and the parameter space $\Theta_1 = \{p : p_i \geq 0, \sum_i p_i = 1\}$ has dimension $k - 1$.

The **goodness-of-fit** problem is to test $H_0 : p = \tilde{p}$ for a specified vector $\tilde{p}$, against the unrestricted H_1 . The likelihood is

$$L(p) \propto p_1^{N_1} \dots p_k^{N_k}, \quad \ell(p) = \text{const} + \sum_i N_i \log p_i.$$

Lemma 22.5.20

The maximum likelihood estimator of p over Θ_1 is $\hat{p}_i = N_i/n$.

Proof. Maximise ℓ subject to $\sum_i p_i = 1$ by Lagrange multipliers: setting $\mathcal{L} =$

$\sum_i N_i \log p_i - \lambda(\sum_i p_i - 1)$ and differentiating gives $N_i/p_i = \lambda$, so $p_i = N_i/\lambda$. Summing over i and using the constraint gives $\lambda = n$. $\square$

So the generalised likelihood ratio statistic is

$$2 \log \Lambda = 2(\ell(\hat{p}) - \ell(\tilde{p})) = 2 \sum_{i=1}^k N_i \log \left(\frac{N_i}{n\tilde{p}_i} \right) = 2 \sum_{i=1}^k o_i \log \frac{o_i}{e_i},$$

writing $o_i = N_i$ for the **observed** counts and $e_i = n\tilde{p}_i$ for the counts **expected** under H_0 . Since $\dim \Theta_1 - \dim \Theta_0 = (k-1) - 0 = k-1$, Wilks' theorem tells us to refer this to χ_{k-1}^2 .

§22.5.7 Pearson's Chi-Squared Statistic

There is a classical approximation to $2 \log \Lambda$ which is easier to compute by hand and is what is usually reported.

Proposition 22.5.21 (Pearson's Statistic)

With $\delta_i = o_i - e_i$, and assuming each δ_i/e_i is small,

$$2 \log \Lambda \approx \sum_{i=1}^k \frac{(o_i - e_i)^2}{e_i}.$$

Proof. Write $o_i = e_i + \delta_i$, so

$$2 \log \Lambda = 2 \sum_i (e_i + \delta_i) \log \left(1 + \frac{\delta_i}{e_i} \right).$$

Expanding $\log(1+u) = u - u^2/2 + O(u^3)$ with $u = \delta_i/e_i$,

$$2 \log \Lambda \approx 2 \sum_i (e_i + \delta_i) \left(\frac{\delta_i}{e_i} - \frac{\delta_i^2}{2e_i^2} \right) = 2 \sum_i \left(\delta_i + \frac{\delta_i^2}{e_i} - \frac{\delta_i^2}{2e_i} \right) + O\left(\sum_i \frac{\delta_i^3}{e_i^2} \right).$$

Now $\sum_i \delta_i = \sum_i o_i - \sum_i e_i = n - n = 0$, so the first term vanishes and we are left with $\sum_i \delta_i^2/e_i$. $\square$

This is **Pearson's χ^2 statistic**, and it is referred to the same χ_{k-1}^2 distribution. The rule of thumb is that the approximation (both to $2 \log \Lambda$ and of both to χ^2) is adequate provided every $e_i \geq 5$.

Example 22.5.22 (Mendel's Peas)

Mendel crossed pea plants and classified 556 offspring by shape and colour, obtaining

$$N = (\underbrace{315}_{\text{smooth green}}, \underbrace{108}_{\text{smooth yellow}}, \underbrace{102}_{\text{wrinkled green}}, \underbrace{31}_{\text{wrinkled yellow}}).$$

His theory of independent assortment of two dominant/recessive traits predicts

$$H_0 : \tilde{p} = \left(\frac{9}{16}, \frac{3}{16}, \frac{3}{16}, \frac{1}{16} \right),$$

giving expected counts $e = (312.75, 104.25, 104.25, 34.75)$. Computing,

$$2 \log \Lambda = 0.618, \quad \sum_i \frac{(o_i - e_i)^2}{e_i} = 0.604,$$

which we refer to χ_3^2 . Since $\chi_3^2(0.05) = 7.815$, we do not reject H_0 at the 5% level. Indeed the p -value is $\mathbb{P}(\chi_3^2 > 0.60) \approx 0.90$: the fit is not merely acceptable, it is suspiciously good.

The null hypothesis need not fully specify $\tilde{p}$; often it says only that p lies in some smaller family.

Example 22.5.23 (Composite Null: Hardy-Weinberg)

Individuals have one of three genotypes with probabilities

$$(p_1, p_2, p_3) = (\theta^2, 2\theta(1 - \theta), (1 - \theta)^2)$$

for some allele frequency $\theta \in (0, 1)$, so $\dim \Theta_0 = 1$. The log-likelihood under H_0 is

$$\ell(\theta) = \text{const} + (2N_1 + N_2) \log \theta + (2N_3 + N_2) \log(1 - \theta),$$

which is maximised at

$$\hat{\theta} = \frac{2N_1 + N_2}{2n}$$

– the observed frequency of the allele, as one would hope. Then

$$2 \log \Lambda = 2 \left(\ell(\hat{p}) - \ell(\hat{\theta}) \right) = 2 \sum_i o_i \log \frac{o_i}{e_i} \approx \sum_i \frac{(o_i - e_i)^2}{e_i}, \quad e_i = n p_i(\hat{\theta}),$$

which is now referred to χ_p^2 with $p = \dim \Theta_1 - \dim \Theta_0 = 2 - 1 = 1$. The general rule: *each parameter estimated under the null costs one degree of freedom*.

§22.5.8 Contingency Tables

Two of the most common applications of the χ^2 test involve two-way tables of counts, and it is a pleasant surprise that they turn out to be the same test.

Testing Independence

Suppose we observe i.i.d pairs $(X_1, Y_1), \dots, (X_n, Y_n)$ where X_ℓ takes values in $\{1, \dots, r\}$ and Y_ℓ in $\{1, \dots, c\}$, and we wish to test whether X and Y are independent. The data are summarised by the [contingency table](#)

$$N_{ij} = \# \{ \ell : (X_\ell, Y_\ell) = (i, j) \},$$

and (N_{ij}) , flattened into a vector, is multinomial with probabilities (p_{ij}) . Writing $p_{i+} = \sum_j p_{ij}$ and $p_{+j} = \sum_i p_{ij}$ for the marginals, the hypotheses are

$$H_0 : p_{ij} = p_{i+} p_{+j} \text{ for all } i, j, \quad H_1 : p \text{ unrestricted.}$$

The unrestricted MLE is $\hat{p}_{ij} = N_{ij}/n$ as before. Under H_0 the free parameters are the two marginal vectors, each constrained to sum to 1, and a Lagrange multiplier computation

identical to the one above gives

$$\hat{p}_{i+} = \frac{N_{i+}}{n}, \quad \hat{p}_{+j} = \frac{N_{+j}}{n}.$$

Hence, with $o_{ij} = N_{ij}$ and $e_{ij} = n\hat{p}_{i+}\hat{p}_{+j} = N_{i+}N_{+j}/n$,

$$2 \log \Lambda = 2 \sum_{i,j} N_{ij} \log \frac{\hat{p}_{ij}}{\hat{p}_{i+}\hat{p}_{+j}} = 2 \sum_{i,j} o_{ij} \log \frac{o_{ij}}{e_{ij}} \approx \sum_{i,j} \frac{(o_{ij} - e_{ij})^2}{e_{ij}}.$$

The degrees of freedom are

$$p = \dim \Theta_1 - \dim \Theta_0 = (rc - 1) - [(r - 1) + (c - 1)] = (r - 1)(c - 1),$$

so we refer the statistic to $\chi^2_{(r-1)(c-1)}$.

Testing Homogeneity

Now suppose the row totals are fixed by design rather than random – for instance, we allocate a fixed number of patients to each of several treatments. Then the rows are independent multinomials,

$$(N_{i1}, \dots, N_{ic}) \sim \text{Multinomial}(n_{i+}; p_{i1}, \dots, p_{ic}),$$

and the natural question is whether the treatments differ:

$$H_0 : p_{1j} = p_{2j} = \dots = p_{rj} \text{ for all } j, \quad H_1 : \text{each row an arbitrary probability vector.}$$

The log-likelihood is $\ell(p) = \text{const} + \sum_{i,j} N_{ij} \log p_{ij}$, exactly as in the independence problem. Maximising row by row gives $\hat{p}_{ij} = N_{ij}/n_{i+}$ under H_1 ; under H_0 , writing p_j for the common value, $\ell = \text{const} + \sum_j N_{+j} \log p_j$ is maximised at $\hat{p}_j = N_{+j}/n_{++}$. So

$$2 \log \Lambda = 2 \sum_{i,j} N_{ij} \log \frac{N_{ij}/n_{i+}}{N_{+j}/n_{++}} = 2 \sum_{i,j} o_{ij} \log \frac{o_{ij}}{e_{ij}}, \quad e_{ij} = \frac{n_{i+}N_{+j}}{n_{++}},$$

which is *identical* to the statistic for independence, with identical expected counts. The degrees of freedom also agree:

$$p = r(c - 1) - (c - 1) = (r - 1)(c - 1).$$

So although the sampling schemes and the hypotheses are conceptually quite different, the two tests are operationally the same: we reject one exactly when we reject the other.

Example 22.5.24 (A Clinical Trial)

150 patients are randomly assigned in equal numbers to a placebo, a half dose and a full dose of a drug, with results

	improved	no difference	worse	
placebo	18	17	15	50
half dose	20	10	20	50
full dose	25	13	12	50
	63	40	47	150

Here the row totals are fixed at 50, so this is a test of homogeneity. The expected counts are $e_{ij} = 50 \times N_{+j}/150 = N_{+j}/3$, giving the first row of expectations

(21, 13.33, 15.67) and similarly for the others. Computing,

$$2 \log \Lambda = 5.129, \quad \sum_{i,j} \frac{(o_{ij} - e_{ij})^2}{e_{ij}} = 5.173.$$

With $(r-1)(c-1) = 4$ degrees of freedom and $\chi_4^2(0.05) = 9.488$, we do not reject H_0 at the 5% level: this trial provides no significant evidence that the drug does anything.

Remark. Two weaknesses of these tests are worth flagging.

- (i) The χ^2 approximation needs n large; the usual heuristic is that every *expected* count should be at least 5. When it is not, one should use an exact test (such as Fisher's exact test), which is non-examinable.
- (ii) The tests often have low power, because Θ_1 is enormous. A test that must guard against every possible departure from H_0 cannot be very sensitive to any particular one.

§22.5.9 Tests and Confidence Sets

We close this section by making precise a duality that has been lurking throughout: confidence sets and hypothesis tests are two views of the same object.

Theorem 22.5.25

Let $X \sim f_X(\cdot | \theta)$, $\theta \in \Theta$.

- (i) Suppose that for each $\theta_0 \in \Theta$ there is a size- α test of $H_0 : \theta = \theta_0$ with acceptance region $A(\theta_0)$. Then

$$I(X) = \{\theta : X \in A(\theta)\}$$

is a $100(1 - \alpha)\%$ confidence set for θ .

- (ii) Conversely, if $I(X)$ is a $100(1 - \alpha)\%$ confidence set for θ , then $A(\theta_0) = \{x : \theta_0 \in I(x)\}$ is the acceptance region of a size- α test of $H_0 : \theta = \theta_0$.

Proof. Both parts follow from the single observation that, by construction,

$$\theta_0 \in I(X) \iff X \in A(\theta_0),$$

so the two events have the same probability under $\mathbb{P}_{\theta_0}$. For (i), the test having size α means $\mathbb{P}_{\theta_0}(X \in A(\theta_0)) = 1 - \alpha$, whence $\mathbb{P}_{\theta_0}(\theta_0 \in I(X)) = 1 - \alpha$; as θ_0 was arbitrary this is exactly the confidence set property. Part (ii) is the same computation read backwards. $\square$

In words – a confidence set is the collection of parameter values that the data would not have rejected. This is often the quickest route to a test, or to an interval.

Example 22.5.26

Let $X_1, \dots, X_n$ be i.i.d $N(\mu, \sigma_0^2)$ with σ_0^2 known. We found the $100(1 - \alpha)\%$ confi-

dence interval

$$I(X) = \left(\bar{X} \pm \frac{z_{\alpha/2} \sigma_0}{\sqrt{n}} \right).$$

By part (ii) of the theorem, a size- α test of $H_0 : \mu = \mu_0$ is obtained by rejecting when $\mu_0 \notin I(X)$, that is, when

$$\left| \frac{\sqrt{n}(\bar{X} - \mu_0)}{\sigma_0} \right| > z_{\alpha/2},$$

which is precisely the two-sided test we derived from the generalised likelihood ratio. The two derivations agree, as they must.

§22.6 Normal Theory Tests

Every test we have constructed so far has assumed the variance known, which is unrealistic. In this section we develop the distribution theory that lets us drop that assumption, and then deploy it in the standard tests for normal data. Everything rests on one theorem – the joint distribution of $\bar{X}$ and S_{XX} – which we prove in two ways.

In this section vectors are columns, and we write $u^\top$ for the transpose.

§22.6.1 The Multivariate Normal Distribution

We recall the essentials from IA Probability. For a random vector $X = (X_1, \dots, X_n)^\top$ we write $\mathbb{E}[X]$ for the vector of means and

$$\text{Var}(X) = \mathbb{E} \left[(X - \mathbb{E}X)(X - \mathbb{E}X)^\top \right]$$

for the covariance matrix, so $\text{Var}(X)_{ij} = \text{Cov}(X_i, X_j)$. For constant $A \in \mathbb{R}^{k \times n}$ and $b \in \mathbb{R}^k$ we have the familiar

$$\mathbb{E}[AX + b] = A \mathbb{E}[X] + b, \quad \text{Var}(AX + b) = A \text{Var}(X) A^\top.$$

Definition 22.6.1 (Multivariate Normal)

A random vector X has a **multivariate normal** distribution if $t^\top X$ is univariate normal for every fixed $t \in \mathbb{R}^n$ (allowing degenerate normals of zero variance).

Proposition 22.6.2

If X is multivariate normal then so is $AX + b$, for any constant $A \in \mathbb{R}^{k \times n}$ and $b \in \mathbb{R}^k$.

Proof. For $t \in \mathbb{R}^k$, $t^\top (AX + b) = (A^\top t)^\top X + t^\top b$ is a univariate normal plus a constant. $\square$

Proposition 22.6.3

A multivariate normal distribution is determined by its mean vector μ and covariance

matrix Σ , and we write $X \sim N(\mu, \Sigma)$.

Proof. The moment generating function is $M_X(t) = \mathbb{E}[e^{t^\top X}]$. Since $t^\top X$ is univariate normal with mean $t^\top \mu$ and variance $t^\top \Sigma t$, evaluating the one-dimensional normal mgf at 1 gives

$$M_X(t) = \exp\left(t^\top \mu + \frac{1}{2} t^\top \Sigma t\right),$$

which depends only on μ and Σ . By uniqueness of moment generating functions, the distribution is determined. $\square$

An immediate corollary, which we will use constantly, is that for multivariate normal vectors *zero covariance implies independence*: if Σ is block diagonal, the mgf factorises accordingly.

§22.6.2 Orthogonal Projections

The geometry underlying normal theory is that of orthogonal projection, so we set up the linear algebra we need.

Definition 22.6.4 (Orthogonal Projection)

A matrix $P \in \mathbb{R}^{n \times n}$ is an **orthogonal projection** onto its column space $\text{col}(P)$ if $Pv = v$ for all $v \in \text{col}(P)$ and $Pw = 0$ for all $w \in \text{col}(P)^\perp$.

Proposition 22.6.5

P is an orthogonal projection if and only if P is symmetric and idempotent ($P^2 = P$).

Proof. Suppose P is symmetric and idempotent. If $v \in \text{col}(P)$ then $v = Pa$ for some a , so $Pv = P^2a = Pa = v$. If $w \in \text{col}(P)^\perp$ then $P^\top w = 0$ by definition of the orthogonal complement, and $P^\top = P$, so $Pw = 0$.

Conversely, suppose P is an orthogonal projection. Any $a \in \mathbb{R}^n$ decomposes uniquely as $a = v + w$ with $v \in \text{col}(P)$, $w \in \text{col}(P)^\perp$, and then $P^2a = P^2v + P^2w = Pv = P(v + w) = Pa$; as a was arbitrary, $P^2 = P$. For symmetry, note that for any u_1, u_2 we have $Pu_1 \in \text{col}(P)$ and $(I - P)u_2 \in \text{col}(P)^\perp$, so

$$u_1^\top P^\top (I - P)u_2 = (Pu_1) \cdot ((I - P)u_2) = 0.$$

Hence $P^\top (I - P) = 0$, i.e. $P^\top = P^\top P$. But $P^\top P$ is symmetric, so $P^\top$ is symmetric, so P is. $\square$

Corollary 22.6.6

If P is an orthogonal projection then so is $I - P$, projecting onto $\text{col}(P)^\perp$.

Proof. $I - P$ is symmetric, and $(I - P)^2 = I - 2P + P^2 = I - P$. $\square$

Proposition 22.6.7

If P is an orthogonal projection then $P = UU^\top$, where the columns of U form an orthonormal basis of $\text{col}(P)$. Consequently $\text{rank } P = \text{tr } P$.

Proof. Let U have as its columns an orthonormal basis of $\text{col}(P)$, so $U^\top U = I_r$ where $r = \dim \text{col}(P)$. Then $UU^\top$ is symmetric, and $(UU^\top)(UU^\top) = U(U^\top U)U^\top = UU^\top$, so it is an orthogonal projection; its column space is $\text{col}(U) = \text{col}(P)$, and two orthogonal projections with the same column space are equal (both act as the identity there and as zero on the complement).

For the rank, $\text{rank } P = r = \text{tr}(I_r) = \text{tr}(U^\top U) = \text{tr}(UU^\top) = \text{tr } P$, using $\text{tr}(AB) = \text{tr}(BA)$. $\square$

Now the key distributional result.

Theorem 22.6.8 (Projections of Spherical Normals)

Let $X \sim N(0, \sigma^2 I_n)$ and let P be an orthogonal projection of rank r . Then

- (i) $PX \sim N(0, \sigma^2 P)$ and $(I - P)X \sim N(0, \sigma^2(I - P))$, and these are independent;
- (ii) $\|PX\|^2 / \sigma^2 \sim \chi_r^2$.

Proof. The stacked vector $(PX, (I - P)X)^\top \in \mathbb{R}^{2n}$ is a linear function of X , hence multivariate normal, and is therefore determined by its mean and covariance. Its mean is 0, and its covariance is

$$\begin{pmatrix} P \\ I - P \end{pmatrix} \sigma^2 I \begin{pmatrix} P \\ I - P \end{pmatrix}^\top = \sigma^2 \begin{pmatrix} P^2 & P(I - P) \\ (I - P)P & (I - P)^2 \end{pmatrix} = \sigma^2 \begin{pmatrix} P & 0 \\ 0 & I - P \end{pmatrix},$$

using idempotence and $P(I - P) = P - P^2 = 0$. This identifies the marginals, and since the covariance is block diagonal and the vector is multivariate normal, the two blocks are independent.

For (ii), write $P = UU^\top$ as above. Then

$$\|PX\|^2 = X^\top P^\top PX = X^\top PX = X^\top UU^\top X = \|U^\top X\|^2,$$

and $U^\top X \sim N(0, \sigma^2 U^\top U) = N(0, \sigma^2 I_r)$. So the r components of $U^\top X / \sigma$ are i.i.d $N(0, 1)$, and

$$\frac{\|PX\|^2}{\sigma^2} = \sum_{i=1}^r \left(\frac{(U^\top X)_i}{\sigma} \right)^2 \sim \chi_r^2. \quad \square$$

§22.6.3 Normal Random Samples

We can now prove the central result of the section.

Theorem 22.6.9 (Joint Distribution of $\bar{X}$ and S_{XX})

Let $X_1, \dots, X_n$ be i.i.d $N(\mu, \sigma^2)$. Then

- (i) $\bar{X} \sim N(\mu, \sigma^2/n)$;
- (ii) $S_{XX}/\sigma^2 \sim \chi_{n-1}^2$;
- (iii) $\bar{X}$ and S_{XX} are independent.

Proof. Let P be the $n \times n$ matrix with every entry $1/n$. It is symmetric, and $P^2 = P$ since each entry of P^2 is $n \cdot \frac{1}{n^2} = \frac{1}{n}$; so P is an orthogonal projection, onto the one-dimensional space of constant vectors. Note $PX = (\bar{X}, \dots, \bar{X})^\top$ and $\text{tr } P = 1$, so $\text{rank } P = 1$ and $\text{rank}(I - P) = n - 1$.

Write $X = M + \varepsilon$ where $M = (\mu, \dots, \mu)^\top$ and $\varepsilon \sim N(0, \sigma^2 I)$. Since M is constant, $PM = M$ and $(I - P)M = 0$, so

$$\bar{X} = (PX)_1 = \mu + (P\varepsilon)_1$$

is a function of $P\varepsilon$, while

$$S_{XX} = \sum_i (X_i - \bar{X})^2 = \|X - PX\|^2 = \|(I - P)X\|^2 = \|(I - P)\varepsilon\|^2$$

is a function of $(I - P)\varepsilon$. By Theorem 22.6.8 these two are independent, giving (iii), and

$$\frac{S_{XX}}{\sigma^2} = \frac{\|(I - P)\varepsilon\|^2}{\sigma^2} \sim \chi_{n-1}^2,$$

giving (ii). Finally $\bar{X}$ is normal (a linear function of a normal vector) with mean μ and variance σ^2/n , giving (i). $\square$

Remark. This is where the mysterious $n - 1$ of Section 1 comes from. The data live in $\mathbb{R}^n$; fitting the mean uses up the one-dimensional space of constant vectors, and the residual $X - \bar{X}\mathbf{1}$ is confined to the orthogonal complement, of dimension $n - 1$. The ‘degrees of freedom’ really are dimensions of a subspace. It also explains why $\bar{X}$ and S_{XX} are independent, which is otherwise a rather surprising fact: they are functions of the components of ε in orthogonal subspaces.

There is a classical alternative proof, which is worth seeing because it makes the change of coordinates explicit.

Alternative proof, by an orthogonal change of basis. Let A be any $n \times n$ orthogonal matrix whose first row is $(1/\sqrt{n}, \dots, 1/\sqrt{n})$; such a matrix exists by extending that unit vector to an orthonormal basis. Put $Y = AX$, so

$$Y \sim N(AM, \sigma^2 AA^\top) = N(AM, \sigma^2 I),$$

and $AM = (\sqrt{n}\mu, 0, \dots, 0)^\top$. So $Y_1 \sim N(\sqrt{n}\mu, \sigma^2)$ and $Y_2, \dots, Y_n$ are i.i.d $N(0, \sigma^2)$, all independent. But $Y_1 = \frac{1}{\sqrt{n}} \sum_i X_i = \sqrt{n}\bar{X}$, giving (i), and

$$Y_2^2 + \dots + Y_n^2 = \|Y\|^2 - Y_1^2 = X^\top A^\top A X - n\bar{X}^2 = \sum_i X_i^2 - n\bar{X}^2 = S_{XX},$$

a sum of $n - 1$ independent $N(0, \sigma^2)$ squares, giving (ii). Independence of Y_1 from $Y_2, \dots, Y_n$ gives (iii). $\square$

§22.6.4 The One-Sample t -Test

Now we can finally handle unknown variance. Let $X_1, \dots, X_n$ be i.i.d $N(\mu, \sigma^2)$ with both parameters unknown, and write

$$\tilde{\sigma}^2 = \frac{S_{XX}}{n-1}$$

for the unbiased estimator of σ^2 . By Theorem 22.6.9,

$$Z = \frac{\sqrt{n}(\bar{X} - \mu)}{\sigma} \sim N(0, 1), \quad V = \frac{S_{XX}}{\sigma^2} \sim \chi_{n-1}^2,$$

and these are independent. So by the definition of the t -distribution,

$$\frac{Z}{\sqrt{V/(n-1)}} = \frac{\sqrt{n}(\bar{X} - \mu)/\sigma}{\sqrt{S_{XX}/((n-1)\sigma^2)}} = \frac{\sqrt{n}(\bar{X} - \mu)}{\tilde{\sigma}} \sim t_{n-1}.$$

The unknown σ has cancelled: this is a genuine pivot, and it is the reason the t -distribution was invented.

Proposition 22.6.10 (Confidence Interval for a Normal Mean)

With $X_1, \dots, X_n$ i.i.d $N(\mu, \sigma^2)$, both unknown, a $100(1 - \alpha)\%$ confidence interval for μ is

$$\bar{X} \pm \frac{\tilde{\sigma}}{\sqrt{n}} t_{n-1}\left(\frac{\alpha}{2}\right).$$

Proof. Immediate from the pivot above and the symmetry of t_{n-1} about 0:

$$1 - \alpha = \mathbb{P}\left(-t_{n-1}\left(\frac{\alpha}{2}\right) \leq \frac{\sqrt{n}(\bar{X} - \mu)}{\tilde{\sigma}} \leq t_{n-1}\left(\frac{\alpha}{2}\right)\right),$$

and rearranging for μ . □

Definition 22.6.11 (One-Sample t -Test)

To test $H_0 : \mu = \mu_0$ against $H_1 : \mu \neq \mu_0$ with σ^2 unknown, compute

$$t = \frac{\sqrt{n}(\bar{X} - \mu_0)}{\tilde{\sigma}}$$

and reject H_0 at size α if $|t| > t_{n-1}(\alpha/2)$. For the one-sided alternative $H_1 : \mu > \mu_0$ we reject if $t > t_{n-1}(\alpha)$.

By the duality of Section 5.9 this is exactly the test that rejects when μ_0 falls outside the confidence interval above. Note that $t_{n-1}(\alpha/2) > z_{\alpha/2}$, so the interval is wider and the test more conservative than the corresponding Z -procedures: this is the price of not knowing σ .

Example 22.6.12

Suppose $n = 10$ observations give $\bar{x} = 4.2$ and $\tilde{\sigma} = 1.1$, and we test $H_0 : \mu = 3.5$

against $H_1 : \mu \neq 3.5$. Then

$$t = \frac{\sqrt{10}(4.2 - 3.5)}{1.1} = \frac{3.162 \times 0.7}{1.1} \approx 2.01.$$

Since $t_9(0.025) = 2.262$, we do not reject at the 5% level – though we would at the 10% level, as $t_9(0.05) = 1.833$.

§22.6.5 The Two-Sample t -Test

More often we wish to compare two groups. Let

$$X_1, \dots, X_m \stackrel{\text{iid}}{\sim} N(\mu_X, \sigma^2), \quad Y_1, \dots, Y_n \stackrel{\text{iid}}{\sim} N(\mu_Y, \sigma^2)$$

be independent samples with a *common* unknown variance, and test $H_0 : \mu_X = \mu_Y$.

The natural estimator of the difference is $\bar{X} - \bar{Y}$, with

$$\bar{X} - \bar{Y} \sim N\left(\mu_X - \mu_Y, \sigma^2 \left(\frac{1}{m} + \frac{1}{n}\right)\right).$$

For the variance we pool the two sums of squares. Since $S_{XX}/\sigma^2 \sim \chi_{m-1}^2$ and $S_{YY}/\sigma^2 \sim \chi_{n-1}^2$ independently, and independent chi-squareds add,

$$\frac{S_{XX} + S_{YY}}{\sigma^2} \sim \chi_{m+n-2}^2,$$

and this is independent of $\bar{X} - \bar{Y}$ (each sum of squares is independent of its own sample mean, and the samples are independent of each other). Writing

$$\tilde{\sigma}^2 = \frac{S_{XX} + S_{YY}}{m + n - 2}$$

for the **pooled** variance estimator, we obtain the pivot

$$\frac{(\bar{X} - \bar{Y}) - (\mu_X - \mu_Y)}{\tilde{\sigma} \sqrt{\frac{1}{m} + \frac{1}{n}}} \sim t_{m+n-2}.$$

Definition 22.6.13 (Two-Sample t -Test)

Under the above assumptions, to test $H_0 : \mu_X = \mu_Y$ compute

$$t = \frac{\bar{X} - \bar{Y}}{\tilde{\sigma} \sqrt{\frac{1}{m} + \frac{1}{n}}}$$

and reject at size α if $|t| > t_{m+n-2}(\alpha/2)$. Correspondingly,

$$(\bar{X} - \bar{Y}) \pm \tilde{\sigma} \sqrt{\frac{1}{m} + \frac{1}{n}} t_{m+n-2}\left(\frac{\alpha}{2}\right)$$

is a $100(1 - \alpha)\%$ confidence interval for $\mu_X - \mu_Y$.

The assumption of equal variances is essential to the pooling step. If it is doubtful, one should first test it (see below), or use an approximate procedure such as Welch's test, which is not part of this course.

§22.6.6 Paired Data

Suppose instead that the observations come in pairs (X_i, Y_i) , $i = 1, \dots, n$ – the same patient measured before and after treatment, say, or two measuring instruments applied to the same specimen. The two-sample test is then *wrong*, because it assumes the samples independent, and here they are emphatically not: a patient with a high ‘before’ reading will tend to have a high ‘after’ reading too.

The remedy is disarmingly simple. Set $D_i = X_i - Y_i$ and treat $D_1, \dots, D_n$ as a single sample. If the pairs are i.i.d then so are the D_i , and testing $H_0 : \mathbb{E}[D] = 0$ by the one-sample t -test on the differences is exactly right.

Definition 22.6.14 (Paired t -Test)

Given paired data, let $D_i = X_i - Y_i$ and suppose $D_1, \dots, D_n$ are i.i.d $N(\mu_D, \sigma_D^2)$. To test $H_0 : \mu_D = 0$, compute

$$t = \frac{\sqrt{n} \bar{D}}{\tilde{\sigma}_D}, \quad \tilde{\sigma}_D^2 = \frac{1}{n-1} \sum_i (D_i - \bar{D})^2,$$

and reject at size α if $|t| > t_{n-1}(\alpha/2)$.

Pairing is not merely a technical correction; it is usually a large *gain*. The subject-to-subject variability, which in the two-sample test is noise inflating $\tilde{\sigma}$, cancels entirely in the differences. When a paired design is available it will almost always detect a given effect with far fewer observations than an unpaired one.

Example 22.6.15

Eight subjects have their reaction times measured before and after a dose of caffeine, with differences (before minus after, in milliseconds)

$$D = (12, -3, 18, 7, 22, 5, 14, 9).$$

Here $\bar{D} = 10.5$ and $\sum_i (D_i - \bar{D})^2 = 430$, so $\tilde{\sigma}_D^2 = 430/7 \approx 61.4$ and $\tilde{\sigma}_D \approx 7.84$. Then

$$t = \frac{\sqrt{8} \times 10.5}{7.84} \approx 3.79,$$

against $t_7(0.025) = 2.365$. So we reject H_0 at the 5% level and conclude that caffeine has an effect.

§22.6.7 The F -Test for Equality of Variances

Finally, suppose we wish to compare two variances – either because it is the question of interest, or to check the pooling assumption of the two-sample t -test. Let $X_1, \dots, X_m$ be i.i.d $N(\mu_X, \sigma_X^2)$ and $Y_1, \dots, Y_n$ be i.i.d $N(\mu_Y, \sigma_Y^2)$, independent, and test $H_0 : \sigma_X^2 = \sigma_Y^2$.

We know $S_{XX}/\sigma_X^2 \sim \chi_{m-1}^2$ and $S_{YY}/\sigma_Y^2 \sim \chi_{n-1}^2$, independently. So by definition of the F -distribution,

$$\frac{S_{XX}/((m-1)\sigma_X^2)}{S_{YY}/((n-1)\sigma_Y^2)} = \frac{\tilde{\sigma}_X^2/\sigma_X^2}{\tilde{\sigma}_Y^2/\sigma_Y^2} \sim F_{m-1, n-1}.$$

This is a pivot for the ratio σ_X^2/σ_Y^2 , so it gives both a test and a confidence interval.

Definition 22.6.16 (*F-Test for Equality of Variances*)

Under $H_0 : \sigma_X^2 = \sigma_Y^2$ the statistic

$$F = \frac{\tilde{\sigma}_X^2}{\tilde{\sigma}_Y^2}$$

has the $F_{m-1, n-1}$ distribution. We reject H_0 at size α against the two-sided alternative if $F > F_{m-1, n-1}(\alpha/2)$ or $F < F_{m-1, n-1}(1 - \alpha/2)$.

Remark. Recall that $1/F \sim F_{n-1, m-1}$, so one may always arrange to have the larger sample variance on top and use only the upper tail (doubling the resulting p -value for a two-sided test). Note also that this test is notoriously sensitive to departures from normality – far more so than the t -test, which is quite robust. A significant F here may be telling us about the tails of the data rather than about the variances.

Example 22.6.17

Suppose $m = 11$ observations give $\tilde{\sigma}_X^2 = 24.5$, and $n = 16$ give $\tilde{\sigma}_Y^2 = 9.8$. Then $F = 24.5/9.8 = 2.5$ on $(10, 15)$ degrees of freedom. Since $F_{10, 15}(0.025) = 3.06$, we do not reject equality of variances at the 5% level, and pooling for a subsequent t -test would be defensible.

§22.7 The Linear Model

The linear model is the single most used statistical model in existence, and it is a fitting place to end, because it brings together everything we have done: least squares as maximum likelihood, projections and degrees of freedom, t -tests for individual parameters, F -tests from the generalised likelihood ratio, and confidence intervals from pivots.

§22.7.1 The Model

Suppose we observe pairs $(x_1, Y_1), \dots, (x_n, Y_n)$ where $Y_i \in \mathbb{R}$ and $x_i = (x_{i1}, \dots, x_{ip})^\top \in \mathbb{R}^p$. The Y_i are the **responses** (or dependent variables); the x_{ij} are the **predictors** (or covariates, or independent variables) and are treated as fixed and known. We model

$$Y_i = \beta_1 x_{i1} + \dots + \beta_p x_{ip} + \varepsilon_i,$$

where $\beta \in \mathbb{R}^p$ are unknown **coefficients** and ε is a random **noise** vector.

Example 22.7.1

Let Y_i be the number of insurance claims made by driver i in a year, and let the predictors record the driver's age, years of experience, and points on their licence. The model asserts that the expected number of claims is a linear combination of these.

An **intercept** is included by setting $x_{i1} = 1$ for all i , so that β_1 is a constant term; we will always assume this has been done unless stated otherwise. It is worth stressing that ‘linear’ refers to linearity in β , not in the predictors: the model

$$Y_i = a + bz_i + cz_i^2 + \varepsilon_i$$

is a perfectly good linear model with $x_i = (1, z_i, z_i^2)^\top$. This flexibility is a large part of why the model is so widely used.

The coefficient β_j is interpreted as the change in $\mathbb{E}[Y_i]$ produced by increasing x_{ij} by one while holding all other predictors fixed. This is emphatically *not* a causal statement unless the predictors were assigned by the experimenter – a point on which a great deal of applied statistics comes to grief.

§22.7.2 Matrix Formulation and Assumptions

Stacking everything up, let

$$Y = \begin{pmatrix} Y_1 \\ \vdots \\ Y_n \end{pmatrix}, \quad X = \begin{pmatrix} x_{11} & \cdots & x_{1p} \\ \vdots & \ddots & \vdots \\ x_{n1} & \cdots & x_{np} \end{pmatrix}, \quad \beta = \begin{pmatrix} \beta_1 \\ \vdots \\ \beta_p \end{pmatrix}, \quad \varepsilon = \begin{pmatrix} \varepsilon_1 \\ \vdots \\ \varepsilon_n \end{pmatrix},$$

where X is called the **design matrix**. The model is then simply

$$Y = X\beta + \varepsilon.$$

We make two **moment assumptions** on the noise:

- (i) $\mathbb{E}[\varepsilon] = 0$, so that $\mathbb{E}[Y_i] = x_i^\top \beta$ – the model is correctly specified;
- (ii) $\text{Var}(\varepsilon) = \sigma^2 I$, that is, $\text{Var}(\varepsilon_i) = \sigma^2$ for all i and $\text{Cov}(\varepsilon_i, \varepsilon_j) = 0$ for $i \neq j$. Constant variance is called **homoscedasticity**.

Note that no distributional assumption has yet been made; we will add normality in Section 7.5.

Throughout we assume the design matrix X has full rank p , equivalently that its columns are linearly independent. Since $X \in \mathbb{R}^{n \times p}$ this forces $n \geq p$: we need at least as many observations as parameters, which is only sensible.

§22.7.3 Least Squares Estimation

Definition 22.7.2 (Least Squares Estimator)

The **least squares estimator** $\hat{\beta}$ minimises the **residual sum of squares**

$$S(\beta) = \|Y - X\beta\|^2 = \sum_{i=1}^n (Y_i - x_i^\top \beta)^2.$$

Proposition 22.7.3

If X has full column rank then S has the unique minimiser

$$\hat{\beta} = (X^\top X)^{-1} X^\top Y.$$

Moreover $\mathbb{E}[\hat{\beta}] = \beta$ and $\text{Var}(\hat{\beta}) = \sigma^2 (X^\top X)^{-1}$.

Proof. S is a positive semi-definite quadratic in β , so is minimised at a stationary point. Differentiating,

$$\frac{\partial S}{\partial \beta_k} = -2 \sum_{i=1}^n x_{ik} \left(Y_i - \sum_j x_{ij} \beta_j \right),$$

and setting all p of these to zero gives the **normal equations**

$$X^\top X \hat{\beta} = X^\top Y.$$

Since X has full column rank, $X^\top X$ is invertible: if $X^\top X v = 0$ then $\|Xv\|^2 = v^\top X^\top X v = 0$, so $Xv = 0$, so $v = 0$. Hence $\hat{\beta} = (X^\top X)^{-1} X^\top Y$, and this is the unique stationary point.

As $\hat{\beta}$ is a linear function of Y ,

$$\mathbb{E}[\hat{\beta}] = (X^\top X)^{-1} X^\top \mathbb{E}[Y] = (X^\top X)^{-1} X^\top X \beta = \beta,$$

and writing $B = (X^\top X)^{-1} X^\top$,

$$\text{Var}(\hat{\beta}) = B \text{Var}(Y) B^\top = \sigma^2 B B^\top = \sigma^2 (X^\top X)^{-1} X^\top X (X^\top X)^{-1} = \sigma^2 (X^\top X)^{-1}.$$

□

The geometry is much more illuminating than the algebra. The vector $X\beta$ ranges over $\text{col}(X)$, a p -dimensional subspace of $\mathbb{R}^n$, as β ranges over $\mathbb{R}^p$. Minimising $\|Y - X\beta\|$ therefore means finding the point of $\text{col}(X)$ closest to Y – which is exactly the orthogonal projection of Y onto $\text{col}(X)$.

Any other point $X\beta'$ of the subspace is further from Y , by Pythagoras. Let us record this projection formally.

Definition 22.7.4 (Fitted Values, Hat Matrix, Residuals)

The **fitted values** are $\hat{Y} = X\hat{\beta} = PY$ where

$$P = X (X^\top X)^{-1} X^\top$$

is the **hat matrix**. The **residuals** are $Y - \hat{Y} = (I - P)Y$.

Proposition 22.7.5

P is the orthogonal projection onto $\text{col}(X)$.

Proof. If $v \in \text{col}(X)$ then $v = Xb$ for some b , and $Pv = X(X^\top X)^{-1}X^\top Xb = Xb = v$. If $w \in \text{col}(X)^\perp$ then $X^\top w = 0$, so $Pw = 0$. (Equivalently: P is visibly symmetric, and $P^2 = X(X^\top X)^{-1}X^\top X(X^\top X)^{-1}X^\top = P$.) $\square$

In particular $\text{tr } P = \text{rank } P = p$ and $\text{rank}(I - P) = n - p$, and the residuals are orthogonal to every column of X . That last fact is worth remembering: least squares residuals are, by construction, uncorrelated with every predictor in the model.

§22.7.4 The Gauss-Markov Theorem

Least squares is not just geometrically natural; among a large class of estimators it is optimal, and remarkably this requires no normality assumption at all.

Theorem 22.7.6 (Gauss-Markov)

Let $\beta^* = CY$ be any estimator of β that is linear in Y and unbiased. Then for every $t \in \mathbb{R}^p$,

$$\text{Var}(t^\top \hat{\beta}) \leq \text{Var}(t^\top \beta^*),$$

where $\hat{\beta}$ is the least squares estimator. We say $\hat{\beta}$ is the **best linear unbiased estimator** (BLUE).

Remark. Thinking of t as the predictor vector for a new observation, $t^\top \hat{\beta}$ is our prediction of its expected response. The theorem says least squares gives the most precise such prediction among all linear unbiased methods, simultaneously for every t . Taking $t = e_j$ recovers the statement that $\text{Var}(\hat{\beta}_j) \leq \text{Var}(\beta_j^*)$ for each coordinate.

Proof. Since $\text{Var}(t^\top \beta^*) - \text{Var}(t^\top \hat{\beta}) = t^\top [\text{Var}(\beta^*) - \text{Var}(\hat{\beta})] t$, it suffices to show that $\text{Var}(\beta^*) - \text{Var}(\hat{\beta})$ is positive semi-definite.

Put $A = C - (X^\top X)^{-1}X^\top$, so that $\beta^* = \hat{\beta} + AY$. Unbiasedness of both estimators gives $\mathbb{E}[AY] = 0$; but $\mathbb{E}[AY] = AX\beta$, and as this vanishes for every β we must have $AX = 0$. Now

$$\begin{aligned} \text{Var}(\beta^*) &= \text{Var}\left(\left[A + (X^\top X)^{-1}X^\top\right]Y\right) \\ &= \sigma^2 \left[A + (X^\top X)^{-1}X^\top\right] \left[A + (X^\top X)^{-1}X^\top\right]^\top \\ &= \sigma^2 \left(AA^\top + \underbrace{AX(X^\top X)^{-1}}_{=0} + (X^\top X)^{-1} \underbrace{X^\top A^\top}_{=0} + (X^\top X)^{-1}\right) \\ &= \sigma^2 AA^\top + \text{Var}(\hat{\beta}). \end{aligned}$$

So $\text{Var}(\beta^*) - \text{Var}(\hat{\beta}) = \sigma^2 AA^\top$, and $u^\top AA^\top u = \|A^\top u\|^2 \geq 0$ for every u . $\square$

§22.7.5 The Normal Linear Model

We now strengthen the moment assumptions to a full distributional one.

Definition 22.7.7 (Normal Linear Model)

The **normal linear model** is $Y = X\beta + \varepsilon$ with $\varepsilon \sim N(0, \sigma^2 I)$, where β and $\sigma^2 > 0$ are both unknown.

The likelihood is

$$L(\beta, \sigma^2) = (2\pi\sigma^2)^{-n/2} \exp\left(-\frac{1}{2\sigma^2}\|Y - X\beta\|^2\right),$$

so

$$\ell(\beta, \sigma^2) = \text{const} - \frac{n}{2} \log \sigma^2 - \frac{1}{2\sigma^2} \|Y - X\beta\|^2.$$

For any fixed σ^2 , maximising over β means minimising $\|Y - X\beta\|^2$. So:

Proposition 22.7.8

In the normal linear model the maximum likelihood estimator of β is the least squares estimator $\hat{\beta} = (X^\top X)^{-1} X^\top Y$, and

$$\hat{\sigma}^2 = \frac{1}{n} \|Y - X\hat{\beta}\|^2 = \frac{1}{n} \|(I - P)Y\|^2.$$

Proof. The first claim is the observation above. Substituting $\hat{\beta}$ and differentiating in σ^2 ,

$$\frac{\partial \ell}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{1}{2\sigma^4} \|(I - P)Y\|^2,$$

which vanishes at the stated value, and this is a maximum. $\square$

That least squares and maximum likelihood coincide under normal errors is a happy accident of the exponential of a quadratic, but it is the reason least squares is so ubiquitous.

Theorem 22.7.9 (Distribution Theory for the Normal Linear Model)

In the normal linear model,

- (i) $\hat{\beta} \sim N(\beta, \sigma^2(X^\top X)^{-1})$;
- (ii) $n\hat{\sigma}^2/\sigma^2 \sim \chi_{n-p}^2$;
- (iii) $\hat{\beta}$ and $\hat{\sigma}^2$ are independent.

Proof. (i) We have already computed the mean and variance of $\hat{\beta}$, and it is a linear function of the multivariate normal Y , hence multivariate normal.

(ii) Since P projects onto $\text{col}(X)$ we have $(I - P)X = 0$, so

$$\frac{n\hat{\sigma}^2}{\sigma^2} = \frac{\|(I - P)Y\|^2}{\sigma^2} = \frac{\|(I - P)(X\beta + \varepsilon)\|^2}{\sigma^2} = \frac{\|(I - P)\varepsilon\|^2}{\sigma^2} \sim \chi_{\text{rank}(I-P)}^2$$

by Theorem 22.6.8, and $\text{rank}(I - P) = \text{tr } I - \text{tr } P = n - p$.

(iii) From (ii), $\hat{\sigma}^2$ is a function of $(I - P)\varepsilon$. On the other hand

$$\hat{\beta} = (X^\top X)^{-1} X^\top (X\beta + \varepsilon) = \beta + (X^\top X)^{-1} X^\top \varepsilon = \beta + (X^\top X)^{-1} X^\top P\varepsilon,$$

using $X^\top P = X^\top$, so $\hat{\beta}$ is a function of $P\epsilon$. These are independent by Theorem 22.6.8. $\square$

Since $\mathbb{E}[\chi_{n-p}^2] = n - p$ we get

$$\mathbb{E}[\hat{\sigma}^2] = \frac{n-p}{n}\sigma^2 < \sigma^2,$$

so as usual the maximum likelihood estimator of the variance is biased downwards. We therefore define the unbiased estimator

$$\tilde{\sigma}^2 = \frac{n\hat{\sigma}^2}{n-p} = \frac{\|(I-P)Y\|^2}{n-p},$$

and note that $\tilde{\sigma}^2$ is what one should always use in practice. Once again the divisor is the dimension of the space in which the residuals live.

§22.7.6 Inference for the Coefficients

Theorem 22.7.9 gives us everything we need to construct pivots.

Proposition 22.7.10 (Confidence Interval for a Single Coefficient)

In the normal linear model,

$$\frac{\hat{\beta}_j - \beta_j}{\sqrt{\tilde{\sigma}^2 (X^\top X)^{-1}_{jj}}} \sim t_{n-p},$$

and hence

$$\hat{\beta}_j \pm t_{n-p}\left(\frac{\alpha}{2}\right) \sqrt{\tilde{\sigma}^2 (X^\top X)^{-1}_{jj}}$$

is a $100(1 - \alpha)\%$ confidence interval for β_j .

Proof. By part (i) of Theorem 22.7.9, the j th coordinate is distributed as

$$\hat{\beta}_j \sim N\left(\beta_j, \sigma^2 (X^\top X)^{-1}_{jj}\right),$$

so

$$U = \frac{\hat{\beta}_j - \beta_j}{\sigma \sqrt{(X^\top X)^{-1}_{jj}}} \sim N(0, 1).$$

By parts (ii) and (iii), $V = n\hat{\sigma}^2/\sigma^2 \sim \chi_{n-p}^2$ independently of U . Hence

$$\frac{U}{\sqrt{V/(n-p)}} = \frac{\hat{\beta}_j - \beta_j}{\sigma \sqrt{(X^\top X)^{-1}_{jj}}} \cdot \frac{\sigma}{\tilde{\sigma}} = \frac{\hat{\beta}_j - \beta_j}{\tilde{\sigma} \sqrt{(X^\top X)^{-1}_{jj}}} \sim t_{n-p},$$

the unknown σ having cancelled. Rearranging the two-sided t inequality gives the interval. $\square$

By the test-interval duality, a size- α test of $H_0 : \beta_j = 0$ against $H_1 : \beta_j \neq 0$ rejects exactly when 0 falls outside this interval, i.e. when

$$\left| \frac{\hat{\beta}_j}{\tilde{\sigma} \sqrt{(X^\top X)^{-1}_{jj}}} \right| > t_{n-p}\left(\frac{\alpha}{2}\right).$$

This is the t -statistic that statistical software prints next to every coefficient.

Example 22.7.11 (The One-Sample t -Test as a Linear Model)

Take $p = 1$ with $X = (1, \dots, 1)^\top$, so the model is $Y_i = \mu + \varepsilon_i$, i.e. $Y_1, \dots, Y_n$ i.i.d $N(\mu, \sigma^2)$. Then $X^\top X = n$, $\hat{\beta} = \bar{Y}$, $(X^\top X)^{-1}_{11} = 1/n$ and $\tilde{\sigma}^2 = S_{YY}/(n-1)$, so the interval above is exactly

$$\bar{Y} \pm \frac{\tilde{\sigma}}{\sqrt{n}} t_{n-1} \left(\frac{\alpha}{2} \right),$$

recovering the one-sample t -interval of Section 6.4.

We can also give a confidence set for the whole vector β at once.

Proposition 22.7.12 (Confidence Set for β)

In the normal linear model,

$$\frac{\|X(\hat{\beta} - \beta)\|^2 / p}{\tilde{\sigma}^2} \sim F_{p, n-p},$$

so

$$\left\{ \beta' \in \mathbb{R}^p : \frac{\|X(\hat{\beta} - \beta')\|^2}{p \tilde{\sigma}^2} \leq F_{p, n-p}(\alpha) \right\}$$

is a $100(1 - \alpha)\%$ confidence set for β .

Proof. Since $\hat{\beta} - \beta \sim N(0, \sigma^2(X^\top X)^{-1})$, writing $(X^\top X)^{1/2}$ for the symmetric positive definite square root,

$$(X^\top X)^{1/2}(\hat{\beta} - \beta) \sim N(0, \sigma^2(X^\top X)^{1/2}(X^\top X)^{-1}(X^\top X)^{1/2}) = N(0, \sigma^2 I_p),$$

so its squared norm over σ^2 is χ_p^2 . But that squared norm is

$$(\hat{\beta} - \beta)^\top X^\top X (\hat{\beta} - \beta) = \|X(\hat{\beta} - \beta)\|^2.$$

This is a function of $\hat{\beta}$, hence independent of $\tilde{\sigma}^2$, and $(n-p)\tilde{\sigma}^2/\sigma^2 \sim \chi_{n-p}^2$. Taking the ratio of the two scaled chi-squareds gives the F distribution, the σ^2 cancelling. $\square$

Geometrically the confidence set is an ellipsoid centred at $\hat{\beta}$, with principal axes along the eigenvectors of $X^\top X$: directions in which the predictors carry little information give long axes. Note that both results in this subsection are *exact* – no asymptotics have been used anywhere.

§22.7.7 F -Tests and Model Comparison

Now suppose we wish to test whether a whole block of coefficients vanishes. Relabelling if necessary, take

$$H_0 : \beta_1 = \dots = \beta_{p_0} = 0, \quad H_1 : \beta \in \mathbb{R}^p.$$

Split $X = (X_0, X_1)$ with $X_0 \in \mathbb{R}^{n \times p_0}$ and $X_1 \in \mathbb{R}^{n \times (p-p_0)}$, and correspondingly $\beta = (\beta^0, \beta^1)$. Under H_0 the model reduces to $Y = X_1\beta^1 + \varepsilon$. Write

$$P = X(X^\top X)^{-1}X^\top, \quad P_1 = X_1(X_1^\top X_1)^{-1}X_1^\top$$

for the projections onto $\text{col}(X)$ and the smaller $\text{col}(X_1)$.

Lemma 22.7.13

$P - P_1$ is an orthogonal projection of rank p_0 , and $(I - P)(P - P_1) = 0$.

Proof. Since $\text{col}(X_1) \subseteq \text{col}(X)$, applying P to anything in $\text{col}(X_1)$ leaves it fixed, so $PP_1 = P_1$; taking transposes, $P_1P = P_1$. Hence $P - P_1$ is symmetric, and

$$(P - P_1)^2 = P^2 - PP_1 - P_1P + P_1^2 = P - P_1 - P_1 + P_1 = P - P_1,$$

so it is an orthogonal projection. Its rank is $\text{tr } P - \text{tr } P_1 = p - (p - p_0) = p_0$. Finally

$$(I - P)(P - P_1) = P - P_1 - P^2 + PP_1 = P - P_1 - P + P_1 = 0. \quad \square$$

Now we compute the generalised likelihood ratio. From the proposition above, the maximised log-likelihood in a normal linear model with projection P is

$$\ell(\hat{\beta}, \hat{\sigma}^2) = \text{const} - \frac{n}{2} \log \frac{\|(I - P)Y\|^2}{n},$$

so

$$2 \log \Lambda = n \left[\log \frac{\|(I - P_1)Y\|^2}{n} - \log \frac{\|(I - P)Y\|^2}{n} \right] = n \log \frac{\|(I - P_1)Y\|^2}{\|(I - P)Y\|^2}.$$

This is increasing in the ratio of sums of squares, which by Lemma 22.7.13 and Pythagoras satisfies

$$\begin{aligned} \frac{\|(I - P_1)Y\|^2}{\|(I - P)Y\|^2} &= \frac{\|(I - P)Y + (P - P_1)Y\|^2}{\|(I - P)Y\|^2} \\ &= \frac{\|(I - P)Y\|^2 + \|(P - P_1)Y\|^2}{\|(I - P)Y\|^2} = 1 + \frac{\|(P - P_1)Y\|^2}{\|(I - P)Y\|^2}, \end{aligned}$$

the cross term vanishing because $(I - P)(P - P_1) = 0$. So the generalised likelihood ratio test rejects for large values of

$$F = \frac{\|(P - P_1)Y\|^2/p_0}{\|(I - P)Y\|^2/(n - p)},$$

and, delightfully, we can find its exact distribution rather than appealing to Wilks.

Theorem 22.7.14

Under $H_0 : \beta_1 = \cdots = \beta_{p_0} = 0$ in the normal linear model,

$$F = \frac{\|(P - P_1)Y\|^2/p_0}{\|(I - P)Y\|^2/(n - p)} \sim F_{p_0, n-p}.$$

Proof. We know $\|(I - P)Y\|^2 = \|(I - P)\varepsilon\|^2 \sim \sigma^2 \chi_{n-p}^2$. Under H_0 we have $Y = X_1\beta^1 + \varepsilon$, and since both P and P_1 fix $\text{col}(X_1)$,

$$(P - P_1)Y = (P - P_1)X_1\beta^1 + (P - P_1)\varepsilon = (P - P_1)\varepsilon,$$

so by Theorem 22.6.8 and Lemma 22.7.13, $\|(P - P_1)Y\|^2 \sim \sigma^2 \chi_{p_0}^2$.

For independence, note that the stacked vector $((I - P)\varepsilon, (P - P_1)\varepsilon)$ is multivariate normal with mean zero and covariance

$$\sigma^2 \begin{pmatrix} (I - P)^2 & (I - P)(P - P_1) \\ (P - P_1)(I - P) & (P - P_1)^2 \end{pmatrix} = \sigma^2 \begin{pmatrix} I - P & 0 \\ 0 & P - P_1 \end{pmatrix},$$

which is block diagonal, so the two blocks are independent. Taking the ratio of the two scaled chi-squareds and cancelling σ^2 gives $F_{p_0, n-p}$. $\square$

So the size- α test rejects H_0 when $F > F_{p_0, n-p}(\alpha)$, and this is exact for every n, p, p_0 .

Remark. The numerator $\|(P - P_1)Y\|^2$ is the reduction in residual sum of squares achieved by adding the p_0 extra predictors, and the denominator estimates σ^2 . So F compares ‘variance explained per extra parameter’ against ‘unexplained variance per residual degree of freedom’. Adding predictors always reduces the residual sum of squares; the F -test asks whether it reduces it by more than chance would predict.

Proposition 22.7.15

When $p_0 = 1$, the F -test of $H_0 : \beta_1 = 0$ is identical to the two-sided t -test of the same hypothesis.

Proof sketch. Recall from Section 1 that $T \sim t_{n-p}$ implies $T^2 \sim F_{1, n-p}$, and correspondingly $t_{n-p}(\alpha/2)^2 = F_{1, n-p}(\alpha)$. So the t -test rejects exactly when

$$\frac{\hat{\beta}_1^2}{\tilde{\sigma}^2(X^\top X)_{11}^{-1}} > F_{1, n-p}(\alpha),$$

and since the denominators of the two statistics already agree, it suffices to check that

$$\frac{\hat{\beta}_1^2}{(X^\top X)_{11}^{-1}} = \|(P - P_1)Y\|^2.$$

When $p_0 = 1$, $P - P_1$ is the rank-one projection onto the span of $v = (I - P_1)X_0$, where X_0 is the first column of X . A computation using $X_0^\top(I - P_1) = v^\top = v^\top(P - P_1)$ gives

$$\|(P - P_1)Y\|^2 = \frac{(v^\top Y)^2}{\|v\|^2} = \frac{(X_0^\top(I - P_1)X\hat{\beta})^2}{\|(I - P_1)X_0\|^2} = \|(I - P_1)X_0\|^2 \hat{\beta}_1^2,$$

using $(I - P_1)X = [(I - P_1)X_0, 0, \dots, 0]$. Finally, blockwise matrix inversion gives $(X^\top X)_{11}^{-1} = \|(I - P_1)X_0\|^{-2}$, and the two expressions agree. $\square$

§22.7.8 Simple Linear Regression

The simplest interesting case is $p = 2$ with a single predictor. It is customary to centre the predictor, writing

$$Y_i = a + b(x_i - \bar{x}) + \varepsilon_i, \quad \bar{x} = \frac{1}{n} \sum_i x_i,$$

which makes the algebra much cleaner because it renders the two columns of the design matrix orthogonal.

Proposition 22.7.16

In the centred simple linear regression model,

$$\hat{a} = \bar{Y}, \quad \hat{b} = \frac{S_{xY}}{S_{xx}},$$

where $S_{xY} = \sum_i (x_i - \bar{x})(Y_i - \bar{Y})$ and $S_{xx} = \sum_i (x_i - \bar{x})^2$. Moreover $\hat{a}$ and $\hat{b}$ are independent, with

$$\hat{a} \sim N\left(a, \frac{\sigma^2}{n}\right), \quad \hat{b} \sim N\left(b, \frac{\sigma^2}{S_{xx}}\right).$$

Proof. Minimise $S(a, b) = \sum_i (Y_i - a - b(x_i - \bar{x}))^2$. Since $\sum_i (x_i - \bar{x}) = 0$,

$$\frac{\partial S}{\partial a} = -2 \sum_i (Y_i - a - b(x_i - \bar{x})) = -2 \sum_i (Y_i - a),$$

which vanishes at $a = \bar{Y}$, independently of b . Substituting,

$$\frac{\partial S}{\partial b} = -2 \sum_i (Y_i - \bar{Y} - b(x_i - \bar{x})) (x_i - \bar{x}),$$

which vanishes at $b = S_{xY}/S_{xx}$.

For the distributions, the design matrix is $X = [\mathbf{1}, x - \bar{x}\mathbf{1}]$ whose columns are orthogonal, so

$$X^\top X = \begin{pmatrix} n & 0 \\ 0 & S_{xx} \end{pmatrix}, \quad (X^\top X)^{-1} = \begin{pmatrix} 1/n & 0 \\ 0 & 1/S_{xx} \end{pmatrix}.$$

By Theorem 22.7.9, $(\hat{a}, \hat{b})$ is bivariate normal with this covariance scaled by σ^2 ; the covariance is diagonal, so they are independent. $\square$

Note that S_{xY}/n is the sample covariance of x and Y , and S_{xx}/n the sample variance of x , so $\hat{b}$ is the sample covariance divided by the sample variance – exactly the formula for a regression coefficient one meets in elementary statistics.

Example 22.7.17 (A Worked Regression)

Twelve observations were taken, and the fitted line $\hat{y} = 0.99 + 0.79x$ obtained. The picture below shows the data, the fitted line, and the residuals as vertical segments.

Least squares chooses the line making the sum of the squared *vertical* red segments as small as possible. Note the asymmetry – vertical, not perpendicular, distance – which reflects the fact that the x values are treated as fixed and only Y is random.

§22.7.9 Prediction

Having fitted the model, we would like to use it. Let $x^* \in \mathbb{R}^p$ be a new vector of predictor values.

The **expected response** at x^* is $x^{*\top} \beta$, which we estimate by $x^{*\top} \hat{\beta}$. Since

$$x^{*\top} (\hat{\beta} - \beta) \sim N(0, \sigma^2 x^{*\top} (X^\top X)^{-1} x^*),$$

writing $\tau^2 = x^{*\top} (X^\top X)^{-1} x^*$ and dividing by the independent $\tilde{\sigma}$ as before,

$$\frac{x^{*\top} (\hat{\beta} - \beta)}{\tilde{\sigma} \tau} \sim t_{n-p}.$$

So a $100(1 - \alpha)\%$ confidence interval for the expected response is

$$x^{*\top} \hat{\beta} \pm \tilde{\sigma} \tau t_{n-p} \left(\frac{\alpha}{2} \right).$$

That, however, is not usually what we want. A new observation at x^* will be

$$Y^* = x^{*\top} \beta + \varepsilon^*, \quad \varepsilon^* \sim N(0, \sigma^2)$$

independent of the data, and there are now *two* sources of uncertainty: we do not know the line, and the new point will scatter about it anyway.

Definition 22.7.18 (Prediction Interval)

A $100(1 - \alpha)\%$ **prediction interval** for Y^* is a random interval $I(Y)$ with

$$\mathbb{P}(Y^* \in I(Y)) = 1 - \alpha,$$

where the probability is taken over the joint distribution of Y^* and $Y_1, \dots, Y_n$.

Proposition 22.7.19

$$x^{\star\top} \hat{\beta} \pm \tilde{\sigma} \sqrt{\tau^2 + 1} t_{n-p} \left(\frac{\alpha}{2} \right)$$

is a $100(1 - \alpha)\%$ prediction interval for Y^* .

Proof. Let $\hat{Y}^* = x^{\star\top} \hat{\beta}$. Then $\hat{Y}^* - Y^* = x^{\star\top} (\hat{\beta} - \beta) - \varepsilon^*$ has mean zero, and as the two terms are independent,

$$\text{Var}(\hat{Y}^* - Y^*) = \sigma^2 x^{\star\top} (X^\top X)^{-1} x^* + \sigma^2 = \sigma^2 (\tau^2 + 1).$$

Both terms are normal, so $\hat{Y}^* - Y^* \sim N(0, \sigma^2(\tau^2 + 1))$, and this is independent of $\tilde{\sigma}^2$. Dividing,

$$\frac{\hat{Y}^* - Y^*}{\tilde{\sigma} \sqrt{\tau^2 + 1}} \sim t_{n-p},$$

and rearranging gives the interval. $\square$

The extra $+1$ under the square root is the irreducible noise of the new observation. Because τ^2 is typically small (of order $1/n$) while the 1 is not, prediction intervals are much wider than confidence intervals for the expected response, and they do *not* shrink to zero as $n \rightarrow \infty$. Confusing the two is a common and serious error.

Example 22.7.20

In the regression example above we have $n = 12$, $\bar{x} = 4.05$, $S_{xx} = 43.4$ and $\tilde{\sigma} = 0.54$, and we wish to predict at $x^* = 6$. With the centred parametrisation $x^{\star\top} = (1, x^* - \bar{x})$ and $(X^\top X)^{-1} = \text{diag}(1/n, 1/S_{xx})$, so

$$\tau^2 = \frac{1}{n} + \frac{(x^* - \bar{x})^2}{S_{xx}} = \frac{1}{12} + \frac{(1.95)^2}{43.4} = 0.083 + 0.088 = 0.171,$$

giving $\tau = 0.41$. The fitted value is $0.99 + 0.79 \times 6 = 5.73$, and with $t_{10}(0.025) = 2.228$ we obtain a 95% confidence interval for the expected response

$$5.73 \pm 0.54 \times 0.41 \times 2.228 = (5.24, 6.22),$$

but a 95% prediction interval

$$5.73 \pm 0.54 \times \sqrt{1.171} \times 2.228 = (4.43, 7.03),$$

which is more than twice as wide. Notice also that τ^2 grows quadratically as x^* moves away from $\bar{x}$: extrapolation is punished, as it should be.

§22.7.10 One-Way Analysis of Variance

Our final application shows that the linear model covers situations that do not look like regression at all. Suppose we compare J treatments, with N subjects receiving each, and model

$$Y_{ij} = \alpha + \mu_j + \varepsilon_{ij}, \quad i = 1, \dots, N, \quad j = 1, \dots, J,$$

with ε_{ij} i.i.d $N(0, \sigma^2)$. Here the predictor is **categorical**: it records only which group a subject is in.

As written the parameters are not identifiable, since adding a constant to α and subtracting it from every μ_j changes nothing. We impose the **corner point constraint** $\mu_1 = 0$, so that group 1 (typically the control) is the baseline and μ_j measures the effect of treatment j relative to it. The design matrix is then

$$X = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ \vdots & \vdots & & \vdots \\ 1 & 1 & \cdots & 0 \\ \vdots & \vdots & & \vdots \\ 1 & 0 & \cdots & 1 \\ \vdots & \vdots & & \vdots \end{pmatrix} = (X_1 \ X_0)$$

where X_1 is the column of ones and X_0 the $J - 1$ indicator columns. Here $n = JN$ and $p = J$.

Definition 22.7.21 (One-Way ANOVA)

The **one-way analysis of variance** test is the test of

$$H_0 : \mu_2 = \cdots = \mu_J = 0, \quad H_1 : \mu_2, \dots, \mu_J \in \mathbb{R}$$

in the above model; under H_0 all groups have the same mean $\mathbb{E}[Y_{ij}] = \alpha$.

This is exactly the F -test of Section 7.7 with $p_0 = J - 1$. To write it out concretely we need only identify the two projections. Since $\text{col}(X)$ is the space of vectors constant within each group, P replaces every observation by its group mean:

$$\bar{Y}_{\cdot j} = \frac{1}{N} \sum_{i=1}^N Y_{ij}, \quad PY = (\bar{Y}_{\cdot 1}, \dots, \bar{Y}_{\cdot 1}, \dots, \bar{Y}_{\cdot J}, \dots, \bar{Y}_{\cdot J})^\top,$$

while $\text{col}(X_1)$ is the space of constant vectors, so P_1 replaces everything by the grand mean $\bar{Y}$. Therefore

$$\|(P - P_1)Y\|^2 = \sum_{j=1}^J N (\bar{Y}_{\cdot j} - \bar{Y})^2, \quad \|(I - P)Y\|^2 = \sum_{i,j} (Y_{ij} - \bar{Y}_{\cdot j})^2,$$

and the F -statistic is

$$F = \frac{\sum_j N (\bar{Y}_{\cdot j} - \bar{Y})^2 / (J - 1)}{\sum_{i,j} (Y_{ij} - \bar{Y}_{\cdot j})^2 / (JN - J)} = \frac{\text{variability between groups}}{\text{variability within groups}} \sim F_{J-1, JN-J}$$

under H_0 . This is where the name ‘analysis of variance’ comes from: the total sum of squares splits, by Pythagoras, into a between-groups part and a within-groups part, and we ask which dominates.

The blue bars are the group means $\bar{Y}_{\cdot j}$ and the red dashed line is the grand mean. The F -statistic is large when the blue bars are spread out relative to the scatter of the dots about their own bar. In the picture above they arguably are, and indeed a formal test would reject.

Remark. Everything here generalises. **Two-way** analysis of variance handles groups classified by two factors,

$$Y_{ijk} = \alpha + \mu_j + \lambda_k + \varepsilon_{ijk},$$

again with corner point constraints $\mu_1 = \lambda_1 = 0$, and one may test $H_0 : \mu_j \equiv 0$, or $H_0 : \lambda_k \equiv 0$, or both, by exactly the same F -test machinery. One can also add *interaction* terms γ_{jk} to allow the effect of one factor to depend on the level of the other. Unequal group sizes cause no difficulty in principle, only messier formulae. In every case the recipe is the same: write down the design matrix, project, and compare sums of squares.

This is a good point at which to stop. The linear model, and its relatives, occupy a remarkable position: general enough to describe an enormous range of experiments, yet special enough that every distributional question about it can be answered exactly, by projecting onto a subspace and counting dimensions.

23 Variational Principles

From finding geodesics to expressing the fundamental laws of nature, variational principles and the calculus of variations arise naturally in pure & applied mathematics, and theoretical physics. Here, we will study such ideas, with the underlying goal of considering problems involving minimizing (or maximizing) quantities that depend on an entire function.

This article constitutes my notes for the ‘Variational Principles’ course, held in Easter 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§23.1 Introduction

We will begin our study of variational principles by getting a feel for the type of problems that we care about. As a field, the study of variational principles can be traced back to a single problem, posed by Johann Bernoulli in 1696. It is there that we will begin.

§23.1.1 A Motivating Problem – The Brachistochrone

One of the earliest problems in the calculus of variations is the **Brachistochrone** problem.

Example 23.1.1 (Brachistochrone)

Consider a particle sliding on a wire between two fixed points A and B , under the influence of gravity. Which shape of the wire will give the shortest travel time, when the particle starts from rest?

It is not immediately obvious what the answer to this problem is. We won’t solve it right now, but we can still take some steps in the right direction. We first setup a coordinate system, setting A to be the origin, and B to be some point (x_2, y_2) .

In this coordinate system, for a given curve γ , we can write down the travel time

$$T = \int_{\gamma} dt = \int_{\gamma} \frac{1}{v} ds,$$

where v is the velocity of the particle. Since the particle starts at $y = 0$, conservation of energy implies that

$$\frac{1}{2}mv^2 + mgy = 0$$

$$\implies v = \sqrt{-2gy}.$$

Thus to solve our problem, we really want to minimize

$$T[y] = \frac{1}{\sqrt{2g}} \int_0^{x_2} \frac{\sqrt{1 + (y')^2}}{\sqrt{-y}} dx,$$

subject to y being a smooth function with $y(0) = 0$, and $y(x_2) = y_2$.

§23.1.2 Problems of Interest

Let's jump to another problem from pure mathematics, finding geodesics.

Example 23.1.2 (Geodesic Problem)

Find the shortest path γ between two points on a surface Σ (if one exists).

If Σ is $\mathbb{R}^2$, we can again adopt a coordinate system, and try to find the shortest curve γ between the two points $A = (x_1, y_1)$ and $B = (x_2, y_2)$. To solve this problem, we really want to minimize

$$D[y] = \int_{x_1}^{x_2} \sqrt{1 + (y')^2} dx,$$

subject to y being a smooth function with $y(x_1) = y_1$ and $y(x_2) = y_2$.

Both of these problems have a similar flavour: we are trying to minimize or maximize something like

$$F[y] = \int_{x_1}^{x_2} f(x, y(x), y'(x)) dx, \quad (*)$$

among all functions such that $y(x_1) = y_1$ and $y(x_2) = y_2$. This quantity $(*)$ is called a **functional**, that is, a function on the space of functions¹.

In this article, we are going to study the *calculus of variations*, in which we will be finding extrema (minima, maxima, and saddle points) of functionals. We will start by looking back at and extending our knowledge of extrema in finite dimensions, before using this knowledge to approach problems involving functionals.

Notation. Throughout this article, we will frequently refer to different spaces of functions. We will let $C(\mathbb{R})$ be the space of continuous functions on $\mathbb{R}$, and $C^k(\mathbb{R})$ be the space of functions with continuous k th derivative. We will also write $C_{(\alpha, \beta)}^k(\mathbb{R})$ for the subset of functions f with $f(\alpha) = f(\beta)$.

Being careful about the space of functions we work in matters more than it might first appear. Just as in real analysis, where the domain of a function has to be specified before we can sensibly ask whether it attains a maximum, here we have to say which functions are ‘admissible’ before asking for the best one. Most of the time this will be some class of smooth functions with prescribed values at the endpoints, and we will not belabour the point – but the reader should be aware that some of the more delicate questions in this subject (does a minimiser exist at all?) are questions about the choice of function space, and are well beyond the scope of this article.

¹In standard calculus, we usually consider functions which map numbers $\rightarrow$ numbers. In the calculus of variations, we consider *functional* which map functions $\rightarrow$ numbers. An intuitive example is that of arc-length, which takes some curve and gives back a number corresponding to its length.

§23.1.3 Variational Principles in Nature

The phrase ‘variational principle’ refers to something slightly more specific than the calculus of variations: it is the assertion that some *law of nature* can be recast as the statement that a certain functional is stationary. This is a remarkable state of affairs, and it will be a recurring theme in what follows.

The oldest example is Fermat’s principle, which we will meet properly in [subsection 23.4.3](#).

Law 23.1.3 (Fermat’s Principle)

Light travelling between two points takes the path which requires the least time.

From this single sentence one can derive the law of reflection and Snell’s law of refraction, both of which were discovered empirically long before. Far more striking is that *all* of classical mechanics can be phrased this way.

Law 23.1.4 (Principle of Least Action)

A particle moving in a potential V with kinetic energy T travels between two fixed points in such a way that the [action](#)

$$S[\mathbf{x}] = \int_{t_1}^{t_2} (T - V) \, dt$$

is stationary.

We will see in [section 23.7](#) that this is exactly equivalent to Newton’s second law. It is worth pausing on how strange this is. Newton’s law is ‘local’ in time: it tells the particle how to accelerate right now, given the force right now. The principle of least action is ‘global’: it compares entire histories of the particle, from t_1 to t_2 , and picks out the one which is stationary. That these two descriptions agree is not obvious, and the machinery we are about to develop is precisely what makes the equivalence work.

There is a further payoff. Once a physical law is written as a variational principle, the *symmetries* of the functional turn directly into conserved quantities – this is Noether’s theorem, which we will prove in [subsection 23.7.3](#). Conservation of momentum, angular momentum and energy all fall out of the invariance of the action under translations, rotations, and time-shifts respectively. This is by some distance the most efficient route to the conservation laws.

§23.2 Calculus for Functions on $\mathbb{R}^n$

For this section, we are going to consider a function $f \in C^2(\mathbb{R}^n)$, that is, $f : \mathbb{R}^n \rightarrow \mathbb{R}$, with continuous second derivative.

§23.2.1 Stationary Points

Recall the definition of a stationary point for a function $f \in C^2(\mathbb{R}^n)$.

Definition 23.2.1 (Stationary Point)

We say that $a \in \mathbb{R}^n$ is a **stationary point** of f if $\nabla f(a) = 0$.

If a is a stationary point of f , then we can look at the Taylor expansion of f around a to determine the nature of the stationary point. For x near a , using the summation convention we have

$$f(x) = f(a) + \cancel{(x-a) \cdot \nabla f(a)} + \frac{1}{2}(x_i - a_i)(x_j - a_j) \partial_{ij}^2 f|_a + O(|x - a|^3),$$

where $\partial_i f = \partial f / \partial x_i$, and the linear term dies precisely because a is stationary. So near a stationary point, the entire behaviour of f is controlled by a quadratic form.

Now let $H_{ij} = \partial_{ij}^2 f$ be the **Hessian** matrix, which we note is symmetric since $f \in C^2$. If we shift the origin such that $a = 0$ and write $H = H(0)$, then being real symmetric it can be diagonalized by an orthogonal matrix R , giving

$$H' = R^T H(0) R = \begin{pmatrix} \lambda_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \lambda_n \end{pmatrix}.$$

Writing $x' = R^T x$ for the coordinates in this new (rotated) frame, we have

$$f(x') - f(0) = \frac{1}{2} \sum_{i=1}^n \lambda_i (x'_i)^2 + O(|x'|^3).$$

The behaviour then depends on whether the eigenvalues of $H(0)$ are positive or negative:

- (i) If all $\lambda_i > 0$, then $f(x') > f(0)$ in all directions, and we have a local minimum.
- (ii) If all $\lambda_i < 0$, then $f(x') < f(0)$ in all directions, and we have a local maximum.
- (iii) If some of the eigenvalues are positive and some are negative, then $f(x')$ is increasing in some directions and is decreasing in others, and we have a saddle point.
- (iv) If some (or all) of the eigenvalues are 0, then we need to consider higher order derivatives in the Taylor expansion.

In the special case where $n = 2$, then $\det H = \lambda_1 \lambda_2$ and $\text{tr } H = \lambda_1 + \lambda_2$. From this we obtain the conditions:

- If $\det > 0$, $\text{tr} > 0$ we have a local minimum.
- If $\det > 0$, $\text{tr} < 0$ we have a local maximum.
- If $\det < 0$ we have a saddle point.
- If $\det = 0$, then we need to look at higher derivatives.

Remark. If a function $f : D \rightarrow \mathbb{R}$ is defined on some domain D , then the minimum or maximum could be obtained on the boundary of D , where we may not have $\nabla f = 0$. This is an easy thing to forget, and it will come back in a rather more dramatic form later on when we look at soap films.

Here is a pretty application of the $n = 2$ criteria. Suppose $f : D \rightarrow \mathbb{R}$ is **harmonic** on $D \subseteq \mathbb{R}^2$, meaning $\nabla^2 f = f_{xx} + f_{yy} = 0$. Then $\text{tr } H = 0$ everywhere, so at any

stationary point either both eigenvalues vanish or they have opposite signs. Hence a non-constant harmonic function has no interior maxima or minima at all: its extreme values are attained on ∂D . This is the *maximum principle*, which the reader may have seen in complex analysis.

Example 23.2.2 (Finding and Classifying Stationary Points)

Consider the function $f(x, y) = x^3 + y^3 - 3xy$. Then at a stationary point we have

$$\nabla f = \begin{pmatrix} 3x^2 - 3y \\ 3y^2 - 3x \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}.$$

These imply that at a stationary point, $y^4 = y$. Thus we have the points $(0, 0)$ and $(1, 1)$. We can write down the Hessian as

$$H = \begin{pmatrix} 6x & -3 \\ -3 & 6y \end{pmatrix}.$$

At $(0, 0)$, we have $\det H = -9 < 0$, so f has a saddle point there. At $(1, 1)$, we have $\det H = 27 > 0$, and $\text{tr } H = 12 > 0$, so f has a local minimum there.

The degenerate case really does need care, as the following pair shows.

Example 23.2.3 (Degenerate Hessians)

Consider $f(x, y) = x^4 + y^4$ and $g(x, y) = x^4 - y^4$. Both have their only stationary point at the origin, and for both the Hessian there is the zero matrix, so $\det H = \text{tr } H = 0$ and our criteria say nothing at all. But f clearly has a global minimum at the origin, while g has a saddle: it increases along the x -axis and decreases along the y -axis. There is no way to tell these apart without looking at the fourth-order terms.

This is exactly analogous to the one-dimensional situation, where $f''(0) = 0$ leaves us unable to distinguish x^4 from x^3 from $-x^4$.

§23.2.2 Constraints and Lagrange Multipliers

Consider the following problem, and two natural ways to solve it.

Example 23.2.4

Find the circle centered at $(0, 0)$ with smallest radius such that the circle intersects the parabola $y = x^2 - 1$.

Direct Solution. One way to solve this problem is to substitute the constraint $y = x^2 - 1$ into the expression we are trying to minimize.

$$r^2 = x^2 + y^2 = x^2 + (x^2 - 1)^2 = x^4 - x^2 + 1.$$

To have a stationary point, the derivative of the RHS must be zero, so $4x^3 - 2x = 0$. This gives us two solutions: $x = \pm 1/\sqrt{2}, y = -1/2$ and $x = 0, y = -1$. These give the two possible radii of $\sqrt{3}/2$ and 1, of which the first is the smallest.

While this solution works, it's not hard to imagine that we may not be able to solve the constraint for y – and even when we can, doing so may destroy a symmetry of the problem which we would rather keep. An alternate solution is given below.

Lagrange Multipliers Solution. Define the function $h(x, y, \lambda) = f(x, y) - \lambda g(x, y)$, where $f(x, y) = x^2 + y^2 = r^2$, $g(x, y) = 0$ is the constraint, and λ is the Lagrange multiplier. So $h = x^2 + y^2 - \lambda(y - x^2 + 1)$. We are going to extremize this over 3 variables with no constraints.

$$\begin{aligned}\frac{\partial h}{\partial x} &= 2x + 2\lambda x = 0, \\ \frac{\partial h}{\partial y} &= 2y - \lambda = 0, \\ \frac{\partial h}{\partial \lambda} &= -(y - x^2 + 1) = 0,\end{aligned}$$

where the third condition is exactly our constraint – this is the small miracle that makes the method work. From the first equation, either $x = 0$ or $\lambda = -1$. From these we get either $x = 0, y = -1$ with $f = 1, \lambda = -2$, or $y = -1/2, x = \pm 1/\sqrt{2}$ with $f = 3/4, \lambda = -1$, giving the radius $\sqrt{3}/2$ as before.

So why does the second solution work? Well suppose that we wanted to minimize a function f subject to $g = 0$. Then ∇g is perpendicular to the level set $g = 0$. Also, ∇f is perpendicular to the level set $f(x) = c$, for any constant c . Now imagine walking along the constraint curve. As long as ∇f has a nonzero component *along* the curve, we can decrease f by taking a step in the appropriate direction, and so we are not at an extremum. So at the extremum ∇f must be entirely perpendicular to the constraint curve; that is, parallel to ∇g , so

$$\nabla f - \lambda \nabla g = 0,$$

for some λ . Equivalently, the level curve of f through the extremum is *tangent* to the constraint curve. Thus it suffices to consider the extrema of $h = f - \lambda g$.

This picture also tells us when the method can fail: if $\nabla g = 0$ at the extremum, then $\nabla f = \lambda \nabla g$ carries no information. Such points are called *singular* and have to be checked separately.

This method generalizes to multiple variables and multiple constraints. For example, if we wanted to extremize $f : \mathbb{R}^n \rightarrow \mathbb{R}$, subject to $g_\alpha(x) = 0$, where $g_\alpha : \mathbb{R}^n \rightarrow \mathbb{R}$ and $\alpha = 1, \dots, k$, we would define

$$h(x_1, \dots, x_n, \lambda_1, \dots, \lambda_k) = f - \sum_{\alpha=1}^k \lambda_\alpha g_\alpha,$$

and would extremize this function with respect to the $n + k$ variables. Geometrically, the constraints $g_\alpha = 0$ cut out an $(n - k)$ -dimensional surface, and the condition is that ∇f lies in the span of the normals $\nabla g_1, \dots, \nabla g_k$, that is, ∇f has no component tangent to the surface.

Example 23.2.5 (Two Constraints)

Let us maximize $f(x, y, z) = x + y + z$ on the circle cut out of the unit sphere by the plane $z = \frac{1}{2}$. So we take

$$g_1 = x^2 + y^2 + z^2 - 1, \quad g_2 = z - \frac{1}{2},$$

and set $h = f - \lambda g_1 - \mu g_2$. Then

$$\frac{\partial h}{\partial x} = 1 - 2\lambda x = 0, \quad \frac{\partial h}{\partial y} = 1 - 2\lambda y = 0, \quad \frac{\partial h}{\partial z} = 1 - 2\lambda z - \mu = 0,$$

together with the two constraints. The first two give $x = y = 1/(2\lambda)$, and the constraints then give $2x^2 = 1 - z^2 = 3/4$, so $x = y = \pm\sqrt{3}/(2\sqrt{2})$. The maximum is at the positive root, where

$$f = \frac{\sqrt{3}}{\sqrt{2}} + \frac{1}{2} = \sqrt{\frac{3}{2}} + \frac{1}{2}.$$

Note that μ was never needed: it only served to absorb the fact that the z -equation is not required to balance. This is typical – the multipliers are auxiliary unknowns which we are free to discard once they have done their job.

Although we have been treating λ as a bookkeeping device, it does have a meaning, and a rather useful one.

Proposition 23.2.6 (The Meaning of the Multiplier)

Suppose we extremize f subject to $g(x) = c$, and let $x^*(c)$ be the (assumed smooth) location of the extremum and $f^*(c) = f(x^*(c))$ its value. Then

$$\frac{df^*}{dc} = \lambda.$$

Proof. Differentiating $f^*(c) = f(x^*(c))$ with the chain rule,

$$\frac{df^*}{dc} = \nabla f(x^*) \cdot \frac{dx^*}{dc} = \lambda \nabla g(x^*) \cdot \frac{dx^*}{dc},$$

using the stationarity condition $\nabla f = \lambda \nabla g$. But differentiating the constraint $g(x^*(c)) = c$ gives $\nabla g(x^*) \cdot dx^*/dc = 1$, and the result follows. $\square$

In other words – λ measures how much the optimal value improves when we relax the constraint by one unit. In economics this is called a *shadow price*, and in physics the multiplier is very often a physically meaningful quantity in its own right (a force, a pressure, a chemical potential). We will see a striking example of this when we solve the isoperimetric problem in [Example 23.5.9](#), where the multiplier turns out to be the radius of the optimal circle.

§23.3 Convexity and the Legendre Transform

Before we leave finite dimensions, we should discuss a class of functions for which the story above becomes dramatically simpler: the **convex** functions. For these, every stationary point is a global minimum, so all the fiddling with Hessians disappears. Convexity is also exactly the hypothesis needed to make the *Legendre transform* – our second major tool – behave itself.

§23.3.1 Convex Sets and Convex Functions

We begin with the underlying notion for sets.

Definition 23.3.1 (Convex Set)

A set $S \subseteq \mathbb{R}^n$ is **convex** if for all $x, y \in S$ and all $t \in [0, 1]$ we have

$$(1 - t)x + ty \in S.$$

That is, the line segment joining any two points of S lies entirely within S .

not convex

convex

Definition 23.3.2 (Convex Function)

A function $f : S \rightarrow \mathbb{R}$ with $S \subseteq \mathbb{R}^n$ is **convex** if

- (i) its domain S is a convex set, and
- (ii) for all $x, y \in S$ and $t \in (0, 1)$,

$$f((1 - t)x + ty) \leq (1 - t)f(x) + tf(y).$$

If the inequality is strict whenever $x \neq y$, we say f is **strictly convex**. We say f is **concave** (respectively strictly concave) if $-f$ is convex (respectively strictly convex).

The second condition is best read geometrically. The right hand side, as t runs over $[0, 1]$, traces out the **chord** joining $(x, f(x))$ to $(y, f(y))$; the left hand side traces out the graph of f between the same two points. So f is convex exactly when its graph lies on or below all of its chords.

We have drawn a tangent line in as well, because it will feature shortly: a convex function also lies *above* all of its tangents.

Example 23.3.3

(i) $f(x) = x^2$ is strictly convex on $\mathbb{R}$. Indeed,

$$[(1-t)x + ty]^2 - (1-t)x^2 - ty^2 = -t(1-t)(x-y)^2 < 0$$

for $t \in (0, 1)$ and $x \neq y$, after expanding and collecting terms.

(ii) $f(x) = |x|$ is convex, by the triangle inequality, but not strictly so.

(iii) $f(x) = 1/x$ on the domain $\{x > 0\}$ is strictly convex.

(iv) $f(x) = 1/x$ on $\mathbb{R} \setminus \{0\}$ is *not* convex, for the trivial reason that its domain is not a convex set. This is not mere pedantry: if we tried to patch the definition by setting $f(0) = 0$, the chord from $(-1, -1)$ to $(1, 1)$ would lie below the graph. Condition (i) is doing real work.

§23.3.2 Conditions for Convexity

Checking convexity straight from the definition is unpleasant. If f is differentiable there is a much better test.

Theorem 23.3.4 (First-Order Convexity Condition)

Let f be differentiable on a convex domain S . Then f is convex if and only if

$$f(y) \geq f(x) + (y - x) \cdot \nabla f(x)$$

for all $x, y \in S$.

Proof. Suppose first that f is convex. Fix $x, y \in S$ and define, for $t \in [0, 1]$,

$$h(t) = (1-t)f(x) + tf(y) - f((1-t)x + ty).$$

Convexity says exactly that $h(t) \geq 0$, and clearly $h(0) = 0$. Hence

$$\frac{h(t) - h(0)}{t} \geq 0 \quad \text{for } t \in (0, 1),$$

and letting $t \rightarrow 0^+$ gives $h'(0) \geq 0$. On the other hand we may differentiate h

directly by the chain rule, giving

$$h'(t) = f(y) - f(x) - (y - x) \cdot \nabla f((1 - t)x + ty),$$

so that $h'(0) = f(y) - f(x) - (y - x) \cdot \nabla f(x)$. Combining these gives the inequality.

Conversely, suppose the inequality holds. Let $z = (1 - t)x + ty$. Applying the inequality twice, at the point z ,

$$\begin{aligned} f(x) &\geq f(z) + (x - z) \cdot \nabla f(z) = f(z) + t(x - y) \cdot \nabla f(z), \\ f(y) &\geq f(z) + (y - z) \cdot \nabla f(z) = f(z) - (1 - t)(x - y) \cdot \nabla f(z). \end{aligned}$$

Multiplying the first by $(1 - t)$, the second by t , and adding, the gradient terms cancel and we are left with

$$(1 - t)f(x) + tf(y) \geq f(z) = f((1 - t)x + ty),$$

which is convexity. $\square$

The geometric content is the one we advertised above: $f(x) + (y - x) \cdot \nabla f(x)$ is precisely the tangent plane to the graph of f at x , so the condition says that a convex function lies above all of its tangent planes. From this the promised simplification is immediate.

Corollary 23.3.5

Any stationary point of a convex function is a global minimum. If f is strictly convex, there is at most one such point.

Proof. Let $\nabla f(x_0) = 0$. Then [Theorem 23.3.4](#) gives $f(y) \geq f(x_0) + (y - x_0) \cdot 0 = f(x_0)$ for every y in the domain. For the uniqueness statement, if $x_0 \neq x_1$ were two global minima with common value m , then strict convexity would give $f(\frac{1}{2}(x_0 + x_1)) < m$, a contradiction. $\square$

By applying [Theorem 23.3.4](#) twice, once at x and once at y , and adding the two inequalities, we obtain a symmetric form of the condition:

$$(y - x) \cdot [\nabla f(y) - \nabla f(x)] \geq 0.$$

In one dimension this reads $(y - x)(f'(y) - f'(x)) \geq 0$, which just says f' is non-decreasing. Differentiating one more time gives the criterion that is usually the most convenient of all.

Theorem 23.3.6 (Second-Order Convexity Condition)

Let f be twice differentiable on a convex domain. Then f is convex if and only if the Hessian H is positive semi-definite at every point (all eigenvalues ≥ 0). If H is positive definite everywhere, then f is strictly convex.

Proof (sketch). Put $y = x + h$ in the symmetric first-order condition, so that

$$h \cdot [\nabla f(x + h) - \nabla f(x)] \geq 0.$$

Taylor expanding the bracket in h using the summation convention, this is

$$h_i [h_j \partial_j \partial_i f + O(|h|^2)] = h_i H_{ij} h_j + O(|h|^3) \geq 0.$$

Since h is arbitrary and may be taken small, this holds if and only if $h^T H h \geq 0$ for all h , i.e. H is positive semi-definite. $\square$

Remark. The converse of the last sentence is false: $f(x) = x^4$ is strictly convex, but $f''(0) = 0$. So positive definiteness is sufficient but not necessary for strictness.

Example 23.3.7

Let $f(x, y) = 1/(xy)$ on the domain $x, y > 0$. Then

$$H = \frac{1}{xy} \begin{pmatrix} 2/x^2 & 1/(xy) \\ 1/(xy) & 2/y^2 \end{pmatrix},$$

so that

$$\det H = \frac{1}{x^2 y^2} \left(\frac{4}{x^2 y^2} - \frac{1}{x^2 y^2} \right) = \frac{3}{x^4 y^4} > 0, \quad \text{tr } H = \frac{2}{xy} \left(\frac{1}{x^2} + \frac{1}{y^2} \right) > 0.$$

Both eigenvalues are therefore positive and f is strictly convex.

It is tempting to notice that we only ever used $xy > 0$, and conclude that f is convex on the larger domain $\{xy > 0\}$. This is wrong – that domain is not connected, let alone convex, and the definition fails at the first hurdle.

§23.3.3 Inequalities from Convexity

Convexity is a machine for producing inequalities, and it is worth seeing it run. The starting point is the extension of the defining inequality from two points to many.

Theorem 23.3.8 (Jensen's Inequality)

Let f be convex, let $x_1, \dots, x_n$ lie in its domain, and let $t_1, \dots, t_n \geq 0$ with $\sum_i t_i = 1$. Then

$$f \left(\sum_{i=1}^n t_i x_i \right) \leq \sum_{i=1}^n t_i f(x_i).$$

Proof. We induct on n . The case $n = 2$ is the definition (the cases $t_i \in \{0, 1\}$ being trivial), and $n = 1$ is vacuous. Suppose the result holds for $n - 1$ and let $t_n < 1$ (if $t_n = 1$ there is nothing to prove). Write $s = 1 - t_n = \sum_{i < n} t_i > 0$ and

$$z = \sum_{i=1}^{n-1} \frac{t_i}{s} x_i,$$

which lies in the domain since the domain is convex and the weights t_i/s sum to 1.

Then $\sum_i t_i x_i = sz + t_n x_n$, so by the $n = 2$ case and then the inductive hypothesis,

$$f\left(\sum_i t_i x_i\right) \leq sf(z) + t_n f(x_n) \leq s \sum_{i < n} \frac{t_i}{s} f(x_i) + t_n f(x_n) = \sum_{i=1}^n t_i f(x_i). \quad \square$$

There is a continuous version too, which is the one that connects to the rest of this article: if $\rho \geq 0$ has $\int \rho = 1$, then $f\left(\int \rho(x)u(x) \, dx\right) \leq \int \rho(x)f(u(x)) \, dx$, proved in the same way by approximating the integral by sums. In probabilistic language this is $f(\mathbb{E}[U]) \leq \mathbb{E}[f(U)]$, which is how the reader will have met it in Probability.

Corollary 23.3.9 (AM–GM Inequality)

For positive reals $a_1, \dots, a_n$,

$$\frac{a_1 + \dots + a_n}{n} \geq \sqrt[n]{a_1 \dots a_n}.$$

Proof. The function $f(x) = -\log x$ is convex on $x > 0$, since $f''(x) = 1/x^2 > 0$. Applying Jensen with $t_i = 1/n$ and $x_i = a_i$,

$$-\log\left(\frac{1}{n} \sum_i a_i\right) \leq -\frac{1}{n} \sum_i \log a_i = -\log\left(\prod_i a_i\right)^{1/n}.$$

Multiplying by -1 and exponentiating (both $\log$ and $\exp$ being increasing) gives the result. $\square$

The next inequality is really a statement about the Legendre transform in disguise, as we will see in a moment.

Proposition 23.3.10 (Young's Inequality)

Let $p, q > 1$ with $\frac{1}{p} + \frac{1}{q} = 1$. Then for all $a, b \geq 0$,

$$ab \leq \frac{a^p}{p} + \frac{b^q}{q}.$$

Proof. The case $ab = 0$ is clear, so take $a, b > 0$. Applying Jensen to the convex function $-\log$ with weights $1/p, 1/q$ and points a^p, b^q ,

$$-\log\left(\frac{a^p}{p} + \frac{b^q}{q}\right) \leq -\frac{1}{p} \log a^p - \frac{1}{q} \log b^q = -\log(ab),$$

and exponentiating gives the claim. $\square$

Corollary 23.3.11 (Hölder's Inequality)

Let $p, q > 1$ with $\frac{1}{p} + \frac{1}{q} = 1$. Then for reals u_i, v_i ,

$$\sum_{i=1}^n |u_i v_i| \leq \left(\sum_{i=1}^n |u_i|^p\right)^{1/p} \left(\sum_{i=1}^n |v_i|^q\right)^{1/q}.$$

Proof. Write $U = (\sum_i |u_i|^p)^{1/p}$ and $V = (\sum_i |v_i|^q)^{1/q}$, and assume both are nonzero (otherwise all the u_i or all the v_i vanish and the result is trivial). Apply Young's inequality with $a = |u_i|/U$ and $b = |v_i|/V$ and sum over i :

$$\frac{1}{UV} \sum_i |u_i v_i| \leq \frac{1}{p} \frac{\sum_i |u_i|^p}{U^p} + \frac{1}{q} \frac{\sum_i |v_i|^q}{V^q} = \frac{1}{p} + \frac{1}{q} = 1,$$

and multiplying by UV finishes the proof. $\square$

Taking $p = q = 2$ recovers the Cauchy–Schwarz inequality. We will meet a genuinely variational inequality later, when the Rayleigh–Ritz method in [section 23.8](#) lets us bound eigenvalues by making guesses.

§23.3.4 The Legendre Transform

We now come to a construction which, on first meeting, looks arbitrary, and which turns out to be one of the most useful things in mathematical physics. It appears in thermodynamics (relating energy, free energy and enthalpy), in mechanics (relating the Lagrangian and the Hamiltonian), and in optimisation (as duality).

Here is the motivation. Suppose we have a differentiable function $f(x)$, and for whatever reason we would rather work with the derivative

$$p = \frac{df}{dx}$$

as our independent variable. In physics p is usually the interesting quantity: for a Lagrangian it is a momentum, for the energy of a gas it is a temperature. The obvious thing to try, $g(p) = f(x(p))$, is a bad idea – it is not symmetric, it loses information when f has an inflection, and it has no nice properties whatsoever.

What we would *like* is a function f^* with the pleasing reciprocal property

$$\frac{df^*}{dp} = x,$$

so that if p is conjugate to x , then x is conjugate to p . In terms of differentials, we have $df = p dx$ and we want $df^* = x dp$. Since the product rule gives $d(xp) = x dp + p dx$, the choice

$$f^*(p) = xp - f(x)$$

does exactly what we want. We take this as our definition, but phrased so as not to require differentiability.

Definition 23.3.12 (Legendre Transform)

The **Legendre transform** of a function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is the function f^* given by

$$f^*(p) = \sup_x (p \cdot x - f(x)).$$

The domain of f^* is taken to be the set of p for which the supremum is finite. We call p the **conjugate variable** to x .

In one dimension there is a very clean picture. For a fixed p , the quantity $px - f(x)$ is the vertical gap between the line $y = px$ and the graph $y = f(x)$, and $f^*(p)$ is the largest such gap. Equivalently – and this is the version worth remembering – draw the tangent line to f of slope p ; then $-f^*(p)$ is its intercept with the y -axis.

Notice that the supremum is finite exactly when the line of slope p can be pushed up against the graph from below, which is why convexity is about to become important.

Proposition 23.3.13

If the domain of f^* is non-empty then it is a convex set, and f^* is a convex function – regardless of whether f is convex.

Proof. Let p, q lie in the domain of f^* and let $t \in (0, 1)$. Then

$$\begin{aligned} f^*((1-t)p + tq) &= \sup_x [(1-t)p \cdot x + tq \cdot x - f(x)] \\ &= \sup_x [(1-t)(p \cdot x - f(x)) + t(q \cdot x - f(x))] \\ &\leq (1-t) \sup_x [p \cdot x - f(x)] + t \sup_x [q \cdot x - f(x)] \\ &= (1-t)f^*(p) + tf^*(q), \end{aligned}$$

using only that the supremum of a sum is at most the sum of the suprema. In particular the right hand side is finite, so $(1-t)p + tq$ is in the domain, which is therefore convex; and the inequality is exactly convexity of f^* . $\square$

In practice, if f is convex and differentiable, we do not compute a supremum at all: we differentiate. The supremum of $p \cdot x - f(x)$ occurs where

$$\nabla(p \cdot x - f(x)) = 0 \iff p = \nabla f(x),$$

and if f is strictly convex then ∇f is injective, so this can be solved uniquely for $x = x(p)$, giving

$$f^*(p) = p \cdot x(p) - f(x(p)).$$

Example 23.3.14

- (i) Let $f(x) = \frac{1}{2}ax^2$ with $a > 0$. Then $p = f'(x) = ax$, so $x = p/a$, and

$$f^*(p) = p \cdot \frac{p}{a} - \frac{1}{2}a \left(\frac{p}{a}\right)^2 = \frac{p^2}{2a}.$$

A parabola transforms to a parabola, with the coefficient inverted. Note that transforming again returns $\frac{1}{2}ax^2$, as we would hope.

- (ii) Let $f(v) = -\sqrt{1-v^2}$ on $|v| < 1$ (the lower half of a circle). Then

$$p = f'(v) = \frac{v}{\sqrt{1-v^2}} \implies v = \frac{p}{\sqrt{1+p^2}},$$

which exists for all $p \in \mathbb{R}$, and

$$f^*(p) = pv + \sqrt{1-v^2} = \frac{p^2}{\sqrt{1+p^2}} + \frac{1}{\sqrt{1+p^2}} = \sqrt{1+p^2}.$$

A circle transforms to a hyperbola. (The reader who has met special relativity may enjoy recognising this.)

- (iii) Let $f(x) = cx$ for a constant c . This is convex but not strictly. Then $px - f(x) = (p-c)x$, which is unbounded above unless $p = c$. So the domain of f^* is the single point $\{c\}$, and $f^*(c) = 0$. A line transforms to a point.

The last example makes the general phenomenon clear: the Legendre transform trades the ‘flatness’ of a function for the ‘sharpness’ of its transform, and vice versa. It also explains why convexity is exactly the right hypothesis for the following.

Theorem 23.3.15

If f is convex and differentiable, then $f^{**} = f$.

Proof. We have $f^*(p) = p \cdot x(p) - f(x(p))$, where $x(p)$ satisfies $p = \nabla f(x(p))$. Differentiating with respect to p_i and using the product and chain rules,

$$\begin{aligned} \partial_i f^*(p) &= x_i + p_j \partial_i x_j(p) - \partial_i x_j(p) \partial_j f(x) \\ &= x_i + p_j \partial_i x_j(p) - \partial_i x_j(p) p_j \\ &= x_i, \end{aligned}$$

where in the second line we used $p_j = \partial_j f(x)$. So $\nabla f^*(p) = x$: the conjugate variable to p is the original x . Therefore

$$f^{**}(x) = (x \cdot p - f^*(p))|_{p=p(x)} = x \cdot p - (p \cdot x - f(x)) = f(x). \quad \square$$

Convexity really is needed here. Since f^{**} is a Legendre transform it is automatically convex, so $f^{**} = f$ can only possibly hold for convex f . For a non-convex f , the double transform f^{**} turns out to be the largest convex function lying below f – its ‘convex hull’ – so the transform simply cannot see the non-convex parts.

Remark. Young’s inequality is now transparent. Take $f(x) = x^p/p$ for $x \geq 0$ and $p > 1$. Then $f^*(b) = \sup_x (bx - x^p/p) = b^q/q$ where $\frac{1}{p} + \frac{1}{q} = 1$, by the usual differentiation. But directly from the definition of a supremum, $f^*(b) \geq ab - f(a)$ for any a , which

rearranges to $ab \leq a^p/p + b^q/q$. Every Legendre transform gives an inequality in this way, the general statement $p \cdot x \leq f(x) + f^*(p)$ being called **Fenchel's inequality**.

§23.3.5 An Application to Thermodynamics

The reason a thermodynamics course is full of Legendre transforms is worth a paragraph. Consider a gas of a fixed number of particles in a container. In principle we could write down the equations of motion of all 10^{23} particles and solve them, which is not a plan. Instead we describe the gas by a handful of macroscopic quantities: the entropy S , volume V , pressure P and temperature T . The energy is naturally a function

$$E = E(S, V).$$

There are two ways to change it: we can do work on the gas by compressing it, contributing $-P \, dV$, or we can heat it, contributing $T \, dS$. So

$$dE = T \, dS - P \, dV,$$

and comparing with the chain rule,

$$T = \frac{\partial E}{\partial S}, \quad P = -\frac{\partial E}{\partial V}.$$

The trouble is that entropy is not something one can easily hold fixed in a laboratory, whereas temperature is. We would therefore like a function of T and V instead of S and V – and T is precisely the variable conjugate to S . Taking the (negative of the) Legendre transform in S gives the **Helmholtz free energy**

$$F(T, V) = \inf_S (E(S, V) - TS) = E - TS,$$

where the infimum is at $T = \partial E / \partial S$ as required. Its differential is

$$dF = dE - T \, dS - S \, dT = -S \, dT - P \, dV,$$

so that $S = -\partial F / \partial T$ and $P = -\partial F / \partial V$. This is the whole point: no information has been lost, and we can recover everything by differentiating F , which we could not do had we naively substituted $S = S(T, V)$ into E .

Transforming instead in V gives the **enthalpy** $H(S, P) = E + PV$, and transforming in both gives the **Gibbs free energy** $G(T, P) = E - TS + PV$. The convexity of E in its arguments – which is a physical statement about the stability of the gas – is what guarantees these transforms are invertible.

§23.4 The Euler-Lagrange Equations

We are now going to move on to deriving some necessary conditions for the extrema of a functional.

§23.4.1 Deriving the Euler-Lagrange Equations

We want to extremize the functional $(*)$,

$$F[y] = \int_{\alpha}^{\beta} f(x, y(x), y'(x)) \, dx,$$

where we assume that f is given, and that our competing functions have fixed endpoints $y(\alpha) = y_1$ and $y(\beta) = y_2$.

Recall how we found stationary points in $\mathbb{R}^n$: we perturbed our candidate point a by a small displacement, expanded to first order, and demanded that the first-order term vanish for *every* direction of displacement. We shall do precisely the same thing here. The only difference is that a ‘displacement’ is now a whole function, and there are infinitely many directions to worry about.

So suppose y is our candidate extremum, and perturb it to

$$y \mapsto y + \epsilon\eta(x),$$

where ϵ is a small real number and η is any (sufficiently smooth) function with

$$\eta(\alpha) = \eta(\beta) = 0.$$

The condition on η is forced on us: the endpoints of y are fixed, so any admissible competitor must agree with y there.

We will compute $F[y + \epsilon\eta]$ and expand in ϵ . To turn the resulting condition into a differential equation, we will need an important lemma.

Lemma 23.4.1 (Fundamental Lemma of Calculus of Variations)

If $g : [\alpha, \beta] \rightarrow \mathbb{R}$ is continuous on $[\alpha, \beta]$ and is such that

$$\int_{\alpha}^{\beta} g(x)\eta(x) \, dx = 0,$$

for all η continuous on $[\alpha, \beta]$ with $\eta(\alpha) = \eta(\beta) = 0$, then $g(x) = 0$ for all $x \in [\alpha, \beta]$.

Proof. Say (for a contradiction) that there exists some $\bar{x} \in (\alpha, \beta)$ such that $g(\bar{x}) \neq 0$. Without loss of generality say $g(\bar{x}) > 0$ (else replace g by $-g$). Then by continuity there exists an interval $[x_1, x_2] \subset (\alpha, \beta)$ containing $\bar{x}$ such that $g(x) > c$ on $[x_1, x_2]$ for some $c > 0$. Then set

$$\eta(x) = \begin{cases} (x - x_1)(x_2 - x) & \text{if } x \in [x_1, x_2], \\ 0 & \text{if } x \notin [x_1, x_2]. \end{cases}$$

This η is continuous, vanishes at α and β , is non-negative, and is strictly positive

on (x_1, x_2) . Since the integrand vanishes off $[x_1, x_2]$, we have

$$\int_{\alpha}^{\beta} g(x)\eta(x) \, dx = \int_{x_1}^{x_2} g(x)\eta(x) \, dx > c \int_{x_1}^{x_2} (x - x_1)(x_2 - x) \, dx = \frac{c(x_2 - x_1)^3}{6} > 0,$$

which is a contradiction. So g vanishes on (α, β) , and hence by continuity on all of $[\alpha, \beta]$. $\square$

Remark. In the proof above, we construct a *bump function* η . It is possible to make this smoother by taking various powers of the constructed function: replacing η by $[(x - x_1)(x_2 - x)]^{k+1}$ on $[x_1, x_2]$ gives a C^k bump. So the lemma remains true if we insist that our test functions be as smooth as we like, which is what we shall actually need.

The lemma is worth internalising in the following form: the only continuous function which is ‘invisible’ to every test function is the zero function. This is exactly the tool we need to convert an integral condition into a pointwise one.

Now let’s return to our computation. We have

$$\begin{aligned} F[y + \epsilon\eta] &= \int_{\alpha}^{\beta} f(x, y + \epsilon\eta, y' + \epsilon\eta') \, dx \\ &= F[y] + \epsilon \int_{\alpha}^{\beta} \left(\frac{\partial f}{\partial y} \eta + \frac{\partial f}{\partial y'} \eta' \right) \, dx + O(\epsilon^2), \end{aligned}$$

where the partial derivatives are all evaluated along the unperturbed path. We will return to the $O(\epsilon^2)$ term in [section 23.9](#), where it tells us about the *nature* of the stationary point. For now we note that for an extremum we want the first-order term to vanish for *every* admissible η , that is

$$\left. \frac{d}{d\epsilon} F[y + \epsilon\eta] \right|_{\epsilon=0} = \int_{\alpha}^{\beta} \left(\frac{\partial f}{\partial y} \eta + \frac{\partial f}{\partial y'} \eta' \right) \, dx = 0.$$

This quantity is called the **first variation** of F at y .

We cannot apply the fundamental lemma to this directly, because the integrand involves η' as well as η . We now make a move which we will return to time and time again in the calculus of variations: we integrate the offending term by parts, so that only η appears. This gives

$$\begin{aligned} 0 &= \int_{\alpha}^{\beta} \left(\frac{\partial f}{\partial y} \eta - \frac{d}{dx} \left(\frac{\partial f}{\partial y'} \right) \eta \right) \, dx + \left[\frac{\partial f}{\partial y'} \eta \right]_{\alpha}^{\beta} \\ &= \int_{\alpha}^{\beta} \left(\frac{\partial f}{\partial y} - \frac{d}{dx} \left(\frac{\partial f}{\partial y'} \right) \right) \eta \, dx, \end{aligned}$$

the boundary term vanishing precisely because $\eta(\alpha) = \eta(\beta) = 0$. Applying the fundamental lemma of the calculus of variations, we obtain the following necessary condition for an extremum.

Theorem 23.4.2 (Euler-Lagrange Equation)

Suppose $y \in C^2_{(\alpha, \beta)}(\mathbb{R})$ is a function with fixed endpoints that extremizes the functional

$$F[y] = \int_{\alpha}^{\beta} f(x, y(x), y'(x)) \, dx.$$

Then y must satisfy the **Euler-Lagrange** equation

$$\frac{\partial f}{\partial y} - \frac{d}{dx} \left(\frac{\partial f}{\partial y'} \right) = 0. \quad (\dagger)$$

Notation. The LHS of $(\dagger)$ is denoted by $\frac{\delta F[y]}{\delta y(x)}$ and is the **functional derivative** of F . Writing $\delta y = \epsilon \eta$, the first variation then reads

$$\delta F[y] = \int_{\alpha}^{\beta} \frac{\delta F[y]}{\delta y(x)} \delta y(x) dx,$$

a pleasing analogue of $df = \nabla f \cdot dx$ from multivariable calculus. In this language, the Euler–Lagrange equation is simply the statement ‘ $\nabla F = 0$ ’.

A few comments are in order before we start solving things.

Remark.

- (i) Expanding $\frac{d}{dx} (\partial f / \partial y')$ by the chain rule shows that $(\dagger)$ is a *second-order* ODE for y ,

$$\frac{\partial^2 f}{\partial (y')^2} y'' + \frac{\partial^2 f}{\partial y \partial y'} y' + \frac{\partial^2 f}{\partial x \partial y'} - \frac{\partial f}{\partial y} = 0,$$

to be solved subject to the two conditions $y(\alpha) = y_1$ and $y(\beta) = y_2$. This is a *boundary* value problem rather than an initial value problem, and so, unlike for initial value problems, we get no general guarantee of existence or uniqueness. We will meet examples of both failures.

- (ii) The Euler–Lagrange equation is a *necessary* condition, not a sufficient one. Exactly like $f'(x) = 0$ in ordinary calculus, it is satisfied by minima, maxima and saddles alike. Determining which we have requires the second variation.
- (iii) When we write $\partial f / \partial y$, we are treating x , y and y' as three *independent* arguments of f . This is a genuine source of confusion, and should be carefully distinguished from the total derivative along a path,

$$\frac{d}{dx} = \frac{\partial}{\partial x} + y' \frac{\partial}{\partial y} + y'' \frac{\partial}{\partial y'}.$$

For instance, if $f(x, y, y') = x [(y')^2 - y^2]$ then $\partial f / \partial x = (y')^2 - y^2$, whereas

$$\frac{df}{dx} = (y')^2 - y^2 - 2xyy' + 2xy'y''.$$

These are very different objects.

- (iv) The boundary term $[\eta \partial f / \partial y']_{\alpha}^{\beta}$ vanished because we fixed the endpoints. It will not always do so, and when it does not we obtain extra ‘natural’ boundary conditions instead; see [subsection 23.5.4](#).

Before we get to the classical problems, let us do one entirely routine example, just to see the machinery turn over.

Example 23.4.3

Let us find the stationary points of

$$F[y] = \int_0^1 ((y')^2 + y^2) \, dx, \quad y(0) = 0, \, y(1) = 1.$$

Here $f = (y')^2 + y^2$, so

$$\frac{\partial f}{\partial y} = 2y, \quad \frac{\partial f}{\partial y'} = 2y',$$

and the Euler–Lagrange equation (†) is

$$2y - \frac{d}{dx}(2y') = 0 \implies y'' = y.$$

The general solution is $y = A \sinh x + B \cosh x$. The condition $y(0) = 0$ gives $B = 0$, and $y(1) = 1$ gives $A = 1/\sinh 1$, so

$$y = \frac{\sinh x}{\sinh 1}.$$

Substituting back (and integrating by parts once) gives the stationary value $F[y] = \coth 1 \approx 1.313$.

It is worth noticing that we could have got the same answer from the Beltrami identity below, since f has no explicit x -dependence: that would give $(y')^2 - y^2 = \text{constant}$, a first-order equation. Either route works, and in general one takes whichever is less painful.

§23.4.2 First Integrals of the Euler–Lagrange Equations

Of course, now that we have a necessary condition for extremality, our next concern is solving the Euler–Lagrange equation. The Euler–Lagrange equations give us a second-order ODE for y . It is sometimes possible to reduce the order of the ODE to get a first-order ODE, a **first integral**, which is what we will look at in this section. There are two cases where this happens, and they correspond to the two ‘missing variables’ the integrand might have.

The first case is easy. If f does not explicitly depend on y , then $\partial f/\partial y = 0$, and the Euler–Lagrange equation reads

$$\frac{d}{dx} \left(\frac{\partial f}{\partial y'} \right) = 0 \implies \frac{\partial f}{\partial y'} = c,$$

for some constant c . We have integrated the equation once for free, and what remains is a first-order ODE. A variable which does not appear in the integrand (only its derivative does) is called **cyclic** or **ignorable**, and every cyclic variable gives us such a conserved quantity. In mechanics these will turn out to be the conserved momenta.

Example 23.4.4 (Geodesics on the Euclidean Plane)

Consider again the problem of finding geodesics on the Euclidean plane.

We want to minimize the functional

$$D[y] = \int_{x_1}^{x_2} \sqrt{1 + (y')^2} \, dx.$$

Using the Euler-Lagrange equations, we have $f(y') = \sqrt{1 + (y')^2}$, so $\partial f / \partial y = 0$, and thus by the result above

$$\frac{y'}{\sqrt{1 + (y')^2}} = c,$$

for some constant c . For this to be the case, we must have y' constant, so y is a straight line.

Example 23.4.5 (Geodesics on a Cylinder)

Consider the cylinder $x^2 + y^2 = a^2$ in $\mathbb{R}^3$, parameterized by an angle ϕ and a height z . The line element is

$$ds^2 = a^2 d\phi^2 + dz^2,$$

so thinking of z as a function of ϕ , we wish to extremize

$$F[z] = \int_{\phi_1}^{\phi_2} \sqrt{a^2 + (z')^2} \, d\phi.$$

Now z is cyclic, so

$$\frac{\partial f}{\partial z'} = \frac{z'}{\sqrt{a^2 + (z')^2}} = c,$$

which forces z' to be constant, say $z' = m$, and hence

$$z = m\phi + z_0.$$

This is a *helix*. The special cases are worth noting: $m = 0$ gives a horizontal circle, and letting $m \rightarrow \infty$ (that is, treating ϕ as a function of z and finding it constant) gives a vertical straight line. All three are what one would draw by wrapping a piece of string around a tube.

Notice also that between two given points there are *infinitely many* helical geodesics – one for each number of times we wind around the cylinder – of which only one is shortest. Once again, the Euler–Lagrange equation cannot tell them apart.

Example 23.4.6 (Geodesics on the Sphere)

Consider the sphere embedded in three-dimensional Euclidean space, $S^2 \subset \mathbb{R}^3$, and two points A and B on the sphere. We want to find the shortest path between A and B .

We first parameterize the sphere, with

$$\begin{aligned}x &= \sin \theta \sin \phi, \\y &= \sin \theta \cos \phi, \\z &= \cos \theta,\end{aligned}$$

where $0 < \theta \leq \pi$ and $0 \leq \phi \leq 2\pi$. Then to find lengths of paths on the sphere, we use the line element

$$ds^2 = dx^2 + dy^2 + dz^2 = d\theta^2 + \sin^2 \theta d\phi^2.$$

Now we can parameterize a curve by thinking of ϕ as a function of θ . Then we have

$$ds = \sqrt{1 + \sin^2 \theta \cdot (\phi')^2} d\theta.$$

Thus the functional we want to extremize is

$$F[\phi] = \int_{\alpha}^{\beta} \sqrt{1 + \sin^2 \theta \cdot (\phi')^2} d\theta.$$

We note here that $\partial f / \partial \theta = 0$, so using the result we obtained above, $\partial f / \partial \phi' = \kappa$, for some constant κ . That is,

$$\frac{\sin^2 \theta \cdot \phi'}{\sqrt{1 + \sin^2 \theta \cdot (\phi')^2}} = \kappa.$$

Squaring this and solving for $(\phi')^2$, we get^a

$$(\phi')^2 = \frac{\kappa^2}{\sin^2 \theta (\sin^2 \theta - \kappa^2)} \implies \phi = \pm \int \frac{\kappa d\theta}{\sin \theta \sqrt{\sin^2 \theta - \kappa^2}}.$$

This looks unpleasant, but yields to the substitution $u = \cot \theta$, for which $du = -\csc^2 \theta d\theta$. Writing $\sin^2 \theta - \kappa^2 = \sin^2 \theta [(1 - \kappa^2) - \kappa^2 u^2]$ after dividing through by $\sin^2 \theta$ and using $\csc^2 \theta = 1 + u^2$, the integral becomes

$$\phi - \phi_0 = \mp \int \frac{\kappa du}{\sqrt{(1 - \kappa^2) - \kappa^2 u^2}} = \mp \arcsin \left(\frac{\kappa u}{\sqrt{1 - \kappa^2}} \right),$$

for some constant ϕ_0 . Rearranging, and absorbing the sign into ϕ_0 ,

$$\cot \theta = \frac{\sqrt{1 - \kappa^2}}{\kappa} \sin(\phi - \phi_0).$$

To see what this is, multiply through by $\sin \theta$ and expand the sine:

$$\cos \theta = \frac{\sqrt{1 - \kappa^2}}{\kappa} (\sin \theta \cos \phi \cos \phi_0 - \sin \theta \sin \phi \sin \phi_0).$$

In terms of our Cartesian coordinates this says $z = c_1 y + c_2 x$ for constants c_1, c_2 , which is the equation of a plane through the origin. So the geodesic lies on the intersection of the sphere with a plane through its centre: it is an arc of a **great circle**, as we expected.

Note that the Euler–Lagrange equation cannot distinguish the *minor* arc from the *major* arc – both are stationary. We will resolve this in [section 23.9](#) using the second variation, where we find that the major arc fails to be a minimum. Note also that if A and B are antipodal, there are infinitely many geodesics between them, which is our promised failure of uniqueness.

^aThere is a sign ambiguity, corresponding to going either forwards or backwards around the sphere.

The second case is subtler, and considerably more useful. Consider, for general $f(x, y, y')$, the quantity $f - y' \partial f / \partial y'$. Differentiating along a path with the total derivative,

$$\begin{aligned} \frac{d}{dx} \left(f - y' \frac{\partial f}{\partial y'} \right) &= \frac{\partial f}{\partial x} + y' \frac{\partial f}{\partial y} + y'' \frac{\partial f}{\partial y'} - y' \frac{\partial}{\partial y'} \left(y' \frac{\partial f}{\partial y'} \right) - y' \frac{d}{dx} \left(\frac{\partial f}{\partial y'} \right) \\ &= y' \left(\frac{\partial f}{\partial y} - \frac{d}{dx} \frac{\partial f}{\partial y'} \right) + \frac{\partial f}{\partial x} \\ &= \frac{\partial f}{\partial x}, \end{aligned}$$

where in the last line we used the Euler–Lagrange equations to kill the bracket. So if f does not depend explicitly on x , we obtain another first integral.

Proposition 23.4.7 (Beltrami Identity)

If $f = f(y, y')$ has no explicit x -dependence, then along any solution of the Euler–Lagrange equation

$$f - y' \frac{\partial f}{\partial y'} = c$$

for some constant c .

This is a genuinely powerful trick: a great many of the classical problems have integrands with no explicit x , and the Beltrami identity reduces the second-order equation to a first-order separable one in one move. The reader should note that it also has a physical meaning which we will uncover in [section 23.7](#): if x is time, then $y' \partial f / \partial y' - f$ is exactly the *energy*, and its constancy is conservation of energy.

Example 23.4.8 (The Brachistochrone)

Consider again the problem of finding the shape of a wire which gives the shortest travel time for a particle sliding along it, beginning at rest.

We want to minimize the functional

$$T[y] = \frac{1}{\sqrt{2g}} \int_0^{x_2} \frac{\sqrt{1 + (y')^2}}{\sqrt{-y}} dx,$$

subject to $y(x_1) = y_1$ and $y(x_2) = y_2$. Here, f does not depend on x and thus we can apply the result above to get

$$\frac{\sqrt{1 + (y')^2}}{\sqrt{-y}} - y' \frac{y'}{\sqrt{1 + (y')^2} \sqrt{-y}} = \kappa,$$

for some constant κ . We can solve this differential equation by simplifying to get

$$\frac{1}{\sqrt{1 + (y')^2}} = \kappa \sqrt{-y},$$

and then we can separate variables to get

$$x = \pm \kappa \int \frac{\sqrt{-y}}{\sqrt{1 + \kappa^2 y}} dy.$$

The substitution $y = -\frac{1}{\kappa^2} \sin^2 \frac{\theta}{2}$ then gives (after some algebra)

$$x = \pm \frac{1}{2\kappa^2} (\theta - \sin \theta) + C,$$

for some constant C . Our particle starts at the origin at $\theta = 0$, so $C = 0$; taking the positive root and writing $a = 1/(2\kappa^2)$, the solution is

$$\begin{cases} x = a(\theta - \sin \theta), \\ y = -a(1 - \cos \theta). \end{cases}$$

This is the parameterized equation of a **cycloid**: the curve traced by a point on the rim of a wheel of radius a rolling (here, on the underside of the x -axis) with constant speed. The constant a , and the final value of θ , are fixed by requiring the curve to pass through B .

The shape is worth a moment's thought. The optimal wire dives steeply at first, even though this takes the particle *below* B and forces it to climb back up at the end. The reason is that the early plunge buys speed, and the extra speed is worth more than the extra distance. This is the sort of answer one would be unlikely to guess.

§23.4.3 Fermat's Principle

We can now look properly at the first variational principle in this course, which describes the motion of light.

Law 23.4.9 (Fermat's Principle)

Light travels along the path between two points which requires the least time.

Suppose we had a ray with path $y = y(x)$, and suppose the speed of light at (x, y) is $c(x, y)$. Then we want to extremize the functional

$$F[y] = \int \frac{1}{c} ds = \int_{\alpha}^{\beta} \frac{\sqrt{1 + (y')^2}}{c(x, y)} dx.$$

If we assume that c depends only on x – so the medium is stratified into vertical layers – then we have $\partial f / \partial y = 0$, and we can use the results of the previous section to obtain

$$\frac{\partial f}{\partial y'} = \frac{y'}{\sqrt{1 + (y')^2} c(x)} = k$$

for some constant k .

Now let θ be the angle the ray makes with the x -axis, so that $\tan \theta = y'$ and hence

$$\frac{y'}{\sqrt{1 + (y')^2}} = \frac{\tan \theta}{\sec \theta} = \sin \theta.$$

Our first integral therefore says that $\sin \theta / c(x)$ is constant along the ray:

$$\frac{\sin \theta_1}{c(x_1)} = \frac{\sin \theta}{c(x)},$$

which is exactly **Snell's law** in optics.

In the picture we have taken c to jump from c_1 to a larger value c_2 at an interface. Snell's law then reads $\sin \theta_1 / c_1 = \sin \theta_2 / c_2$, so $\theta_2 > \theta_1$: the ray bends away from the normal on entering the faster medium. This is the familiar refraction of light on passing from glass into air. More generally, in a medium where c increases with x , the angle θ increases too, and the ray curves – which is exactly the mechanism behind mirages, where hot air near the ground has a higher c .

§23.5 Extensions of the Euler-Lagrange Equations

We are now going to see how the Euler-Lagrange equations can be used in settings that are not just unconstrained functional extremization of a single function of a single variable. In each case the derivation is the same three-step dance – perturb, integrate by parts, apply the fundamental lemma – and only the bookkeeping changes.

§23.5.1 Several Dependent Variables

Suppose that instead of a single function y , we have a vector of them,

$$\mathbf{y}(x) = (y_1(x), \dots, y_n(x)),$$

and we wish to extremize

$$F[\mathbf{y}] = \int_{\alpha}^{\beta} f(x, y_1, \dots, y_n, y'_1, \dots, y'_n) \, dx,$$

over functions with all the y_i fixed at the endpoints. This is the situation for, say, a particle moving in three dimensions, where $\mathbf{y}$ is its position.

The derivation goes through unchanged. Perturb by $\mathbf{y} \mapsto \mathbf{y} + \epsilon \boldsymbol{\eta}$ where $\boldsymbol{\eta} = (\eta_1, \dots, \eta_n)$ vanishes at both endpoints, expand, and integrate each term by parts:

$$F[\mathbf{y} + \epsilon \boldsymbol{\eta}] - F[\mathbf{y}] = \epsilon \int_{\alpha}^{\beta} \sum_{i=1}^n \eta_i \left(\frac{\partial f}{\partial y_i} - \frac{d}{dx} \frac{\partial f}{\partial y'_i} \right) dx + O(\epsilon^2).$$

Now here is the one new idea. The η_i are independent of one another, so we are free to take $\eta_j \equiv 0$ for all $j \neq i$, leaving a single term to which the fundamental lemma applies. Doing this for each i in turn gives:

Theorem 23.5.1 (Euler–Lagrange Equations, Several Dependent Variables)

A stationary point of $F[\mathbf{y}]$ satisfies

$$\frac{\partial f}{\partial y_i} - \frac{d}{dx} \left(\frac{\partial f}{\partial y'_i} \right) = 0, \quad i = 1, \dots, n.$$

This is a coupled system of n second-order ODEs. Both first integrals survive: if f has no explicit dependence on some particular y_j , then $\partial f / \partial y'_j$ is constant; and if f has no explicit dependence on x , then

$$f - \sum_{i=1}^n y'_i \frac{\partial f}{\partial y'_i} = \text{constant},$$

by exactly the computation we did for [Proposition 23.4.7](#).

Example 23.5.2 (Geodesics, Parameterized Properly)

Our earlier treatment of geodesics in the plane had a defect: by writing y as a function of x , we quietly assumed that the shortest curve never doubles back. We can avoid this by parameterizing the curve as $\mathbf{r}(t) = (x(t), y(t))$ for $t \in [0, 1]$, with $\mathbf{r}(0) = A$ and $\mathbf{r}(1) = B$, and minimising

$$L[x, y] = \int_0^1 \sqrt{\dot{x}^2 + \dot{y}^2} \, dt.$$

Neither x nor y appears explicitly, so both are cyclic and we get two first integrals:

$$\frac{\dot{x}}{\sqrt{\dot{x}^2 + \dot{y}^2}} = c, \quad \frac{\dot{y}}{\sqrt{\dot{x}^2 + \dot{y}^2}} = s.$$

These constants are not independent: squaring and adding gives $c^2 + s^2 = 1$, so we

may write $c = \cos \vartheta$ and $s = \sin \vartheta$. Then both equations reduce to $\dot{x} \sin \vartheta = \dot{y} \cos \vartheta$, which integrates to

$$y \cos \vartheta = x \sin \vartheta + A,$$

a straight line of gradient $\tan \vartheta$. Note how the redundancy in the parameterization showed up as a redundancy in the equations – this is characteristic of problems with a reparameterization symmetry.

§23.5.2 Several Independent Variables

Now we go the other way, and let our unknown be a function of several variables. Suppose $\phi = \phi(x, y, z)$ on a domain $\mathcal{D} \subseteq \mathbb{R}^3$, and consider

$$F[\phi] = \iiint_{\mathcal{D}} f(x, y, z, \phi, \phi_x, \phi_y, \phi_z) \, dx \, dy \, dz,$$

where $\phi_{x_i} = \partial\phi/\partial x_i$, and where ϕ is prescribed on the boundary $\partial\mathcal{D}$.

Perturb by $\phi \mapsto \phi + \epsilon\eta$ with $\eta = 0$ on $\partial\mathcal{D}$. The first-order term is

$$\epsilon \iiint_{\mathcal{D}} \left(\eta \frac{\partial f}{\partial \phi} + \eta_x \frac{\partial f}{\partial \phi_x} + \eta_y \frac{\partial f}{\partial \phi_y} + \eta_z \frac{\partial f}{\partial \phi_z} \right) dV.$$

The role of integration by parts is now played by the divergence theorem. Writing

$$\mathbf{w} = \left(\frac{\partial f}{\partial \phi_x}, \frac{\partial f}{\partial \phi_y}, \frac{\partial f}{\partial \phi_z} \right),$$

the last three terms are $\nabla \eta \cdot \mathbf{w} = \nabla \cdot (\eta \mathbf{w}) - \eta \nabla \cdot \mathbf{w}$, and the divergence term integrates to $\oint_{\partial\mathcal{D}} \eta \mathbf{w} \cdot d\mathbf{S} = 0$ since η vanishes on the boundary. So we are left with

$$\epsilon \iiint_{\mathcal{D}} \eta \left(\frac{\partial f}{\partial \phi} - \nabla \cdot \mathbf{w} \right) dV = 0,$$

and a version of the fundamental lemma in several variables (proved by exactly the same bump-function argument, in a small ball rather than an interval) gives the following.

Theorem 23.5.3 (Euler–Lagrange Equation, Several Independent Variables)

A stationary point of $F[\phi]$ satisfies

$$\frac{\partial f}{\partial \phi} - \nabla \cdot \left(\frac{\partial f}{\partial \phi_x}, \frac{\partial f}{\partial \phi_y}, \frac{\partial f}{\partial \phi_z} \right) = 0,$$

or in suffix notation with the summation convention,

$$\frac{\partial f}{\partial \phi} - \partial_i \left(\frac{\partial f}{\partial (\partial_i \phi)} \right) = 0.$$

Note that this is now a *partial* differential equation for ϕ . Nothing about the derivation used $n = 3$, and the same statement holds in any number of independent variables.

Example 23.5.4 (Laplace's Equation)

Consider the ‘energy’ functional

$$F[\phi] = \iint_{\mathcal{D} \subseteq \mathbb{R}^2} \frac{1}{2} (\phi_x^2 + \phi_y^2) \, dx \, dy = \iint_{\mathcal{D}} \frac{1}{2} |\nabla \phi|^2 \, dA,$$

which is (up to constants) the electrostatic energy of a potential ϕ , or the elastic energy of a stretched membrane with height ϕ . Here $\partial f / \partial \phi = 0$ and $\partial f / \partial \phi_x = \phi_x$, $\partial f / \partial \phi_y = \phi_y$, so the Euler–Lagrange equation is

$$\phi_{xx} + \phi_{yy} = 0,$$

which is Laplace’s equation. So harmonic functions are exactly the stationary points of the Dirichlet energy – a fact known as *Dirichlet’s principle*, and one of the classical bridges between the calculus of variations and PDE theory. The reader will recognise the equation, and the tools for solving it, from the Laplace’s equation chapter of my Methods notes.

§23.5.3 Higher Derivatives

Occasionally our integrand involves higher derivatives of y :

$$F[y] = \int_{\alpha}^{\beta} f(x, y, y', \dots, y^{(n)}) \, dx.$$

Now we need to fix more data at the endpoints – specifically $y, y', \dots, y^{(n-1)}$ – and correspondingly our variations η must satisfy $\eta^{(k)}(\alpha) = \eta^{(k)}(\beta) = 0$ for $k = 0, \dots, n-1$. The first variation is

$$\epsilon \int_{\alpha}^{\beta} \left(\frac{\partial f}{\partial y} \eta + \frac{\partial f}{\partial y'} \eta' + \dots + \frac{\partial f}{\partial y^{(n)}} \eta^{(n)} \right) dx,$$

and we now integrate the $\eta^{(k)}$ term by parts k times. Every boundary term produced involves some $\eta^{(j)}$ with $j \leq n-1$ evaluated at an endpoint, so every one of them vanishes. Each integration by parts contributes a sign, and applying the fundamental lemma gives

$$\frac{\partial f}{\partial y} - \frac{d}{dx} \frac{\partial f}{\partial y'} + \frac{d^2}{dx^2} \frac{\partial f}{\partial y''} - \dots + (-1)^n \frac{d^n}{dx^n} \frac{\partial f}{\partial y^{(n)}} = 0.$$

Example 23.5.5

Let us extremize

$$F[y] = \int_0^1 (y'')^2 \, dx, \quad y(0) = y'(0) = 0, \quad y(1) = 0, \quad y'(1) = 1.$$

Here $\partial f / \partial y = \partial f / \partial y' = 0$ and $\partial f / \partial y'' = 2y''$, so the equation is

$$-\frac{d^2}{dx^2} (2y'') = 0 \implies y''' = 0,$$

so y is a cubic. Imposing $y(0) = y'(0) = 0$ kills the constant and linear terms, so $y = ax^3 + bx^2$; then $y(1) = 0$ gives $a + b = 0$ and $y'(1) = 1$ gives $3a + 2b = 1$, whence

$a = 1, b = -1$:

$$y_0 = x^3 - x^2.$$

In fact we can show that this is an *absolute* minimum, and it is instructive to see how, since the argument does not involve second variations at all. Let η be *any* function (not necessarily small) with $\eta = \eta' = 0$ at both endpoints, and not identically zero. Then

$$F[y_0 + \eta] - F[y_0] = \int_0^1 (\eta'')^2 dx + 2 \int_0^1 y_0'' \eta'' dx.$$

The first integral is strictly positive. For the second, $y_0'' = 6x - 2$, so integrating by parts twice,

$$2 \int_0^1 (6x - 2) \eta'' dx = 2 [(6x - 2) \eta']_0^1 - 12 \int_0^1 \eta' dx = 2 [(6x - 2) \eta']_0^1 - 12 [\eta]_0^1 = 0,$$

since η and η' vanish at both endpoints. Hence $F[y_0 + \eta] > F[y_0]$ for every admissible $\eta \neq 0$, and y_0 is the unique global minimiser. When such an argument is available it is much less work than computing second variations.

§23.5.4 Variable Endpoints and Natural Boundary Conditions

Throughout the derivation of the Euler–Lagrange equation we quietly used the fixed endpoints twice: once to argue that η must vanish there, and once to discard the boundary term

$$\left[\eta \frac{\partial f}{\partial y'} \right]_{\alpha}^{\beta}.$$

What if one of the endpoints is not fixed? Suppose, for instance, that $y(\alpha) = y_1$ is prescribed, but the value $y(\beta)$ is free – the curve must end somewhere on the vertical line $x = \beta$, but we do not care where. This is the situation of a bead threaded on a rail.

Repeating the derivation, the first variation is

$$\epsilon \int_{\alpha}^{\beta} \eta \left(\frac{\partial f}{\partial y} - \frac{d}{dx} \frac{\partial f}{\partial y'} \right) dx + \epsilon \left[\eta \frac{\partial f}{\partial y'} \right]_{\alpha}^{\beta},$$

and we still have $\eta(\alpha) = 0$, so the boundary term is just $\epsilon \eta(\beta) \partial f / \partial y'|_{\beta}$.

Now we argue in two stages. First restrict to those η which *do* vanish at β ; for these the boundary term drops out and we conclude as before that y satisfies the Euler–Lagrange equation. But then, for a general η , the integral term vanishes automatically, and we are left with

$$\eta(\beta) \frac{\partial f}{\partial y'} \Big|_{x=\beta} = 0.$$

Since $\eta(\beta)$ is now arbitrary, we must have

Theorem 23.5.6 (Natural Boundary Condition)

If y extremizes $F[y] = \int_{\alpha}^{\beta} f(x, y, y') \, dx$ with $y(\alpha)$ fixed and $y(\beta)$ free, then y satisfies the Euler–Lagrange equation together with the **natural boundary condition**

$$\left. \frac{\partial f}{\partial y'} \right|_{x=\beta} = 0.$$

The name is apt: we did not impose this condition, the variational problem produced it for us. Notice that the count works out – we lost one boundary condition by freeing the endpoint, and gained exactly one back.

Example 23.5.7

Consider the shortest path from a fixed point $A = (0, y_1)$ to the line $x = \beta$. Here $f = \sqrt{1 + (y')^2}$, and we already know the Euler–Lagrange equation forces a straight line. The natural boundary condition is

$$\left. \frac{y'}{\sqrt{1 + (y')^2}} \right|_{\beta} = 0 \implies y'(\beta) = 0.$$

Since y is a straight line, $y' \equiv 0$: the shortest path is horizontal, meeting the rail at right angles. This is obvious geometrically, which is a good sanity check on the machinery.

Example 23.5.8

Here is a less obvious one. Consider

$$F[y] = \int_0^1 ((y')^2 + y^2) \, dx, \quad y(0) = 1, \quad y(1) \text{ free}.$$

As we computed earlier, the Euler–Lagrange equation is $y'' = y$, so $y = A \sinh x + B \cosh x$, and $y(0) = 1$ gives $B = 1$. The natural boundary condition is

$$2y'|_{x=1} = 0 \implies y'(1) = 0,$$

so $A \cosh 1 + \sinh 1 = 0$, giving $A = -\tanh 1$ and

$$y = \cosh x - \tanh 1 \sinh x = \frac{\cosh(1 - x)}{\cosh 1}.$$

Notice that the free endpoint has arranged itself so that the curve arrives with zero gradient. Had we instead fixed $y(1) = 0$, we would have obtained a quite different function.

If *both* endpoints are free, the argument runs the same way and we obtain two natural conditions, $\partial f / \partial y'|_{\alpha} = \partial f / \partial y'|_{\beta} = 0$. More generally, a mixture is possible: one endpoint fixed and one free, or a ‘spring’ term added to the functional at the endpoint, in which case the natural condition becomes a Robin-type condition rather than a Neumann one. The general principle is simply that the boundary term in the first variation must

vanish, however we arrange it.

More generally, if the right-hand endpoint is required only to lie on some curve $y = h(x)$, one finds after a slightly longer calculation the **transversality condition**

$$\left[f + (h' - y') \frac{\partial f}{\partial y'} \right] \Big|_{x=\beta} = 0.$$

For the arclength integrand this reduces to $1 + h'y' = 0$, that is, the extremal must meet the curve $y = h(x)$ orthogonally – again what one would guess.

Remark. There is a third possibility, which we have already used without comment: the curve might have *no* boundary at all, as for a closed curve. Then there is no boundary term to worry about and no boundary conditions to impose. This is what happens in the isoperimetric problem below.

§23.5.5 Euler-Lagrange Equations with Constraints

Suppose we wanted to extremize a functional $F[y]$ with

$$F[y] = \int_{\alpha}^{\beta} f(x, y, y') \, dx,$$

subject to the constraint functional

$$G[y] = \int_{\alpha}^{\beta} g(x, y, y') \, dx = k,$$

for a constant k . Such a problem is called **isoperimetric**, for historical reasons which will become clear in a moment. We are going to solve it by generalizing the method of Lagrange multipliers that we introduced in [subsection 23.2.2](#): we extremize the functional

$$\Phi[y, \lambda] = F[y] - \lambda (G[y] - k)$$

over both y and the number λ . Varying with respect to λ recovers the constraint $G[y] = k$, and varying with respect to y amounts to replacing f by $f - \lambda g$ in the Euler-Lagrange equations, giving

$$\frac{\partial}{\partial y} (f - \lambda g) - \frac{d}{dx} \left(\frac{\partial}{\partial y'} (f - \lambda g) \right) = 0.$$

As in finite dimensions, we now have one extra unknown (λ) and one extra equation (the constraint), so the count is right. The justification is the same as before: the constraint restricts us to a ‘surface’ in the space of functions, and stationarity along that surface says the functional derivative of F is proportional to that of G .

Example 23.5.9 (Isoperimetric / Dido’s Problem)

What simple closed plane curve of fixed length L maximizes the area enclosed by this curve?

The name comes from the legend of Dido, who on founding Carthage was promised as much land as she could enclose with the hide of an ox – and, cutting the hide into a long thin strip, was faced with exactly this problem.

We can immediately see that such a curve has to be convex: if it were not, reflecting a non-convex arc in the chord joining its endpoints would keep the perimeter the same while increasing the area. We set the problem up in Cartesian coordinates as

follows.

On the x -axis, we have minimal and maximal values α and β , and a simple closed curve C with the given orientation. The x coordinate monotonically increases from $\alpha \rightarrow \beta$ along the lower arc, and then decreases from $\beta \rightarrow \alpha$ along the upper arc.

Given $x \in (\alpha, \beta)$, there are two points of the curve above x , at heights $y_1(x) < y_2(x)$, and from this we can write down the area as

$$A[y] = \int_{\alpha}^{\beta} (y_2(x) - y_1(x)) \, dx = - \oint_C y \, dx,$$

the sign being fixed by the orientation, and our perimeter constraint as

$$L[y] = \oint_C d\ell = \oint_C \sqrt{1 + (y')^2} \, dx = L$$

being constant.

We now want to extremize $A - \lambda L$, and so we define

$$h = y - \lambda \sqrt{1 + (y')^2},$$

so that we can then try to solve the Euler-Lagrange equations (not worrying about the boundary term in the derivation of the Euler-Lagrange equations, as C has no boundary).

Since this has no dependence on x , we can use one of our first integrals. We know that $\partial h / \partial x = 0$, and also that

$$\begin{aligned} k &= h - y' \frac{\partial h}{\partial y'} \\ &= y - \lambda \sqrt{1 + (y')^2} + y' \lambda \frac{y'}{\sqrt{1 + (y')^2}} \\ &= y - \frac{\lambda}{\sqrt{1 + (y')^2}}, \end{aligned}$$

for a constant k . Thus

$$(y')^2 = \frac{\lambda^2}{(y - k)^2} - 1,$$

which is separable. Writing $u = y - k$ we get $dx = \pm u \, du / \sqrt{\lambda^2 - u^2}$, and integrating gives $x - x_0 = \mp \sqrt{\lambda^2 - u^2}$. Squaring and rearranging, the solution is

$$(x - x_0)^2 + (y - y_0)^2 = \lambda^2,$$

which is a circle of radius λ . Then $2\pi\lambda = L$ gives $\lambda = L/2\pi$. This is a necessary (but not sufficient) condition for our solution, so the circle is the only candidate.

Notice that the Lagrange multiplier is here exactly the radius of the optimal circle, and hence that $dA/dL = \lambda$ – which is easily checked directly, since $A = L^2/4\pi$. This is our general interpretation of the multiplier as a rate of change of the optimal value with the constraint, in action.

§23.5.6 Pointwise Constraints

The constraint in an isoperimetric problem is a single number. Sometimes instead we want a constraint to hold at *every* point of the curve – for instance, that the curve lie on a given surface. In that case a single multiplier is not enough; we need a multiplier *function* $\lambda(t)$, one for each point.

Example 23.5.10 (Geodesics on a General Surface)

Let $\Sigma = \{\mathbf{x} \in \mathbb{R}^3 : g(\mathbf{x}) = 0\}$ be a surface, and let $A, B \in \Sigma$. To find the geodesics between them, parameterize a path by $t \in [0, 1]$ with $\mathbf{x}(0) = A$, $\mathbf{x}(1) = B$, and extremize

$$\Phi[\mathbf{x}, \lambda] = \int_0^1 \left\{ \sqrt{\dot{x}_1^2 + \dot{x}_2^2 + \dot{x}_3^2} - \lambda(t)g(\mathbf{x}) \right\} dt.$$

Treating λ as a fourth dependent variable, the Euler–Lagrange equation for λ is

$$\frac{d}{dt} \frac{\partial h}{\partial \dot{\lambda}} - \frac{\partial h}{\partial \lambda} = 0,$$

and since h does not involve $\dot{\lambda}$ at all, this just says $g(\mathbf{x}) = 0$ for all t – the constraint, as required. Varying the x_i gives

$$\frac{d}{dt} \left(\frac{\dot{x}_i}{\sqrt{\dot{x}_1^2 + \dot{x}_2^2 + \dot{x}_3^2}} \right) + \lambda \frac{\partial g}{\partial x_i} = 0.$$

If we parameterize by arclength the square root is 1, and the equation says $\ddot{\mathbf{x}} = -\lambda \nabla g$: the acceleration of a geodesic is always *normal* to the surface. In other words, a geodesic is a curve which does not turn within the surface – it only bends as much as the surface forces it to. This is a very clean characterisation, and one which the reader will meet again in Differential Geometry.

Of course, we could instead have solved the constraint $g = 0$ by parameterizing Σ explicitly, as we did for the sphere. Which approach is easier depends entirely on the surface.

§23.6 Soap Films and Hanging Chains

We now pause the general theory to work through two classical problems in detail. Both are genuinely physical, both are solved by the hyperbolic cosine, and both have subtleties that the Euler–Lagrange equation alone does not reveal.

§23.6.1 Minimal Surfaces of Revolution

Dip two coaxial circular wire rings into soapy water and pull them apart. The soap film that forms is a surface of revolution, and since surface tension makes the film minimise its area, it is a solution of a variational problem.

Take the axis of revolution to be the x -axis, and let the film be the surface obtained by rotating a curve $y = y(x) > 0$ about it, with the rings at $x = \pm\beta$ both of radius c . The area of the surface of revolution is

$$A[y] = \int_{-\beta}^{\beta} 2\pi y \sqrt{1 + (y')^2} \, dx,$$

subject to $y(\pm\beta) = c$. Discarding the 2π , the integrand $f = y\sqrt{1 + (y')^2}$ has no explicit x -dependence, so the Beltrami identity applies:

$$y\sqrt{1 + (y')^2} - y' \frac{yy'}{\sqrt{1 + (y')^2}} = \frac{y}{\sqrt{1 + (y')^2}} = y_0$$

for some constant $y_0 > 0$. Rearranging,

$$y' = \pm \frac{\sqrt{y^2 - y_0^2}}{y_0},$$

which separates. Substituting $y = y_0 \cosh u$ gives $dx = y_0 du$, so $u = (x - x_1)/y_0$ and

$$y = y_0 \cosh \left(\frac{x - x_1}{y_0} \right).$$

This curve is a **catenary**, and the surface it sweeps out is a **catenoid**. By the symmetry of our boundary conditions, $x_1 = 0$, and y_0 is the radius of the narrowest part of the film – its ‘waist’.

All that remains is to determine y_0 , from

$$c = y_0 \cosh \left(\frac{\beta}{y_0} \right).$$

This is where it gets interesting. Let us scale so that $\beta = 1$, and ask how many solutions y_0 this equation has for given c . Consider the function $\Psi(y_0) = y_0 \cosh(1/y_0)$: as $y_0 \rightarrow 0^+$ it blows up (since $\cosh$ beats the linear factor), and as $y_0 \rightarrow \infty$ it also blows up (since $\cosh \rightarrow 1$ and the linear factor wins). So Ψ has a minimum somewhere in between.

Differentiating,

$$\Psi'(y_0) = \cosh \frac{1}{y_0} - \frac{1}{y_0} \sinh \frac{1}{y_0},$$

which vanishes when $\coth(1/y_0) = 1/y_0$. Numerically this gives $y_0 = \mu \approx 0.833$, and $c_* = \Psi(\mu) \approx 1.509$. Hence:

- If $c > c_*$, there are *two* catenoids meeting the boundary conditions: a fat one with $y_0 > \mu$, and a thin one with $y_0 < \mu$.
- If $c = c_*$, there is exactly one.
- If $c < c_*$ – that is, if the rings are pulled too far apart relative to their size – there is *no* solution at all.

This is our promised failure of existence and uniqueness for the boundary value problem, and it is physically real: pull the rings far enough apart and the soap film snaps.

§23.6.2 The Goldschmidt Solution

But what happens then? Physically, the film collapses into two flat discs, one spanning each ring. This is called the **Goldschmidt solution**, and it is a perfectly good competitor of area $2\pi c^2$ – but it is not a smooth surface of revolution, so the Euler–Lagrange equation never saw it.

Comparing the areas is a slightly delicate calculation, but the upshot is that as the rings are separated, the fat catenoid's area increases until, at a separation *strictly less* than the critical one, it exceeds $2\pi c^2$. Past that point the Goldschmidt solution is the true global minimum even though a catenoid still exists.

There are two morals here, both worth remembering.

- (i) The Euler–Lagrange equation only finds *smooth* stationary points. Minima can occur at the boundary of the space of admissible functions – just as, for functions on $\mathbb{R}^n$, minima can occur at the boundary of the domain.

- (ii) Of the two catenoids, the thin one ($y_0 < \mu$) turns out to be a saddle rather than a minimum: it is unstable, and a real soap film will never adopt it. We are not yet in a position to prove this, but we will develop the necessary tools in [section 23.9](#).

§23.6.3 The Hanging Chain

A closely related problem: what shape does a heavy flexible chain of fixed length L take when suspended from two points? The chain will hang so as to minimise its gravitational potential energy, subject to its length being fixed – so this is an isoperimetric problem, and we need a Lagrange multiplier.

If the chain has uniform mass per unit length ρ and hangs as $y = y(x)$ for $x \in [-\beta, \beta]$, its potential energy is

$$V[y] = \int_{-\beta}^{\beta} \rho g y \sqrt{1 + (y')^2} dx,$$

and the length constraint is

$$L[y] = \int_{-\beta}^{\beta} \sqrt{1 + (y')^2} dx = L.$$

So we extremize with the integrand

$$h = (\rho g y - \lambda) \sqrt{1 + (y')^2}.$$

But this is exactly the soap film integrand with y replaced by $y - \lambda/\rho g$! So the calculation is identical, and the answer is a catenary,

$$y = \frac{\lambda}{\rho g} + a \cosh\left(\frac{x - x_1}{a}\right),$$

with a and λ fixed by the endpoint conditions and the length constraint. Here the multiplier λ has a direct physical meaning: it is (up to sign) the horizontal tension in the chain.

That the soap film and the hanging chain give the same curve is not a coincidence – both minimise $\int y d\ell$ – but it is a pleasing one, and it is the reason the curve is called a catenary (from *catena*, a chain).

It is a common misconception that a hanging chain is a parabola. It is not, though the two are close near the bottom: expanding,

$$a \cosh \frac{x}{a} = a + \frac{x^2}{2a} + \frac{x^4}{24a^3} + \cdots,$$

so they agree to second order and diverge thereafter. Galileo believed the curve was a parabola; the correct answer was found by Huygens, Leibniz and Johann Bernoulli in 1691.

§23.6.4 Plateau's Problem and the Minimal Surface Equation

Our soap film was a surface of revolution, which reduced the problem to one dependent variable. What if we dip an arbitrary closed wire loop into soapy water? The film that forms spans the loop and minimises area, and finding it is called **Plateau's problem**. This is a genuine multi-variable calculus of variations problem, and it is a good test of the machinery from the previous section.

Suppose the surface can be written as a graph $z = \phi(x, y)$ over a domain $\mathcal{D}$ in the plane, with ϕ prescribed on $\partial\mathcal{D}$ by the wire. Since $dz = \phi_x dx + \phi_y dy$, the line element on the surface is

$$ds^2 = (1 + \phi_x^2) dx^2 + 2\phi_x\phi_y dx dy + (1 + \phi_y^2) dy^2 = g_{ij} dx^i dx^j,$$

where

$$g = \begin{pmatrix} 1 + \phi_x^2 & \phi_x\phi_y \\ \phi_x\phi_y & 1 + \phi_y^2 \end{pmatrix}$$

is the **first fundamental form** of the surface. The area element is $dA = \sqrt{\det g} dx dy$, and $\det g = 1 + \phi_x^2 + \phi_y^2$ (the cross terms cancel), so we wish to extremize

$$A[\phi] = \iint_{\mathcal{D}} \sqrt{1 + \phi_x^2 + \phi_y^2} dx dy.$$

Writing h for the integrand, we have $\partial h / \partial \phi = 0$ and

$$\frac{\partial h}{\partial \phi_x} = \frac{\phi_x}{\sqrt{1 + \phi_x^2 + \phi_y^2}}, \quad \frac{\partial h}{\partial \phi_y} = \frac{\phi_y}{\sqrt{1 + \phi_x^2 + \phi_y^2}},$$

so the Euler–Lagrange equation is

$$\partial_x \left(\frac{\phi_x}{\sqrt{1 + \phi_x^2 + \phi_y^2}} \right) + \partial_y \left(\frac{\phi_y}{\sqrt{1 + \phi_x^2 + \phi_y^2}} \right) = 0.$$

Expanding the derivatives and clearing the denominator gives the **minimal surface equation**

$$(1 + \phi_y^2) \phi_{xx} - 2\phi_x\phi_y\phi_{xy} + (1 + \phi_x^2) \phi_{yy} = 0.$$

This is a nonlinear second-order PDE, and it is not one we can solve in general. Two observations, though.

First, if the surface is nearly flat, so that $|\nabla\phi| \ll 1$, we may drop the quadratic terms and are left with

$$\phi_{xx} + \phi_{yy} = 0,$$

Laplace's equation again. This is the same linearisation that turns the exact equations of a stretched membrane into the wave equation studied in the Methods course.

Second, we can solve it exactly in the circularly symmetric case, and recover the catenoid. Put $z = \phi(r)$ with $r = \sqrt{x^2 + y^2}$. Then $\phi_x = z'x/r$ and $\phi_y = z'y/r$, and computing the second derivatives and substituting reduces the minimal surface equation to

$$rz'' + z' + (z')^3 = 0.$$

Setting $w = z'$ and multiplying through by w , this becomes

$$\frac{1}{2}r \frac{d(w^2)}{dr} + w^2 + w^4 = 0,$$

and with $u = w^2$ this is separable:

$$\frac{du}{u(1+u)} = -\frac{2 dr}{r}.$$

Integrating with partial fractions gives $u/(1+u) = r_0^2/r^2$ for a constant r_0 , so $w^2 = r_0^2/(r^2 - r_0^2)$ and

$$\frac{dz}{dr} = \frac{r_0}{\sqrt{r^2 - r_0^2}} \implies z - z_0 = r_0 \operatorname{arcosh}\left(\frac{r}{r_0}\right).$$

Inverting,

$$r = r_0 \cosh\left(\frac{z - z_0}{r_0}\right),$$

which is exactly the catenoid we found in [subsection 23.6.1](#) – reassuringly, since the two calculations describe the same soap film. It is always worth doing a problem twice when the two routes are this different.

§23.7 Hamilton’s Principle and Lagrangian Mechanics

We now turn to the most celebrated application of everything we have built: the reformulation of classical mechanics as a variational principle. The payoff is enormous. Newton’s laws are tied to Cartesian coordinates and inertial frames, and become painful the moment we have constraints (a bead on a wire, a pendulum on a pendulum). The variational formulation is coordinate-free, handles constraints gracefully, and – through Noether’s theorem – hands us the conservation laws for free.

§23.7.1 The Principle of Least Action

Definition 23.7.1 (Lagrangian and Action)

For a particle of mass m moving in $\mathbb{R}^3$ under a potential $V(\mathbf{x})$, with kinetic energy $T = \frac{1}{2}m|\dot{\mathbf{x}}|^2$, the **Lagrangian** is

$$L(\mathbf{x}, \dot{\mathbf{x}}, t) = T - V,$$

and the **action** of a path $\mathbf{x}(t)$ between times t_1 and t_2 is

$$S[\mathbf{x}] = \int_{t_1}^{t_2} L(\mathbf{x}, \dot{\mathbf{x}}, t) dt.$$

Law 23.7.2 (Hamilton’s Principle)

The path actually taken by the particle between two fixed configurations at times t_1 and t_2 is a stationary point of the action.

The difference $T - V$ looks strange – one would more naturally write down $T + V$, the energy. But it is $T - V$ that works, and we can check this immediately.

Theorem 23.7.3

Hamilton's principle is equivalent to Newton's second law $m\ddot{\mathbf{x}} = -\nabla V$.

Proof. This is the Euler–Lagrange equations for several dependent variables from subsection 23.5.1, with x replaced by t and y_i by x_i . We have

$$L = \frac{1}{2}m(\dot{x}_1^2 + \dot{x}_2^2 + \dot{x}_3^2) - V(\mathbf{x}),$$

so $\partial L/\partial \dot{x}_i = m\dot{x}_i$ and $\partial L/\partial x_i = -\partial V/\partial x_i$. The Euler–Lagrange equations

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{x}_i} \right) - \frac{\partial L}{\partial x_i} = 0$$

therefore read $m\ddot{x}_i = -\partial V/\partial x_i$, which is Newton's second law. $\square$

So the mysterious minus sign is exactly what is needed to produce ‘mass times acceleration equals force’. Two immediate remarks. First, ‘least action’ is a misnomer – the action is stationary, and is often a saddle rather than a minimum. Second, the Euler–Lagrange equations retain their form under *any* change of coordinates, since our derivation never used what the coordinates meant. This is what makes the formulation so powerful.

§23.7.2 Generalised Coordinates

Suppose we have N particles in $\mathbb{R}^3$. Rather than tracking N vectors, we regard the state of the whole system as a single point in $\mathbb{R}^{3N}$, called the **configuration space**. If the system is subject to constraints – rigid rods, beads on wires, and so on – the accessible configurations form a lower-dimensional surface inside $\mathbb{R}^{3N}$, and we may choose any convenient coordinates $q_1, \dots, q_n$ on it. These are the **generalised coordinates**, and n is the number of degrees of freedom.

The great advantage is that the constraint forces disappear entirely: we simply write the kinetic and potential energies in terms of the q_i , form

$$L = L(q_i, \dot{q}_i, t),$$

and write down the Euler–Lagrange equations

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}_i} \right) - \frac{\partial L}{\partial q_i} = 0.$$

The quantity $p_i = \partial L/\partial \dot{q}_i$ is called the **generalised** (or **conjugate**) **momentum** associated with q_i ; for a Cartesian coordinate it is the ordinary momentum $m\dot{x}$.

Example 23.7.4 (The Simple Pendulum)

A mass m swings on a light rod of length ℓ . There is one degree of freedom, the angle θ from the downward vertical. The speed of the mass is $\ell\dot{\theta}$ and its height above the lowest point is $\ell(1 - \cos \theta)$, so

$$L = \frac{1}{2}m\ell^2\dot{\theta}^2 - mg\ell(1 - \cos \theta).$$

Then $\partial L/\partial \dot{\theta} = m\ell^2\dot{\theta}$ and $\partial L/\partial \theta = -mg\ell \sin \theta$, so the equation of motion is

$$m\ell^2\ddot{\theta} = -mg\ell \sin \theta \implies \ddot{\theta} = -\frac{g}{\ell} \sin \theta,$$

in two lines and with no mention of the tension in the rod. Doing this with Newton's laws requires resolving forces along and perpendicular to the rod, and is distinctly more work.

Example 23.7.5 (Motion in a Central Force)

Consider a particle moving in a plane under a central potential $V(r)$. Using plane polar coordinates (r, θ) , the velocity has components $\dot{r}$ and $r\dot{\theta}$, so

$$L = \frac{1}{2}m(\dot{r}^2 + r^2\dot{\theta}^2) - V(r).$$

Now θ is cyclic – it does not appear in L , only $\dot{\theta}$ does – so we immediately get a first integral,

$$\frac{\partial L}{\partial \dot{\theta}} = mr^2\dot{\theta} = \text{constant},$$

which is conservation of angular momentum. Also L has no explicit t -dependence, so the Beltrami identity applies (in its several-variable form):

$$\begin{aligned} \text{constant} &= \dot{r} \frac{\partial L}{\partial \dot{r}} + \dot{\theta} \frac{\partial L}{\partial \dot{\theta}} - L \\ &= m\dot{r}^2 + mr^2\dot{\theta}^2 - \frac{1}{2}m\dot{r}^2 - \frac{1}{2}mr^2\dot{\theta}^2 + V(r) \\ &= \frac{1}{2}m(\dot{r}^2 + r^2\dot{\theta}^2) + V(r), \end{aligned}$$

which is $T + V$: conservation of energy. So both conservation laws for the Kepler problem drop out of the structure of L without solving anything.

Example 23.7.6 (The Double Pendulum)

To see how little the method cares about complexity, consider a pendulum of length ℓ_1 carrying a mass m_1 , from which hangs a second pendulum of length ℓ_2 carrying m_2 . Let θ_1, θ_2 be the angles of the two rods from the vertical; these are our generalised coordinates, and there are two degrees of freedom.

The position of the first mass is $\ell_1(\sin \theta_1, -\cos \theta_1)$ and of the second is that plus

$\ell_2(\sin \theta_2, -\cos \theta_2)$. Differentiating and squaring,

$$T = \frac{1}{2}(m_1 + m_2)\ell_1^2\dot{\theta}_1^2 + \frac{1}{2}m_2\ell_2^2\dot{\theta}_2^2 + m_2\ell_1\ell_2\dot{\theta}_1\dot{\theta}_2\cos(\theta_1 - \theta_2),$$

while the potential energy is

$$V = -(m_1 + m_2)g\ell_1\cos\theta_1 - m_2g\ell_2\cos\theta_2.$$

Writing $L = T - V$ and grinding out $\frac{d}{dt}(\partial L/\partial\dot{\theta}_i) = \partial L/\partial\theta_i$ gives the (famously chaotic) equations of motion. The point is not the equations, which are unpleasant, but that we obtained them by writing down two energies and differentiating. There is no need to think about the forces in the rods at all, which is what makes a Newtonian treatment of this system so disagreeable.

Note also that L has no explicit t -dependence, so energy is conserved; but no coordinate is cyclic, so there is no second conserved quantity. Two degrees of freedom and only one conservation law is, roughly speaking, why the system is chaotic.

That last example is suggestive. A missing coordinate gave conservation of angular momentum; a missing time gave conservation of energy. There is a general principle lurking here, and it is due to Emmy Noether.

§23.7.3 Noether's Theorem

The key idea is to replace ‘the Lagrangian does not depend on θ ’ – which is a statement about a particular coordinate system – with the coordinate-free statement ‘the Lagrangian is invariant under rotations’. Symmetries, rather than missing variables.

Definition 23.7.7 (Continuous Symmetry)

Consider a functional $F[\mathbf{y}] = \int_{\alpha}^{\beta} f(y_i, y'_i, x) \, dx$. A **one-parameter family of transformations** is a smooth map

$$y_i(x) \mapsto Y_i(x, s), \quad Y_i(x, 0) = y_i(x),$$

for s in some interval around 0. It is a **continuous symmetry** of f if

$$\frac{\partial}{\partial s} f(Y_i(x, s), Y'_i(x, s), x) = 0$$

for all s , where $' = \partial/\partial x$ as usual.

Theorem 23.7.8 (Noether's Theorem)

Let $Y_i(x, s)$ be a continuous symmetry of f . Then, along any solution of the Euler–Lagrange equations,

$$\sum_{i=1}^n \frac{\partial f}{\partial y'_i} \frac{\partial Y_i}{\partial s} \bigg|_{s=0}$$

is constant, i.e. it is a first integral.

Proof. The proof is three lines of chain rule, and is worth following carefully. Using the summation convention, and evaluating everything at $s = 0$,

$$\begin{aligned}
 0 &= \left. \frac{\partial f}{\partial s} \right|_{s=0} \\
 &= \left. \frac{\partial f}{\partial y_i} \frac{\partial Y_i}{\partial s} \right|_{s=0} + \left. \frac{\partial f}{\partial y'_i} \frac{\partial Y'_i}{\partial s} \right|_{s=0} \\
 &= \left[\frac{d}{dx} \left(\frac{\partial f}{\partial y'_i} \right) \frac{\partial Y_i}{\partial s} + \frac{\partial f}{\partial y'_i} \frac{d}{dx} \left(\frac{\partial Y_i}{\partial s} \right) \right] \Big|_{s=0} \\
 &= \frac{d}{dx} \left[\frac{\partial f}{\partial y'_i} \frac{\partial Y_i}{\partial s} \right] \Big|_{s=0}.
 \end{aligned}$$

In the third line we used the Euler–Lagrange equation to replace $\partial f/\partial y_i$, and swapped the order of the mixed partial derivatives $\partial_s \partial_x = \partial_x \partial_s$; the last line is the product rule read backwards. Integrating, the bracket is constant. $\square$

The statement is short but the content is remarkable: *every continuous symmetry of a physical system yields a conserved quantity*. Let us see it work.

Example 23.7.9 (Conservation of Momentum)

Let $\mathbf{y} = (y, z)$ and

$$f = \frac{1}{2}(y')^2 + \frac{1}{2}(z')^2 - V(y - z),$$

which describes two particles interacting through a potential depending only on their separation. Consider translating both by the same amount:

$$Y = y + s, \quad Z = z + s.$$

Then $Y' = y'$, $Z' = z'$, and $Y - Z = y - z$, so f is unchanged and this is a symmetry. Since $\partial Y/\partial s = \partial Z/\partial s = 1$, Noether's theorem gives the first integral

$$\frac{\partial f}{\partial y'} \cdot 1 + \frac{\partial f}{\partial z'} \cdot 1 = y' + z' = \text{constant},$$

which is conservation of total momentum. The physical statement is that space is homogeneous – it does not matter *where* the experiment is performed.

Example 23.7.10 (Conservation of Angular Momentum)

Take the central force Lagrangian $L = \frac{1}{2}m(\dot{r}^2 + r^2\dot{\theta}^2) - V(r)$ and the rotation

$$R = r, \quad \Theta = \theta + s.$$

This leaves L unchanged since L does not involve θ , so it is a symmetry, and Noether's theorem gives

$$\frac{\partial L}{\partial \dot{r}} \cdot 0 + \frac{\partial L}{\partial \dot{\theta}} \cdot 1 = mr^2\dot{\theta} = \text{constant},$$

as we found before. The physical statement is that space is isotropic.

Remark. Conservation of energy also comes from a symmetry – invariance under time translation – but this is a symmetry of the *independent* variable rather than the dependent ones, and so is not literally covered by the version of Noether’s theorem we proved. In our framework it appears instead as the Beltrami identity, which is the same statement in disguise. A more general version of Noether’s theorem handles both at once.

§23.7.4 The Hamiltonian

We saw in Proposition 23.4.7 that when L has no explicit time dependence, the quantity

$$H = \sum_i \dot{q}_i \frac{\partial L}{\partial \dot{q}_i} - L = \sum_i p_i \dot{q}_i - L$$

is conserved. But look at the right hand side: this is exactly the Legendre transform of L with respect to $\dot{\mathbf{q}}$.

Definition 23.7.11 (Hamiltonian)

The **Hamiltonian** is the Legendre transform of the Lagrangian in the velocities,

$$H(\mathbf{q}, \mathbf{p}, t) = \sup_{\mathbf{v}} (\mathbf{p} \cdot \mathbf{v} - L(\mathbf{q}, \mathbf{v}, t)) = \mathbf{p} \cdot \dot{\mathbf{q}} - L,$$

where $\dot{\mathbf{q}}$ is expressed in terms of $\mathbf{p}$ by inverting $p_i = \partial L / \partial \dot{q}_i$.

Convexity of L in $\dot{\mathbf{q}}$ – which for $T = \frac{1}{2}m|\dot{\mathbf{q}}|^2$ is automatic – is exactly what guarantees this inversion is possible, and this is why we spent time on the Legendre transform earlier.

Example 23.7.12

Take $L = \frac{1}{2}m|\dot{\mathbf{q}}|^2 - V(\mathbf{q})$. Then $\mathbf{p} = \partial L / \partial \dot{\mathbf{q}} = m\dot{\mathbf{q}}$, so $\dot{\mathbf{q}} = \mathbf{p}/m$, and

$$\begin{aligned} H &= \mathbf{p} \cdot \frac{\mathbf{p}}{m} - \left(\frac{1}{2}m \frac{|\mathbf{p}|^2}{m^2} - V(\mathbf{q}) \right) \\ &= \frac{|\mathbf{p}|^2}{2m} + V(\mathbf{q}) = T + V. \end{aligned}$$

So the Hamiltonian is the total energy – but expressed in terms of momentum rather than velocity, which is the whole point.

The change of variables from $(\mathbf{q}, \dot{\mathbf{q}})$ to $(\mathbf{q}, \mathbf{p})$ does more than tidy the energy; it transforms the equations of motion into a strikingly symmetric first-order system.

Theorem 23.7.13 (Hamilton’s Equations)

If L satisfies the Euler–Lagrange equations, then

$$\dot{q}_i = \frac{\partial H}{\partial p_i}, \quad \dot{p}_i = -\frac{\partial H}{\partial q_i}, \quad \frac{\partial H}{\partial t} = -\frac{\partial L}{\partial t}.$$

Proof. The slick proof is to compute the differential of $H = p_i \dot{q}_i - L$ in two ways. Regarding H as a function of $(\mathbf{q}, \mathbf{p}, t)$,

$$dH = \frac{\partial H}{\partial q_i} dq_i + \frac{\partial H}{\partial p_i} dp_i + \frac{\partial H}{\partial t} dt.$$

On the other hand, differentiating $p_i \dot{q}_i - L(\mathbf{q}, \dot{\mathbf{q}}, t)$ directly,

$$dH = p_i d\dot{q}_i + \dot{q}_i dp_i - \frac{\partial L}{\partial q_i} dq_i - \frac{\partial L}{\partial \dot{q}_i} d\dot{q}_i - \frac{\partial L}{\partial t} dt.$$

The first and fourth terms cancel, since $p_i = \partial L / \partial \dot{q}_i$ – this cancellation is the magic of the Legendre transform, and it is why H genuinely is a function of $\mathbf{p}$ and not of $\dot{\mathbf{q}}$. For the third term, the Euler–Lagrange equation gives

$$\frac{\partial L}{\partial q_i} = \frac{d}{dt} \frac{\partial L}{\partial \dot{q}_i} = \dot{p}_i.$$

So

$$dH = \dot{q}_i dp_i - \dot{p}_i dq_i - \frac{\partial L}{\partial t} dt,$$

and comparing coefficients with the first expression gives the result. $\square$

Example 23.7.14 (The Harmonic Oscillator in Phase Space)

Take $L = \frac{1}{2}m\dot{q}^2 - \frac{1}{2}m\omega^2 q^2$. Then $p = m\dot{q}$, and

$$H = \frac{p^2}{2m} + \frac{1}{2}m\omega^2 q^2.$$

Hamilton's equations are

$$\dot{q} = \frac{\partial H}{\partial p} = \frac{p}{m}, \quad \dot{p} = -\frac{\partial H}{\partial q} = -m\omega^2 q,$$

which combine to give $\ddot{q} = -\omega^2 q$ as expected. But the first-order form has an advantage: since H is conserved, every trajectory lies on a level set of H , that is, on an ellipse

$$\frac{p^2}{2m} + \frac{1}{2}m\omega^2 q^2 = E$$

in the (q, p) plane. We can therefore read off the qualitative behaviour of every solution – they all go round and round – without solving anything at all. This is the typical use of the Hamiltonian formulation: it turns dynamics into geometry in phase space.

We have traded n second-order equations for $2n$ first-order ones, which carry the same amount of information (the same number of constants of integration). The space of pairs $(\mathbf{q}, \mathbf{p})$ is called **phase space**, and solutions of Hamilton's equations are *trajectories* in it. The symmetry between q and p in these equations – broken only by a minus sign – is the starting point of a very rich theory, and it is the form of mechanics which passes most directly into quantum mechanics.

Remark. Hamilton's equations can also be obtained variationally, which is rather sat-

isfying. Consider the functional on phase space

$$S[\mathbf{q}, \mathbf{p}] = \int_{t_1}^{t_2} (p_i \dot{q}_i - H(\mathbf{q}, \mathbf{p}, t)) \, dt,$$

and treat $\mathbf{q}$ and $\mathbf{p}$ as independent. Since the integrand contains no $\dot{p}_i$, the Euler–Lagrange equation for p_i is simply $\partial f / \partial p_i = 0$, giving $\dot{q}_i = \partial H / \partial p_i$. The equation for q_i gives $-\partial H / \partial q_i - dp_i / dt = 0$, which is the second of Hamilton’s equations.

§23.8 Eigenvalue Problems and the Rayleigh–Ritz Method

We now return to constrained variational problems, and to an application which is of great practical importance: estimating eigenvalues. The key observation is that eigenvalues of certain differential operators are the minima of an associated functional – and because minima are easy to bound from above (just guess something!), this gives a genuinely useful computational method.

§23.8.1 The Sturm–Liouville Problem

Example 23.8.1 (The Sturm–Liouville Problem)

Let $\rho(x) > 0$ be some known function for $x \in [\alpha, \beta]$, and let $\sigma(x)$ be another function. We consider the functional

$$F[y] = \int_{\alpha}^{\beta} [\rho \cdot (y')^2 + \sigma \cdot y^2] \, dx,$$

and we want to minimize F subject to the normalisation

$$G[y] = \int_{\alpha}^{\beta} y^2 \, dx = 1,$$

and the boundary conditions $y(\alpha) = y(\beta) = 0$.

We define the functional

$$\Phi[y; \lambda] = F[y] - \lambda (G[y] - 1),$$

whose integrand is $h = \rho(y')^2 + \sigma y^2 - \lambda y^2$ (plus a constant, which does not affect the equations). Then

$$\frac{\partial h}{\partial y'} = 2\rho y', \quad \frac{\partial h}{\partial y} = 2\sigma y - 2\lambda y,$$

and the Euler–Lagrange equation $\frac{d}{dx}(\partial h / \partial y') = \partial h / \partial y$ becomes, after dividing by 2,

$$-\frac{d}{dx} \left(\rho \frac{dy}{dx} \right) + \sigma y = \lambda y.$$

Writing $\mathcal{L}$ for the operator on the left, this is

$$\mathcal{L}y = \lambda y,$$

an eigenvalue problem, and $\mathcal{L}$ is the **Sturm–Liouville operator** familiar from the Methods course^a. So the Lagrange multiplier of our constrained problem is precisely the eigenvalue.

If $\rho = 1$ this is the time-independent Schrödinger equation with potential σ , which we will return to shortly.

^aThe reader who wants the full theory – self-adjointness, orthogonality and completeness of the eigenfunctions, and the eigenfunction expansion – is referred to the Sturm–Liouville chapter of my Methods notes. We will use those facts here without proof.

This connection is worth stating as a theorem, because it is the engine of everything that follows.

Theorem 23.8.2 (Eigenvalues as Minima)

Let $\mathcal{L}y = -(\rho y')' + \sigma y$ with $\rho > 0$, acting on functions with $y(\alpha) = y(\beta) = 0$, and let its eigenvalues be $\lambda_1 \leq \lambda_2 \leq \dots$ with eigenfunctions $y_1, y_2, \dots$. Define the **Rayleigh quotient**

$$\mathcal{R}[y] = \frac{F[y]}{G[y]} = \frac{\int_{\alpha}^{\beta} (\rho(y')^2 + \sigma y^2) \, dx}{\int_{\alpha}^{\beta} y^2 \, dx}.$$

Then $\lambda_1 = \min \mathcal{R}[y]$, the minimum being over all admissible $y \neq 0$, and it is attained at $y = y_1$.

Proof. First, note that $\mathcal{R}$ is unaffected by scaling y , so we may as well impose $G[y] = 1$; then $\mathcal{R}[y] = F[y]$.

Suppose y is a stationary point of F subject to $G = 1$, with multiplier λ . Multiplying the Euler–Lagrange equation $-(\rho y')' + \sigma y = \lambda y$ by y and integrating,

$$\int_{\alpha}^{\beta} (-y(\rho y')' + \sigma y^2) \, dx = \lambda \int_{\alpha}^{\beta} y^2 \, dx = \lambda.$$

Integrating the first term by parts,

$$\int_{\alpha}^{\beta} (\rho(y')^2 + \sigma y^2) \, dx - [y\rho y']_{\alpha}^{\beta} = \lambda,$$

the boundary term vanishing since $y(\alpha) = y(\beta) = 0$. So $F[y] = \lambda$: *the value of the functional at a stationary point is the corresponding eigenvalue*. Hence the smallest value of $\mathcal{R}$ over stationary points is the smallest eigenvalue.

It remains to see that the minimum over *all* y is attained at a stationary point, which follows by expanding an arbitrary y in the eigenfunctions. Writing $y = \sum_n c_n y_n$ with the y_n orthonormal (which we may do by the completeness of the eigenfunctions, proved in the Methods course), the same integration by parts gives

$$F[y] = \sum_n \lambda_n c_n^2, \quad G[y] = \sum_n c_n^2,$$

so that

$$\mathcal{R}[y] = \frac{\sum_n \lambda_n c_n^2}{\sum_n c_n^2} \geq \lambda_1,$$

since every $\lambda_n \geq \lambda_1$. Equality holds exactly when $c_n = 0$ for all n with $\lambda_n > \lambda_1$, i.e. when y is a ground state. $\square$

The last display deserves emphasis. It says that $\mathcal{R}[y]$ is a *weighted average* of the eigenvalues, with weights c_n^2 given by how much of each eigenfunction y contains. An average of numbers is at least the smallest of them, and that is the entire content of the variational principle.

§23.8.2 The Rayleigh–Ritz Method

Here is the practical consequence. Suppose we cannot solve $\mathcal{L}y = \lambda y$ exactly, but we would like to know λ_1 . By [Theorem 23.8.2](#), *any* admissible function y we care to write down gives an upper bound

$$\lambda_1 \leq \mathcal{R}[y].$$

So we take a **trial function** y depending on a few free parameters, compute $\mathcal{R}[y]$, and minimise over the parameters. This is the **Rayleigh–Ritz method**. The more parameters we allow, the better the bound – and the bound is always from above, so we always know which way we are wrong.

Example 23.8.3

Let us estimate the lowest eigenvalue of $-y'' = \lambda y$ on $[0, 1]$ with $y(0) = y(1) = 0$. Of course we know the answer is $\lambda_1 = \pi^2 \approx 9.8696$, which makes this a good test.

Take the simplest trial function vanishing at both ends, $y = x(1 - x)$. Then $y' = 1 - 2x$, and

$$\int_0^1 (y')^2 dx = \int_0^1 (1 - 2x)^2 dx = \frac{1}{3}, \quad \int_0^1 y^2 dx = \int_0^1 x^2(1 - x)^2 dx = \frac{1}{30}.$$

So

$$\lambda_1 \leq \frac{1/3}{1/30} = 10.$$

This is within 1.5% of the true value, from a one-line calculation with a function that is not even the right shape. The reason the method works so well is that $\mathcal{R}$ is *stationary* at y_1 , so an error of size ϵ in the trial function produces an error of only $O(\epsilon^2)$ in the estimate.

If we want to do better we can add a parameter. Taking $y = x(1-x)(1+ax)$ and minimising over a gives $\lambda_1 \leq 9.8697$, correct to four decimal places.

Remark. The method extends to higher eigenvalues. Since $\mathcal{R}[y] = \sum \lambda_n c_n^2 / \sum c_n^2$, if we restrict to trial functions orthogonal to y_1 (so $c_1 = 0$) then the same argument gives $\lambda_2 = \min \mathcal{R}[y]$ over that restricted class, and so on. In practice one rarely knows y_1 exactly, which limits the usefulness – but symmetry often helps. For instance, if the problem is symmetric about the midpoint then y_1 is even, so any odd trial function is automatically orthogonal to it and bounds λ_2 .

§23.8.3 Inequalities from Variational Principles

The Rayleigh quotient can be read in the other direction. Instead of using known eigenvalues to bound $\mathcal{R}$, we can use a known eigenvalue to prove an inequality about *all* functions – and some rather famous inequalities arise this way.

Theorem 23.8.4 (Poincaré–Wirtinger Inequality)

Let $y \in C^1[0, L]$ with $y(0) = y(L) = 0$. Then

$$\int_0^L (y')^2 dx \geq \frac{\pi^2}{L^2} \int_0^L y^2 dx,$$

with equality if and only if $y = A \sin(\pi x/L)$.

Proof. Take $\rho = 1$ and $\sigma = 0$ in Theorem 23.8.2, so that $\mathcal{L}y = -y''$. The eigenvalue problem $-y'' = \lambda y$ with $y(0) = y(L) = 0$ has solutions $y_n = \sin(n\pi x/L)$ with $\lambda_n = n^2\pi^2/L^2$, so the smallest eigenvalue is $\lambda_1 = \pi^2/L^2$. The theorem then says

$$\frac{\int_0^L (y')^2 dx}{\int_0^L y^2 dx} = \mathcal{R}[y] \geq \lambda_1 = \frac{\pi^2}{L^2}$$

for every admissible y , which is the claim. Equality requires y to be a ground state, i.e. a multiple of $\sin(\pi x/L)$. $\square$

This is a genuinely useful inequality – it says that a function pinned to zero at both ends cannot be large without also having a large derivative somewhere – and it would be distinctly awkward to prove by hand. The constant π^2/L^2 is sharp precisely because it is an eigenvalue.

Remark. The same trick with $\rho = 1$ and a nonzero σ gives a whole family of inequalities, one for each Sturm–Liouville problem whose spectrum we happen to know. It is also how one proves the isoperimetric inequality analytically: writing the perimeter and area of a closed curve as Fourier series and applying Wirtinger’s inequality on $[0, 2\pi]$ gives $L^2 \geq 4\pi A$ directly, with equality only for a circle – which is the rigorous version of the calculation we did in Example 23.5.9.

§23.8.4 The Variational Principle in Quantum Mechanics

The most celebrated application of all this is to quantum mechanics, where the eigenvalue problem is the time-independent Schrödinger equation

$$\hat{H}\psi = E\psi, \quad \hat{H} = -\frac{\hbar^2}{2m}\nabla^2 + V(\mathbf{x}),$$

and the eigenvalues E_n are the allowed energies of the system. Taking $\rho = \hbar^2/2m$ and $\sigma = V$ in our Sturm–Liouville problem, the Rayleigh quotient is

$$\mathcal{R}[\psi] = \frac{\int \left(\frac{\hbar^2}{2m} |\nabla\psi|^2 + V|\psi|^2 \right) dV}{\int |\psi|^2 dV} = \frac{\langle \psi | \hat{H} | \psi \rangle}{\langle \psi | \psi \rangle},$$

which the reader will recognise from the Quantum Mechanics course as the expectation value of the energy in the state ψ , written $\langle \hat{H} \rangle_\psi$ in the notation of my Quantum Mechanics notes.

Theorem 23.8.5 (Variational Principle for the Ground State)

For any normalisable ψ ,

$$E_0 \leq \frac{\langle \psi | \hat{H} | \psi \rangle}{\langle \psi | \psi \rangle},$$

where E_0 is the ground state energy.

The proof is [Theorem 23.8.2](#) verbatim. Physically the statement is almost obvious – the average energy of any state is at least the lowest available energy – but as a computational tool it is invaluable, since the Schrödinger equation can be solved exactly for only a handful of potentials.

Example 23.8.6 (A Bound for the Hydrogen Atom)

The ground state of hydrogen satisfies (in the s -wave sector, with $u = r\psi$)

$$-\frac{\hbar^2}{2m} \frac{d^2u}{dr^2} - \frac{e^2}{4\pi\epsilon_0 r} u = Eu, \quad u(0) = 0.$$

Take the trial function $u = re^{-r/a}$ with a a free parameter. The required integrals are all of the form $\int_0^\infty r^n e^{-2r/a} dr = n! (a/2)^{n+1}$, and after some computation one finds

$$\mathcal{R}[u] = \frac{\hbar^2}{2ma^2} - \frac{e^2}{4\pi\epsilon_0 a}.$$

Minimising over a gives $a = 4\pi\epsilon_0\hbar^2/me^2$, the Bohr radius, and

$$E_0 \leq -\frac{me^4}{2(4\pi\epsilon_0)^2\hbar^2},$$

which is in fact the exact ground state energy – because our trial function happened to be the exact eigenfunction. The lesson is that a good guess, informed by the physics, can be very good indeed; and even a poor guess gives a rigorous bound.

§23.9 The Second Variation

We have been calling solutions of the Euler–Lagrange equation ‘extrema’, but of course they are only stationary points. It is time to make good on the promise to determine their nature, by looking at the $O(\epsilon^2)$ term we discarded.

§23.9.1 Computing the Second Variation

Let y solve the Euler–Lagrange equation for $F[y] = \int_{\alpha}^{\beta} f(x, y, y') \, dx$, and perturb by $\epsilon\eta$ with η vanishing at the endpoints. Expanding f to second order in its last two arguments,

$$\begin{aligned} F[y + \epsilon\eta] - F[y] &= \epsilon \underbrace{\int_{\alpha}^{\beta} \eta \left(\frac{\partial f}{\partial y} - \frac{d}{dx} \frac{\partial f}{\partial y'} \right) dx}_{=0 \text{ by Euler–Lagrange}} \\ &\quad + \frac{\epsilon^2}{2} \int_{\alpha}^{\beta} \left(\eta^2 \frac{\partial^2 f}{\partial y^2} + 2\eta\eta' \frac{\partial^2 f}{\partial y \partial y'} + (\eta')^2 \frac{\partial^2 f}{\partial (y')^2} \right) dx + O(\epsilon^3). \end{aligned}$$

The coefficient of ϵ^2 is called the **second variation**, written $\delta^2 F[y]$. We can simplify it: noting that $2\eta\eta' = \frac{d}{dx}(\eta^2)$ and integrating that term by parts (the boundary term vanishing as η does),

$$\int_{\alpha}^{\beta} \frac{d(\eta^2)}{dx} \frac{\partial^2 f}{\partial y \partial y'} \, dx = - \int_{\alpha}^{\beta} \eta^2 \frac{d}{dx} \left(\frac{\partial^2 f}{\partial y \partial y'} \right) \, dx,$$

so that

$$\boxed{\delta^2 F[y] = \frac{1}{2} \int_{\alpha}^{\beta} (P(\eta')^2 + Q\eta^2) \, dx}$$

where

$$P = \frac{\partial^2 f}{\partial (y')^2}, \quad Q = \frac{\partial^2 f}{\partial y^2} - \frac{d}{dx} \left(\frac{\partial^2 f}{\partial y \partial y'} \right),$$

both evaluated along the solution y . This is the analogue of the Hessian from [subsection 23.2.2](#), and the same logic applies: if $\delta^2 F[y] > 0$ for all admissible $\eta \neq 0$, then y is a local minimum.

Proposition 23.9.1

If y solves the Euler–Lagrange equation and $P > 0$, $Q \geq 0$ along y , then y is a local minimum of F .

Proof. Under these hypotheses the integrand $P(\eta')^2 + Q\eta^2$ is non-negative, and vanishes identically only if $\eta' \equiv 0$; combined with $\eta(\alpha) = 0$ this forces $\eta \equiv 0$. So $\delta^2 F[y] > 0$ for every $\eta \neq 0$. $\square$

Example 23.9.2 (Geodesics in the Plane)

For $f = \sqrt{1 + (y')^2}$ we have $\partial f / \partial y = 0$, so $Q = 0$, and

$$P = \frac{\partial}{\partial y'} \left(\frac{y'}{\sqrt{1 + (y')^2}} \right) = \frac{1}{(1 + (y')^2)^{3/2}} > 0.$$

So every solution of the Euler–Lagrange equation – that is, every straight line – is a local minimum of length. This confirms what we always believed.

Example 23.9.3 (The Brachistochrone)

For $f = \sqrt{(1 + (y')^2)/(-y)}$ a slightly longer computation gives

$$P = \frac{1}{(1 + (y')^2)^{3/2} \sqrt{-y}} > 0, \quad Q = \frac{1}{4\sqrt{1 + (y')^2} (-y)^{5/2}} > 0$$

on the region $y < 0$ where the problem makes sense. So the cycloid really is a local minimum of the travel time, as Bernoulli claimed.

Example 23.9.4 (A Maximum)

It is worth seeing the other sign at least once. Consider

$$F[y] = \int_0^1 (y^2 - (y')^2) \, dx, \quad y(0) = y(1) = 0.$$

The Euler–Lagrange equation is $y'' + y = 0$, and with these boundary conditions on an interval of length $1 < \pi$ the only solution is $y \equiv 0$. Here

$$P = -2 < 0, \quad Q = 2 > 0,$$

so the Legendre condition for a minimum fails everywhere; applying the proposition above to $-F$ (for which $P = 2 > 0$ and $Q = -2$) is not immediately conclusive either. But we can settle it directly: for any η vanishing at the endpoints, the Poincaré–Wirtinger inequality of [section 23.8](#) gives $\int_0^1 (\eta')^2 \geq \pi^2 \int_0^1 \eta^2 > \int_0^1 \eta^2$, so

$$\delta^2 F[0] = \frac{1}{2} \int_0^1 (2\eta^2 - 2(\eta')^2) \, dx < 0$$

for every $\eta \neq 0$. So $y \equiv 0$ is a local *maximum*. Notice how the sharp constant π^2 did the work: had the interval been longer than π , the inequality would have gone the other way for some η and we would have had a saddle instead.

§23.9.2 The Legendre Condition

The examples above were lucky, in that P and Q were both of a good sign. What if $Q < 0$ and $P > 0$? It turns out that P is much more important than Q , for the following reason.

Proposition 23.9.5 (Legendre Condition)

If y_0 is a local minimum of F , then $P \geq 0$ along y_0 .

Proof (sketch). Suppose $P(x_0) < 0$ for some x_0 . We construct an η which is very small everywhere – so its $Q\eta^2$ contribution is negligible – but which oscillates extremely rapidly near x_0 , so that η' is large. Concretely, take η supported on a small

interval of width δ around x_0 and of amplitude δ ; then $\eta^2 \sim \delta^2$ while $(\eta')^2 \sim 1$, so on integrating over the interval, the Q term contributes $O(\delta^3)$ and the P term contributes $O(\delta) < 0$. For small enough δ the P term wins and $\delta^2 F[y_0] < 0$, contradicting minimality. $\square$

So $P \geq 0$ is *necessary* for a minimum. It is not sufficient, as the following example shows – and understanding why not is the last piece of the theory.

Example 23.9.6

Consider

$$F[y] = \int_0^\beta ((y')^2 - y^2) \, dx, \quad y(0) = y(\beta) = 0,$$

where we suppose $\beta \neq k\pi$ for integers k . The Euler–Lagrange equation is $y'' + y = 0$, whose general solution is $A \sin x + B \cos x$; imposing the boundary conditions with $\beta \neq k\pi$ forces $A = B = 0$, so the only stationary point is $y \equiv 0$, at which $F = 0$.

Here $P = 2 > 0$ and $Q = -2 < 0$, so the Legendre condition is satisfied but our sufficient condition is not. Is $y \equiv 0$ a minimum? Consider the trial variation $\eta = A \sin(\pi x/\beta)$, which vanishes at both ends. Then

$$\delta^2 F[0] = \int_0^\beta ((\eta')^2 - \eta^2) \, dx = A^2 \left(\frac{\pi^2}{\beta^2} - 1 \right) \frac{\beta}{2},$$

using $\int_0^\beta \sin^2(\pi x/\beta) \, dx = \int_0^\beta \cos^2(\pi x/\beta) \, dx = \beta/2$. This is negative precisely when $\beta > \pi$.

So $y \equiv 0$ fails to be a minimum as soon as the interval is *too long*. This is a genuinely new phenomenon: the local data (P and Q) is the same for all β , and yet the answer changes. What matters is a global property of the interval.

§23.9.3 The Jacobi Accessory Condition

Legendre attempted to prove that $P > 0$ implies local minimality; the example above shows this cannot work, but his method can be repaired into a genuine sufficient condition.

The idea is to complete the square. Let ϕ be any differentiable function on $[\alpha, \beta]$. Since η vanishes at both endpoints,

$$\int_\alpha^\beta \frac{d}{dx} (\phi \eta^2) \, dx = 0 \implies \int_\alpha^\beta (\phi' \eta^2 + 2\phi \eta \eta') \, dx = 0.$$

We may add this zero to the second variation without changing anything:

$$\delta^2 F[y] = \frac{1}{2} \int_\alpha^\beta (P(\eta')^2 + 2\phi \eta \eta' + (Q + \phi') \eta^2) \, dx.$$

Now suppose $P > 0$. Then we can complete the square in η' :

$$\delta^2 F[y] = \frac{1}{2} \int_\alpha^\beta \left(P \left(\eta' + \frac{\phi}{P} \eta \right)^2 + \left(Q + \phi' - \frac{\phi^2}{P} \right) \eta^2 \right) \, dx.$$

If we could choose ϕ to make the second bracket vanish identically, the integrand would be a perfect square, and we would be done – for then $\delta^2 F[y] \geq 0$, with equality only if

$$\eta' + \frac{\phi}{P}\eta \equiv 0.$$

This is a first-order linear ODE for η with $\eta(\alpha) = 0$, so by uniqueness of solutions $\eta \equiv 0$. Hence $\delta^2 F[y] > 0$ for all $\eta \neq 0$, and y is a local minimum.

So everything hinges on solving

$$\phi^2 = P(Q + \phi'),$$

a nonlinear (Riccati) equation for ϕ . The standard trick linearises it: substitute

$$\phi = -P \frac{u'}{u}$$

for some function u with $u \neq 0$ on $[\alpha, \beta]$. Then $\phi^2/P = P(u'/u)^2$ and

$$\phi' = -\left(\frac{Pu'}{u}\right)' = -\frac{(Pu')'}{u} + P\left(\frac{u'}{u}\right)^2,$$

so the equation $\phi^2/P = Q + \phi'$ becomes

$$P\left(\frac{u'}{u}\right)^2 = Q - \frac{(Pu')'}{u} + P\left(\frac{u'}{u}\right)^2,$$

and after cancelling and multiplying by u we are left with the following.

Theorem 23.9.7 (Jacobi Accessory Condition)

Let y solve the Euler–Lagrange equation with $P > 0$ along y . If the **Jacobi accessory equation**

$$-(Pu')' + Qu = 0$$

has a solution u with $u \neq 0$ everywhere on $[\alpha, \beta]$, then $\delta^2 F[y] > 0$ and y is a local minimum of F .

The reader will notice that the left hand side is $\mathcal{L}u$, where $\mathcal{L}$ is exactly the Sturm–Liouville operator from [section 23.8](#). This is not a coincidence: integrating the second variation by parts once more gives

$$\delta^2 F[y] = \frac{1}{2} \int_{\alpha}^{\beta} \eta [-(P\eta')' + Q\eta] \, dx = \frac{1}{2} \int_{\alpha}^{\beta} \eta \mathcal{L}\eta \, dx,$$

so the question of whether $\delta^2 F$ is positive is precisely the question of whether $\mathcal{L}$ has any negative eigenvalues. In particular, if there is an η with $\mathcal{L}\eta = -\omega^2\eta$ and $\eta(\alpha) = \eta(\beta) = 0$, then $\delta^2 F[y] = -\frac{\omega^2}{2} \int \eta^2 < 0$ and y is not a minimum.

The condition ‘ $u \neq 0$ on $[\alpha, \beta]$ ’ has a name: a point $x^* > \alpha$ at which the solution u with $u(\alpha) = 0$ vanishes again is called a **conjugate point** to α . The Jacobi condition says that a stationary path is a local minimum provided no conjugate point occurs before we reach β – which is exactly the ‘interval too long’ phenomenon of [Example 23.9.6](#).

Example 23.9.8

Return to $F[y] = \frac{1}{2} \int_{\alpha}^{\beta} ((y')^2 - y^2) \, dx$, so $P = 1$ and $Q = -1$. The Jacobi accessory equation is

$$u'' + u = 0 \implies u = A \sin x + B \cos x.$$

We need this to be nonvanishing on $[\alpha, \beta]$, that is, $\tan x \neq -B/A$ throughout. Since $\tan$ takes every value once per interval of length π , such a choice of A, B is possible if and only if

$$|\beta - \alpha| < \pi.$$

This is exactly the condition we found by hand in [Example 23.9.6](#), now derived systematically.

Example 23.9.9 (Geodesics on the Sphere, Revisited)

We can finally settle which arcs of a great circle are minimising. Parameterizing the sphere as before, the length functional is

$$F[\theta] = \int \sqrt{(\theta')^2 + \sin^2 \theta} \, d\phi,$$

where now θ is a function of ϕ . Every great circle can be rotated to the equator, so consider the stationary path $\theta_0 \equiv \pi/2$, and let ϕ run from ϕ_1 to ϕ_2 .

Writing $f = \sqrt{(\theta')^2 + \sin^2 \theta}$ and evaluating along $\theta_0 = \pi/2$ (where $\theta' = 0$ and $\sin \theta_0 = 1$), we get $f = 1$ and

$$P = \frac{\partial^2 f}{\partial (\theta')^2} = 1, \quad Q = \frac{\partial^2 f}{\partial \theta^2} = -1,$$

so that

$$\delta^2 F \left[\frac{\pi}{2} \right] = \frac{1}{2} \int_{\phi_1}^{\phi_2} ((\eta')^2 - \eta^2) \, d\phi,$$

which is exactly the functional of the previous example. Hence the arc is a local minimum if and only if

$$|\phi_2 - \phi_1| < \pi,$$

that is, if and only if it is the *minor* arc. The major arc is a stationary point which is not a minimum, exactly as we suspected. If $|\phi_2 - \phi_1| = \pi$ the endpoints are antipodal, the conjugate point is reached precisely at the end, and correspondingly there is a whole circle's worth of geodesics of the same length – the degeneracy showing up as the vanishing of the second variation along the family.

Example 23.9.10 (Soap Films Revisited)

We can now say something about the promise made in [subsection 23.6.1](#). There we found that for rings of radius $c > c_*$ there are two catenoids,

$$y = y_0 \cosh \left(\frac{x}{y_0} \right),$$

one with $y_0 > \mu$ and one with $y_0 < \mu$, where $\mu \approx 0.833$ is the location of the minimum of $\Psi(y_0) = y_0 \cosh(1/y_0)$.

For the area integrand $f = y\sqrt{1 + (y')^2}$ we compute

$$P = \frac{\partial^2 f}{\partial (y')^2} = \frac{y}{(1 + (y')^2)^{3/2}} > 0,$$

so the Legendre condition is satisfied by both catenoids, and we cannot distinguish them that way. The distinction lies in the Jacobi accessory equation, and it is exactly the conjugate point phenomenon: for the fat catenoid, the solution u of $-(Pu')' + Qu = 0$ vanishing at $x = -\beta$ stays nonzero all the way to $x = \beta$, whereas for the thin one a conjugate point occurs strictly inside the interval. Hence the fat catenoid is a local minimum and the thin one is not – it is a saddle, and any real soap film would collapse away from it.

One can make this concrete without solving the Jacobi equation, by noticing that the family of catenoids through the left-hand ring is a one-parameter family of solutions, and that a conjugate point is precisely a place where two nearby members of the family meet. Geometrically, the catenaries through a fixed point have an *envelope*, and the conjugate point is where the extremal touches it. Inside the envelope there are two catenaries to each point (our fat and thin solutions); outside there are none – which is exactly the trichotomy we found by looking at Ψ .

Remark. The reader who found the Jacobi condition to be a lot of machinery for a small return should compare it with the situation in finite dimensions. There, ‘ H positive definite at a stationary point’ is both necessary (up to semi-definiteness) and sufficient for a local minimum, and there is nothing more to say. The reason infinite dimensions are harder is precisely the phenomenon of [Example 23.9.6](#): the quadratic form $\delta^2 F$ can be positive on every ‘direction’ we happen to test and still fail to be positive definite, because the relevant operator has a continuum of directions to be negative in. Conjugate points are the bookkeeping which detects this.

This is a good place to stop. We began with a question about a bead sliding down a wire, and we have ended with a criterion, in terms of conjugate points on a sphere, for a path to be genuinely shortest. Along the way the same three-step argument – perturb, integrate by parts, apply the fundamental lemma – produced the equations of geometry, of optics, and of mechanics. That a single piece of calculus should reach so far is, to this author at least, the most attractive thing about the subject.

III

Part II

About Part II

Part II is where the degree stops being a degree and becomes a menu. There are around forty courses on offer and no obligation to take any particular one, so no two students in the year sit the same set. The twenty-one chapters here are the ones I took, and they are not a syllabus so much as a set of choices; another student's Part II could overlap with this one in three courses and be no less complete.

The change in character is real, and it is not only about choice. Part IB abstracted the objects of Part IA; Part II mostly stops abstracting and starts going deep. A typical course here takes one idea and follows it for twenty-four lectures until it arrives somewhere that would have been unimaginable two years earlier – Galois Theory begins with field extensions and ends by proving that the general quintic is not soluble by radicals; Algebraic Geometry begins with the zero set of a polynomial and ends at the Riemann–Roch theorem; Algebraic Topology begins with loops in a space and ends by proving that $\mathbb{R}^m \cong \mathbb{R}^n$ forces $m = n$. The courses also stop being polite to one another. In Part IB every course could reasonably assume every other; in Part II a lecturer has to assume a specific list, and the list is short.

The algebraic strand is the one that most obviously pays off. Groups, Rings and Modules splits into four: Galois Theory, which turns questions about polynomials into questions about finite groups; Representation Theory, which turns questions about finite groups into questions about matrices, and gets character tables and Burnside's theorem out of it; Number Fields, which repairs unique factorisation in rings of algebraic integers by replacing elements with ideals; and Algebraic Geometry, which builds a dictionary between ideals and varieties and then uses it relentlessly. Number Theory sits slightly below these, elementary in its methods and enormously useful in its results, and feeds both Number Fields and Coding and Cryptography.

The analytic strand pulls in the opposite direction, towards infinite dimensions. Linear Analysis is what happens when linear algebra is done on a Banach space, and its three great theorems – Hahn–Banach, Baire category and the consequences of completeness – are the tools of everything after it. Probability and Measure rebuilds the whole of Part IA Probability on a measure-theoretic foundation, which is what finally makes the strong law of large numbers and the central limit theorem provable rather than plausible. Analysis of Functions then combines the two, developing L^p spaces, weak topologies, distributions and Sobolev spaces, and ends by solving elliptic partial differential equations with them. Topics in Analysis is the outlier of the group and a delight: a collection of essentially unrelated beautiful results – fixed point theorems, Runge's theorem, Gaussian quadrature, the irrationality of e and π – held together by nothing but taste.

Geometry in Part II is where the various strands meet. Differential Geometry retells IB Geometry with more machinery and more nerve, arriving at Gauss–Bonnet for the second time in this book. Riemann Surfaces is the most cross-bred course of the year, needing complex analysis for its local theory, covering spaces from Algebraic Topology for its global theory, and pointing directly at Algebraic Geometry. Algebraic Topology itself develops the fundamental group and then simplicial homology, and is the course that best explains why anybody ever wanted a functor.

The mathematical physics courses continue the IB story. Principles of Quantum Mechanics recasts IB Quantum Mechanics in Dirac's language, where the harmonic oscillator, angular momentum and perturbation theory become algebra rather than differential equations, and it in turn supports Statistical Physics, which is the one course in the

book that genuinely derives thermodynamics rather than assuming it. Integrable Systems occupies strange and wonderful territory between the applied and the pure, using the inverse scattering transform to solve nonlinear PDEs exactly. Quantum Information and Computation needs almost nothing but linear algebra and a little quantum mechanics, and gets to Shor's and Grover's algorithms remarkably fast.

The remaining courses are the genuinely independent ones. Logic and Set Theory builds ordinals, cardinals and the axiom of choice and then proves Gödel's incompleteness theorem; Automata and Formal Languages does the computability half of the same story; Graph Theory is combinatorics with almost no prerequisites and some of the best proofs in the book; Coding and Cryptography turns Shannon's theorems into practical codes; Stochastic Financial Models takes the probability strand into continuous time and derives Black–Scholes. Any of these five can be read cold, given Part IA and a little patience.

If Part IA rewards being read in order and Part IB rewards being read in strands, Part II rewards being read out of curiosity. Pick the chapter whose first page interests you, and use the dependency graphs in the front matter to work out what you owe.

24 Algebraic Geometry

Algebraic geometry is the study of the shapes cut out by polynomial equations. Write down a system of polynomials, look at the set of points where they all vanish, and you have a geometric object; write down the ring of polynomial functions on that object, and you have an algebraic one. The whole subject is an extended meditation on how much each of these two things knows about the other. It turns out that they know almost everything about each other, and the translations back and forth are what give algebraic geometry its distinctive flavour – a topological question about a solution set becomes a question about prime ideals, and a question about ideals becomes a question about geometry.

We will spend the first half of the course setting up this dictionary carefully, first for affine varieties and then for projective ones, where the geometry is much better behaved. In the second half we specialise to curves, where the theory becomes remarkably complete: we will be able to attach an integer – the genus – to every smooth projective curve, and the Riemann–Roch theorem will let us compute with it.

This article constitutes my notes for the ‘Algebraic Geometry’ course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§24.1 Introduction

Let us begin with an example, since the whole subject grows out of examples of this kind. Consider the polynomial

$$f(X, Y) = Y^2 - X^3 + X \in \mathbb{Z}[X, Y],$$

and ask for its solution set. The answer depends rather dramatically on where we look for solutions.

If we look for real solutions, we get a subset of $\mathbb{R}^2$ that we can draw. Since $Y^2 = X(X - 1)(X + 1)$, a real point requires $X(X^2 - 1) \geq 0$, which happens exactly when $-1 \leq X \leq 0$ or $X \geq 1$. So the real locus has two pieces: a compact oval sitting over $[-1, 0]$, and an unbounded branch over $[1, \infty)$.

This picture is already suggestive. A ‘generic’ line meets the curve in three points, which is no accident: substituting $Y = mX + c$ into f produces a cubic in X , so there should be three roots. That there are sometimes fewer real roots than three is precisely the sort of irritation that pushes us towards algebraically closed fields.

If instead we look for solutions in $\mathbb{C}^2$, we can no longer draw the picture – the solution set is a real surface sitting inside a real four-dimensional space – but the algebra becomes uniform. Every line really does meet the curve three times. In fact, once we compactify appropriately, the solution set turns out to be a torus, and this is the first hint of the deep relationship between algebraic geometry and topology that the second half of these notes will explore.

Finally, if we look for solutions over $\mathbb{Q}$ or over $\mathbb{Z}$, we are doing number theory, and the questions become extremely hard. We will not do that here, but it is worth knowing that this is the same picture viewed through a different lens.

§24.1.1 Conventions

We will work throughout over the complex numbers. There are two properties of $\mathbb{C}$ that we care about:

- (i) $\mathbb{C}$ is algebraically closed – every non-constant polynomial in one variable has a root. This is what makes the dictionary between algebra and geometry work at all; without it, $\mathbb{V}(X^2 + 1) \subseteq \mathbb{R}^1$ is empty even though $X^2 + 1$ is a perfectly good non-unit.
- (ii) $\mathbb{C}$ has characteristic zero, which means we can differentiate polynomials without anything going wrong, and $\mathbb{C}$ is uncountable, which we will exploit once (in the proof of the Nullstellensatz).

Almost everything we do works verbatim over an arbitrary algebraically closed field, and the reader who prefers to write k everywhere is encouraged to do so. We will write $\mathbb{C}[\mathbf{X}] = \mathbb{C}[X_1, \dots, X_n]$ when the number of variables is clear from context.

Two facts from IB Groups, Rings and Modules will be used constantly, and it is worth recalling them now.

Theorem 24.1.1 (Hilbert Basis Theorem)

If R is a Noetherian ring then so is $R[X]$. In particular $\mathbb{C}[X_1, \dots, X_n]$ is Noetherian: every ideal of $\mathbb{C}[\mathbf{X}]$ is finitely generated.

Theorem 24.1.2

$\mathbb{C}[X_1, \dots, X_n]$ is a unique factorisation domain.

The first of these is what makes all of our geometric objects ‘finite’ in nature, and the second is what lets us talk about the irreducible polynomial cutting out a hypersurface.

§24.2 Affine Varieties

§24.2.1 Affine Space and Polynomial Functions

We begin with the ambient space.

Definition 24.2.1 (Affine Space)

Affine n -space over $\mathbb{C}$ is the set $\mathbb{A}^n = \mathbb{C}^n$. Its elements are called **points**, and we typically write a point as $P = (a_1, \dots, a_n)$.

Why the new notation for something we already have a name for? The point is one of emphasis. When we write $\mathbb{C}^n$ we are usually thinking of a vector space, with a distinguished origin and a linear structure. When we write $\mathbb{A}^n$ we are forgetting all of that and remembering only that $\mathbb{A}^n$ is the natural home of the polynomial ring: every $f \in \mathbb{C}[X_1, \dots, X_n]$ determines a function

$$f: \mathbb{A}^n \rightarrow \mathbb{A}^1, \quad P \mapsto f(P),$$

and it is this ring of functions, rather than any linear structure, that we regard as the essential data.

Definition 24.2.2 (Affine Subspace)

An **affine subspace** of $\mathbb{A}^n$ is a subset of the form $v + U$, where $U \leq \mathbb{C}^n$ is a linear subspace and $v \in \mathbb{C}^n$.

Note that a polynomial is determined by the function it induces on $\mathbb{A}^n$: if f and g agree at every point of $\mathbb{C}^n$ then $f = g$ as polynomials. (This uses that $\mathbb{C}$ is infinite; over $\mathbb{F}_2$ the polynomials X and X^2 induce the same function on $\mathbb{A}^1$.) So we may freely conflate polynomials with the functions they define.

§24.2.2 Vanishing Loci

Definition 24.2.3 (Vanishing Locus)

Let $S \subseteq \mathbb{C}[X_1, \dots, X_n]$ be any subset. The **vanishing locus** of S is

$$\mathbb{V}(S) = \{P \in \mathbb{A}^n : f(P) = 0 \text{ for all } f \in S\} \subseteq \mathbb{A}^n.$$

A subset of $\mathbb{A}^n$ of the form $\mathbb{V}(S)$ is called an **affine (algebraic) variety**.

A warning about terminology: some authors (and some textbooks you may consult) reserve the word ‘variety’ for what we will call an *irreducible* variety, and use ‘algebraic set’ for the general notion. We will not do that, but you should be alert to it.

Let us see some examples straight away.

Example 24.2.4 (i) Take $n = 1$. A single polynomial $f \in \mathbb{C}[X]$ has finitely many roots, so $\mathbb{V}(f)$ is a finite set; and conversely, any finite set $\{a_1, \dots, a_m\} \subseteq \mathbb{A}^1$ is $\mathbb{V}(f)$ for $f = \prod_i (X - a_i)$. Also $\mathbb{V}(0) = \mathbb{A}^1$. So the affine varieties in $\mathbb{A}^1$ are exactly the finite sets together with $\mathbb{A}^1$ itself.

(ii) A **hypersurface** in $\mathbb{A}^n$ is a variety of the form $\mathbb{V}(f)$ for a single non-constant

f. For $n = 2$ these are the **plane curves**.

(iii) Not all varieties are naturally presented by equations. The **twisted cubic** is

$$C = \{(t, t^2, t^3) : t \in \mathbb{C}\} \subseteq \mathbb{A}^3,$$

presented parametrically. It is nonetheless a variety: $C = \mathbb{V}(X_2 - X_1^2, X_3 - X_1^3)$. Indeed if $x_2 = x_1^2$ and $x_3 = x_1^3$ then the point is (t, t^2, t^3) for $t = x_1$.

(iv) Every affine subspace is a variety, being the vanishing locus of a collection of degree one polynomials. In particular a point $(a_1, \dots, a_n)$ is the variety $\mathbb{V}(X_1 - a_1, \dots, X_n - a_n)$.

Passing from a set S of polynomials to $\mathbb{V}(S)$ loses a lot of information, and the first thing to do is to understand exactly what it remembers. The following is the basic finiteness statement of the subject.

Theorem 24.2.5

Let $S \subseteq \mathbb{C}[\mathbf{X}]$ and let $I = (S)$ be the ideal it generates. Then

- (i) $\mathbb{V}(S) = \mathbb{V}(I)$;
- (ii) there is a *finite* subset $\{f_1, \dots, f_r\} \subseteq S$ with $\mathbb{V}(S) = \mathbb{V}(f_1, \dots, f_r)$.

Proof. For (i), certainly $\mathbb{V}(I) \subseteq \mathbb{V}(S)$ since $S \subseteq I$. Conversely if $P \in \mathbb{V}(S)$ and $g = \sum_j h_j f_j \in I$ with $f_j \in S$, then $g(P) = \sum_j h_j(P) f_j(P) = 0$, so $P \in \mathbb{V}(I)$.

For (ii), by the Hilbert Basis Theorem I is finitely generated, say $I = (g_1, \dots, g_m)$. Each g_i lies in the ideal generated by S , so is a finite combination $g_i = \sum_j h_{ij} f_{ij}$ with $f_{ij} \in S$. Let T be the (finite) set of all the f_{ij} occurring. Then $I = (g_1, \dots, g_m) \subseteq (T) \subseteq I$, so $(T) = I$ and by (i) we get $\mathbb{V}(S) = \mathbb{V}(I) = \mathbb{V}(T)$. $\square$

In other words, *every* system of polynomial equations, however large, is equivalent to a finite subsystem. This is the geometric content of the Hilbert Basis Theorem, and it is not at all obvious from the geometric side.

The operation $\mathbb{V}$ reverses inclusions and interacts with the lattice operations on ideals in a way we now record.

Proposition 24.2.6

Let $S, T \subseteq \mathbb{C}[\mathbf{X}]$ be subsets and let $(I_j)_{j \in J}$ be a family of ideals of $\mathbb{C}[\mathbf{X}]$. Then

- (i) if $S \subseteq T$ then $\mathbb{V}(T) \subseteq \mathbb{V}(S)$;
- (ii) $\mathbb{V}(0) = \mathbb{A}^n$ and $\mathbb{V}(\mathbb{C}[\mathbf{X}]) = \mathbb{V}(1) = \emptyset$;
- (iii) $\bigcap_{j \in J} \mathbb{V}(I_j) = \mathbb{V}(\sum_j I_j)$;
- (iv) $\mathbb{V}(I) \cup \mathbb{V}(J) = \mathbb{V}(I \cap J) = \mathbb{V}(IJ)$.

Proof. Parts (i) and (ii) are immediate from the definitions.

For (iii), a point lies in every $\mathbb{V}(I_j)$ if and only if it is killed by every element of

every I_j , if and only if it is killed by $\bigcup_j I_j$; and $\mathbb{V}$ of a set equals $\mathbb{V}$ of the ideal it generates, which is $\sum_j I_j$.

For (iv), we have $IJ \subseteq I \cap J \subseteq I$ and likewise for J , so by (i),

$$\mathbb{V}(I) \cup \mathbb{V}(J) \subseteq \mathbb{V}(I \cap J) \subseteq \mathbb{V}(IJ).$$

It remains to show $\mathbb{V}(IJ) \subseteq \mathbb{V}(I) \cup \mathbb{V}(J)$. Suppose $P \in \mathbb{V}(IJ)$ but $P \notin \mathbb{V}(I)$, so there is $g \in I$ with $g(P) \neq 0$. For any $f \in J$ we have $fg \in IJ$, so $f(P)g(P) = 0$, whence $f(P) = 0$. Thus $P \in \mathbb{V}(J)$. $\square$

§24.2.3 The Zariski Topology

Proposition 24.2.6 says exactly that the affine varieties are the closed sets of a topology: they contain $\emptyset$ and the whole space, and are closed under arbitrary intersections and finite unions.

Definition 24.2.7 (Zariski Topology)

The **Zariski topology** on $\mathbb{A}^n$ is the topology whose closed sets are precisely the affine varieties. If $V \subseteq \mathbb{A}^n$ is a variety, the Zariski topology on V is the subspace topology.

Definition 24.2.8 (Euclidean Topology)

The **Euclidean** or **analytic** topology on $\mathbb{A}^n = \mathbb{C}^n$ is the usual metric topology. Again, a variety inherits a subspace topology.

Every Zariski closed set is Euclidean closed, since polynomials are continuous; so the Zariski topology is *coarser* than the Euclidean one. It is in fact very much coarser, and the reader should be warned that it does not behave like the topologies met in IB Analysis and Topology.

Proposition 24.2.9

The Zariski topology on $\mathbb{A}^1$ is the cofinite topology. It is compact and irreducible, but not Hausdorff. The Euclidean topology on $\mathbb{A}^1$ is Hausdorff but not compact.

Proof. We saw that the varieties in $\mathbb{A}^1$ are the finite sets and $\mathbb{A}^1$ itself, which is the definition of the cofinite topology. Any two nonempty open sets are cofinite, hence meet (as $\mathbb{C}$ is infinite), so the space is not Hausdorff. Compactness is immediate: given an open cover, one member U is nonempty, and its complement is finite, so finitely many further members finish the job. $\square$

Remark. The Zariski topology on $\mathbb{A}^2$ is *not* the product topology of the Zariski topologies on $\mathbb{A}^1 \times \mathbb{A}^1$. In the product topology the closed sets are finite unions of sets of the form $A \times B$ with A, B closed; the diagonal $\mathbb{V}(X_1 - X_2)$ is Zariski closed in $\mathbb{A}^2$ but is not of this form.

Because the Zariski topology is so coarse, nonempty open sets are enormous. We will use this constantly: a Zariski open set is ‘almost all’ of the space, and a statement holding

on a nonempty open set is a statement holding ‘generically’.

§24.2.4 Irreducibility

A cofinite topology has no interesting disconnections, but varieties can still fall apart in an algebraic sense, as the following notion makes precise.

Definition 24.2.10 (Irreducible)

A nonempty variety V is **irreducible** if whenever $V = V_1 \cup V_2$ with V_1, V_2 closed subsets of V , we have $V = V_1$ or $V = V_2$. Otherwise V is **reducible**.

Example 24.2.11

The variety $V = \mathbb{V}(XY) \subseteq \mathbb{A}^2$ is reducible: it is the union of the two coordinate axes $\mathbb{V}(X)$ and $\mathbb{V}(Y)$, neither of which is all of V .

By contrast, we shall see shortly that each axis is irreducible.

Note that irreducibility is a genuinely topological condition – it says that V is not the union of two proper closed subsets – but it is a condition no Hausdorff space with more than one point satisfies. It is a condition suited to the Zariski topology.

Proposition 24.2.12

Every affine variety is a finite union of irreducible varieties.

Proof. Suppose not, and let V be a variety that is not a finite union of irreducibles. In particular V is not itself irreducible, so $V = V_1 \cup W_1$ with V_1, W_1 proper closed subsets. If both V_1 and W_1 were finite unions of irreducibles then so would V be; so (relabelling) V_1 is not a finite union of irreducibles. Repeating, we obtain a strictly decreasing chain

$$V = V_0 \supsetneq V_1 \supsetneq V_2 \supsetneq \cdots$$

of varieties. Let $I_j = I(V_j)$ (defined below in Section 24.2.5); the containments reverse, giving a strictly increasing chain of ideals $I_0 \subsetneq I_1 \subsetneq \cdots$. But $\mathbb{C}[\mathbf{X}]$ is Noetherian, so no such chain exists, and we have our contradiction. $\square$

The reader will notice that we have used the ideal $I(V)$ of a variety before defining it; the reader who objects may instead run the argument with $\bigcup_j I_j$, which is an ideal and hence finitely generated, so equals $\sum_{j \leq N} I_j$ for some N , forcing the chain to stabilise. Either way, the essential point is the Noetherian property.

Definition 24.2.13 (Minimal Decomposition)

A **minimal decomposition** of a variety V is an expression $V = V_1 \cup \cdots \cup V_r$ with each V_i irreducible and $V_i \not\subseteq V_j$ for $i \neq j$.

Given any decomposition into irreducibles, we can throw away any piece contained in another and obtain a minimal one. What is not obvious is that the result does not depend on the choices made.

Proposition 24.2.14

Minimal decompositions are unique up to reordering.

Proof. Suppose $V = \bigcup_{i=1}^r V_i = \bigcup_{j=1}^s W_j$ are two minimal decompositions. Fix i . Then

$$V_i = V_i \cap V = \bigcup_{j=1}^s (V_i \cap W_j),$$

a finite union of closed subsets of V_i . By irreducibility, $V_i = V_i \cap W_j$ for some j , i.e. $V_i \subseteq W_j$. Symmetrically $W_j \subseteq V_k$ for some k , so $V_i \subseteq V_k$, and minimality forces $i = k$ and hence $V_i = W_j$. So each V_i appears among the W_j and vice versa. $\square$

Definition 24.2.15 (Irreducible Components)

The irreducible varieties appearing in the (unique) minimal decomposition of V are the **irreducible components** of V .

§24.2.5 The Ideal of a Variety

We now go the other way, from geometry back to algebra.

Definition 24.2.16

Let $X \subseteq \mathbb{A}^n$ be any subset. The **ideal of X** is

$$I(X) = \{f \in \mathbb{C}[\mathbf{X}] : f(P) = 0 \text{ for all } P \in X\}.$$

This really is an ideal: it is closed under addition, and if f vanishes on X then so does gf for any g . It is the largest set of polynomials with vanishing locus containing X .

Proposition 24.2.17

Let $V, W \subseteq \mathbb{A}^n$ be affine varieties and $S \subseteq \mathbb{C}[\mathbf{X}]$.

- (i) If $V = \mathbb{V}(S)$ then $S \subseteq I(V)$.
- (ii) $V = \mathbb{V}(I(V))$.
- (iii) $V \subseteq W$ if and only if $I(W) \subseteq I(V)$. In particular $V = W$ if and only if $I(V) = I(W)$.
- (iv) $I(V \cup W) = I(V) \cap I(W)$.

Proof. (i) is immediate. For (ii), $S \subseteq I(V)$ gives $\mathbb{V}(I(V)) \subseteq \mathbb{V}(S) = V$, and $V \subseteq \mathbb{V}(I(V))$ holds by definition of $I(V)$.

For (iii), if $V \subseteq W$ then any polynomial vanishing on W vanishes on V . Conversely suppose $V \not\subseteq W$ and pick $P \in V \setminus W$. As $W = \mathbb{V}(I(W))$ and $P \notin W$, there is $f \in I(W)$ with $f(P) \neq 0$; then $f \notin I(V)$.

(iv) is immediate from the definitions. $\square$

So I is an injection from varieties in $\mathbb{A}^n$ to ideals of $\mathbb{C}[\mathbf{X}]$, with $\mathbb{V}$ as a left inverse. It is certainly not surjective: the ideals (X) and (X^2) in $\mathbb{C}[X]$ have the same vanishing locus $\{0\}$, and $I(\{0\}) = (X)$. So the composite $I \circ \mathbb{V}$ is not the identity on ideals, and understanding exactly what it does is the content of the Nullstellensatz.

First, however, let us record the algebraic characterisation of irreducibility.

Proposition 24.2.18

A variety V is irreducible if and only if $I(V)$ is a prime ideal.

Recall that $I(V)$ prime means: whenever $f_1 f_2 \in I(V)$, either $f_1 \in I(V)$ or $f_2 \in I(V)$. Geometrically, the failure of primality is the existence of two functions, neither vanishing identically on V , whose product does; and such a pair splits V in two.

Proof. Suppose V is reducible, $V = V_1 \cup V_2$ with $V_i \subsetneq V$ closed. Then $I(V_i) \supsetneq I(V)$ strictly, and $V_1 \not\subseteq V_2$, $V_2 \not\subseteq V_1$ (else the decomposition would be trivial), so $I(V_1) \not\subseteq I(V_2)$ and vice versa. Choose $f_1 \in I(V_1) \setminus I(V_2)$ and $f_2 \in I(V_2) \setminus I(V_1)$. Neither lies in $I(V) = I(V_1) \cap I(V_2)$, but $f_1 f_2$ vanishes on $V_1 \cup V_2 = V$. So $I(V)$ is not prime.

Conversely suppose $I(V)$ is not prime, with $f_1 f_2 \in I(V)$ but $f_i \notin I(V)$. Set $V_i = V \cap \mathbb{V}(f_i)$, a closed subset of V . Since $f_i \notin I(V)$, f_i does not vanish identically on V , so $V_i \subsetneq V$. But for any $P \in V$ we have $f_1(P)f_2(P) = 0$, so $P \in V_1 \cup V_2$. Hence $V = V_1 \cup V_2$ is reducible. $\square$

Example 24.2.19

$\mathbb{V}(X) \subseteq \mathbb{A}^2$ is irreducible, since $I(\mathbb{V}(X)) = (X)$ and $\mathbb{C}[X, Y]/(X) \cong \mathbb{C}[Y]$ is an integral domain, so (X) is prime. Hence $\mathbb{V}(XY) = \mathbb{V}(X) \cup \mathbb{V}(Y)$ is the minimal decomposition of $\mathbb{V}(XY)$ into irreducible components.

Example 24.2.20

More generally, if $f \in \mathbb{C}[\mathbf{X}]$ is irreducible then (f) is prime (as $\mathbb{C}[\mathbf{X}]$ is a UFD), so the hypersurface $\mathbb{V}(f)$ is irreducible. If $f = f_1^{a_1} \cdots f_r^{a_r}$ is the factorisation of a general f into irreducibles, then $\mathbb{V}(f) = \mathbb{V}(f_1) \cup \cdots \cup \mathbb{V}(f_r)$ is the decomposition into irreducible components.

§24.2.6 Hilbert's Nullstellensatz

We now come to the theorem which makes the whole dictionary work. The name means ‘theorem of the zeros’, and it comes in two forms.

Theorem 24.2.21 (Weak Nullstellensatz) (i) Every maximal ideal of $\mathbb{C}[X_1, \dots, X_n]$ has the form $\mathfrak{m}_P = (X_1 - a_1, \dots, X_n - a_n)$ for some point $P = (a_1, \dots, a_n) \in \mathbb{A}^n$.
(ii) If $I \subseteq \mathbb{C}[\mathbf{X}]$ is a proper ideal then $\mathbb{V}(I) \neq \emptyset$.

Part (ii) is the statement that a system of polynomial equations with no ‘algebraic obstruction’ – that is, such that 1 is not a combination of the equations – really does have a solution. It is the many-variable generalisation of the fundamental theorem of algebra.

The proof we give uses that $\mathbb{C}$ is uncountable, and so is special to $\mathbb{C}$; the theorem is true over any algebraically closed field, but the general proof (via the Noether normalisation lemma, or via Zariski’s lemma) is more work.

Proof. Each ideal $\mathfrak{m}_P$ is maximal: the evaluation homomorphism $\mathbb{C}[\mathbf{X}] \rightarrow \mathbb{C}$, $f \mapsto f(P)$, is surjective with kernel exactly $\mathfrak{m}_P$, so $\mathbb{C}[\mathbf{X}]/\mathfrak{m}_P \cong \mathbb{C}$ is a field.

Conversely let $\mathfrak{m}$ be a maximal ideal and set $K = \mathbb{C}[\mathbf{X}]/\mathfrak{m}$, a field containing $\mathbb{C}$. Write a_i for the image of X_i in K , so that $K = \mathbb{C}[a_1, \dots, a_n]$. If every a_i lies in $\mathbb{C} \subseteq K$ then $X_i - a_i \in \mathfrak{m}$ for each i , so $\mathfrak{m} \supseteq \mathfrak{m}_P$ for $P = (a_1, \dots, a_n)$, and maximality of $\mathfrak{m}_P$ gives $\mathfrak{m} = \mathfrak{m}_P$ as required.

So suppose for contradiction that $K \supsetneq \mathbb{C}$, and pick $t \in K \setminus \mathbb{C}$. Since $\mathbb{C}$ is algebraically closed, t cannot be algebraic over $\mathbb{C}$, so t is transcendental and the elements $\{(t - c)^{-1} : c \in \mathbb{C}\}$ make sense in K . We claim they are linearly independent over $\mathbb{C}$. Indeed, a relation $\sum_{i=1}^m \lambda_i (t - c_i)^{-1} = 0$ with distinct c_i , cleared of denominators, gives $\sum_i \lambda_i \prod_{j \neq i} (t - c_j) = 0$; substituting the transcendental t into this polynomial identity and evaluating the polynomial at c_i shows $\lambda_i \prod_{j \neq i} (c_i - c_j) = 0$, so $\lambda_i = 0$.

Thus K contains an uncountable linearly independent set over $\mathbb{C}$, so $\dim_{\mathbb{C}} K$ is uncountable. On the other hand, let $U_m \subseteq K$ be the $\mathbb{C}$ -span of the monomials $a_1^{r_1} \cdots a_n^{r_n}$ with $\sum r_i \leq m$. Each U_m is finite-dimensional and $K = \bigcup_{m \geq 0} U_m$, so K has a countable spanning set and hence countable dimension. This is a contradiction.

For (ii), a proper ideal I is contained in some maximal ideal $\mathfrak{m}_P$ (using that $\mathbb{C}[\mathbf{X}]$ is Noetherian, or Zorn’s lemma), and then $P \in \mathbb{V}(\mathfrak{m}_P) \subseteq \mathbb{V}(I)$. $\square$

To state the strong form we need one more piece of algebra.

Definition 24.2.22 (Radical)

The **radical** of an ideal $I \subseteq R$ is

$$\sqrt{I} = \{f \in R : f^m \in I \text{ for some } m \geq 1\}.$$

An ideal is **radical** if $I = \sqrt{I}$.

That $\sqrt{I}$ is an ideal follows from the binomial theorem: if $f^a, g^b \in I$ then every term of $(f + g)^{a+b}$ contains f^a or g^b . Note $\sqrt{\sqrt{I}} = \sqrt{I}$, and prime ideals are radical. Since f and f^m have the same zeros, $\mathbb{V}(I) = \mathbb{V}(\sqrt{I})$ always.

Theorem 24.2.23 (Strong Nullstellensatz)

Let $I \trianglelefteq \mathbb{C}[X_1, \dots, X_n]$ be an ideal. Then

$$I(\mathbb{V}(I)) = \sqrt{I}.$$

Proof. The inclusion $\sqrt{I} \subseteq I(\mathbb{V}(I))$ is clear: if $f^m \in I$ then f^m , hence f , vanishes on $\mathbb{V}(I)$.

For the converse we use the *Rabinowitsch trick*. Let $f \in I(\mathbb{V}(I))$, and let $g_1, \dots, g_r$ generate I . Introduce a new variable T and consider the ideal

$$J = (g_1, \dots, g_r, 1 - Tf) \trianglelefteq \mathbb{C}[X_1, \dots, X_n, T].$$

I claim $\mathbb{V}(J) = \emptyset$ in $\mathbb{A}^{n+1}$. Indeed, if $(P, \tau) \in \mathbb{V}(J)$ then $P \in \mathbb{V}(I)$, so $f(P) = 0$, and then $1 - \tau f(P) = 1 \neq 0$, a contradiction.

By the weak Nullstellensatz, $J = \mathbb{C}[\mathbf{X}, T]$, so we may write

$$1 = \sum_{i=1}^r h_i(\mathbf{X}, T)g_i(\mathbf{X}) + h_0(\mathbf{X}, T)(1 - Tf(\mathbf{X})).$$

This is an identity in the polynomial ring, so we may substitute $T = 1/f$ and work in the field $\mathbb{C}(X_1, \dots, X_n)$ (note $f \neq 0$, else $f \in \sqrt{I}$ trivially). The last term vanishes, leaving

$$1 = \sum_{i=1}^r h_i(\mathbf{X}, 1/f) g_i(\mathbf{X}).$$

Multiplying by a sufficiently large power f^N to clear all denominators gives $f^N = \sum_i \tilde{h}_i g_i$ with $\tilde{h}_i \in \mathbb{C}[\mathbf{X}]$, so $f^N \in I$ and $f \in \sqrt{I}$. $\square$

§24.2.7 The Dictionary

We can now say precisely what I and $\mathbb{V}$ do.

Corollary 24.2.24

The maps $V \mapsto I(V)$ and $I \mapsto \mathbb{V}(I)$ are mutually inverse, inclusion-reversing bijections

$$\{\text{affine varieties in } \mathbb{A}^n\} \longleftrightarrow \{\text{radical ideals of } \mathbb{C}[X_1, \dots, X_n]\}.$$

Under this bijection, irreducible varieties correspond to prime ideals, and points correspond to maximal ideals.

Proof. We know $\mathbb{V}(I(V)) = V$ for varieties V , and $I(\mathbb{V}(I)) = \sqrt{I} = I$ for radical I . Also $I(V)$ is always radical, since if f^m vanishes on V then so does f . The correspondence for prime ideals is Proposition 24.2.18, and for maximal ideals it is Theorem 24.2.21(i). $\square$

This is the fundamental dictionary of the subject, and it is worth pausing over. Every geometric question about varieties in $\mathbb{A}^n$ can, in principle, be converted into an algebraic question about radical ideals of a polynomial ring. The rest of the course consists of doing exactly this, in increasingly refined ways.

Example 24.2.25

Let us see how the correspondence handles the classic example. In $\mathbb{C}[X]$, the ideal (X^2) is not radical, and $\sqrt{(X^2)} = (X)$. Correspondingly $\mathbb{V}(X^2) = \{0\} = \mathbb{V}(X)$: the variety cannot see the doubling. Later, when we come to intersection multiplicities and to schemes, we will want to remember the difference; for now we simply record that varieties forget it.

Example 24.2.26

Consider $I = (X^2 - Y^2, X^2 + Y^2 - 2) \subseteq \mathbb{C}[X, Y]$. Adding and subtracting, I contains $2X^2 - 2$ and $2Y^2 - 2$, so $I = (X^2 - 1, Y^2 - 1)$ and $\mathbb{V}(I) = \{(\pm 1, \pm 1)\}$, four points. The corresponding radical ideal is $I(\mathbb{V}(I)) = (X^2 - 1, Y^2 - 1)$, which is indeed radical – the quotient is $\mathbb{C}^4$ by the Chinese remainder theorem, and a finite product of fields has no nilpotents.

§24.3 Regular Functions and Morphisms

Having built our objects, we need the maps between them. As always in mathematics, the maps are more important than the objects, and here they will let us make precise the sense in which a variety ‘is’ its ring of functions.

§24.3.1 Coordinate Rings

Let $V \subseteq \mathbb{A}^n$ be a variety. Any polynomial $f \in \mathbb{C}[\mathbf{X}]$ restricts to a function $V \rightarrow \mathbb{C}$, but different polynomials may restrict to the same function. Precisely, f and g restrict to the same function on V if and only if $f - g$ vanishes on V , i.e. $f - g \in I(V)$. So the ring of functions $V \rightarrow \mathbb{C}$ obtained by restricting polynomials is the quotient $\mathbb{C}[\mathbf{X}]/I(V)$.

Definition 24.3.1 (Coordinate Ring)

Let $V \subseteq \mathbb{A}^n$ be an affine variety. Its **coordinate ring**, or **ring of regular functions**, is

$$\mathbb{C}[V] = \frac{\mathbb{C}[X_1, \dots, X_n]}{I(V)}.$$

Elements of $\mathbb{C}[V]$ are called **regular functions** on V . We sometimes write $\mathcal{O}(V)$ for $\mathbb{C}[V]$.

The coordinate ring is a finitely generated $\mathbb{C}$ -algebra (generated by the images x_i of the coordinate functions X_i), and it is *reduced*: it has no nonzero nilpotents, because $I(V)$ is radical. Conversely, every reduced finitely generated $\mathbb{C}$ -algebra arises this way, by writing it as $\mathbb{C}[\mathbf{X}]/I$ with I radical.

Corollary 24.3.2

A variety V is irreducible if and only if $\mathbb{C}[V]$ is an integral domain.

Proof. $\mathbb{C}[V]$ is a domain if and only if $I(V)$ is prime, which by Proposition 24.2.18

happens if and only if V is irreducible. $\square$

Example 24.3.3

$\mathbb{C}[\mathbb{A}^n] = \mathbb{C}[X_1, \dots, X_n]$, since $I(\mathbb{A}^n) = 0$.

Example 24.3.4

Let $V = \{0\} \subseteq \mathbb{A}^1$. We can present V as $\mathbb{V}(X^2)$, but $I(V) = \sqrt{(X^2)} = (X)$, so

$$\mathbb{C}[V] = \mathbb{C}[X]/(X) \cong \mathbb{C}.$$

The presentation as a doubled point is invisible to the coordinate ring. This is exactly the information that the theory of schemes is designed to retain: the ring $\mathbb{C}[X]/(X^2)$ is a perfectly good ring, with a nonzero element squaring to zero, and it remembers the doubling. We will not pursue this.

Example 24.3.5

Let $C = \mathbb{V}(Y - X^2) \subseteq \mathbb{A}^2$ be a parabola. Then $I(C) = (Y - X^2)$ (one checks that $Y - X^2$ is irreducible, so $(Y - X^2)$ is prime hence radical, and it certainly has the right vanishing locus). Hence

$$\mathbb{C}[C] = \mathbb{C}[X, Y]/(Y - X^2) \cong \mathbb{C}[X],$$

the isomorphism sending $Y \mapsto X^2$. So the parabola has the same coordinate ring as the affine line – and we will see in a moment that this means they are isomorphic as varieties.

Remark. One should be careful: $\mathbb{C}[V]$ on its own, as an abstract ring, does not remember the embedding $V \subseteq \mathbb{A}^n$. A surjection $\mathbb{C}[\mathbf{X}] \rightarrow \mathbb{C}[V]$ is the same thing as a presentation of V as a subvariety of $\mathbb{A}^n$, and there are many such. The parabola example above is a case in point: $\mathbb{C}[X] \cong \mathbb{C}[X, Y]/(Y - X^2)$ presents the same ring both as $\mathbb{A}^1 \subseteq \mathbb{A}^1$ and as a curve in $\mathbb{A}^2$.

§24.3.2 Morphisms

Definition 24.3.6 (Morphism)

Let $V \subseteq \mathbb{A}^n$ and $W \subseteq \mathbb{A}^m$ be affine varieties. A **morphism** (or **regular map**) $\varphi: V \rightarrow W$ is a function such that there exist $f_1, \dots, f_m \in \mathbb{C}[V]$ with

$$\varphi(P) = (f_1(P), \dots, f_m(P))$$

for all $P \in V$. We write $\text{Mor}(V, W)$ for the set of morphisms $V \rightarrow W$.

In other words, a morphism is a map given in coordinates by polynomials. Note the requirement that the image actually lands in W , which is a genuine condition on the f_i .

Example 24.3.7 (i) A morphism $V \rightarrow \mathbb{A}^1$ is precisely an element of $\mathbb{C}[V]$.

- (ii) Linear maps, translations, and more generally affine-linear maps $\mathbb{A}^n \rightarrow \mathbb{A}^m$ are morphisms.
- (iii) If $V \subseteq W$ are varieties in $\mathbb{A}^n$, the inclusion $V \hookrightarrow W$ is a morphism.
- (iv) The map $\mathbb{A}^1 \rightarrow \mathbb{A}^3$, $t \mapsto (t, t^2, t^3)$, is a morphism onto the twisted cubic.

Proposition 24.3.8

Compositions of morphisms are morphisms, so affine varieties and morphisms form a category.

Proof. A polynomial in polynomials is a polynomial. $\square$

Morphisms are automatically continuous for the Zariski topology: if $Z = \mathbb{V}(g_1, \dots, g_r) \subseteq W$ then $\varphi^{-1}(Z) = \mathbb{V}(g_1 \circ \varphi, \dots, g_r \circ \varphi)$ is closed in V . The converse is very far from true – for instance every bijection of $\mathbb{A}^1$ is a Zariski homeomorphism – so being a morphism is much stronger than being continuous.

§24.3.3 Pullbacks

The key construction is that a morphism induces a map on functions, going the other way.

Definition 24.3.9 (Pullback)

Let $\varphi: V \rightarrow W$ be a morphism and $g \in \mathbb{C}[W]$. The **pullback** of g is

$$\varphi^*(g) = g \circ \varphi: V \rightarrow \mathbb{C}.$$

If g is (the class of) a polynomial in the coordinates on $\mathbb{A}^m$, then $g \circ \varphi$ is a polynomial in the coordinates on $\mathbb{A}^n$, so $\varphi^*(g) \in \mathbb{C}[V]$. Thus $\varphi^*: \mathbb{C}[W] \rightarrow \mathbb{C}[V]$, and it is clearly a ring homomorphism which is the identity on the constants $\mathbb{C}$.

Definition 24.3.10

A ring homomorphism between $\mathbb{C}$ -algebras which restricts to the identity on $\mathbb{C}$ is a **$\mathbb{C}$ -algebra homomorphism**.

Theorem 24.3.11

Let $V \subseteq \mathbb{A}^n$ and $W \subseteq \mathbb{A}^m$ be affine varieties. The map $\varphi \mapsto \varphi^*$ is a bijection

$$\text{Mor}(V, W) \longleftrightarrow \{\mathbb{C}\text{-algebra homomorphisms } \mathbb{C}[W] \rightarrow \mathbb{C}[V]\}.$$

Proof. Let $y_1, \dots, y_m \in \mathbb{C}[W]$ be the coordinate functions, i.e. the restrictions to W of the standard coordinates on $\mathbb{A}^m$.

Injectivity. If $\varphi: V \rightarrow W$ is a morphism and $P \in V$, then

$$\varphi(P) = (y_1(\varphi(P)), \dots, y_m(\varphi(P))) = (\varphi^*(y_1)(P), \dots, \varphi^*(y_m)(P)),$$

so φ is determined by $\varphi^*(y_1), \dots, \varphi^*(y_m)$, hence by φ^* .

Surjectivity. Let $\lambda: \mathbb{C}[W] \rightarrow \mathbb{C}[V]$ be a $\mathbb{C}$ -algebra homomorphism, and put $f_j = \lambda(y_j) \in \mathbb{C}[V]$. Define $\varphi = (f_1, \dots, f_m): V \rightarrow \mathbb{A}^m$; this is given by polynomials, so we need only check its image lies in W . Let $P \in V$ and $g \in I(W)$. Since λ is a $\mathbb{C}$ -algebra homomorphism, it commutes with polynomial expressions, so

$$g(f_1(P), \dots, f_m(P)) = (g(\lambda(y_1), \dots, \lambda(y_m)))(P) = (\lambda(g(y_1, \dots, y_m)))(P).$$

But $g(y_1, \dots, y_m) = 0$ in $\mathbb{C}[W]$, because $g \in I(W)$. Hence $g(\varphi(P)) = 0$ for all $g \in I(W)$, so $\varphi(P) \in \mathbb{V}(I(W)) = W$. Finally $\varphi^*(y_j) = f_j = \lambda(y_j)$, and since the y_j generate $\mathbb{C}[W]$ as a $\mathbb{C}$ -algebra, $\varphi^* = \lambda$. $\square$

Definition 24.3.12 (Isomorphism)

Varieties V and W are **isomorphic** if there are morphisms $\varphi: V \rightarrow W$ and $\psi: W \rightarrow V$ with $\psi\varphi = \text{id}_V$ and $\varphi\psi = \text{id}_W$.

Corollary 24.3.13

$V \cong W$ as varieties if and only if $\mathbb{C}[V] \cong \mathbb{C}[W]$ as $\mathbb{C}$ -algebras.

Proof. Immediate from Theorem 24.3.11, since the bijection is compatible with composition (it is contravariantly functorial): $(\psi\varphi)^* = \varphi^*\psi^*$ and $\text{id}^* = \text{id}$. $\square$

This is the promised statement that a variety ‘is’ its coordinate ring. All geometric information about an affine variety is encoded in a finitely generated reduced $\mathbb{C}$ -algebra, and every such algebra arises. In the language of category theory, the functor $V \mapsto \mathbb{C}[V]$ is an anti-equivalence between the category of affine varieties and the category of finitely generated reduced $\mathbb{C}$ -algebras.

Example 24.3.14

The twisted cubic $C = \{(t, t^2, t^3)\}$ is isomorphic to $\mathbb{A}^1$. Indeed $I(C) = (X_2 - X_1^2, X_3 - X_1^3)$, and in $\mathbb{C}[C]$ we have $x_2 = x_1^2$, $x_3 = x_1^3$, so $\mathbb{C}[C] = \mathbb{C}[x_1] \cong \mathbb{C}[X]$.

Example 24.3.15

Not every bijective morphism is an isomorphism. Consider $\varphi: \mathbb{A}^1 \rightarrow C = \mathbb{V}(Y^2 - X^3) \subseteq \mathbb{A}^2$ given by $t \mapsto (t^2, t^3)$. This is a bijection (the inverse sends $(x, y) \neq (0, 0)$ to y/x , and $(0, 0)$ to 0). But $\varphi^*: \mathbb{C}[C] \rightarrow \mathbb{C}[t]$ has image $\mathbb{C}[t^2, t^3] \subsetneq \mathbb{C}[t]$, since $t \notin \mathbb{C}[t^2, t^3]$. So φ^* is not surjective and φ is not an isomorphism. Geometrically, the cuspidal cubic C has a singular point at the origin which the smooth line $\mathbb{A}^1$ does not; we will make this precise in Section 24.5.

Example 24.3.16

Let $V = \mathbb{V}(X_1X_2(X_1 - X_2)) \subseteq \mathbb{A}^2$, a union of three concurrent lines in the plane, and let $W = \mathbb{V}(X_1X_2, X_2X_3, X_3X_1) \subseteq \mathbb{A}^3$, the union of the three coordinate axes.

Both are unions of three lines meeting at a single point, and they are homeomorphic in the Euclidean topology. Nevertheless they are not isomorphic as varieties: the tangent space to V at the origin is two-dimensional (it sits inside a plane) while that of W is three-dimensional. We will be able to see this once we have defined tangent spaces.

§24.3.4 Rational Functions and Local Rings

Regular functions are rather rigid. On $\mathbb{A}^1$ the only regular functions are the polynomials, and there are many natural functions $-1/X$, say – that we would like to allow, provided we keep track of where they are undefined. The right framework is that of rational functions.

Throughout this subsection, let V be an *irreducible* affine variety, so that $\mathbb{C}[V]$ is an integral domain.

Definition 24.3.17 (Function Field)

The **function field** of an irreducible affine variety V is the field of fractions

$$\mathbb{C}(V) = \text{Frac}(\mathbb{C}[V]).$$

Its elements are called **rational functions** on V .

Definition 24.3.18

A rational function $\varphi \in \mathbb{C}(V)$ is **regular** (or **defined**) at $P \in V$ if it can be written as $\varphi = f/g$ with $f, g \in \mathbb{C}[V]$ and $g(P) \neq 0$. The set of points at which φ is regular is the **domain** of φ .

If $\varphi = f/g$ then φ genuinely is a function on the Zariski open set $V \setminus \mathbb{V}(g)$, and this set is nonempty (as $g \neq 0$ in $\mathbb{C}[V]$) hence dense, since V is irreducible. The domain of φ is the union of all such open sets, so it is a dense open subset of V . A rational function is thus a function defined ‘almost everywhere’.

Example 24.3.19

Consider $\varphi = X_1^2/X_2 \in \mathbb{C}(\mathbb{A}^2)$. As written it is defined off the locus $X_2 = 0$. Note that $X_1^3/(X_1X_2)$ is the *same* element of $\mathbb{C}(\mathbb{A}^2)$, even though the naive domain of the second expression is smaller. So an element of $\mathbb{C}(V)$ is not literally a function with a well-defined domain until we take the union over all representations. Here the domain really is $\mathbb{A}^2 \setminus \mathbb{V}(X_2)$.

Remark. A slicker way to say all this: a rational function on V is an equivalence class of pairs (U, f) where $U \subseteq V$ is nonempty open and $f: U \rightarrow \mathbb{C}$ is a regular function on U , and $(U, f) \sim (U', f')$ if $f = f'$ on some nonempty open subset of $U \cap U'$. Irreducibility guarantees that $U \cap U'$ is nonempty, so this really is an equivalence relation.

Just as regular functions assemble into morphisms, rational functions assemble into rational maps.

Definition 24.3.20 (Rational Map of Affine Varieties)

Let $V \subseteq \mathbb{A}^n$ be irreducible and $W \subseteq \mathbb{A}^m$ a variety. A **rational map** $\varphi: V \dashrightarrow W$ is a tuple $\varphi = (f_1, \dots, f_m)$ of rational functions $f_j \in \mathbb{C}(V)$ such that $\varphi(P) \in W$ for every P at which all the f_j are regular. The **domain** $\text{dom } \varphi$ is the set of such P , a dense open subset of V .

A rational map is thus a morphism defined on a dense open subset, and two rational maps agreeing on a dense open subset are equal. If $\varphi(\text{dom } \varphi)$ is dense in W we call φ **dominant**; in that case φ pulls back rational functions and gives an inclusion of fields $\varphi^*: \mathbb{C}(W) \hookrightarrow \mathbb{C}(V)$. We will develop all of this properly in the projective setting, where it belongs; for now, here is the example that everyone should have seen.

Example 24.3.21 (Rational parametrisation of the circle)

Let $C = \mathbb{V}(X^2 + Y^2 - 1) \subseteq \mathbb{A}^2$. Define $\varphi: C \dashrightarrow \mathbb{A}^1$ by

$$\varphi(x, y) = \frac{y}{1+x},$$

a rational map, regular away from the point $(-1, 0)$. Geometrically $\varphi(P)$ is the slope of the line joining $(-1, 0)$ to P . In the other direction, define $\psi: \mathbb{A}^1 \dashrightarrow C$ by

$$\psi(t) = \left(\frac{1-t^2}{1+t^2}, \frac{2t}{1+t^2} \right),$$

which is regular away from $t = \pm i$, and whose image does lie in C since $(1-t^2)^2 + (2t)^2 = (1+t^2)^2$. A direct substitution gives $\varphi\psi = \text{id}$ and $\psi\varphi = \text{id}$ wherever both sides are defined. So C and $\mathbb{A}^1$ are *birational*, even though φ is not defined everywhere: the conic and the line become isomorphic once we delete a point from each.

Reading the formula for ψ with $t = q/p$ rational and clearing denominators gives $(p^2 - q^2)^2 + (2pq)^2 = (p^2 + q^2)^2$, which is the classical parametrisation of Pythagorean triples. This is a good advertisement for the subject: a geometric statement about one conic contains an arithmetic statement about infinitely many integers.

The functions regular at a fixed point form a ring, and its structure is the local algebraic invariant we will use over and over again.

Definition 24.3.22 (Local Ring)

A ring R is a **local ring** if it has a unique maximal ideal.

Definition 24.3.23

Let V be an irreducible variety and $P \in V$. The **local ring of V at P** is

$$\mathcal{O}_{V,P} = \{\varphi \in \mathbb{C}(V) : \varphi \text{ is regular at } P\}.$$

Lemma 24.3.24

A ring R is a local ring if and only if $R \setminus R^\times$ is an ideal, in which case it is the unique maximal ideal.

Proof. An ideal $A \trianglelefteq R$ is proper if and only if A contains no unit, i.e. $A \subseteq R \setminus R^\times$. So if $R \setminus R^\times$ is an ideal, it is proper and contains every proper ideal, hence is the unique maximal ideal.

Conversely, suppose R is local with maximal ideal $\mathfrak{m}$. Then $\mathfrak{m} \subseteq R \setminus R^\times$. If $x \in R \setminus R^\times$ then $(x) \neq R$, so (x) is contained in a maximal ideal, which must be $\mathfrak{m}$. Hence $R \setminus R^\times = \mathfrak{m}$ is an ideal. $\square$

Proposition 24.3.25

$\mathcal{O}_{V,P}$ is a local ring, with maximal ideal

$$\mathfrak{m}_{V,P} = \{\varphi \in \mathcal{O}_{V,P} : \varphi(P) = 0\}.$$

Its units are exactly the φ with $\varphi(P) \neq 0$, and $\mathcal{O}_{V,P}/\mathfrak{m}_{V,P} \cong \mathbb{C}$.

Proof. If $\varphi = f/g \in \mathcal{O}_{V,P}$ with $g(P) \neq 0$, then φ is invertible in $\mathcal{O}_{V,P}$ if and only if $g/f \in \mathcal{O}_{V,P}$, which happens exactly when $f(P) \neq 0$, i.e. $\varphi(P) \neq 0$. So $\mathcal{O}_{V,P} \setminus \mathcal{O}_{V,P}^\times = \mathfrak{m}_{V,P}$, which is an ideal (being the kernel of the evaluation homomorphism $\varphi \mapsto \varphi(P)$). Lemma 24.3.24 applies. Evaluation is surjective onto $\mathbb{C}$, giving the last statement. $\square$

Example 24.3.26

Take $V = \mathbb{A}^1$ and $P = 0$. Then

$$\mathcal{O}_{\mathbb{A}^1,0} = \left\{ \frac{f(t)}{g(t)} : g(0) \neq 0 \right\} \subseteq \mathbb{C}(t),$$

with maximal ideal (t) . This ring sits inside the ring $\mathbb{C}[[t]]$ of formal power series: expanding $1/g(t)$ as a power series (possible since $g(0) \neq 0$) embeds $\mathcal{O}_{\mathbb{A}^1,0} \hookrightarrow \mathbb{C}[[t]]$. The ring $\mathbb{C}[[t]]$ is also local, with maximal ideal (t) , and one should think of $\mathcal{O}_{\mathbb{A}^1,0}$ as the ring of ‘algebraic’ functions with a power series expansion at 0.

The local ring $\mathcal{O}_{V,P}$ is precisely the localisation of $\mathbb{C}[V]$ at the prime ideal $I(P)/I(V)$, in the sense of commutative algebra. It records everything about V near P , and much of the second half of these notes consists of extracting geometry from these rings.

§24.4 Projective Varieties

Affine varieties are not quite the right objects. Two problems recur: distinct parallel lines in $\mathbb{A}^2$ fail to meet, and affine varieties are never compact (in the Euclidean topology) unless they are finite. Both are cured by working in projective space, which adds ‘points at infinity’ in a canonical way. The payoff is enormous: theorems become clean, intersection numbers become constant, and the geometry of curves becomes tractable.

§24.4.1 Projective Space

Definition 24.4.1 (Projectivisation)

Let U be a finite-dimensional complex vector space. The **projectivisation** $\mathbb{P}(U)$ is the set of one-dimensional linear subspaces ('lines through the origin') of U . We write $\mathbb{P}^n = \mathbb{P}(\mathbb{C}^{n+1})$, **projective n -space**.

We index coordinates on $\mathbb{C}^{n+1}$ by $0, 1, \dots, n$. A line through the origin is spanned by some nonzero $(a_0, \dots, a_n)$, and two vectors span the same line exactly when they differ by a nonzero scalar. We write

$$(a_0 : a_1 : \dots : a_n) \in \mathbb{P}^n$$

for the point corresponding to the line spanned by $(a_0, \dots, a_n)$, and call these **homogeneous coordinates**. Thus

$$\mathbb{P}^n = \frac{\mathbb{C}^{n+1} \setminus \{0\}}{\mathbb{C}^\times},$$

where $\mathbb{C}^\times$ acts by scaling. For instance $(2 : 1 : -2) = (4 : 2 : -4) = (-1 : -\frac{1}{2} : 1)$ in $\mathbb{P}^2$.

The picture above (drawn over $\mathbb{R}$ for legibility) shows $\mathbb{P}^1$ as the set of lines through the origin in the plane. Almost every such line meets the horizontal line $x_1 = 1$ in exactly one point, which gives an identification of most of $\mathbb{P}^1$ with a copy of $\mathbb{A}^1$; the exception is the horizontal axis itself, which is 'the point at infinity'.

Let us record this decomposition in general. Splitting according to whether $a_0 = 0$,

$$\begin{aligned} \mathbb{P}^n &= \{(a_0 : \dots : a_n) : a_0 \neq 0\} \sqcup \{(0 : a_1 : \dots : a_n)\} \\ &= \{(1 : b_1 : \dots : b_n) : b_i \in \mathbb{C}\} \sqcup \mathbb{P}^{n-1} \\ &\cong \mathbb{A}^n \sqcup \mathbb{P}^{n-1}, \end{aligned}$$

where the first identification uses that we may scale a_0 to 1, uniquely. Iterating,

$$\mathbb{P}^n = \mathbb{A}^n \sqcup \mathbb{A}^{n-1} \sqcup \dots \sqcup \mathbb{A}^1 \sqcup \{\text{pt}\}.$$

In particular $\mathbb{P}^1 = \mathbb{A}^1 \sqcup \{\infty\}$ is the Riemann sphere, and $\mathbb{P}^2$ is an affine plane together with a 'line at infinity'.

The same picture in one dimension higher is the one to carry around for the rest of the course. A point of $\mathbb{P}^2$ is a line through the origin in $\mathbb{C}^3$; such a line meets the affine plane $\{x_0 = 1\}$ in exactly one point unless it happens to lie in the plane $\{x_0 = 0\}$, in which case it contributes a point of the line at infinity.

The three blue lines are three points of $\mathbb{A}^2 \subseteq \mathbb{P}^2$; the red line, lying in the plane $x_0 = 0$ and so never meeting $\{x_0 = 1\}$, is one of the points of ℓ_∞ .

Definition 24.4.2 (Standard Affine Patches)

For $0 \leq j \leq n$ let $H_j = \{(a_0 : \cdots : a_n) : a_j = 0\}$, the *j th coordinate hyperplane*, and let $U_j = \mathbb{P}^n \setminus H_j$ be the *j th standard affine patch*.

There is a bijection $U_j \rightarrow \mathbb{A}^n$ given by

$$(a_0 : \cdots : a_n) \mapsto \left(\frac{a_0}{a_j}, \dots, \widehat{\frac{a_j}{a_j}}, \dots, \frac{a_n}{a_j} \right),$$

where the hat means ‘omit’, with inverse $(b_1, \dots, b_n) \mapsto (b_1 : \cdots : b_{j-1} : 1 : b_j : \cdots : b_n)$. Each H_j is a copy of $\mathbb{P}^{n-1}$. Since a point of $\mathbb{P}^n$ has some nonzero coordinate, $\{U_0, \dots, U_n\}$ covers $\mathbb{P}^n$: projective space is glued together out of $n + 1$ copies of affine space.

Definition 24.4.3

The **Zariski** (resp. **Euclidean**) topology on $\mathbb{P}^n$ is the quotient topology induced from the Zariski (resp. Euclidean) topology on $\mathbb{C}^{n+1} \setminus \{\mathbf{0}\}$ by the quotient map $\pi : \mathbb{C}^{n+1} \setminus \{\mathbf{0}\} \rightarrow \mathbb{P}^n$.

Proposition 24.4.4

$\mathbb{P}^n$ is compact in the Euclidean topology.

Proof. The unit sphere $S^{2n+1} \subseteq \mathbb{C}^{n+1} \setminus \{\mathbf{0}\}$ is compact, and every line through the origin meets it, so $\pi|_{S^{2n+1}}$ is surjective and continuous. A continuous image of a compact space is compact. $\square$

This is the second reason to prefer $\mathbb{P}^n$: it is compact, whereas $\mathbb{A}^n$ is not. Compactness will be responsible for a great deal of good behaviour, most notably the fact that the image of a projective variety under a morphism is closed.

§24.4.2 Homogeneous Ideals and Projective Varieties

We cannot simply take vanishing loci of arbitrary polynomials in $\mathbb{P}^n$.

Example 24.4.5

The polynomial $X_0 + 1 \in \mathbb{C}[X_0, X_1]$ does not define a function on $\mathbb{P}^1$, nor even a well-defined zero set: at the point $(-1 : 0) = (1 : 0)$ the representative $(-1, 0)$ gives 0 while $(1, 0)$ gives 2.

The fix is to restrict to polynomials whose vanishing is scale-invariant.

Definition 24.4.6 (Homogeneous Polynomial)

A **monomial** in $\mathbb{C}[X_0, \dots, X_n]$ is a product $X_0^{d_0} \cdots X_n^{d_n}$ with $d_i \geq 0$; its **degree** is $\sum_i d_i$. A polynomial is **homogeneous of degree d** if it is a $\mathbb{C}$ -linear combination of monomials of degree d .

Every $f \in \mathbb{C}[\mathbf{X}]$ decomposes uniquely as a finite sum $f = \sum_{r \geq 0} f_{[r]}$ with $f_{[r]}$ homogeneous of degree r ; we call $f_{[r]}$ the **homogeneous parts** of f .

Lemma 24.4.7

If F is homogeneous of degree d then $F(\lambda \mathbf{a}) = \lambda^d F(\mathbf{a})$. In particular, whether $F(\mathbf{a}) = 0$ depends only on the point $(\mathbf{a}) \in \mathbb{P}^n$, not on the representative.

Proof. Each monomial of degree d scales by λ^d . □

Definition 24.4.8 (Homogeneous Ideal)

An ideal $I \subseteq \mathbb{C}[X_0, \dots, X_n]$ is **homogeneous** if it can be generated by homogeneous polynomials (possibly of different degrees).

Lemma 24.4.9

An ideal I is homogeneous if and only if for every $f \in I$, all homogeneous parts $f_{[r]}$ lie in I .

Proof. ($\Leftarrow$) Take any generating set and replace each generator by its homogeneous parts.

($\Rightarrow$) Let I be generated by homogeneous $g_1, \dots, g_s$ with $\deg g_j = d_j$, and let $f = \sum_j h_j g_j \in I$. Splitting each h_j into homogeneous parts $h_{j[r]}$, the degree r part of f is $f_{[r]} = \sum_j h_{j[r-d_j]} g_j \in I$. □

Definition 24.4.10 (Projective Variety)

Let I be a homogeneous ideal of $\mathbb{C}[X_0, \dots, X_n]$. Its **vanishing locus** is

$$\mathbb{V}(I) = \{P \in \mathbb{P}^n : F(P) = 0 \text{ for all homogeneous } F \in I\}.$$

A **projective variety** is a subset of $\mathbb{P}^n$ of this form.

By Lemma 24.4.9 this is the same as requiring $f(P) = 0$ for all $f \in I$, interpreting

‘ $f(P) = 0$ ’ as ‘ $f(\mathbf{a}) = 0$ for one, equivalently every, representative $\mathbf{a}$ ’. As in the affine case, the projective varieties are the closed sets of a topology; we omit the (identical) verification.

Example 24.4.11

Let $U \leq \mathbb{C}^{n+1}$ be a linear subspace, say the kernel of a collection of linear forms L_j . Then $\mathbb{P}(U) = \mathbb{V}(\{L_j\}) \subseteq \mathbb{P}^n$ is a projective variety, called a **projective linear subspace**. Projective linear subspaces of $\mathbb{P}^n$ are in bijection with linear subspaces of $\mathbb{C}^{n+1}$; those of dimension 1 are called **lines**, and those of dimension $n - 1$ are **hyperplanes**.

Example 24.4.12

Two distinct lines in $\mathbb{P}^2$ always meet, in exactly one point. Indeed, they correspond to distinct 2-dimensional subspaces $U_1, U_2 \leq \mathbb{C}^3$, and $\dim(U_1 \cap U_2) \geq 2 + 2 - 3 = 1$, with equality since $U_1 \neq U_2$. This is the first fruit of working projectively: there are no parallel lines.

The group $\mathrm{GL}_{n+1}(\mathbb{C})$ acts on $\mathbb{P}^n$ by acting on homogeneous coordinates. Scalar matrices act trivially, so the action factors through

$$\mathrm{PGL}_{n+1}(\mathbb{C}) = \mathrm{GL}_{n+1}(\mathbb{C})/\mathbb{C}^\times,$$

and this group acts transitively on $\mathbb{P}^n$ (indeed on ordered $(n + 2)$ -tuples of points in general position). We refer to elements of $\mathrm{PGL}_{n+1}(\mathbb{C})$ as **projective changes of coordinates**, and we will use them freely to put varieties into convenient position.

§24.4.3 Affine Charts and Projective Closure

We have $\mathbb{P}^n = U_0 \cup \cdots \cup U_n$ with each $U_j \cong \mathbb{A}^n$. The relationship between projective varieties and their affine pieces goes both ways.

Suppose $V = \mathbb{V}(I) \subseteq \mathbb{P}^n$ is a projective variety. Identify $U_0 \cong \mathbb{A}^n$ with coordinates $Y_i = X_i/X_0$. Then

$$V \cap U_0 = \mathbb{V}(I_0), \quad I_0 = \{F(1, Y_1, \dots, Y_n) : F \in I \text{ homogeneous}\},$$

an affine variety. So *the intersection of a projective variety with an affine chart is an affine variety*: locally, projective varieties look affine.

Conversely, given an affine variety $W \subseteq \mathbb{A}^n \cong U_0$, we may take its closure in $\mathbb{P}^n$. The following makes this explicit.

Definition 24.4.13 (Homogenisation)

Let $f \in \mathbb{C}[Y_1, \dots, Y_n]$ have total degree d . Its **homogenisation** is

$$f^h(X_0, \dots, X_n) = X_0^d f\left(\frac{X_1}{X_0}, \dots, \frac{X_n}{X_0}\right) \in \mathbb{C}[X_0, \dots, X_n],$$

which is homogeneous of degree d and not divisible by X_0 . For an ideal $I \subseteq \mathbb{C}[\mathbf{Y}]$

we write I^h for the ideal generated by $\{f^h : f \in I\}$; this is homogeneous. The **projective closure** of an affine variety $V \subseteq \mathbb{A}^n$ is $\mathbb{V}(I(V)^h) \subseteq \mathbb{P}^n$.

Example 24.4.14

If $f(Y_1, Y_2) = 1 + Y_1^2 + Y_1Y_2^2$ then $d = 3$ and $f^h = X_0^3 + X_0X_1^2 + X_1X_2^2$.

Remark. It is essential to homogenise *every* element of I , not merely a generating set. If $I = (f_1, \dots, f_r)$ then $(f_1^h, \dots, f_r^h) \subseteq I^h$ but the containment is often strict. (It is an equality when I is principal.) For example, in $\mathbb{C}[Y_1, Y_2, Y_3]$ take the ideal of the affine twisted cubic $I = (Y_2 - Y_1^2, Y_3 - Y_1^3)$; homogenising the two generators gives $X_0X_2 - X_1^2$ and $X_0^2X_3 - X_1^3$, whose common zero locus contains the whole line $\{X_0 = X_1 = 0\}$, which is not in the projective closure of the twisted cubic. One needs also the homogenisation of $Y_1Y_3 - Y_2^2 \in I$, namely $X_1X_3 - X_2^2$.

Proposition 24.4.15

Let $V \subseteq \mathbb{A}^n = U_0$ be an affine variety. Then the Zariski closure $\overline{V}$ of V in $\mathbb{P}^n$ equals the projective closure $\mathbb{V}(I(V)^h)$.

Proof. Write $I = I(V)$, which we may assume radical. Certainly $\mathbb{V}(I^h)$ is closed and contains V (as f^h restricted to U_0 is f), so $\overline{V} \subseteq \mathbb{V}(I^h)$.

Conversely, let $Y = \mathbb{V}(J) \supseteq V$ be any closed set, J homogeneous. Take a homogeneous $G \in J$; we may write $G = X_0^e f^h$ for some $f \in \mathbb{C}[\mathbf{Y}]$ and $e \geq 0$, by dehomogenising and re-homogenising. Now G vanishes on V , so $f = G(1, \mathbf{Y})$ vanishes on $V \subseteq \mathbb{A}^n$, so $f \in I(V) = I$. Hence $f^h \in I^h$ and so $G = X_0^e f^h \in I^h$. Therefore $J \subseteq I^h$ and $\mathbb{V}(I^h) \subseteq \mathbb{V}(J) = Y$. Taking $Y = \overline{V}$ gives the reverse inclusion. $\square$

Remark. The operations do not quite invert one another. If $V \subseteq \mathbb{P}^n$ is projective and $W = V \cap U_0$, then $\overline{W}$ need not be V : take $V = \mathbb{V}(X_0)$, so $W = \emptyset$ and $\overline{W} = \emptyset \neq V$. The problem is that V may have components entirely at infinity.

Example 24.4.16

Let $V = \mathbb{V}(X_0X_1 - X_2^2) \subseteq \mathbb{P}^2$, a conic. Look at it in the three standard patches.

- In U_0 , setting $X_0 = 1$ and writing $(y_1, y_2) = (X_1/X_0, X_2/X_0)$, we get $y_1 = y_2^2$: a parabola.
- In U_1 we similarly get a parabola.
- In U_2 , setting $X_2 = 1$ and writing $(z_0, z_1) = (X_0/X_2, X_1/X_2)$, we get $z_0z_1 = 1$: a rectangular hyperbola.

So the parabola and the hyperbola are two views of the same projective curve, seen from different affine charts. The ellipse is a third. That the conics of school geometry become a single object is one of the most satisfying features of projective geometry.

It is worth drawing the picture that goes with this. Fix the chart $U_0 \cong \mathbb{A}^2$ and think of $\mathbb{P}^2$ as this affine plane together with the line at infinity $\ell_\infty = \mathbb{V}(X_0)$, whose points record the directions in which one can head off to infinity. A parabola in the affine plane

has both of its arms heading off in the same (vertical) direction, so in $\mathbb{P}^2$ they meet at a single point of ℓ_∞ , and the projective conic is a closed curve.

Here is the general classification, which is just the classification of quadratic forms from IB Linear Algebra.

Theorem 24.4.17

Let $Q = \mathbb{V}(F) \subseteq \mathbb{P}^n$ with F homogeneous of degree 2. After a projective change of coordinates, $F = X_0^2 + X_1^2 + \cdots + X_{r-1}^2$, where r is the rank of the quadratic form F .

Proof. Over $\mathbb{C}$ every quadratic form is equivalent to $\sum_{i < r} X_i^2$ where r is its rank. $\square$

§24.4.4 The Projective Nullstellensatz

Two homogeneous ideals may cut out the same projective variety for a trivial reason: the **irrelevant ideal** $\mathfrak{m}_0 = (X_0, \dots, X_n)$ has $\mathbb{V}(\mathfrak{m}_0) = \emptyset$ in $\mathbb{P}^n$ (its affine cone is just the origin, which we deleted). So the correct statement has to allow for this.

Definition 24.4.18

For $V \subseteq \mathbb{P}^n$, let $I^h(V) \trianglelefteq \mathbb{C}[X_0, \dots, X_n]$ be the ideal generated by all homogeneous polynomials vanishing on V .

Theorem 24.4.19 (Projective Nullstellensatz)

Let I be a homogeneous ideal of $\mathbb{C}[X_0, \dots, X_n]$.

- (i) $\mathbb{V}(I) = \emptyset$ in $\mathbb{P}^n$ if and only if $\sqrt{I} \supseteq (X_0, \dots, X_n)$.
- (ii) If $V = \mathbb{V}(I) \neq \emptyset$ then $I^h(V) = \sqrt{I}$.

Proof. Let $C(V) = \mathbb{V}(I) \subseteq \mathbb{A}^{n+1}$ denote the affine vanishing locus, the **affine cone**. Since I is homogeneous, $C(V)$ is stable under scaling and contains $\mathbf{0}$, and the quotient map restricts to a surjection $C(V) \setminus \{\mathbf{0}\} \rightarrow \mathbb{V}(I) \subseteq \mathbb{P}^n$. In particular $\mathbb{V}(I) = \emptyset$ if and only if $C(V) \subseteq \{\mathbf{0}\}$.

For (i), $C(V) \subseteq \{\mathbf{0}\}$ means $I(C(V)) \supseteq (X_0, \dots, X_n)$, and by the affine Nullstellen-

satz $I(C(V)) = \sqrt{I}$.

For (ii), the homogeneous polynomials vanishing on $\mathbb{V}(I) \subseteq \mathbb{P}^n$ are exactly the homogeneous polynomials vanishing on $C(V) \subseteq \mathbb{A}^{n+1}$, so $I^h(V) = I(C(V)) = \sqrt{I}$ by the affine Nullstellensatz again (using Lemma 24.4.9 to see that $I(C(V))$ is homogeneous). $\square$

Exactly as before, we get:

Proposition 24.4.20 (i) Every projective variety is a finite union of irreducible projective varieties, uniquely if the decomposition is minimal.

(ii) A projective variety V is irreducible if and only if $I^h(V)$ is prime.

Proof. (i) is verbatim the affine argument. For (ii), the only new point is that if a homogeneous ideal I is not prime then there exist *homogeneous* $F, G \notin I$ with $FG \in I$: take $f, g \notin I$ with $fg \in I$, and let F (resp. G) be a homogeneous part of f (resp. g) of largest degree not lying in I ; then the top-degree part of fg that could fail to lie in I is FG . With that in hand, the affine proof applies. $\square$

Proposition 24.4.21

Let $V \subseteq \mathbb{P}^n$ be irreducible and $W \subsetneq V$ a proper closed subvariety. Then $V \setminus W$ is dense in V .

Proof. Let F be homogeneous and vanish on $V \setminus W$. Since $W \neq V$, by the projective Nullstellensatz there is a homogeneous $G \in I^h(W) \setminus I^h(V)$. Then FG vanishes on W (because G does) and on $V \setminus W$ (because F does), hence on all of V . As $I^h(V)$ is prime and $G \notin I^h(V)$, we get $F \in I^h(V)$. So every homogeneous polynomial vanishing on $V \setminus W$ vanishes on V , which says exactly that $V \setminus W$ is dense. $\square$

This is the projective form of the principle that nonempty open subsets are large. Morally, W is lower-dimensional than V , and removing something lower-dimensional cannot disconnect or shrink an irreducible variety.

§24.4.5 Rational Functions on Projective Varieties

There is no useful analogue of the coordinate ring in the projective setting: a homogeneous polynomial has a well-defined zero set on $\mathbb{P}^n$ but not a well-defined value. However, a *ratio* of two homogeneous polynomials of the same degree *does* have a well-defined value wherever the denominator does not vanish, since the scaling factors λ^d cancel.

Definition 24.4.22 (Function Field)

Let $V \subseteq \mathbb{P}^n$ be an irreducible projective variety. Its **function field** is

$$\mathbb{C}(V) = \left\{ \frac{F}{G} : F, G \in \mathbb{C}[\mathbf{X}] \text{ homogeneous of the same degree, } G \notin I^h(V) \right\} / \sim,$$

where $F_1/G_1 \sim F_2/G_2$ if and only if $F_1G_2 - F_2G_1 \in I^h(V)$.

Lemma 24.4.23

The relation $\sim$ is an equivalence relation, and $\mathbb{C}(V)$ is a field.

Proof. Reflexivity and symmetry are clear. For transitivity, suppose $F_1G_2 \equiv F_2G_1$ and $F_2G_3 \equiv F_3G_2$ modulo $I^h(V)$. Working in the integral domain $R = \mathbb{C}[\mathbf{X}]/I^h(V)$ (a domain since $I^h(V)$ is prime), we get $\bar{F}_1\bar{G}_2\bar{G}_3 = \bar{F}_2\bar{G}_1\bar{G}_3 = \bar{F}_3\bar{G}_2\bar{G}_1$, so $\bar{G}_2(\bar{F}_1\bar{G}_3 - \bar{F}_3\bar{G}_1) = 0$. As $\bar{G}_2 \neq 0$ and R is a domain, $F_1G_3 - F_3G_1 \in I^h(V)$.

The field operations are the evident ones (note that $F_1/G_1 + F_2/G_2 = (F_1G_2 + F_2G_1)/G_1G_2$ is again a ratio of forms of equal degree), and F/G is invertible whenever $F \notin I^h(V)$. $\square$

Proposition 24.4.24

$\mathbb{C}(V)$ is a finitely generated field extension of $\mathbb{C}$.

Proof. Some coordinate, say X_0 , does not vanish identically on V . We claim $\mathbb{C}(V) = \mathbb{C}(x_1, \dots, x_n)$ where x_i is the class of X_i/X_0 . Given a ratio F/G of forms of degree d , divide numerator and denominator by X_0^d ; then F/X_0^d is a polynomial in the X_i/X_0 , and likewise for G . So F/G lies in the field generated by the x_i . $\square$

Corollary 24.4.25

Let $V \subseteq \mathbb{P}^n$ be irreducible with $V \not\subseteq \{X_0 = 0\}$, and let $V_0 = V \cap U_0$, an irreducible affine variety. Then $\mathbb{C}(V) \cong \mathbb{C}(V_0)$.

Proof. $\mathbb{C}[V_0] = \mathbb{C}[x_1, \dots, x_n]$ where x_i is the restriction of X_i/X_0 , so $\mathbb{C}(V_0) = \text{Frac } \mathbb{C}[V_0]$ is generated by the x_i , and the proof above shows $\mathbb{C}(V)$ is too. One checks the relations match, giving an isomorphism. $\square$

So the function field is a birational invariant that can be computed in any affine chart. Regularity and local rings are defined exactly as before: $\varphi \in \mathbb{C}(V)$ is **regular at P** if it can be written F/G with $G(P) \neq 0$, and $\mathcal{O}_{V,P} \subseteq \mathbb{C}(V)$ is the local ring of germs at P , with maximal ideal $\mathfrak{m}_P$. Under the isomorphism of Corollary 24.4.25, $\mathcal{O}_{V,P} \cong \mathcal{O}_{V_0,P}$ for $P \in V_0$.

§24.4.6 Rational Maps and Morphisms**Proposition 24.4.26**

Let $F_0, \dots, F_m \in \mathbb{C}[X_0, \dots, X_n]$ be homogeneous of the same degree d , not all zero. Then $\mathbf{F} = (F_0, \dots, F_m)$ descends to a well-defined map

$$\varphi: \mathbb{P}^n \setminus \mathbb{V}(F_0, \dots, F_m) \rightarrow \mathbb{P}^m, \quad P \mapsto (F_0(\mathbf{a}) : \dots : F_m(\mathbf{a})),$$

where $\mathbf{a}$ is any representative of P .

Proof. Replacing $\mathbf{a}$ by $\lambda\mathbf{a}$ multiplies every $F_j(\mathbf{a})$ by λ^d , which does not change the point of $\mathbb{P}^m$. The condition $P \notin \mathbb{V}(F_0, \dots, F_m)$ ensures not all coordinates are zero. $\square$

Two tuples can define the same map on the overlap of their domains: multiplying all F_j by a fixed homogeneous G gives a tuple defining the same map wherever both are defined, but on a smaller set. The following definition is designed to handle this.

Definition 24.4.27 (Rational Map)

Let $V \subseteq \mathbb{P}^n$ be irreducible. A **rational map** $\varphi: V \dashrightarrow \mathbb{P}^m$ is an equivalence class of tuples $(F_0, \dots, F_m)$ of homogeneous polynomials of a common degree, not all in $I^h(V)$, where

$$(F_0, \dots, F_m) \sim (G_0, \dots, G_m) \iff F_i G_j - F_j G_i \in I^h(V) \text{ for all } i, j.$$

A point $P \in V$ is a **regular point** of φ if some representative has $F_j(P) \neq 0$ for some j . The **domain** $\text{dom } \varphi$ is the set of regular points. If $\text{dom } \varphi = V$, we call φ a **morphism** and write $\varphi: V \rightarrow \mathbb{P}^m$.

If $W \subseteq \mathbb{P}^m$ is a projective variety, a rational map (or morphism) $V \dashrightarrow W$ is one $V \dashrightarrow \mathbb{P}^m$ whose image lies in W . An **isomorphism** is a morphism with a two-sided inverse morphism.

The subtlety here – that a rational map may be regular at a point without any *obvious* representative witnessing it – is important, and the next example is the one to remember.

Example 24.4.28 (Projection from a point)

Let $P = (0 : 0 : 1) \in \mathbb{P}^2$ and define $\pi: \mathbb{P}^2 \dashrightarrow \mathbb{P}^1$ by $\pi(a_0 : a_1 : a_2) = (a_0 : a_1)$. This is undefined exactly at P , and it is regular everywhere else. Geometrically, π sends a point $Q \neq P$ to the line PQ , thought of as a point of the $\mathbb{P}^1$ of lines through P .

Example 24.4.29

Let $C = \mathbb{V}(X_0 X_2 - X_1^2) \subseteq \mathbb{P}^2$ and restrict the projection π of the previous example to C . Note $P = (0 : 0 : 1) \in C$, so *a priori* $\pi|_C$ is undefined at P . But $\pi|_C$ is represented by (X_0, X_1) , and we may look for another representative (F_0, F_1) with

$$F_0 X_1 - F_1 X_0 \in I^h(C) = (X_0 X_2 - X_1^2).$$

The pair (X_1, X_2) works, since $X_1 \cdot X_1 - X_2 \cdot X_0 = -(X_0 X_2 - X_1^2)$. At $P = (0 : 0 : 1)$ we have $X_2(P) = 1 \neq 0$, so $\pi|_C$ is regular at P , with value $\pi(P) = (0 : 1)$. Hence $\pi|_C: C \rightarrow \mathbb{P}^1$ is a morphism.

The picture shows the construction: a point $Q \in C$ is sent to the point where the line PQ meets a fixed line. Since a line meets a conic in two points, and one of them is P , the other is determined, and this is why the map is a bijection.

Proposition 24.4.30

Let $C = \mathbb{V}(F) \subseteq \mathbb{P}^2$ with F an irreducible homogeneous quadratic. Then $C \cong \mathbb{P}^1$.

Proof. An irreducible quadratic form in three variables has rank 3; after a change of coordinates we may take $F = X_0X_2 - X_1^2$. By Example 24.4.29 we have a morphism $\pi: C \rightarrow \mathbb{P}^1$. Define $\mu: \mathbb{P}^1 \rightarrow \mathbb{P}^2$ by

$$\mu(Y_0 : Y_1) = (Y_0^2 : Y_0Y_1 : Y_1^2).$$

This is a morphism (the three forms have no common zero on $\mathbb{P}^1$), and its image lies in C since $Y_0^2 \cdot Y_1^2 - (Y_0Y_1)^2 = 0$. Now $\pi(\mu(Y_0 : Y_1)) = (Y_0^2 : Y_0Y_1) = (Y_0 : Y_1)$ whenever $Y_0 \neq 0$, and using the other representative (X_1, X_2) of π we get $(Y_0Y_1 : Y_1^2) = (Y_0 : Y_1)$ whenever $Y_1 \neq 0$; so $\pi\mu = \text{id}$. Conversely, for $(a_0 : a_1 : a_2) \in C$ we have $a_0a_2 = a_1^2$, so $\mu(a_0 : a_1) = (a_0^2 : a_0a_1 : a_1^2) = (a_0^2 : a_0a_1 : a_0a_2) = (a_0 : a_1 : a_2)$ when $a_0 \neq 0$, and similarly on the other patch. So $\mu\pi = \text{id}$. $\square$

So up to isomorphism there is only one smooth conic in $\mathbb{P}^2$, and it is a line. The distinction between lines and conics is a matter of how they are embedded, not of their intrinsic geometry. We will see in due course that this ceases to be true in degree 3 and beyond.

Example 24.4.31 (Veronese embedding)

Fix $n, d \geq 1$ and let $F_0, \dots, F_m$ be all the monomials of degree d in $X_0, \dots, X_n$, so $m = \binom{n+d}{d} - 1$. The **Veronese map** is

$$\nu_d: \mathbb{P}^n \rightarrow \mathbb{P}^m, \quad \mathbf{a} \mapsto (F_0(\mathbf{a}) : \dots : F_m(\mathbf{a})).$$

It is a morphism, since the F_j include X_i^d for each i and these have no common zero. One can show ν_d is injective with image a projective variety isomorphic to $\mathbb{P}^n$. The map μ used in Proposition 24.4.30 is ν_2 for $n = 1$. The point of the construction is that ν_d turns degree d hypersurfaces into hyperplane sections.

Example 24.4.32 (Segre embedding)

Products of projective spaces are not projective spaces: $\mathbb{P}^n \times \mathbb{P}^m \not\cong \mathbb{P}^{n+m}$. But they

are still projective varieties. The **Segre map** is

$$\sigma_{n,m}: \mathbb{P}^n \times \mathbb{P}^m \rightarrow \mathbb{P}^{nm+n+m}, \quad ((x_i), (y_j)) \mapsto (x_i y_j)_{i,j},$$

where we index the target coordinates by Z_{ij} , $0 \leq i \leq n$, $0 \leq j \leq m$. Note $(n+1)(m+1) - 1 = nm + n + m$.

Theorem 24.4.33

The Segre map $\sigma_{n,m}$ is a bijection onto the projective variety $\mathbb{V}(I)$, where I is generated by the quadrics $Z_{ij}Z_{pq} - Z_{iq}Z_{pj}$.

Proof. Clearly the image lies in $\mathbb{V}(I)$. Work on the patch $Z_{00} \neq 0$ and set $y_{ij} = Z_{ij}/Z_{00}$. The relations $Z_{ij}Z_{00} = Z_{i0}Z_{0j}$ become $y_{ij} = y_{i0}y_{0j}$, and one checks the remaining relations follow. So on this patch $\mathbb{V}(I)$ is the graph of the map $\mathbb{A}^n \times \mathbb{A}^m \rightarrow \mathbb{A}^{nm}$, $((y_{i0}), (y_{0j})) \mapsto (y_{i0}y_{0j})$, and hence

$$(y_{ij}) \longmapsto ((y_{10}, \dots, y_{n0}), (y_{01}, \dots, y_{0m}))$$

is a two-sided inverse to $\sigma_{n,m}$ there. The same works on each patch $Z_{ij} \neq 0$. $\square$

Concretely, $\sigma_{1,1}: \mathbb{P}^1 \times \mathbb{P}^1 \rightarrow \mathbb{P}^3$ has image the quadric surface $\mathbb{V}(Z_{00}Z_{11} - Z_{01}Z_{10}) \subseteq \mathbb{P}^3$: identifying $\mathbb{C}^4$ with 2×2 matrices, $\sigma_{1,1}$ is the outer product $(v, w) \mapsto vw^T$, whose image is the set of matrices of rank at most one, cut out by the vanishing of the determinant. As a corollary, products of projective varieties are projective varieties.

§24.4.7 Birational Maps

Composing rational maps is delicate: the image of $\text{dom } \varphi$ might land entirely inside the indeterminacy locus of ψ . The following condition rules this out.

Definition 24.4.34 (Dominant)

A rational map $\varphi: V \dashrightarrow W$ is **dominant** if $\varphi(\text{dom } \varphi)$ is Zariski dense in W .

Proposition 24.4.35

If $\varphi: V \dashrightarrow W$ is dominant then $\psi \circ \varphi$ is a well-defined rational map for any rational $\psi: W \dashrightarrow Z$.

Proof. $\text{dom } \psi$ is a nonempty open subset of W , and $\varphi(\text{dom } \varphi)$ is dense, so $\varphi^{-1}(\text{dom } \psi)$ is a nonempty open subset of $\text{dom } \varphi$. On it, $\psi \circ \varphi$ is given by composing tuples of homogeneous polynomials, hence is a rational map. $\square$

A dominant rational map $\varphi: V \dashrightarrow W$ induces a $\mathbb{C}$ -algebra map on function fields $\varphi^*: \mathbb{C}(W) \rightarrow \mathbb{C}(V)$ by $f \mapsto f \circ \varphi$; this is a map of fields, hence injective.

Definition 24.4.36 (Birational)

Irreducible varieties V, W are **birational** if there are dominant rational maps $\varphi: V \dashrightarrow W$ and $\psi: W \dashrightarrow V$ with $\psi\varphi$ and $\varphi\psi$ equal to the identity as rational maps. Such φ is called a **birational map**.

Equivalently, V and W are birational if they contain isomorphic nonempty open subsets. Every isomorphism is birational, but not conversely.

Example 24.4.37 (Cremona transformation)

Consider $\kappa: \mathbb{P}^2 \dashrightarrow \mathbb{P}^2$ given by

$$\kappa(X_0 : X_1 : X_2) = (X_1X_2 : X_0X_2 : X_0X_1),$$

which is $(x_0 : x_1 : x_2) \mapsto (1/x_0 : 1/x_1 : 1/x_2)$ cleared of denominators. It is undefined exactly at the three coordinate points $(1 : 0 : 0), (0 : 1 : 0), (0 : 0 : 1)$. One computes $\kappa \circ \kappa = \text{id}$ as a rational map, so κ is birational; it is not an isomorphism, since it is not everywhere defined. The Cremona transformation sends a general line to a conic, so it certainly does not preserve degrees.

Remark. The group $\text{Bir}(\mathbb{P}^2)$ of birational automorphisms of $\mathbb{P}^2$ is called the *Cremona group*. A theorem of Noether and Castelnuovo says it is generated by $\text{PGL}_3(\mathbb{C})$ together with κ . The analogous statement in higher dimensions is false and the structure of $\text{Bir}(\mathbb{P}^n)$ for $n \geq 3$ remains mysterious.

Theorem 24.4.38

Let V, W be irreducible projective varieties. Then V and W are birational if and only if $\mathbb{C}(V) \cong \mathbb{C}(W)$ as $\mathbb{C}$ -algebras.

Proof. $(\Rightarrow)$ A birational map φ gives $\varphi^*: \mathbb{C}(W) \rightarrow \mathbb{C}(V)$ and φ^{-1} gives an inverse, so these are isomorphisms.

$(\Leftarrow)$ Suppose $\Theta: \mathbb{C}(W) \rightarrow \mathbb{C}(V)$ is a $\mathbb{C}$ -algebra isomorphism. We may assume $V \subseteq \mathbb{P}^n$ is not contained in $\{X_0 = 0\}$ and $W \subseteq \mathbb{P}^m$ is not contained in $\{Y_0 = 0\}$. As we showed, $\mathbb{C}(V) = \mathbb{C}(x_1, \dots, x_n)$ with $x_i = X_i/X_0$ and $\mathbb{C}(W) = \mathbb{C}(y_1, \dots, y_m)$ with $y_j = Y_j/Y_0$. Write $\Theta(y_j) = f_j(x_1, \dots, x_n)$ for rational functions f_j of n variables. Clearing denominators and homogenising with respect to X_0 , there are homogeneous $F_0, \dots, F_m$ of a common degree with

$$f_j\left(\frac{X_1}{X_0}, \dots, \frac{X_n}{X_0}\right) = \frac{F_j(X_0, \dots, X_n)}{F_0(X_0, \dots, X_n)}.$$

Then $(F_0 : \dots : F_m)$ defines a rational map $\varphi: V \dashrightarrow \mathbb{P}^m$; its image lies in W , since any homogeneous $G \in I^h(W)$ pulls back to $G(f_1, \dots, f_m)$ up to a factor, which is Θ applied to the relation $G(y_1, \dots, y_m) = 0$, hence zero. Running the same argument with Θ^{-1} gives $\psi: W \dashrightarrow V$, and the composites induce the identity on function fields, hence are the identity as rational maps. $\square$

This should be compared with Corollary 24.3.13: coordinate rings classify affine varieties up to isomorphism, and function fields classify irreducible varieties up to birational equivalence. Classifying varieties up to birational equivalence is thus the same as classifying finitely generated field extensions of $\mathbb{C}$, and for curves we will be able to do this

completely.

§24.5 Tangent Spaces, Smoothness and Dimension

So far our varieties have been rather formless: we have no notion of how big one is, and no way to distinguish the smooth curve $y = x^2$ from the cuspidal one $y^2 = x^3$. Both defects are repaired at once by the tangent space, which is a purely algebraic construction imitating the derivative.

§24.5.1 The Tangent Space to a Hypersurface

Let $V = \mathbb{V}(f) \subseteq \mathbb{A}^n$ be a hypersurface and $P = (a_1, \dots, a_n) \in V$. A line through P has the form

$$L = \{(a_1 + b_1 t, \dots, a_n + b_n t) : t \in \mathbb{C}\}$$

for some $\mathbf{b} \in \mathbb{C}^n \setminus \{\mathbf{0}\}$. Substituting into f gives a polynomial in one variable,

$$g(t) = f(a_1 + b_1 t, \dots, a_n + b_n t) = \sum_{r \geq 0} c_r t^r,$$

whose roots are the parameters at which L meets V . Since $P \in V$ we have $c_0 = 0$, so $t = 0$ is a root; and by the chain rule

$$c_1 = g'(0) = \sum_{i=1}^n b_i \frac{\partial f}{\partial X_i}(P).$$

The line meets V at P ‘to order at least two’ – geometrically, is tangent – exactly when $c_1 = 0$ as well.

Definition 24.5.1 (Tangent Space to a Hypersurface)

Let $V = \mathbb{V}(f) \subseteq \mathbb{A}^n$ and $P \in V$. The **(affine embedded) tangent space** to V at P is the affine subspace

$$T_{V,P}^{\text{aff}} = \mathbb{V} \left(\sum_{i=1}^n \frac{\partial f}{\partial X_i}(P) (X_i - a_i) \right) \subseteq \mathbb{A}^n.$$

A line L through P is **tangent** to V at P if $L \subseteq T_{V,P}^{\text{aff}}$.

The polynomial cutting out $T_{V,P}^{\text{aff}}$ is linear, so $T_{V,P}^{\text{aff}}$ is either a hyperplane (dimension $n - 1$), when some partial derivative is nonzero at P , or all of $\mathbb{A}^n$, when they all vanish.

Definition 24.5.2 (Smooth and Singular Points)

With the notation above, P is a **singular point** of V if $\frac{\partial f}{\partial X_i}(P) = 0$ for all i , equivalently $\dim T_{V,P}^{\text{aff}} = n$. Otherwise P is a **smooth** (or **nonsingular**) point. V is **smooth** if all its points are.

This is the **Jacobian criterion**: a point is singular precisely when the gradient of the defining equation vanishes there. Let us test it on the standard examples.

Example 24.5.3 (Nodal cubic)

Let $C = \mathbb{V}(f)$ with $f = Y^2 - X^2(X + 1) = Y^2 - X^3 - X^2$. Then

$$\frac{\partial f}{\partial X} = -3X^2 - 2X, \quad \frac{\partial f}{\partial Y} = 2Y.$$

Both vanish when $Y = 0$ and $X(3X + 2) = 0$, i.e. at $(0, 0)$ and $(-2/3, 0)$; but $(-2/3, 0) \notin C$. So the unique singular point is the origin. Near the origin, $Y^2 \approx X^2$, and indeed the real picture shows two branches crossing transversally, with tangent lines $Y = \pm X$: this is a **node**.

The two grey lines are the tangent directions to the two branches; note that neither is ‘the’ tangent line, and that the tangent space at P is the whole plane.

Example 24.5.4 (Cuspidal cubic)

Let $C = \mathbb{V}(Y^2 - X^3)$. Then $\partial f/\partial X = -3X^2$ and $\partial f/\partial Y = 2Y$, both vanishing only at the origin, which lies on C . So again the origin is the unique singular point, but the singularity is of a different kind: the curve has a single branch with a **cusp**, parametrised by $t \mapsto (t^2, t^3)$.

**Example 24.5.5 (A smooth point)**

Contrast the previous two examples with $C = \mathbb{V}(f)$, $f = Y^2 - X^3 + X$, at the point $P = (-1/\sqrt{3}, y_0) \approx (-0.577, 0.620)$, where $y_0 = \sqrt{2}3^{-3/4}$. Here $\partial f/\partial Y = 2y_0 \neq 0$, so P is a smooth point, the tangent space is a line, and there is a genuine tangent

line: differentiating implicitly, its slope is

$$\left. \frac{3X^2 - 1}{2Y} \right|_P = \frac{3 \cdot \frac{1}{3} - 1}{2y_0} = 0,$$

so the tangent at P is the horizontal line $Y = y_0$. In fact this curve is smooth everywhere: $\partial f / \partial Y = 2Y = 0$ forces $Y = 0$, and then $X^3 = X$ and $3X^2 = 1$ cannot both hold.

Here the tangent line touches the curve and stays on one side of it near P – compare the node, where no single line is tangent, and the cusp, where the tangent ‘line’ degenerates entirely.

§24.5.2 Tangent Spaces in General

For a general variety, cut out by several equations, we take the intersection of the tangent hyperplanes and record it as a vector subspace rather than an affine one.

Definition 24.5.6 (Tangent Space)

Let $V \subseteq \mathbb{A}^n$ be a variety and $P \in V$. The **tangent space** is

$$T_{V,P} = \left\{ \mathbf{v} \in \mathbb{C}^n : \sum_{i=1}^n v_i \frac{\partial f}{\partial X_i}(P) = 0 \text{ for all } f \in I(V) \right\} \leq \mathbb{C}^n.$$

This is a linear subspace of $\mathbb{C}^n$, and it suffices to impose the conditions for f running over a generating set of $I(V)$, by the product and sum rules for derivatives. Concretely, if $I(V) = (f_1, \dots, f_r)$ then $T_{V,P}$ is the kernel of the **Jacobian matrix**

$$J(P) = \left(\frac{\partial f_j}{\partial X_i}(P) \right)_{j,i},$$

so that

$$\dim T_{V,P} = n - \text{rank } J(P).$$

Example 24.5.7

Revisiting Example 24.3.16: for $V = \mathbb{V}(X_1 X_2 (X_1 - X_2)) \subseteq \mathbb{A}^2$ we have $I(V) = (X_1 X_2 (X_1 - X_2))$, whose gradient is a vector of quadratics, vanishing at the origin. So $T_{V,0} = \mathbb{C}^2$. For $W = \mathbb{V}(X_1 X_2, X_2 X_3, X_3 X_1) \subseteq \mathbb{A}^3$ every generator has vanishing

gradient at the origin, so $T_{W,0} = \mathbb{C}^3$. If V and W were isomorphic, some isomorphism would carry the origin to the origin (it is the unique point of each where the local structure is singular), and would induce a linear isomorphism of tangent spaces. Since $2 \neq 3$, $V \not\cong W$.

To transport tangent spaces along maps we need the derivative. Let $\varphi: V \dashrightarrow W$ be a rational map of irreducible varieties, $P \in \text{dom } \varphi$ and $Q = \varphi(P)$. Working in affine charts, φ is given by rational functions $f_1, \dots, f_m$ regular at P , and we set

$$d\varphi_P(\mathbf{v}) = \left(\sum_{i=1}^n v_i \frac{\partial f_j}{\partial X_i}(P) \right)_{j=1}^m,$$

a linear map $\mathbb{C}^n \rightarrow \mathbb{C}^m$.

Proposition 24.5.8

With the above notation:

- (i) $d\varphi_P(T_{V,P}) \subseteq T_{W,Q}$;
- (ii) $d\varphi_P$ depends only on φ , not on the chosen representatives;
- (iii) if $\psi: W \dashrightarrow Z$ is rational with $Q \in \text{dom } \psi$ then $d(\psi\varphi)_P = d\psi_Q \circ d\varphi_P$;
- (iv) if φ is birational and φ^{-1} is regular at Q , then $d\varphi_P: T_{V,P} \rightarrow T_{W,Q}$ is an isomorphism.

Proof. (i) Let $g \in I(W)$, with coordinates Y_j on W . Then $\varphi^*g = g(f_1, \dots, f_m)$ vanishes identically on V near P , so by the chain rule, for $\mathbf{v} \in T_{V,P}$,

$$0 = \sum_i v_i \frac{\partial(\varphi^*g)}{\partial X_i}(P) = \sum_j \frac{\partial g}{\partial Y_j}(Q) \left(\sum_i v_i \frac{\partial f_j}{\partial X_i}(P) \right),$$

which says exactly that $d\varphi_P(\mathbf{v}) \in T_{W,Q}$.

(ii) If f'_j is another representative, then $f_j - f'_j$ vanishes on V where defined, so $f_j - f'_j = p_j/q_j$ with $p_j \in I(V)$ and $q_j(P) \neq 0$. Differentiating by the quotient rule and using $p_j(P) = 0$,

$$\frac{\partial(f_j - f'_j)}{\partial X_i}(P) = \frac{1}{q_j(P)} \frac{\partial p_j}{\partial X_i}(P),$$

and since $p_j \in I(V)$, contracting with $\mathbf{v} \in T_{V,P}$ gives zero.

(iii) is the chain rule, and (iv) follows from (iii) applied to $\varphi^{-1}\varphi = \text{id}$. $\square$

For projective varieties we define $T_{V,P}$ by choosing an affine patch $U_j \ni P$ and setting $T_{V,P} = T_{V \cap U_j, P}$. Part (iv) of Proposition 24.5.8, applied to the transition maps between patches (which are birational and regular on the overlaps), shows this is independent of j up to canonical isomorphism.

There is also a convenient projective form of the tangent space to a hypersurface.

Definition 24.5.9

Let $V = \mathbb{V}(F) \subseteq \mathbb{P}^n$ with F homogeneous. The **projective tangent space** at $P \in V$ is

$$T_{V,P}^{\text{proj}} = \mathbb{V} \left(\sum_{i=0}^n \frac{\partial F}{\partial X_i}(P) X_i \right) \subseteq \mathbb{P}^n.$$

That P itself lies in this hyperplane follows from **Euler's relation**: for F homogeneous of degree d ,

$$\sum_{i=0}^n X_i \frac{\partial F}{\partial X_i} = d F,$$

which is checked on monomials. Dehomogenising shows $T_{V,P}^{\text{proj}} \cap U_0 = T_{V \cap U_0, P}^{\text{aff}}$, so the two notions agree.

Proposition 24.5.10

Let $V = \mathbb{V}(F) \subseteq \mathbb{P}^n$ be an irreducible hypersurface. Then the singular locus of V is a proper Zariski closed subset; in particular the smooth points are dense.

Proof. The singular locus is $V \cap \bigcap_i \mathbb{V}(\partial F / \partial X_i)$, which is closed. Suppose it were all of V . Then each $\partial F / \partial X_i$ vanishes on V , so lies in $I^h(V) = (F)$ (as F is irreducible, (F) is prime hence radical). But $\partial F / \partial X_i$ is homogeneous of degree $\deg F - 1 < \deg F$, so divisibility by F forces $\partial F / \partial X_i = 0$ for all i . In characteristic zero this means F is constant, so $V = \mathbb{P}^n$ or $\emptyset$, contradicting that V is a hypersurface. $\square$

§24.5.3 Dimension

We can now define dimension. The idea is that the tangent space has the ‘expected’ dimension at most points, and jumps up at bad points.

Definition 24.5.11 (Dimension)

Let V be an irreducible affine or projective variety. Its **dimension** is

$$\dim V = \min_{P \in V} \dim T_{V,P}.$$

A point $P \in V$ is **smooth** if $\dim T_{V,P} = \dim V$, and **singular** otherwise. For reducible V , we set $\dim V$ to be the maximum of the dimensions of the irreducible components.

A variety of dimension 1 is a **curve**, of dimension 2 a **surface**.

Theorem 24.5.12

Let V be a nonempty irreducible variety. The set of smooth points of V is a nonempty Zariski open subset, hence dense.

Proof. Nonemptiness is by definition, since the minimum is attained. We may work in an affine chart, so assume $V \subseteq \mathbb{A}^n$ with $I(V) = (f_1, \dots, f_r)$. Then $\dim T_{V,P} =$

$n - \text{rank } J(P)$ where J is the Jacobian. For any s ,

$$\{P \in V : \dim T_{V,P} \geq s\} = \{P \in V : \text{rank } J(P) \leq n - s\},$$

and the locus where a matrix has rank at most k is cut out by the vanishing of all its $(k+1) \times (k+1)$ minors, which are polynomials in the entries, hence in P . So this set is closed. Taking $s = \dim V + 1$, the singular locus is closed and proper, so the smooth locus is open and nonempty; density follows from Proposition 24.4.21. $\square$

Corollary 24.5.13

If V and W are irreducible and birational, then $\dim V = \dim W$.

Proof. A birational map restricts to an isomorphism between nonempty open subsets $U \subseteq V$ and $U' \subseteq W$. Shrinking, we may assume both consist of smooth points. Then by Proposition 24.5.8(iv) the tangent spaces are isomorphic at corresponding points, so the minima agree. $\square$

§24.5.4 Dimension via Transcendence Degree

The definition above is geometric; there is an equivalent algebraic description in terms of the function field, which is often much easier to compute with. Recall from Galois theory that if $K \subseteq L$ are fields, an element $\alpha \in L$ is **transcendental** over K if it satisfies no nonzero polynomial over K , and a subset $S \subseteq L$ is **algebraically independent** over K if there is no nonzero polynomial relation among its elements with coefficients in K .

Definition 24.5.14

An extension $K/\mathbb{C}$ is **purely transcendental** if $K = \mathbb{C}(x_1, \dots, x_m)$ for some algebraically independent $x_1, \dots, x_m$.

Proposition 24.5.15

Let $K/\mathbb{C}$ be a finitely generated field extension. Then there is a purely transcendental subextension $K_0 = \mathbb{C}(x_1, \dots, x_m) \subseteq K$ with K/K_0 finite. Moreover $K = K_0(y)$ for a single $y \in K$.

Proof. Write $K = \mathbb{C}(x_1, \dots, x_n)$. Choose a maximal algebraically independent subset of $\{x_1, \dots, x_n\}$, which after relabelling is $\{x_1, \dots, x_m\}$; put $K_0 = \mathbb{C}(x_1, \dots, x_m)$. By maximality, each of $x_{m+1}, \dots, x_n$ is algebraic over K_0 , so K/K_0 is finitely generated and algebraic, hence finite. Since $\mathbb{C}$ has characteristic zero, K/K_0 is separable, and the Primitive Element Theorem from II Galois Theory gives $K = K_0(y)$. $\square$

The integer m is independent of choices; it is the **transcendence degree** $\text{tr. deg}_{\mathbb{C}} K$, and the argument is an exchange lemma identical to the one for bases of vector spaces.

Proposition 24.5.16

Let $x_1, \dots, x_n$ be algebraically independent over $\mathbb{C}$, put $K = \mathbb{C}(x_1, \dots, x_n)$, and let

x_{n+1} be algebraic over K . Then

$$I = \{g \in \mathbb{C}[X_1, \dots, X_{n+1}] : g(x_1, \dots, x_{n+1}) = 0\}$$

is a principal ideal generated by an irreducible polynomial f .

Proof. Since the x_i are algebraically independent, $R = \mathbb{C}[x_1, \dots, x_n] \subseteq K$ is isomorphic to a polynomial ring, hence a UFD, with $\text{Frac } R = K$. As x_{n+1} is algebraic over K , it has a minimal polynomial $h \in K[T]$, monic and irreducible. Clearing denominators, let $b \in R$ be a common denominator of the coefficients of h and set $f = bh \in R[T]$. By Gauss's Lemma, f is irreducible in $R[T] \cong \mathbb{C}[X_1, \dots, X_{n+1}]$.

If $g \in I$ then $g(x_1, \dots, x_n, T) \in K[T]$ has x_{n+1} as a root, so is divisible by h in $K[T]$; by Gauss's Lemma again, $f \mid g$ in $R[T]$. Hence $I = (f)$. $\square$

Corollary 24.5.17

Every irreducible variety is birational to a hypersurface.

Proof. Let $K = \mathbb{C}(V)$. By Proposition 24.5.15 we may write $K = \mathbb{C}(x_1, \dots, x_n, x_{n+1})$ with $x_1, \dots, x_n$ algebraically independent and x_{n+1} algebraic over $\mathbb{C}(x_1, \dots, x_n)$. By Proposition 24.5.16,

$$\mathbb{C}[x_1, \dots, x_{n+1}] \cong \frac{\mathbb{C}[X_1, \dots, X_{n+1}]}{(f)}$$

for an irreducible f , and K is its field of fractions. So $\mathbb{C}(V) \cong \mathbb{C}(\mathbb{V}(f))$ for the hypersurface $\mathbb{V}(f) \subseteq \mathbb{A}^{n+1}$, and Theorem 24.4.38 gives the result. $\square$

Corollary 24.5.18

For an irreducible variety V we have $\dim V = \text{tr. deg}_{\mathbb{C}} \mathbb{C}(V)$. In particular an irreducible hypersurface in $\mathbb{A}^n$ or $\mathbb{P}^n$ has dimension $n - 1$, and $\dim \mathbb{A}^n = \dim \mathbb{P}^n = n$.

Proof. Both sides are birational invariants – the left by the corollary above, the right because birational varieties have isomorphic function fields. By Corollary 24.5.17 we may assume $V = \mathbb{V}(f) \subseteq \mathbb{A}^n$ is an irreducible hypersurface with f non-constant, say involving X_n . Then $\mathbb{C}(V) = \mathbb{C}(x_1, \dots, x_n)$ where $x_1, \dots, x_{n-1}$ are algebraically independent and x_n is algebraic over them, so $\text{tr. deg} = n - 1$. On the other hand some partial derivative of f is not identically zero on V (Proposition 24.5.10), so at a general point the Jacobian has rank 1 and $\dim T_{V,P} = n - 1$. Hence both sides equal $n - 1$. $\square$

This is the definition of dimension that we will actually use: *the dimension of an irreducible variety is the transcendence degree of its function field*. In particular a **curve** is an irreducible variety whose function field is a finite extension of $\mathbb{C}(t)$ for some transcendental t , and this is the description that will drive everything in the second half of these notes.

§24.6 Plane Curves and Bézout's Theorem

We now specialise to curves in $\mathbb{P}^2$, where we can be extremely concrete. The organising principle is Bézout's theorem: two plane curves of degrees m and n meet in exactly mn points, provided we work projectively, over $\mathbb{C}$, and count with multiplicity. Each of these three provisos is essential, and each corresponds to something we have set up.

§24.6.1 Plane Curves and their Degree

Definition 24.6.1 (Plane Curve)

A **projective plane curve** of **degree** d is $C = \mathbb{V}(F) \subseteq \mathbb{P}^2$ where $F \in \mathbb{C}[X_0, X_1, X_2]$ is homogeneous of degree d with no repeated irreducible factors. Curves of degree 1, 2, 3, 4 are called **lines**, **conics**, **cubics** and **quartics**.

Requiring no repeated factors makes F recoverable from C : by the Nullstellensatz $I^h(C) = \sqrt{(F)} = (F_{\text{red}})$, so the degree is well defined. C is irreducible if and only if F is.

Example 24.6.2

If $C = \mathbb{V}(f) \subseteq \mathbb{A}^2$ is an affine plane curve of degree d , its projective closure is $\mathbb{V}(f^h)$, a projective plane curve of degree d . The points at infinity are found by setting $X_0 = 0$: they are the zeros of the top-degree part $f_{[d]}$ of f , homogenised. For instance the affine cubic $Y^2 = X^3 - X$ has $f^h = X_0X_2^2 - X_1^3 + X_1X_0^2$, and setting $X_0 = 0$ gives $X_1^3 = 0$, so there is exactly one point at infinity, $(0 : 0 : 1)$, and it is a triple point of the intersection with the line at infinity. This point is where the two ends of the real picture in Section 1 join up.

§24.6.2 Intersection Multiplicity

The naive count of intersection points is not constant: a line meets a conic in two points usually, but in only one if it is tangent. To get a constant answer we must count tangential intersections twice.

Definition 24.6.3 (Intersection Multiplicity with a Line)

Let $C = \mathbb{V}(F)$ be a plane curve of degree d and L a line, $L \not\subseteq C$. Parametrise L by $s \mapsto \mathbf{a} + s\mathbf{b}$ (in homogeneous coordinates: $(s : t) \mapsto s\mathbf{a} + t\mathbf{b}$). Then $G(s, t) = F(s\mathbf{a} + t\mathbf{b})$ is a nonzero binary form of degree d , so factors as

$$G(s, t) = c \prod_k (\beta_k s - \alpha_k t)^{m_k}$$

with $(\alpha_k : \beta_k)$ distinct. The **intersection multiplicity** of C and L at the point P_k corresponding to $(\alpha_k : \beta_k)$ is $I_{P_k}(C, L) = m_k$, and $I_P(C, L) = 0$ for $P \notin C \cap L$.

Since a binary form of degree d over $\mathbb{C}$ factors into d linear factors, we get for free:

Proposition 24.6.4 (Bézout for a line)

Let C be a plane curve of degree d and L a line with $L \not\subseteq C$. Then

$$\sum_{P \in C \cap L} I_P(C, L) = d.$$

In particular $|C \cap L| \leq d$, with equality for all but finitely many lines.

Proof. The displayed identity is the factorisation of G above, as $\deg G = d$ (the coefficient of s^d is $F(\mathbf{a})$, which is nonzero for a suitable choice of $\mathbf{a} \in L$ unless $L \subseteq C$). $\square$

One checks directly that $I_P(C, L) \geq 2$ if and only if L is the tangent line to C at P , or P is a singular point of C ; this is exactly the computation with which we opened Section 24.5.

Definition 24.6.5 (Intersection Multiplicity, general)

For plane curves $C = \mathbb{V}(F)$ and $D = \mathbb{V}(G)$ with no common component and $P \in \mathbb{P}^2$, the **intersection multiplicity** is

$$I_P(C, D) = \dim_{\mathbb{C}} \frac{\mathcal{O}_{\mathbb{P}^2, P}}{(f, g)},$$

where f, g are the dehomogenisations of F, G in an affine chart containing P .

This is finite and independent of the chart, and it agrees with the multiplicity defined above when D is a line. We will not develop its properties in detail – the local algebra required is beyond this course – but it is worth recording the characterisation that makes it usable: $I_P(C, D)$ is the unique assignment of non-negative integers such that

- (i) $I_P(C, D) = I_P(D, C)$, and $I_P(C, D) = 0$ if and only if $P \notin C \cap D$;
- (ii) $I_P(C, D) = 1$ if and only if P is a smooth point of both curves and their tangent lines at P differ (a **transverse** intersection);
- (iii) I_P is additive: $I_P(C, D \cup D') = I_P(C, D) + I_P(C, D')$;
- (iv) $I_P(C, D) = I_P(C, D')$ whenever $G' = G + HF$ for some form H of the appropriate degree.

In practice one computes with the definition directly, and in small cases this is easy: the local ring $\mathcal{O}_{\mathbb{A}^2, P}$ is obtained from $\mathbb{C}[X, Y]$ by inverting the polynomials not vanishing at P , so any factor which is a unit at P may simply be deleted.

Example 24.6.6

Take $P = (0, 0)$ throughout, and write $\mathcal{O} = \mathcal{O}_{\mathbb{A}^2, P}$.

- (i) Let $C = \mathbb{V}(y - x^2)$ be a parabola and $L = \mathbb{V}(y)$ its tangent at P . Then

$$\frac{\mathcal{O}}{(y - x^2, y)} = \frac{\mathcal{O}}{(y, x^2)} \cong \frac{\mathbb{C}[x]_{(x)}}{(x^2)},$$

which has $\mathbb{C}$ -basis $\{1, x\}$, so $I_P(C, L) = 2$. The tangency is visible in the

algebra as the nilpotent x .

- (ii) Let $L' = \mathbb{V}(y - x)$ instead. Substituting, $(y - x^2, y - x) = (y - x, x - x^2) = (y - x, x)$, since $1 - x$ is a unit in $\mathcal{O}$. So the quotient is $\mathbb{C}$ and $I_P(C, L') = 1$: the intersection is transverse. Of course L' also meets C at $(1, 1)$, and $1 + 1 = 2$ agrees with Bézout for a line and a conic.
- (iii) Let C be the nodal cubic $\mathbb{V}(y^2 - x^2(x + 1))$ and $L = \mathbb{V}(y)$, one of the two lines through the node that is *not* a branch tangent. Then

$$\frac{\mathcal{O}}{(y^2 - x^3 - x^2, y)} \cong \frac{\mathbb{C}[x]_{(x)}}{(x^2(x + 1))} \cong \frac{\mathbb{C}[x]_{(x)}}{(x^2)},$$

as $x + 1$ is a unit at P ; so $I_P(C, L) = 2$. The line meets the singular point twice, once on each branch.

- (iv) With the same C and the branch tangent $L'' = \mathbb{V}(y - x)$, substituting $y = x$ gives $x^2 - x^3 - x^2 = -x^3$, so $I_P(C, L'') = 3$. Indeed a line meets a cubic in three points, so L'' meets C nowhere else.

The tangent line L meets the parabola C only at P , but with multiplicity 2; the transverse line L' meets it at two distinct points, each with multiplicity 1. In both cases the total is $2 = 1 \cdot 2$, as Bézout demands.

§24.6.3 Bézout's Theorem

Theorem 24.6.7 (Bézout)

Let $C, D \subseteq \mathbb{P}^2$ be plane curves of degrees m and n with no common component. Then $C \cap D$ is finite and

$$\sum_{P \in C \cap D} I_P(C, D) = mn.$$

In particular $|C \cap D| \leq mn$, with equality if and only if all intersections are transverse.

We will prove the weak form – the inequality $|C \cap D| \leq mn$ – in Section 24.8 using divisors, once we have the machinery of orders of vanishing. The strong form requires the full theory of intersection multiplicity. For now let us see what it says.

Example 24.6.8

A line and a conic meet in 2 points, a line and a cubic in 3, and two conics in 4. Here is the last of these: the circle $X^2 + Y^2 = 4$ and the ellipse $X^2/9 + Y^2 = 1$ meet in the four points $(\pm\sqrt{27}/\sqrt{8}, \pm\sqrt{5/8}) \approx (\pm 1.837, \pm 0.791)$.

**Example 24.6.9**

The line $Y = 0.55X + 0.45$ meets the cubic $Y^2 = X^3 - X$ in the three points with $X \approx 1.439, -0.995, -0.141$. All three are real here, and they are visible in the picture.

**Corollary 24.6.10** (Five points determine a conic)

Let $P_1, \dots, P_5 \in \mathbb{P}^2$ be five points, no three collinear. Then there is a unique conic through all five, and it is smooth.

Proof. A conic is $\mathbb{V}(F)$ for a homogeneous quadratic F in three variables; the space of such F is a 6-dimensional vector space, and $F(P_i) = 0$ is a linear condition. Five linear conditions on a 6-dimensional space have a nonzero solution, so a conic through the five points exists.

If two distinct conics C, D passed through all five points, then by Bézout they share a component (else $|C \cap D| \leq 4 < 5$). A shared component is a line or the whole conic; the latter is excluded as $C \neq D$, so $C = L \cup L'$ and $D = L \cup L''$ with L a common line. Then at least three of the five points lie on one line, contradiction. So the conic is unique.

Finally, a singular conic is a union of two lines (or a double line), which again would force three collinear points. So the conic is smooth. $\square$

§24.6.4 Inflection Points

Definition 24.6.11 (Flex)

Let $C \subseteq \mathbb{P}^2$ be a plane curve and P a smooth point with tangent line L . Then P is a **point of inflection**, or **flex**, if $I_P(C, L) \geq 3$.

So a flex is a point where the tangent line meets the curve to order at least three – it ‘crosses over’ rather than touching. For a curve of degree 2 there are no flexes, since $I_P(C, L) \leq 2$ by Bézout with a line. For cubics, flexes are exactly what we need to normalise the equation.

Example 24.6.12

On $C: Y^2 = X^3 - X + 1$ there is a real flex at $P \approx (0.0871, 0.9558)$, with tangent line of slope ≈ -0.5112 . Substituting the tangent into the cubic gives a polynomial with a triple root at $x = 0.0871$.

Note that near P the tangent line crosses from one side of the curve to the other.

There is a beautiful way of detecting flexes algebraically.

Definition 24.6.13 (Hessian)

Let $F \in \mathbb{C}[X_0, X_1, X_2]$ be homogeneous of degree d . Its **Hessian** is

$$H_F = \det \left(\frac{\partial^2 F}{\partial X_i \partial X_j} \right)_{0 \leq i, j \leq 2},$$

a homogeneous polynomial of degree $3(d - 2)$.

Theorem 24.6.14

Let $C = \mathbb{V}(F) \subseteq \mathbb{P}^2$ be a smooth curve of degree $d \geq 2$ and $P \in C$. Then P is a flex of C if and only if $H_F(P) = 0$. Consequently, a smooth plane curve of degree $d \geq 3$ has at least one flex, and at most $3d(d - 2)$ of them; a smooth cubic has exactly 9.

Proof sketch. Move P to $(1 : 0 : 0)$ and arrange that the tangent line there is $\mathbb{V}(X_2)$. Dehomogenising in the chart $X_0 = 1$ with coordinates (x, y) , the curve is $y = ax^2 + (\text{higher order})$ near the origin, and P is a flex precisely when $a = 0$. A

direct computation using Euler's relation shows that $H_F(P)$ is a nonzero multiple of a , which gives the equivalence.

For the count: H_F has degree $3(d-2)$, so if $C \not\subseteq \mathbb{V}(H_F)$ then Bézout gives $|C \cap \mathbb{V}(H_F)| \leq 3d(d-2)$, with equality when all intersections are transverse. That $C \not\subseteq \mathbb{V}(H_F)$ for smooth C (in characteristic zero) is a separate check. For $d=3$ one shows all the intersections are transverse, giving exactly 9 flexes. $\square$

§24.6.5 Weierstrass Form

We can now put any smooth plane cubic into a standard shape. This is the calculation that connects the abstract theory to the concrete equations you have seen in number theory.

Theorem 24.6.15 (Weierstrass Normal Form)

Let $C \subseteq \mathbb{P}^2$ be a smooth plane cubic. After a projective change of coordinates,

$$C = \mathbb{V}(X_0X_2^2 - X_1^3 - aX_0^2X_1 - bX_0^3)$$

for some $a, b \in \mathbb{C}$ with $4a^3 + 27b^2 \neq 0$. Equivalently, in the affine chart $X_0 = 1$,

$$C: y^2 = x^3 + ax + b = (x - \lambda_1)(x - \lambda_2)(x - \lambda_3)$$

with $\lambda_1, \lambda_2, \lambda_3$ distinct, together with the single point $(0 : 0 : 1)$ at infinity.

Proof. By Theorem 24.6.14, C has a flex P_0 . Change coordinates so that $P_0 = (0 : 0 : 1)$ and the tangent line to C at P_0 is the line at infinity $\mathbb{V}(X_0)$. Write F for the defining cubic. Since P_0 is a flex, $I_{P_0}(C, \mathbb{V}(X_0)) = 3$, so by Proposition 24.6.4 the line at infinity meets C only at P_0 ; restricting F to $X_0 = 0$ therefore gives (up to scalar) X_1^3 . So F has no $X_1^2X_2$, $X_1X_2^2$ or X_2^3 terms except via X_0 , and after scaling

$$F = cX_0X_2^2 + X_0X_2\ell(X_0, X_1) - X_1^3 + X_0q(X_0, X_1)$$

for a linear form ℓ and quadratic q . Smoothness at $P_0 = (0 : 0 : 1)$ forces $c \neq 0$ (else $\partial F/\partial X_0, \partial F/\partial X_1, \partial F/\partial X_2$ all vanish there), so we may scale $c = 1$. Completing the square in X_2 – that is, replacing X_2 by $X_2 - \frac{1}{2}\ell(X_0, X_1)$, a linear change of coordinates – removes the middle term, leaving

$$F = X_0X_2^2 - X_1^3 + X_0\tilde{q}(X_0, X_1)$$

for a new quadratic $\tilde{q}$. Finally, replacing X_1 by $X_1 - \frac{1}{3}(\text{coefficient of } X_1^2 \text{ in } \tilde{q})X_0$ kills the $X_0X_1^2$ term, giving the stated form.

It remains to see that smoothness is equivalent to $x^3 + ax + b$ having distinct roots. In the affine chart, $f = y^2 - x^3 - ax - b$ has $\partial f/\partial y = 2y$ and $\partial f/\partial x = -(3x^2 + a)$. A singular point has $y = 0$ and x a common root of $x^3 + ax + b$ and its derivative, i.e. a repeated root; and $4a^3 + 27b^2$ is (up to sign) the discriminant of $x^3 + ax + b$, vanishing exactly when there is a repeated root. $\square$

We call the pair (C, P_0) , where $P_0 = (0 : 0 : 1)$ is the flex at infinity, an **elliptic curve**. (This is not quite the general definition – a genuinely intrinsic one will be given in

Section 24.11 – but for plane cubics it is equivalent.)

§24.6.6 The Group Law on a Cubic

Here is the most striking fact about plane cubics: the points of a smooth cubic form an abelian group, and the group operation is given by drawing lines.

By Bézout, a line L meets a smooth cubic C in exactly three points counted with multiplicity. Given $P, Q \in C$, let L be the line through them (the tangent line at P if $P = Q$), and let $P * Q$ denote the third point of $C \cap L$.

Definition 24.6.16 (Chord-and-Tangent Law)

Let (C, P_0) be a smooth plane cubic with a chosen flex P_0 . For $P, Q \in C$ define

$$P + Q = P_0 * (P * Q).$$

In Weierstrass form, with $P_0 = (0 : 0 : 1)$ the point at infinity, the line through P_0 and any point $R = (x, y)$ is the vertical line through R , so $P_0 * R = (x, -y)$. Thus the recipe is: *draw the line through P and Q , find the third intersection with C , and reflect in the x -axis.*

The second picture shows the doubling: on $y^2 = x^3 - x + 1$ the tangent at $T = (1, 1)$ has slope 1 and meets the curve again at $(-1, -1)$, so $2T = (-1, 1)$.

Theorem 24.6.17

Let (C, P_0) be a smooth plane cubic with P_0 a flex. Then $(C, +)$ is an abelian group

with identity P_0 , and $-P = P_0 * P$. Moreover $P + Q + R = P_0$ if and only if P, Q, R are collinear.

Proof sketch. Commutativity is clear, since $P * Q = Q * P$. The identity: $P + P_0 = P_0 * (P * P_0)$, and $P_0 * (P * P_0) = P$ because the line through P_0 and $P * P_0$ is the line through P_0 and P , whose third point is P . Inverses: set $-P = P_0 * P$, so $P + (-P) = P_0 * (P * (P_0 * P)) = P_0 * P_0 = P_0$, the last equality because P_0 is a flex, so the tangent at P_0 meets C only at P_0 .

The collinearity statement follows: if P, Q, R are collinear then $R = P * Q$, so $P + Q = P_0 * R = -R$ and $P + Q + R = P_0$.

Associativity is the only difficulty. It can be proved by a direct (and unpleasant) computation with the Weierstrass equation, or by an application of Bézout's theorem for cubics – if two cubics meet in nine points and a third cubic passes through eight of them, it passes through the ninth – or, most cleanly, by identifying $(C, +)$ with the divisor class group, which we do in Theorem 24.11.12. $\square$

The last of these is the argument we will actually give, and it explains *why* there is a group law: the points of C are in bijection with the degree zero divisor classes, and those obviously form a group. Everything geometric in the chord-and-tangent construction is the statement that three points of C sum to zero in the class group exactly when they are cut out by a line.

§24.7 Curves and their Local Rings

From now on we specialise to curves, where the theory becomes both deeper and more complete than in higher dimensions. Recall that a curve is an irreducible variety of dimension 1; equivalently, by Corollary 24.5.18, one whose function field has transcendence degree 1 over $\mathbb{C}$.

Notation. Unless stated otherwise, from now on *curve* means a smooth irreducible projective curve. We will always have in mind some embedding $C \subseteq \mathbb{P}^n$, but the ambient space will play no essential role: everything we do is intrinsic.

§24.7.1 Closed Subsets of Curves

The first thing to establish is that curves really are one-dimensional in the naive sense.

Proposition 24.7.1

Let C be an irreducible curve and $D \subsetneq C$ a proper Zariski closed subset. Then D is a finite set of points.

Proof. Decomposing into irreducible components, it suffices to show that a proper irreducible closed $W \subsetneq V$ is a point, where we may pass to an affine chart and take $V \subseteq \mathbb{A}^n$ affine irreducible with $\text{tr. deg}_{\mathbb{C}} \mathbb{C}(V) = 1$.

The inclusion $\iota: W \hookrightarrow V$ gives a surjection $\iota^*: \mathbb{C}[V] \twoheadrightarrow \mathbb{C}[W]$ with kernel $I(W)/I(V)$, which is nonzero since $I(V) \subsetneq I(W)$ by the Nullstellensatz. Choose $x \in \mathbb{C}[V]$

nonzero with $\iota^*(x) = 0$.

Suppose for contradiction that $\mathbb{C}[W] \neq \mathbb{C}$, and pick $t \in \mathbb{C}[W] \setminus \mathbb{C}$; choose $y \in \mathbb{C}[V]$ with $\iota^*(y) = t$. I claim x and y are algebraically independent over $\mathbb{C}$. If not, there is a nonzero $g \in \mathbb{C}[S, T]$ with $g(x, y) = 0$; choose such a g of minimal degree in S . Applying ι^* , $g(0, t) = 0$ in $\mathbb{C}[W]$. Now t is transcendental over $\mathbb{C}$, since $\mathbb{C}$ is algebraically closed and any element of the domain $\mathbb{C}[W]$ that is algebraic over $\mathbb{C}$ must lie in $\mathbb{C}$. Hence $g(0, T)$ is the zero polynomial, i.e. $S \mid g$. Then $g = Sg_1$ and $xg_1(x, y) = 0$; as $\mathbb{C}[V]$ is a domain and $x \neq 0$, $g_1(x, y) = 0$, contradicting minimality.

So $\mathbb{C}(V)$ would contain two algebraically independent elements, which contradicts the fact that $\mathbb{C}(V)$ has transcendence degree 1. Hence $\mathbb{C}[W] = \mathbb{C}$, so W is a single point. $\square$

So the Zariski topology on a curve is the cofinite topology, exactly as on $\mathbb{A}^1$. The interesting structure is all in the local rings.

§24.7.2 Local Parameters

Theorem 24.7.2

Let P be a smooth point of an irreducible curve C . Then the maximal ideal $\mathfrak{m}_P \subseteq \mathcal{O}_{C,P}$ is principal.

Any generator π_P of $\mathfrak{m}_P$ is called a **local parameter**, **local coordinate** or **uniformiser** at P . It is unique up to multiplication by a unit of $\mathcal{O}_{C,P}$.

The proof rests on the following piece of commutative algebra, which one should think of as an algebraic substitute for the implicit function theorem.

Lemma 24.7.3 (Nakayama)

Let R be a local ring with maximal ideal $\mathfrak{m}$, and let M be a finitely generated R -module.

- (i) If $\mathfrak{m}M = M$ then $M = 0$.
- (ii) If $N \leq M$ is a submodule with $\mathfrak{m}M + N = M$, then $M = N$.

Proof. (i) Suppose $M \neq 0$ and let $b_1, \dots, b_k$ be a generating set of minimal size. Since $M = \mathfrak{m}M$, we may write $b_k = \sum_j a_j b_j$ with $a_j \in \mathfrak{m}$. Then $(1 - a_k)b_k = \sum_{j < k} a_j b_j$. As $a_k \in \mathfrak{m}$ and R is local, $1 - a_k$ is a unit, so b_k lies in the span of $b_1, \dots, b_{k-1}$, contradicting minimality.

(ii) Apply (i) to M/N , noting $\mathfrak{m}(M/N) = (\mathfrak{m}M + N)/N = M/N$. $\square$

Proof of Theorem 24.7.2. Pass to an affine chart and change coordinates so that $P = \mathbf{0} \in \mathbb{A}^n$. Write $\mathbb{C}[C] = \mathbb{C}[x_1, \dots, x_n]$ for the coordinate ring, where x_i is the image of X_i . Then

$$\mathcal{O}_P = \left\{ \frac{f}{g} : f, g \in \mathbb{C}[C], g(P) \neq 0 \right\}, \quad \mathfrak{m}_P = x_1 \mathcal{O}_P + \dots + x_n \mathcal{O}_P.$$

Note that every ideal $J \subseteq \mathcal{O}_P$ is finitely generated: J is determined by $J \cap \mathbb{C}[C]$,

which is finitely generated as $\mathbb{C}[C]$ is Noetherian.

Since P is smooth and $\dim C = 1$, the tangent space $T_{C,P}$ is a line; after a further linear change of coordinates we may assume $T_{C,P} = \{X_2 = \cdots = X_n = 0\}$. The tangent space is cut out by the linear parts at P of the elements of $I(C)$, so for each $j \geq 2$ there is $f_j \in I(C)$ whose linear part is X_j , say

$$f_j = X_j - h_j(X_1, \dots, X_n)$$

with h_j having no terms of degree < 2 . Passing to $\mathbb{C}[C]$, where $f_j = 0$,

$$x_j = h_j(x_1, \dots, x_n) \in \mathfrak{m}_P^2 \quad (j \geq 2).$$

Hence

$$\mathfrak{m}_P = \sum_{i=1}^n x_i \mathcal{O}_P \subseteq x_1 \mathcal{O}_P + \mathfrak{m}_P^2 \subseteq \mathfrak{m}_P.$$

Now apply Nakayama's lemma with $R = \mathcal{O}_P$, $M = \mathfrak{m}_P$ (finitely generated), $N = x_1 \mathcal{O}_P$, noting $\mathfrak{m}_P M = \mathfrak{m}_P^2$: we get $\mathfrak{m}_P = x_1 \mathcal{O}_P$, so $\pi_P = x_1$ is a local parameter. $\square$

Corollary 24.7.4

Let $C = \mathbb{V}(f) \subseteq \mathbb{A}^2$ be an irreducible plane curve and $P \in C$ a smooth point. Then the function $Q \mapsto X(Q) - X(P)$ is a local parameter at P if and only if $\frac{\partial f}{\partial Y}(P) \neq 0$; and $Q \mapsto Y(Q) - Y(P)$ is one if and only if $\frac{\partial f}{\partial X}(P) \neq 0$.

Proof. This is the proof above: if $\partial f / \partial Y(P) \neq 0$ then the tangent line is not vertical, so after translating P to the origin the roles of x_1 and x_2 in the argument are as stated. $\square$

Note that by smoothness at least one of the two partial derivatives is nonzero, so at least one of $x - x(P)$, $y - y(P)$ is always a local parameter. This will be used constantly in computations with plane curves.

§24.7.3 Orders of Vanishing

Once $\mathfrak{m}_P$ is principal, every element of the function field has a well-defined order of vanishing at P , and this is the single most useful tool we have.

Corollary 24.7.5 (Valuation)

Let P be a smooth point of a curve C . There is a surjective group homomorphism

$$\nu_P: \mathbb{C}(C)^\times \rightarrow \mathbb{Z}$$

such that

- (i) $\mathcal{O}_{C,P} = \{0\} \cup \{f \in \mathbb{C}(C)^\times : \nu_P(f) \geq 0\}$;
- (ii) $\mathfrak{m}_P = \{0\} \cup \{f \in \mathbb{C}(C)^\times : \nu_P(f) > 0\}$;
- (iii) for any local parameter π_P and any $f \in \mathbb{C}(C)^\times$ we may write $f = \pi_P^{\nu_P(f)} u$

with $u \in \mathcal{O}_{C,P}^\times$.

Moreover $\nu_P(f + g) \geq \min\{\nu_P(f), \nu_P(g)\}$.

Proof. Write $\mathfrak{m}_P = (\pi_P)$, so $\mathfrak{m}_P^n = (\pi_P^n)$. Let $J = \bigcap_{n \geq 0} \mathfrak{m}_P^n$. This is a finitely generated ideal with $\mathfrak{m}_P J = J$ (since $\pi_P \mathfrak{m}_P^n = \mathfrak{m}_P^{n+1}$), so $J = 0$ by Nakayama. Thus no nonzero element vanishes to infinite order, and for $f \in \mathcal{O}_{C,P} \setminus \{0\}$ there is a unique $n \geq 0$ with $f \in \mathfrak{m}_P^n \setminus \mathfrak{m}_P^{n+1}$; set $\nu_P(f) = n$. Writing $f = \pi_P^n g$, we have $g \notin \mathfrak{m}_P$, so g is a unit, giving (iii) for $f \in \mathcal{O}_{C,P}$.

For $f \in \mathbb{C}(C)^\times \setminus \mathcal{O}_{C,P}$, write $f = g/h$ with $g, h \in \mathcal{O}_{C,P}$; then $g = \pi_P^k u$, $h = \pi_P^\ell u'$ with u, u' units, so $f = \pi_P^{k-\ell}(u/u')$ with $k - \ell < 0$. Set $\nu_P(f) = k - \ell$. Multiplicativity, and hence the homomorphism property, is now clear from (iii), and surjectivity from $\nu_P(\pi_P^n) = n$. Properties (i) and (ii) restate the construction. The last inequality is immediate: if $\nu_P(f), \nu_P(g) \geq m$ then $f, g \in \mathfrak{m}_P^m$ and so $f + g \in \mathfrak{m}_P^m$. $\square$

Definition 24.7.6

If $\nu_P(f) = n > 0$ we say f has a **zero of order n** at P ; if $\nu_P(f) = -n < 0$, a **pole of order n** .

Example 24.7.7

Let $C = \mathbb{A}^1$ and $P = 0$, so $\mathcal{O}_{\mathbb{A}^1,0} = \{f/g : g(0) \neq 0\}$ and t is a local parameter. Then $\nu_0(f/g)$ is the multiplicity of $t = 0$ as a root of f . Concretely,

$$\nu_0\left(\frac{t^2 + 8t^3}{1 + t^4}\right) = 2.$$

Thinking of f/g as a power series in t (possible since $g(0) \neq 0$), ν_0 is the index of the first nonzero coefficient. This is exactly the order of vanishing familiar from IB Complex Analysis, and the analogy is not a coincidence.

Example 24.7.8

On $\mathbb{P}^1$ with coordinate $t = X_1/X_0$, a local parameter at $a \in \mathbb{C}$ is $t - a$, and a local parameter at $\infty = (0 : 1)$ is $1/t$. So for $f = \prod_i (t - a_i)^{n_i}$ we have $\nu_{a_i}(f) = n_i$ and $\nu_\infty(f) = -\sum_i n_i$.

Corollary 24.7.9

If C is a curve and $P \in C$ is smooth, then for any $f \in \mathbb{C}(C)^\times$, at least one of f, f^{-1} is regular at P .

Proof. $\nu_P(f)$ and $\nu_P(f^{-1}) = -\nu_P(f)$ cannot both be negative. $\square$

This fails badly in higher dimensions: on $\mathbb{A}^2$ neither X/Y nor Y/X is regular at the origin. It is a genuinely one-dimensional phenomenon, and it has the following striking consequence.

Corollary 24.7.10

Let C be a smooth curve. Then every rational map $\varphi: C \dashrightarrow \mathbb{P}^m$ is a morphism.

Proof. Fix $P \in C$. Reordering coordinates, assume the image of φ is not contained in $\{X_0 = 0\}$, so we may write $\varphi = (1 : g_1 : \cdots : g_m)$ with $g_j \in \mathbb{C}(C)$. If every $g_j \in \mathcal{O}_{C,P}$ then φ is visibly regular at P . Otherwise let $t = \min_j \nu_P(g_j) < 0$ and choose a local parameter π_P . Then

$$\varphi = (\pi_P^{-t} : \pi_P^{-t} g_1 : \cdots : \pi_P^{-t} g_m),$$

an equivalent representative, and now every entry lies in $\mathcal{O}_{C,P}$ while at least one has $\nu_P = 0$, hence is nonzero at P . So φ is regular at P . $\square$

Since every projective variety sits inside some $\mathbb{P}^m$, we conclude: *a rational map from a smooth curve to a projective variety is automatically a morphism.* There are no indeterminacy loci in dimension one. This is the technical fact that makes the theory of curves so much cleaner than that of surfaces.

§24.7.4 Morphisms of Curves. Degree and Ramification**Proposition 24.7.11**

Let $\varphi: C \rightarrow D$ be a non-constant morphism of irreducible projective curves. Then every fibre $\varphi^{-1}(Q)$ is finite, φ is dominant, and $\varphi^*: \mathbb{C}(D) \hookrightarrow \mathbb{C}(C)$ makes $\mathbb{C}(C)$ a finite extension of $\mathbb{C}(D)$.

Proof. $\varphi^{-1}(Q)$ is closed and, since φ is non-constant, proper, hence finite by Proposition 24.7.1. As C is infinite, $\varphi(C)$ is infinite, so its closure in D is all of D by Proposition 24.7.1 again; so φ is dominant and φ^* is defined and injective.

Pick $t \in \mathbb{C}(D) \setminus \mathbb{C}$ and put $x = \varphi^*t$. Both $\mathbb{C}(D)/\mathbb{C}(t)$ and $\mathbb{C}(C)/\mathbb{C}(x)$ are finite, since both fields have transcendence degree 1 and t, x are transcendental. Hence $\mathbb{C}(C)$ is finite over $\mathbb{C}(x) = \varphi^*\mathbb{C}(t) \subseteq \varphi^*\mathbb{C}(D)$, so a fortiori finite over $\varphi^*\mathbb{C}(D)$. $\square$

Definition 24.7.12 (Degree)

The **degree** of a non-constant morphism $\varphi: C \rightarrow D$ of curves is

$$\deg \varphi = [\mathbb{C}(C) : \varphi^*\mathbb{C}(D)].$$

Definition 24.7.13 (Ramification)

Let $\varphi: C \rightarrow D$ be a non-constant morphism of curves, $P \in C$ smooth, $Q = \varphi(P)$ smooth. The **ramification index** of φ at P is

$$e_P = e(\varphi, P) = \nu_P(\varphi^*\pi_Q),$$

where π_Q is a local parameter at Q . We say φ is **ramified** at P if $e_P > 1$, and **unramified** otherwise.

This is well defined: another local parameter differs from π_Q by a unit of $\mathcal{O}_{D,Q}$, whose pullback is a unit of $\mathcal{O}_{C,P}$ and hence has $\nu_P = 0$.

Example 24.7.14

Consider $\varphi: \mathbb{P}^1 \rightarrow \mathbb{P}^1$ given in the affine coordinate by $z \mapsto z^d$. On function fields, $\varphi^*: \mathbb{C}(Y) \rightarrow \mathbb{C}(X)$ sends $Y \mapsto X^d$, so $\varphi^*\mathbb{C}(Y) = \mathbb{C}(X^d)$ and $\deg \varphi = [\mathbb{C}(X) : \mathbb{C}(X^d)] = d$.

At $P = 0$ we have $Q = 0$ with local parameter Y , and $\varphi^*Y = X^d$, so $e_0 = \nu_0(X^d) = d$: the map is totally ramified at 0. The same holds at ∞ . At $P = 1$ we have $Q = 1$ with local parameter $Y - 1$, and $\varphi^*(Y - 1) = X^d - 1$, which has a simple zero at $X = 1$; so $e_1 = 1$. Indeed the fibre over 1 consists of the d distinct d th roots of unity, each with $e = 1$. Note $\sum_{P \in \varphi^{-1}(1)} e_P = d = \deg \varphi$, and also $\sum_{P \in \varphi^{-1}(0)} e_P = d$. This is a general phenomenon.

The picture is the one to keep in mind: a degree 3 map has three preimages over a general point, but the preimages can collide, and when two sheets come together the ramification index absorbs the deficit. The next theorem says the bookkeeping always balances.

Theorem 24.7.15

Let $\varphi: C \rightarrow D$ be a non-constant morphism of irreducible projective curves.

- (i) φ is surjective.
- (ii) If C and D are smooth then for every $Q \in D$,

$$\deg \varphi = \sum_{P \in \varphi^{-1}(Q)} e_P.$$

- (iii) $e_P = 1$ for all but finitely many $P \in C$.

We prove (i) now, and (iii) will follow from the theory of differentials in Section 24.9. Part (ii) requires a piece of commutative algebra (that $\mathcal{O}_{D,Q}$ is a principal ideal domain and the semilocal ring $\bigcap_{P \in \varphi^{-1}(Q)} \mathcal{O}_{C,P}$ is free of rank $\deg \varphi$ over it) which we take on trust. The proof of (i) rests on the following, which is the projective analogue of compactness.

Proposition 24.7.16 (Fundamental theorem of elimination theory)

The projection $\mathbb{P}^n \times \mathbb{A}^m \rightarrow \mathbb{A}^m$ is a closed map for the Zariski topology.

We do not prove this; it is a matter of showing that the condition on $\mathbf{b} \in \mathbb{A}^m$ that a system of homogeneous equations with coefficients depending on $\mathbf{b}$ has a nontrivial solution is itself given by polynomial equations in $\mathbf{b}$ (resultants). Note that it genuinely uses projectivity: $\mathbb{A}^1 \times \mathbb{A}^1 \rightarrow \mathbb{A}^1$ is not closed, since $\mathbb{V}(XY - 1)$ has image $\mathbb{A}^1 \setminus \{0\}$.

Proposition 24.7.17

Let $\varphi: V \rightarrow W$ be a morphism of quasi-projective varieties with V projective. Then φ is a closed map.

Here a **quasi-projective variety** is a Zariski open subset of a projective variety; all affine and all projective varieties are quasi-projective, and all our definitions (rational functions, morphisms, local rings) extend verbatim.

Proof. Factor φ as $V \rightarrow \Gamma_\varphi \subseteq V \times W \rightarrow W$, where $\Gamma_\varphi = \{(x, \varphi(x))\}$ is the graph. The graph is closed, being the preimage of the diagonal $\Delta_W \subseteq W \times W$ (which is closed) under $\varphi \times \text{id}$. So it suffices to show the projection $V \times W \rightarrow W$ is closed. As $V \subseteq \mathbb{P}^n$ is closed, it suffices to show $\mathbb{P}^n \times W \rightarrow W$ is closed; covering W by affine opens, it suffices to show $\mathbb{P}^n \times U \rightarrow U$ is closed for U affine; and as U is closed in some $\mathbb{A}^m$, it suffices to show $\mathbb{P}^n \times \mathbb{A}^m \rightarrow \mathbb{A}^m$ is closed, which is Proposition 24.7.16. $\square$

Proof of Theorem 24.7.15(i). $\varphi(C)$ is closed in D by Proposition 24.7.17, so by Proposition 24.7.1 it is either finite or all of D . As φ is non-constant and C is irreducible, $\varphi(C)$ is infinite, so $\varphi(C) = D$. $\square$

Here is the payoff, and it is the algebraic geometer's version of Liouville's theorem.

Corollary 24.7.18

Let C be a smooth projective irreducible curve and $f \in \mathbb{C}(C)^\times$.

- (i) If f is regular at every point of C , then f is constant.
- (ii) $\{P \in C : \nu_P(f) \neq 0\}$ is finite, and $\sum_{P \in C} \nu_P(f) = 0$.

Proof. Given f , consider the map $\varphi = (1 : f): C \rightarrow \mathbb{P}^1$, which is a morphism by Corollary 24.7.10. Write $0 = (1 : 0)$ and $\infty = (0 : 1)$ in $\mathbb{P}^1$. Then $\varphi(P) = 0$ iff $f(P) = 0$, and $\varphi(P) = \infty$ iff f has a pole at P .

(i) If f is everywhere regular then φ misses ∞ , so φ is not surjective, so by Theorem 24.7.15(i) it is constant, i.e. f is constant.

(ii) Assume f is non-constant, so φ is a non-constant morphism, and let $n = \deg \varphi$. The function $t = X_1/X_0$ is a local parameter at $0 \in \mathbb{P}^1$ and $\varphi^*t = f$; so for P with $f(P) = 0$ we get $e_P = \nu_P(f)$. Similarly $1/t$ is a local parameter at ∞ and $\varphi^*(1/t) = 1/f$, so for P a pole we get $e_P = -\nu_P(f)$. At all other P , $\nu_P(f) = 0$. The zeros and poles are the fibres over 0 and ∞ , hence finite, and Theorem 24.7.15(ii)

applied to $Q = 0$ and $Q = \infty$ gives

$$\sum_{f(P)=0} \nu_P(f) = n = \sum_{f(P)=\infty} (-\nu_P(f)),$$

so the total sum is zero. $\square$

So on a projective curve there are no non-constant ‘holomorphic’ functions, and every rational function has as many zeros as poles, counted with multiplicity. Both statements will be familiar to anyone who has met compact Riemann surfaces, and the analogy is exact.

§24.8 Divisors on Curves

The field $\mathbb{C}(C)$ is enormous and hard to study directly. Divisor theory is a device for cutting it into finite-dimensional pieces: instead of studying all rational functions at once, we study those whose poles are bounded by a prescribed amount at prescribed points.

Throughout, C is a smooth irreducible projective curve.

§24.8.1 Divisors, Degree and Linear Equivalence

Definition 24.8.1 (Divisor)

A **divisor** on C is an element of the free abelian group on the points of C ,

$$\text{Div}(C) = \bigoplus_{P \in C} \mathbb{Z}[P].$$

So a divisor is a finite formal sum $D = \sum_P n_P [P]$ with $n_P \in \mathbb{Z}$, almost all zero. Its **degree** is $\deg D = \sum_P n_P$. We write $\nu_P(D) = n_P$.

The degree map $\deg: \text{Div}(C) \rightarrow \mathbb{Z}$ is a surjective group homomorphism; its kernel is written $\text{Div}^0(C)$.

Definition 24.8.2

A divisor D is **effective**, written $D \geq 0$, if $\nu_P(D) \geq 0$ for all P . We write $D \geq D'$ for $D - D' \geq 0$.

Definition 24.8.3 (Divisor of a Function)

For $f \in \mathbb{C}(C)^\times$, the **divisor of f** is

$$\text{div}(f) = \sum_{P \in C} \nu_P(f) [P] \in \text{Div}(C).$$

Divisors of this form are called **principal**, and they form a subgroup $\text{Prin}(C) \leq \text{Div}(C)$.

That the sum is finite, and that $\deg \text{div}(f) = 0$, is Corollary 24.7.18. That $\text{Prin}(C)$ is a

subgroup follows from $\operatorname{div}(fg) = \operatorname{div}(f) + \operatorname{div}(g)$, which is the multiplicativity of ν_P . So $\operatorname{Prin}(C) \leq \operatorname{Div}^0(C)$.

Definition 24.8.4 (Picard Group)

The **Picard group** or **divisor class group** of C is

$$\operatorname{Pic}(C) = \operatorname{Cl}(C) = \operatorname{Div}(C) / \operatorname{Prin}(C),$$

and $\operatorname{Pic}^0(C) = \operatorname{Cl}^0(C) = \operatorname{Div}^0(C) / \operatorname{Prin}(C)$. Divisors D, D' are **linearly equivalent**, written $D \sim D'$, if $D - D'$ is principal.

The degree descends to $\operatorname{Pic}(C) \rightarrow \mathbb{Z}$, so linearly equivalent divisors have the same degree. The group $\operatorname{Pic}^0(C)$ measures the failure of the converse, and it turns out to be a subtle and extremely interesting invariant.

Proposition 24.8.5

On $\mathbb{P}^1$, every degree zero divisor is principal; that is, $\operatorname{Pic}^0(\mathbb{P}^1) = 0$ and $\operatorname{Pic}(\mathbb{P}^1) \cong \mathbb{Z}$ via the degree.

Proof. Identify $\mathbb{P}^1 = \mathbb{C} \cup \{\infty\}$ with coordinate t , and let $D = \sum_{a \in \mathbb{C}} n_a [a] + n_\infty [\infty]$ have degree 0, so $n_\infty = -\sum_a n_a$. Put

$$f = \prod_{a \in \mathbb{C}} (t - a)^{n_a} \in \mathbb{C}(t)^\times,$$

a finite product. Then $\nu_a(f) = n_a$ for each $a \in \mathbb{C}$, since $t - a$ is a local parameter at a and the other factors are units there. At ∞ , using the local parameter $1/t$, each factor $(t - a)$ has $\nu_\infty = -1$, so $\nu_\infty(f) = -\sum_a n_a = n_\infty$. Hence $\operatorname{div}(f) = D$. $\square$

That this fails for other curves is the source of the whole theory. We will see, for instance, that on a smooth cubic $\operatorname{Pic}^0(C) \cong C$ as a set, which is a very large group indeed.

§24.8.2 Hyperplane Sections and the Degree of a Curve

There is a second, geometric, source of divisors.

Definition 24.8.6 (Hyperplane Section)

Let $C \subseteq \mathbb{P}^n$ be a curve and L a nonzero linear form with $C \not\subseteq \mathbb{V}(L)$. The **hyperplane section** of C by $\mathbb{V}(L)$ is

$$\operatorname{div}(L) = \sum_{P \in C} n_P [P], \quad n_P = \nu_P \left(\frac{L}{X_i} \right) \text{ for any } i \text{ with } X_i(P) \neq 0.$$

This is well defined: if $X_i(P), X_j(P) \neq 0$ then $X_i/X_j \in \mathcal{O}_{C,P}^\times$, so $\nu_P(X_i/X_j) = 0$ and $\nu_P(L/X_i) = \nu_P(L/X_j)$. Note $\operatorname{div}(L)$ is effective, since L/X_i is regular at every such P , and it is supported on $C \cap \mathbb{V}(L)$, a finite set.

Proposition 24.8.7

If L, L' are linear forms with $C \not\subseteq \mathbb{V}(L) \cup \mathbb{V}(L')$, then

$$\operatorname{div}(L) - \operatorname{div}(L') = \operatorname{div}\left(\frac{L}{L'}\right),$$

which is principal. In particular $\deg \operatorname{div}(L) = \deg \operatorname{div}(L')$.

Proof. At a point P with $X_i(P) \neq 0$ we have $\nu_P(L/L') = \nu_P(L/X_i) - \nu_P(L'/X_i)$, since ν_P is a homomorphism. The degrees agree because principal divisors have degree 0. $\square$

Definition 24.8.8 (Degree of a Curve)

The **degree** of a curve $C \subseteq \mathbb{P}^n$ is $\deg C = \deg \operatorname{div}(L)$ for any linear form L not vanishing on C .

So the degree of a curve counts, with multiplicity, the points in which a general hyperplane meets it. A line in $\mathbb{P}^2$ has degree 1, a smooth conic degree 2, and in general a plane curve $\mathbb{V}(F)$ with $\deg F = d$ has degree d by Proposition 24.6.4.

The construction generalises in two useful directions. First, if $\varphi: C \rightarrow \mathbb{P}^n$ is any non-constant morphism with $\varphi(C) \not\subseteq \mathbb{V}(L)$, we may set $\operatorname{div}(L) = \sum_P \nu_P(\varphi^*L/X_i)[P]$; taking φ to be an inclusion recovers the above. Secondly, if G is homogeneous of degree $m \geq 1$ and does not vanish on C , we set

$$\operatorname{div}(G) = \sum_{P \in C} \nu_P\left(\frac{\varphi^*G}{X_i^m}\right)[P],$$

again independent of the choice of i with $X_i(P) \neq 0$. The same argument as above shows $\operatorname{div}(G) \sim m \operatorname{div}(L)$ for any linear form L , because G/L^m is a rational function on C . This is exactly what we need to prove Bézout.

Theorem 24.8.9 (Weak Bézout)

Let $C, C' \subseteq \mathbb{P}^2$ be distinct smooth irreducible projective plane curves of degrees m and n . Then $|C \cap C'| \leq mn$.

Proof. Write $C = \mathbb{V}(F)$, $C' = \mathbb{V}(G)$ with $\deg F = m$, $\deg G = n$. Restricting G to C gives a divisor $\operatorname{div}(G)$ on C , which is effective and supported exactly on $C \cap C'$ – if $\nu_P(G/X_i^n) > 0$ then G vanishes at P . Since $C \neq C'$ and both are irreducible, G does not vanish identically on C , so $\operatorname{div}(G)$ is defined.

By the remark above, $\operatorname{div}(G) \sim n \operatorname{div}(L)$ for a linear form L , so

$$\deg \operatorname{div}(G) = n \deg \operatorname{div}(L) = n \deg C = nm.$$

As $\operatorname{div}(G)$ is effective with support $C \cap C'$, each point contributes at least 1 to the degree, so $|C \cap C'| \leq mn$. $\square$

The full Bézout theorem is the assertion that $\nu_P(G/X_i^n)$ is exactly the intersection multiplicity $I_P(C, C')$, so that the count is an equality when weighted correctly. With

the definition of I_P we gave, this is essentially a tautology; the work is in showing that definition has the expected properties.

§24.8.3 Riemann–Roch Spaces

Now we come to the central construction.

Definition 24.8.10 (Riemann–Roch Space)

Let $D \in \text{Div}(C)$. The **Riemann–Roch space** of D is

$$L(D) = \{f \in \mathbb{C}(C)^\times : \text{div}(f) + D \geq 0\} \cup \{0\},$$

that is, the set of f with $\nu_P(f) \geq -\nu_P(D)$ for all P . We write $\ell(D) = \dim_{\mathbb{C}} L(D)$.

Unwinding: if $\nu_P(D) = n > 0$, then f is allowed a pole of order at most n at P ; if $\nu_P(D) = -n < 0$, then f is required to vanish to order at least n at P ; and if $\nu_P(D) = 0$, then f must be regular at P . So $L(D)$ is the space of rational functions with poles bounded by D .

Proposition 24.8.11

$L(D)$ is a $\mathbb{C}$ -vector subspace of $\mathbb{C}(C)$.

Proof. Closure under scalars is clear, and $\nu_P(f + g) \geq \min\{\nu_P(f), \nu_P(g)\}$ from Corollary 24.7.5 gives closure under addition. $\square$

Example 24.8.12

Let $C = \mathbb{P}^1$, $\infty = (0 : 1)$, and $D = m[\infty]$ with $m \geq 0$. An element of $L(D)$ is a rational function with no poles in $\mathbb{C}$ – hence a polynomial in t , by Proposition 24.8.5 type reasoning – with a pole of order at most m at infinity, hence of degree at most m . So $L(D)$ is spanned by $1, t, t^2, \dots, t^m$ and

$$\ell(m[\infty]) = m + 1 = \deg D + 1.$$

Proposition 24.8.13

Let D be a divisor on C .

- (i) $L(0) = \mathbb{C}$, so $\ell(0) = 1$.
- (ii) If $\deg D < 0$ then $L(D) = 0$.
- (iii) For any $P \in C$, $\ell(D) \leq \ell(D - [P]) + 1$.
- (iv) If $\deg D \geq 0$ then $\ell(D) \leq \deg D + 1$. In particular $L(D)$ is always finite-dimensional.

Proof. (i) $L(0)$ is the set of everywhere-regular functions, which is $\mathbb{C}$ by Corollary 24.7.18(i).

(ii) If $f \in L(D)$ is nonzero then $\operatorname{div}(f) + D \geq 0$, so $0 \leq \deg(\operatorname{div} f + D) = \deg D$.

(iii) Let $n = \nu_P(D)$ and π_P a local parameter. Define

$$\operatorname{ev}_P: L(D) \rightarrow \mathbb{C}, \quad f \mapsto (\pi_P^n f)(P).$$

This makes sense: $f \in L(D)$ has $\nu_P(f) \geq -n$, so $\nu_P(\pi_P^n f) \geq 0$ and $\pi_P^n f$ is regular at P . The map is $\mathbb{C}$ -linear, and its kernel is $\{f : \nu_P(\pi_P^n f) > 0\} = \{f : \nu_P(f) \geq -n + 1\} \cap L(D) = L(D - [P])$. So $\ell(D) \leq \ell(D - [P]) + 1$.

(iv) Let $d = \deg D \geq 0$ and pick any P . Applying (iii) $d + 1$ times,

$$\ell(D) \leq \ell(D - (d + 1)[P]) + d + 1 = d + 1,$$

since $\deg(D - (d + 1)[P]) = -1 < 0$ and (ii) applies. $\square$

Intuitively, (iii) says that relaxing the pole bound at one point by one can only gain one dimension: you gain the possibility of one extra term in the local expansion.

Proposition 24.8.14

If $D \sim E$ then $L(D) \cong L(E)$ as $\mathbb{C}$ -vector spaces; in particular $\ell(D) = \ell(E)$.

Proof. Write $D - E = \operatorname{div}(g)$. Multiplication by g is a $\mathbb{C}$ -linear map $L(D) \rightarrow L(E)$: if $\operatorname{div}(f) + D \geq 0$ then $\operatorname{div}(fg) + E = \operatorname{div}(f) + \operatorname{div}(g) + E = \operatorname{div}(f) + D \geq 0$. Multiplication by g^{-1} is its inverse. $\square$

So ℓ is a function on $\operatorname{Pic}(C)$, and computing it is the central problem that Riemann–Roch solves.

§24.9 Differentials

We have produced divisors in two ways so far: from rational functions, and from hyperplane sections. There is a third source, which will turn out to be the most important of all: differentials. Their divisor class is intrinsic to the curve – it does not depend on any embedding – and the dimension of its Riemann–Roch space is the genus.

§24.9.1 Differentials of a Field Extension

The construction is formal, imitating the rules of calculus.

Definition 24.9.1 (Space of Differentials)

Let $K/\mathbb{C}$ be a field extension. The **space of differentials** $\Omega_{K/\mathbb{C}}$ is the quotient M/N , where M is the K -vector space with basis the symbols δx for $x \in K$, and $N \leq M$ is the subspace generated by

$$\delta(x + y) - \delta x - \delta y, \quad \delta(xy) - x \delta y - y \delta x, \quad \delta a$$

for $x, y \in K$ and $a \in \mathbb{C}$. We write dx for the image of δx , and $d: K \rightarrow \Omega_{K/\mathbb{C}}$ for the resulting map, the **exterior derivative**. We abbreviate $\Omega_{K/\mathbb{C}}$ to Ω_K .

So Ω_K is the universal recipient of a ‘derivative’.

Definition 24.9.2 (Derivation)

Let U be a K -vector space. A $\mathbb{C}$ -linear map $D: K \rightarrow U$ is a **derivation** if $D(xy) = xD(y) + yD(x)$ for all x, y .

Lemma 24.9.3 (Universal property)

A $\mathbb{C}$ -linear map $D: K \rightarrow U$ is a derivation if and only if there is a (necessarily unique) K -linear map $\lambda: \Omega_K \rightarrow U$ with $D = \lambda \circ d$.

Proof. If such a λ exists then D inherits the Leibniz rule from d , which satisfies it by construction. Conversely, given a derivation D , define $\tilde{\lambda}: M \rightarrow U$ on the basis by $\delta x \mapsto D(x)$ and extend K -linearly. The relations generating N are exactly the statements that D is additive, Leibniz and kills $\mathbb{C}$ (note $D(1) = D(1 \cdot 1) = 2D(1)$, so $D(1) = 0$, and $\mathbb{C}$ -linearity gives $D(a) = 0$). So $\tilde{\lambda}(N) = 0$ and $\tilde{\lambda}$ descends. $\square$

Remark. Every derivation obeys the quotient rule: if $y \neq 0$ then $D(x) = D(y \cdot \frac{x}{y}) = yD(\frac{x}{y}) + \frac{x}{y}D(y)$, so

$$D\left(\frac{x}{y}\right) = \frac{yD(x) - xD(y)}{y^2}.$$

Lemma 24.9.4 (i) Let $f = h/g \in \mathbb{C}(X_1, \dots, X_n)$ and let $x_1, \dots, x_n \in K$ be such that $y = f(x_1, \dots, x_n)$ is defined. Then

$$dy = \sum_{i=1}^n \frac{\partial f}{\partial X_i}(x_1, \dots, x_n) dx_i.$$

(ii) If $K = \mathbb{C}(x_1, \dots, x_n)$ then Ω_K is spanned over K by $dx_1, \dots, dx_n$.

Proof. (i) By $\mathbb{C}$ -linearity it suffices to treat monomials, where it is the Leibniz rule and induction, and then quotients, where it is the quotient rule. (ii) is immediate from (i), since every element of K is such an $f(x_1, \dots, x_n)$. $\square$

Theorem 24.9.5

Let $K/\mathbb{C}(t)$ be a finite extension with t transcendental over $\mathbb{C}$. Then Ω_K is a one-dimensional K -vector space, spanned by dt .

Proof. First suppose $K = \mathbb{C}(t)$. By Lemma 24.9.4(ii), Ω_K is spanned by dt , so it has dimension 0 or 1; we must rule out 0. By Lemma 24.9.3 it suffices to exhibit one nonzero derivation on K , and $\frac{d}{dt}: \mathbb{C}(t) \rightarrow \mathbb{C}(t)$ is one.

Now suppose $K \supsetneq K_0 = \mathbb{C}(t)$. Since $\mathbb{C}$ has characteristic zero, K/K_0 is separable, so $K = K_0(\alpha)$ for some α ; let $h \in K_0[T]$ be its minimal polynomial. As h is irreducible and K_0 has characteristic zero, h has no repeated roots, so $h'(\alpha) \neq 0$.

By Lemma 24.9.4, Ω_K is spanned by dt and $d\alpha$. Writing $D_t h$ for the polynomial obtained by differentiating the coefficients of h with respect to t , applying d to the relation $h(\alpha) = 0$ gives

$$0 = (D_t h)(\alpha) dt + h'(\alpha) d\alpha,$$

so $d\alpha = -\frac{(D_t h)(\alpha)}{h'(\alpha)} dt$ and Ω_K is spanned by dt alone.

It remains to show $\Omega_K \neq 0$, for which we exhibit a nonzero derivation. Define $D: K_0[T] \rightarrow K$ by

$$D\left(\sum_i c_i T^i\right) = \sum_i (D_t c_i) \alpha^i + \left(\sum_i i c_i \alpha^{i-1}\right) \cdot \left(\frac{-(D_t h)(\alpha)}{h'(\alpha)}\right).$$

One checks that D is a derivation and that $D(hK_0[T]) = 0$, using the displayed formula for $D(h)$; hence D descends to a nonzero derivation $K = K_0[T]/(h) \rightarrow K$. $\square$

Since the function field of a curve is exactly a finite extension of some $\mathbb{C}(t)$ with t transcendental (Proposition 24.5.15), the theorem applies to all our curves.

§24.9.2 Rational Differentials on a Curve

Definition 24.9.6

Let C be a curve. Write $\Omega_C = \Omega_{\mathbb{C}(C)/\mathbb{C}}$; its elements are **rational differentials** on C . A differential $\omega \in \Omega_C$ is **regular** at P if it can be written $\omega = \sum_i f_i dg_i$ with all $f_i, g_i \in \mathcal{O}_{C,P}$. We write

$$\Omega_{C,P} = \{\omega \in \Omega_C : \omega \text{ regular at } P\}.$$

Note $\Omega_{C,P}$ is an $\mathcal{O}_{C,P}$ -module but not a $\mathbb{C}(C)$ -subspace: multiplying a regular differential by a function with a pole destroys regularity.

Theorem 24.9.7

Let $P \in C$ be a point with local parameter π_P . Then $\Omega_{C,P}$ is a free $\mathcal{O}_{C,P}$ -module of rank one generated by $d\pi_P$; that is,

$$\Omega_{C,P} = \{f d\pi_P : f \in \mathcal{O}_{C,P}\}.$$

Proof. First, $\Omega_{C,P}$ is finitely generated over $\mathcal{O}_{C,P}$: choose an affine patch $C_0 \ni P$ with $\mathbb{C}[C_0] = \mathbb{C}[x_1, \dots, x_n]$. Given $f \in \mathcal{O}_{C,P}$, write $f = g/h$ with g, h polynomials in the x_i and $h(P) \neq 0$; by the quotient rule and Lemma 24.9.4,

$$df = \sum_{i=1}^n \frac{h \frac{\partial g}{\partial X_i} - g \frac{\partial h}{\partial X_i}}{h^2}(x_1, \dots, x_n) dx_i,$$

and every coefficient is regular at P since $h(P) \neq 0$. So $\Omega_{C,P}$ is generated by $dx_1, \dots, dx_n$.

Now clearly $\mathcal{O}_{C,P} d\pi_P \subseteq \Omega_{C,P}$. Conversely, for $f \in \mathcal{O}_{C,P}$ we have $f - f(P) \in \mathfrak{m}_P =$

(π_P) , so $f = f(P) + \pi_P g$ with $g \in \mathcal{O}_{C,P}$; the Leibniz rule gives

$$df = g d\pi_P + \pi_P dg \in \mathcal{O}_{C,P} d\pi_P + \mathfrak{m}_P \Omega_{C,P}.$$

Hence $\Omega_{C,P} = \mathcal{O}_{C,P} d\pi_P + \mathfrak{m}_P \Omega_{C,P}$, and Nakayama's lemma (Lemma 24.7.3(ii)) gives $\Omega_{C,P} = \mathcal{O}_{C,P} d\pi_P$. Freeness holds because $d\pi_P \neq 0$ in the one-dimensional space Ω_C and $\mathcal{O}_{C,P}$ is a domain. $\square$

Since Ω_C is one-dimensional over $\mathbb{C}(C)$, every $\omega \in \Omega_C$ can be written $\omega = f d\pi_P$ for a unique $f \in \mathbb{C}(C)$. This lets us define orders of vanishing for differentials.

Definition 24.9.8

For $\omega \in \Omega_C \setminus \{0\}$ and $P \in C$, write $\omega = f d\pi_P$ and set $\nu_P(\omega) = \nu_P(f)$.

This is well defined: if π' is another local parameter then $\pi' = u\pi_P$ with u a unit, so $d\pi' = u d\pi_P + \pi_P du$, and $du = h d\pi_P$ with h regular, so $d\pi' = (u + \pi_P h) d\pi_P$ with $u + \pi_P h$ a unit. Hence ν_P is unchanged.

Lemma 24.9.9

Let $\omega \in \Omega_C$ be nonzero. Then $\nu_P(\omega) \neq 0$ for only finitely many P .

Proof. Since $\nu_P(fdg) = \nu_P(f) + \nu_P(dg)$ and $\nu_P(f) = 0$ for all but finitely many P , it suffices to treat $\omega = dg$. Here g is non-constant (else $dg = 0$), so g is transcendental over $\mathbb{C}$ and $\mathbb{C}(C)/\mathbb{C}(g)$ is finite. Consider the morphism $\varphi = (1 : g) : C \rightarrow \mathbb{P}^1$. By Corollary 24.7.18 there are finitely many P with $g(P) = \infty$, and by Theorem 24.7.15(iii) finitely many with $e_P > 1$.

At any other P , put $Q = \varphi(P) = g(P) \in \mathbb{C}$. Then $t - g(P)$ is a local parameter at Q , and since $e_P = 1$, $\varphi^*(t - g(P)) = g - g(P)$ is a local parameter at P . Hence $dg = d(g - g(P))$ is d of a local parameter, so $\nu_P(dg) = 0$. $\square$

(Strictly, this argument uses Theorem 24.7.15(iii), which we have not yet proved. The logic is not circular: (iii) follows from the case $\omega = dt$ on $\mathbb{P}^1$, computed explicitly in Example 24.9.13 below, together with the ramification formula of Lemma 24.10.7. We record the dependency and move on.)

Definition 24.9.10 (Canonical Divisor)

For $\omega \in \Omega_C \setminus \{0\}$, set $\text{div}(\omega) = \sum_{P \in C} \nu_P(\omega)[P] \in \text{Div}(C)$.

Proposition 24.9.11

If ω, ω' are nonzero rational differentials on C , then $\text{div}(\omega) - \text{div}(\omega')$ is principal.

Proof. Ω_C is one-dimensional over $\mathbb{C}(C)$, so $\omega = f\omega'$ for some $f \in \mathbb{C}(C)^\times$, and then $\nu_P(\omega) = \nu_P(f) + \nu_P(\omega')$ at every P . $\square$

Definition 24.9.12 (Canonical Class)

The class $K_C = [\text{div}(\omega)] \in \text{Pic}(C)$, for any nonzero $\omega \in \Omega_C$, is the **canonical class** of C . Any divisor in this class is a **canonical divisor**.

Example 24.9.13

Let $C = \mathbb{P}^1$ with affine coordinate t . For $a \in \mathbb{C}$, $t - a$ is a local parameter at a and $dt = d(t - a)$, so $\nu_a(dt) = 0$. At ∞ , the local parameter is $s = 1/t$, and $t = 1/s$ gives $dt = -s^{-2}ds$, so

$$\nu_\infty(dt) = \nu_\infty(-s^{-2}) = -2.$$

Hence

$$\text{div}(dt) = -2[\infty], \quad \deg K_{\mathbb{P}^1} = -2.$$

In particular $K_{\mathbb{P}^1}$ has nonzero degree, so it is not principal: there is no rational differential on $\mathbb{P}^1$ with neither zeros nor poles.

§24.9.3 The Genus**Definition 24.9.14 (Genus)**

The **genus** of a curve C is $g(C) = \ell(K_C)$.

By Proposition 24.8.14 this is well defined, even though $L(K_C)$ itself depends on the choice of representative. Concretely, $L(K_C)$ is (isomorphic to) the space of **regular differentials** on C : for ω_0 a fixed nonzero differential, $f \mapsto f\omega_0$ identifies $L(\text{div } \omega_0)$ with $\{\omega \in \Omega_C : \text{div } \omega \geq 0\}$, the differentials with no poles. So the genus counts the everywhere-regular differentials.

Example 24.9.15

$g(\mathbb{P}^1) = 0$. Indeed $K_{\mathbb{P}^1} = -2[\infty]$ has degree $-2 < 0$, so $\ell(K_{\mathbb{P}^1}) = 0$ by Proposition 24.8.13(ii).

The genus is the invariant that will organise everything that follows. Topologically, a smooth projective curve over $\mathbb{C}$ is a compact orientable real surface, and g is the number of handles: $\mathbb{P}^1$ is a sphere ($g = 0$), a smooth cubic is a torus ($g = 1$), and in general the genus g surface looks like this.

a curve of genus 3

This is not a definition we can use – we have defined g algebraically – but it is the right picture, and the numerology will confirm it: we will show $\deg K_C = 2g - 2$, and $2 - 2g$ is precisely the Euler characteristic of a genus g surface.

§24.9.4 The Canonical Class of a Plane Curve

We can compute the canonical class of a smooth plane curve completely explicitly. The following calculation is the model for everything: choose a convenient differential, and compute its order of vanishing at every point using Corollary 24.7.4.

Example 24.9.16 (Smooth plane cubics)

Let $C = \mathbb{V}(F) \subseteq \mathbb{P}^2$ with $F = X_0X_2^2 - \prod_{i=1}^3(X_1 - \lambda_i X_0)$ and $\lambda_1, \lambda_2, \lambda_3$ distinct; this is the Weierstrass form of Theorem 24.6.15, and it is smooth. In the affine chart $X_0 = 1$ with coordinates $x = X_1/X_0$, $y = X_2/X_0$, the equation is

$$f(x, y) = y^2 - p(x) = 0, \quad p(x) = \prod_{i=1}^3 (x - \lambda_i).$$

Applying d gives the relation $2y dy = p'(x) dx$ in Ω_C . Take

$$\omega = \frac{dx}{y} = \frac{2 dy}{p'(x)}.$$

We compute $\text{div}(\omega)$.

If $P = (a, b)$ with $b \neq 0$, then $\partial f / \partial y = 2b \neq 0$, so $x - a$ is a local parameter at P by Corollary 24.7.4, and $\nu_P(dx) = 0$; also $\nu_P(1/y) = 0$. So $\nu_P(\omega) = 0$.

If $P = (\lambda_i, 0)$, then $\partial f / \partial x = -p'(\lambda_i) \neq 0$ (the λ_i are distinct), so y is a local parameter at P and $\nu_P(dy) = 0$; also $\nu_P(p'(x)) = 0$ since $p'(\lambda_i) \neq 0$. Using the second expression, $\nu_P(\omega) = 0$.

Finally, at the point at infinity $P_0 = (0 : 0 : 1)$: in the chart $X_2 = 1$, with $z = X_0/X_2 = 1/y$ and $w = X_1/X_2 = x/y$, the equation becomes $z = \prod_i (w - \lambda_i z)$, and one computes that w is a local parameter at P_0 with $\nu_{P_0}(z) = 3$, $\nu_{P_0}(x) = \nu_{P_0}(w/z) = -2$ and $\nu_{P_0}(y) = \nu_{P_0}(1/z) = -3$. Then $\nu_{P_0}(dx) = \nu_{P_0}(x) - 1 = -3$, so

$$\nu_{P_0}(\omega) = \nu_{P_0}(dx) - \nu_{P_0}(y) = -3 - (-3) = 0.$$

Hence $\text{div}(\omega) = 0$ and $K_C = 0$. Therefore

$$g(C) = \ell(K_C) = \ell(0) = 1.$$

Theorem 24.9.17

Every smooth plane cubic has genus 1. In particular no smooth plane cubic is isomorphic to $\mathbb{P}^1$.

Proof. By Theorem 24.6.15 we may change coordinates into the shape of Example 24.9.16, and the genus is an isomorphism invariant. Since $g(\mathbb{P}^1) = 0 \neq 1$, the last statement follows. $\square$

The general computation runs along exactly the same lines.

Theorem 24.9.18

Let $C = \mathbb{V}(F) \subseteq \mathbb{P}^2$ be a smooth plane curve of degree d . Then

$$K_C = (d - 3)H,$$

where H is the class of a hyperplane section of C . In particular $\deg K_C = d(d - 3)$.

Proof. Change coordinates so that $(0 : 1 : 0) \notin C$. Let $x = X_1/X_0$ and $y = X_2/X_0$ in $\mathbb{C}(C)$, and set $f(X, Y) = F(1, X, Y)$, so $f(x, y) = 0$. Applying d ,

$$\frac{\partial f}{\partial X}(x, y) dx + \frac{\partial f}{\partial Y}(x, y) dy = 0 \quad \text{in } \Omega_C.$$

Choose

$$\omega = \frac{dx}{\frac{\partial f}{\partial Y}(x, y)} = \frac{-dy}{\frac{\partial f}{\partial X}(x, y)}.$$

If $P \in C \cap U_0$ has $\frac{\partial f}{\partial Y}(P) \neq 0$, then $x - x(P)$ is a local parameter and $\nu_P(\omega) = -\nu_P(\frac{\partial f}{\partial Y}) = 0$. Otherwise smoothness gives $\frac{\partial f}{\partial X}(P) \neq 0$, and the second expression gives $\nu_P(\omega) = 0$ likewise. So ω has neither zeros nor poles on the affine patch U_0 .

Since $(0 : 1 : 0) \notin C$, the points of C at infinity (i.e. with $X_0 = 0$) all have $X_2 \neq 0$, so lie in U_2 . Work there with $z = X_0/X_2$ and $w = X_1/X_2$, and $g(Z, W) = F(Z, W, 1)$, and set

$$\eta = \frac{dz}{\frac{\partial g}{\partial W}(z, w)} = \frac{-dw}{\frac{\partial g}{\partial Z}(z, w)}.$$

The same argument gives $\nu_P(\eta) = 0$ for all $P \in C \cap U_2$.

It remains to compare ω and η . We have $z = 1/y$, $w = x/y$, and F homogeneous of degree d gives $f(X, Y) = Y^d g(1/Y, X/Y)$. Differentiating this identity and substituting, a short computation yields

$$\omega = z^{d-3} \eta.$$

Hence for P with $X_2(P) \neq 0$,

$$\nu_P(\omega) = (d - 3)\nu_P(z) + \nu_P(\eta) = (d - 3)\nu_P(z),$$

and since $z = X_0/X_2$, the divisor $\sum_P \nu_P(z)[P]$ restricted to U_2 is exactly $\text{div}(X_0)$, the hyperplane section by $\mathbb{V}(X_0)$ (which is supported at infinity, where ω was not already computed to be zero). Combining the two patches,

$$\text{div}(\omega) = (d - 3)\text{div}(X_0),$$

which is $(d - 3)H$. □

Corollary 24.9.19

Smooth plane curves of distinct degrees $d, d' \geq 2$ are never isomorphic.

Proof. $\deg K_C = d(d - 3)$ depends only on the isomorphism class of C , and $d \mapsto d(d - 3)$ is injective on $\{d \geq 2\}$ (it is strictly increasing for $d \geq 2$ apart from $d(d - 3)$ taking the values $-2, 0, 4, 10, \dots$ at $d = 2, 3, 4, 5$, which are distinct). □

In particular there are infinitely many pairwise non-isomorphic smooth projective curves, which is already far from obvious.

Proposition 24.9.20

Let C be a smooth plane curve of degree $d \geq 3$ with affine equation $f(x, y) = 0$ as above. Then

$$\left\{ \frac{x^r y^s dx}{\frac{\partial f}{\partial Y}(x, y)} : r, s \geq 0, r + s \leq d - 3 \right\}$$

is a basis for $L(K_C)$, taking the representative $(d - 3)H$ with H the hyperplane at infinity. Consequently

$$g(C) = \#\{(r, s) : r, s \geq 0, r + s \leq d - 3\} = \binom{d-1}{2} = \frac{(d-1)(d-2)}{2}.$$

Proof sketch. The proof runs exactly as in Theorem 24.9.18: multiplying ω by the monomial $x^r y^s$ shifts the order of vanishing at infinity by a controlled amount, and the condition $r + s \leq d - 3$ is exactly what keeps $\text{div}(x^r y^s \omega) + (d - 3)H$ effective. Linear independence holds because the monomials $x^r y^s$ with $r + s \leq d - 3$ are linearly independent in $\mathbb{C}(C)$, as $\deg f = d$. We omit the details. $\square$

The formula $g = \frac{(d-1)(d-2)}{2}$ is the **genus–degree formula**. For $d = 1, 2$ it gives $g = 0$, consistent with lines and conics being isomorphic to $\mathbb{P}^1$; for $d = 3$ it gives $g = 1$, matching Theorem 24.9.17; for $d = 4$ it gives $g = 3$. We will re-derive it from Riemann–Roch in a moment, which is the more illuminating route.

§24.10 The Riemann–Roch Theorem

We have two invariants of a divisor D on a curve C : the degree $\deg D$, which is easy to compute, and the dimension $\ell(D)$, which is what we actually want. Proposition 24.8.13 gives the crude bound $\ell(D) \leq \deg D + 1$. Riemann–Roch says that this is an equality up to a correction term measured by the genus and a second Riemann–Roch space.

Theorem 24.10.1 (Riemann–Roch)

Let C be a smooth irreducible projective curve of genus g , and let $D \in \text{Div}(C)$. Let $K = K_C$ be a canonical divisor. Then

$$\ell(D) - \ell(K - D) = \deg D - g + 1.$$

The proof is beyond the scope of this course. It is worth knowing that it is a genuinely deep statement, and that it has several very different proofs: a sheaf-cohomological one, in which $\ell(D) = \dim H^0(C, \mathcal{O}(D))$ and $\ell(K - D) = \dim H^1(C, \mathcal{O}(D))$ and the theorem is a computation of Euler characteristics; an analytic one via Hodge theory; and Weil’s original adelic proof. It is closely related to Stokes’ theorem and the Gauss–Bonnet theorem, both of which relate a local differential-geometric quantity to a global topological one.

Let us extract its consequences, which is where all the fun is.

§24.10.1 First Consequences**Corollary 24.10.2**

$$\deg K_C = 2g - 2.$$

Proof. Apply Riemann–Roch with $D = K$:

$$\ell(K) - \ell(0) = \deg K - g + 1.$$

Now $\ell(K) = g$ by definition of the genus and $\ell(0) = 1$ by Proposition 24.8.13(i), so $g - 1 = \deg K - g + 1$, giving $\deg K = 2g - 2$. $\square$

Note that $2g - 2 = -\chi(C)$ where χ is the Euler characteristic of the associated real surface. This is the promised confirmation that our algebraic genus is the topological one.

Corollary 24.10.3

If $\deg D > 2g - 2$ then $\ell(D) = \deg D - g + 1$.

Proof. $\deg(K - D) = 2g - 2 - \deg D < 0$, so $\ell(K - D) = 0$ by Proposition 24.8.13(ii). $\square$

So for divisors of large degree, ℓ is completely determined by the degree and the genus. The ‘interesting’ range $0 \leq \deg D \leq 2g - 2$ is exactly where the geometry of the particular curve enters.

Corollary 24.10.4 (Genus–degree formula)

Let $C \subseteq \mathbb{P}^2$ be a smooth plane curve of degree d . Then

$$g(C) = \frac{(d-1)(d-2)}{2}.$$

Proof. For $d = 1, 2$ we know $C \cong \mathbb{P}^1$ (Proposition 24.4.30), so $g = 0$, matching the formula. For $d \geq 3$, Theorem 24.9.18 gives $K_C = (d-3)H$ with $\deg H = \deg C = d$, so $\deg K_C = d(d-3)$. By Corollary 24.10.2,

$$2g - 2 = d(d-3) \implies g = \frac{d^2 - 3d + 2}{2} = \frac{(d-1)(d-2)}{2}. \quad \square$$

Example 24.10.5

A smooth plane quartic has genus 3, a quintic genus 6, a sextic genus 10. Note that not every integer occurs: there is no smooth plane curve of genus 2. (There are plenty of genus 2 curves; they just do not embed smoothly in $\mathbb{P}^2$.)

Corollary 24.10.6

If $g(C) = 0$ then $C \cong \mathbb{P}^1$.

Proof. Pick any point $P \in C$ and let $D = [P]$, of degree $1 > -2 = 2g - 2$. By Corollary 24.10.3, $\ell(D) = 1 - 0 + 1 = 2$. So $L(D)$ contains a non-constant function f (as the constants give only a one-dimensional subspace), whose only possible pole is a simple pole at P . Consider $\varphi = (1 : f) : C \rightarrow \mathbb{P}^1$, a morphism by Corollary 24.7.10. Its degree equals the number of poles of f counted with multiplicity, which by the proof of Corollary 24.7.18 is $-\nu_P(f) = 1$. A degree 1 morphism induces an isomorphism of function fields, so $C \cong \mathbb{P}^1$ by Theorem 24.4.38; and a birational morphism of smooth projective curves is an isomorphism (its inverse is a rational map, hence a morphism by Corollary 24.7.10). $\square$

So genus 0 curves are exactly the rational ones, and there is only one of them.

§24.10.2 Riemann–Hurwitz

We now compare the genera of two curves related by a morphism. The key is that differentials pull back.

Let $\varphi : C \rightarrow D$ be a non-constant morphism of curves. If $\omega = f dt \in \Omega_D$, define

$$\varphi^*\omega = (\varphi^*f) d(\varphi^*t) \in \Omega_C.$$

This is well defined by Theorem 24.9.5 applied on both sides.

Lemma 24.10.7

Let $P \in C$, $Q = \varphi(P)$, with local parameters π_P, π_Q and ramification index e_P . Then for any nonzero $\omega \in \Omega_D$,

$$\nu_P(\varphi^*\omega) = e_P \nu_Q(\omega) + e_P - 1.$$

Proof. By definition of e_P we may write $\varphi^*\pi_Q = u\pi_P^{e_P}$ with $u \in \mathcal{O}_{C,P}^\times$. Differentiating,

$$\varphi^*(d\pi_Q) = d(u\pi_P^{e_P}) = \left(e_P u \pi_P^{e_P-1} + \pi_P^{e_P} \frac{du}{d\pi_P} \right) d\pi_P.$$

The bracket has $\nu_P = e_P - 1$: the first term has order exactly $e_P - 1$ (here we use characteristic zero, so $e_P \neq 0$ in $\mathbb{C}$), and the second has order at least e_P . So $\nu_P(\varphi^*d\pi_Q) = e_P - 1$, which is the case $\nu_Q(\omega) = 0$.

In general write $\omega = v\pi_Q^m d\pi_Q$ with $v \in \mathcal{O}_{D,Q}^\times$ and $m = \nu_Q(\omega)$, using Theorem 24.9.7. Then

$$\varphi^*\omega = (\varphi^*v)(\varphi^*\pi_Q)^m \varphi^*(d\pi_Q),$$

and taking ν_P gives $0 + me_P + (e_P - 1)$ as claimed. $\square$

The formula generalises the elementary fact that $\frac{d}{dx}x^n = nx^{n-1}$ drops the order by one; ramification of order e costs $e - 1$.

Theorem 24.10.8 (Riemann–Hurwitz)

Let $\varphi : C \rightarrow D$ be a non-constant morphism of smooth projective irreducible curves

of degree n . Then

$$2g(C) - 2 = n(2g(D) - 2) + \sum_{P \in C} (e_P - 1).$$

Proof. Choose a nonzero $\omega \in \Omega_D$. Then $\varphi^*\omega$ is a nonzero element of Ω_C , so $\text{div}(\varphi^*\omega)$ is a canonical divisor on C and by Corollary 24.10.2 its degree is $2g(C) - 2$. Now compute, grouping the points of C into fibres and using Lemma 24.10.7:

$$\begin{aligned} 2g(C) - 2 &= \sum_{P \in C} \nu_P(\varphi^*\omega) \\ &= \sum_{Q \in D} \sum_{P \in \varphi^{-1}(Q)} (e_P \nu_Q(\omega) + e_P - 1) \\ &= \sum_{Q \in D} \left(\nu_Q(\omega) \sum_{P \in \varphi^{-1}(Q)} e_P + \sum_{P \in \varphi^{-1}(Q)} (e_P - 1) \right) \\ &= \sum_{Q \in D} (n \nu_Q(\omega)) + \sum_{P \in C} (e_P - 1) \\ &= n \deg \text{div}(\omega) + \sum_{P \in C} (e_P - 1) \\ &= n(2g(D) - 2) + \sum_{P \in C} (e_P - 1), \end{aligned}$$

where the fourth line uses Theorem 24.7.15(ii). □

Note that the ramification term is a sum of non-negative integers, and (by Theorem 24.7.15(iii)) all but finitely many terms vanish, so the sum is finite. Conversely, running the argument in the case $D = \mathbb{P}^1$ shows that the sum *must* be finite, which is how one proves Theorem 24.7.15(iii).

Corollary 24.10.9

With notation as above, $g(C) \geq g(D)$. If $g(C) < g(D)$ then every rational map $C \dashrightarrow D$ is constant.

Proof. If $g(D) \geq 1$ then $2g(D) - 2 \geq 0$ and Riemann–Hurwitz gives $2g(C) - 2 \geq n(2g(D) - 2) \geq 2g(D) - 2$ since $n \geq 1$, so $g(C) \geq g(D)$. If $g(D) = 0$ there is nothing to prove. For the second statement, recall that a rational map from a smooth curve is a morphism (Corollary 24.7.10), so a non-constant one would contradict the first part. □

Example 24.10.10

There is no non-constant morphism $\mathbb{P}^1 \rightarrow C$ for any curve C of genus ≥ 1 . In particular a smooth plane cubic cannot be parametrised by rational functions – which is a purely algebraic statement with a genuinely geometric proof.

Example 24.10.11 (Hyperelliptic curves)

Consider the smooth projective model C of the affine curve $y^2 = p(x)$ where p has degree $2m$ with distinct roots, and let $\varphi: C \rightarrow \mathbb{P}^1$ be $(x, y) \mapsto x$. This has degree 2, since $\mathbb{C}(C) = \mathbb{C}(x)[y]/(y^2 - p(x))$ is a degree 2 extension of $\mathbb{C}(x)$.

Ramification occurs exactly where the two preimages coincide, i.e. at the $2m$ roots of p , and there $e_P = 2$; one checks the two points at infinity are unramified when $\deg p$ is even. So Riemann–Hurwitz gives

$$2g(C) - 2 = 2(-2) + 2m \cdot 1 = 2m - 4,$$

so $g(C) = m - 1$. Taking $m = 2$ (a quartic p) gives $g = 1$; $m = 3$ gives $g = 2$; and in general every genus is achieved. So genus 2 curves exist even though no plane curve has genus 2.

Example 24.10.12

The map $\varphi: \mathbb{P}^1 \rightarrow \mathbb{P}^1$, $z \mapsto z^d$, has degree d and is ramified exactly at 0 and ∞ , each with $e = d$. Riemann–Hurwitz reads

$$-2 = d(-2) + 2(d - 1),$$

which is indeed an identity. This is a useful sanity check on the signs.

The next example is the classical one, and it is worth doing slowly because it shows Riemann–Hurwitz being used to count something one would not otherwise know how to count.

Example 24.10.13 (The class of a plane curve)

Let $C \subseteq \mathbb{P}^2$ be a smooth plane curve of degree $d \geq 2$, so $g = \frac{(d-1)(d-2)}{2}$ by Corollary 24.10.4. Fix a point $R \in \mathbb{P}^2 \setminus C$ and let $\pi: C \rightarrow \mathbb{P}^1$ be the projection from R of Example 24.4.28, restricted to C ; this is a morphism by Corollary 24.7.10. The fibre over a point of $\mathbb{P}^1$ is $C \cap L$ for the corresponding line L through R , so $\deg \pi = d$.

What is the ramification? Choose R general – in particular not on any tangent line of C that is tangent at two points, and not on any flex tangent. Then $e_P = I_P(C, L) \leq 2$ for the line $L = \overline{RP}$, with $e_P = 2$ exactly when L is tangent to C at P . So $\sum_P (e_P - 1)$ counts the points of C at which the tangent line passes through R . Riemann–Hurwitz gives

$$(d - 1)(d - 2) - 2 = d \cdot (-2) + \sum_P (e_P - 1),$$

so

$$\sum_P (e_P - 1) = d^2 - 3d + 2 - 2 + 2d = d(d - 1).$$

Thus from a general point of $\mathbb{P}^2$ there are exactly $d(d - 1)$ tangent lines to a smooth plane curve of degree d . This number is called the **class** of C . For $d = 2$ it says there are two tangents from an external point to a conic, which is familiar; for $d = 3$ it gives six tangents to a smooth cubic.

Example 24.10.14

Projecting from a point R on C instead, the line $\overline{RP}$ already meets C at R , so the fibres have size $d - 1$ and $\deg \pi = d - 1$. Riemann–Hurwitz now reads

$$(d - 1)(d - 2) - 2 = (d - 1)(-2) + \sum_P (e_P - 1),$$

giving $\sum_P (e_P - 1) = d^2 - d - 2$. For $d = 3$ this is 4: a smooth cubic, projected from a point on it, is a double cover of $\mathbb{P}^1$ branched over four points. That is exactly the degree 2 map $(x, y) \mapsto x$ on $y^2 = p(x)$ with $\deg p = 3$, branched at the three roots of p and at infinity.

Definition 24.10.15

A curve C with $g(C) \geq 2$ is **hyperelliptic** if it admits a morphism $C \rightarrow \mathbb{P}^1$ of degree 2.

The curves of Example 24.10.11 with $m \geq 3$ are hyperelliptic. One shows (it is on the last example sheet) that C is hyperelliptic if and only if there is a divisor D with $\deg D = 2$ and $\ell(D) = 2$; the degree 2 map is then φ_D , constructed below.

§24.11 Curves of Low Genus

We finish by using Riemann–Roch to answer concrete questions: which curves are there, and how do we embed them in projective space?

§24.11.1 Maps to Projective Space from Divisors

Riemann–Roch produces functions; functions produce maps to projective space. Here is the construction.

Definition 24.11.1

Let D be a divisor on C with $\ell(D) = n + 1 \geq 2$, and let $f_0, \dots, f_n$ be a basis of $L(D)$. The **morphism associated to D** is

$$\varphi_D: C \rightarrow \mathbb{P}^n, \quad P \mapsto (f_0(P) : \dots : f_n(P)).$$

This is a rational map, hence (Corollary 24.7.10) a morphism, and it is independent of the choice of basis up to an element of $\mathrm{PGL}_{n+1}(\mathbb{C})$. We say φ_D is an **embedding** if it is an isomorphism onto its image.

Definition 24.11.2

A divisor D satisfies condition $(\star)$ if for all $P, Q \in C$ (not necessarily distinct),

$$\ell(D - [P] - [Q]) = \ell(D) - 2.$$

By Proposition 24.8.13(iii), $\ell(D) - 2 \leq \ell(D - [P] - [Q]) \leq \ell(D)$ always, so $(\star)$ says the drop is as large as possible. Geometrically: taking $P \neq Q$, condition $(\star)$ says there is a

function in $L(D)$ vanishing at P but not at Q , i.e. φ_D separates P and Q ; taking $P = Q$, it says φ_D separates tangent directions at P , i.e. $d(\varphi_D)_P$ is injective.

Theorem 24.11.3

φ_D is an embedding if and only if D satisfies $(\star)$.

We omit the proof, which is a careful unwinding of the two conditions in the previous paragraph.

Corollary 24.11.4

If $\deg D > 2g$ then φ_D is an embedding.

Proof. Both $\deg D$ and $\deg(D - [P] - [Q]) = \deg D - 2$ exceed $2g - 2$, so Corollary 24.10.3 applies to both, giving

$$\ell(D) - \ell(D - [P] - [Q]) = \deg D - (\deg D - 2) = 2. \quad \square$$

Corollary 24.11.5

Every curve of genus g embeds in $\mathbb{P}^N$ for some N depending only on g .

Proof. If $g \geq 2$, take D in the class $2K_C$, of degree $4g - 4 > 2g$. If $g = 1$, take $D = 3[P_0]$ for any P_0 , of degree $3 > 2$. If $g = 0$, $C \cong \mathbb{P}^1$ already. In each case $\deg D > 2g$, so Corollary 24.11.4 applies, and $N = \ell(D) - 1$ is determined by g via Corollary 24.10.3. $\square$

Theorem 24.11.6 (Canonical embedding)

Let C be a non-hyperelliptic curve of genus $g \geq 3$. Then $\varphi_{K_C}: C \rightarrow \mathbb{P}^{g-1}$ is an embedding.

Proof. Note $\ell(K) = g \geq 3 \geq 2$, so φ_K is defined and maps to $\mathbb{P}^{g-1}$. Suppose K fails $(\star)$, so there are P, Q with $\ell(K - [P] - [Q]) \geq g - 1$. Apply Riemann–Roch to $D = [P] + [Q]$:

$$\ell(D) - \ell(K - D) = \deg D - g + 1 = 3 - g,$$

so $\ell(D) \geq (g - 1) + 3 - g = 2$. But $\ell(D) = 2$ with $\deg D = 2$ says exactly that C is hyperelliptic, contradiction. (And $\ell(D) \leq \deg D + 1 = 3$; if $\ell(D) = 3$ then by Corollary 24.10.6-type reasoning $C \cong \mathbb{P}^1$, excluded since $g \geq 3$.) $\square$

So every non-hyperelliptic curve has a canonical model in $\mathbb{P}^{g-1}$, determined intrinsically with no choices. For $g = 3$ this is a plane quartic, matching the genus–degree formula.

§24.11.2 Genus Zero: Rational Curves

We have already done this case, but let us collect the statements.

Theorem 24.11.7

For a smooth projective irreducible curve C , the following are equivalent:

- (i) $g(C) = 0$;
- (ii) $C \cong \mathbb{P}^1$;
- (iii) $\mathbb{C}(C) \cong \mathbb{C}(t)$;
- (iv) C has a divisor of degree 1 that is linearly equivalent to an effective divisor with $\ell = 2$;
- (v) $\text{Pic}^0(C) = 0$.

Proof. (i) $\Rightarrow$ (ii) is Corollary 24.10.6. (ii) $\Rightarrow$ (iii) is clear, and (iii) $\Rightarrow$ (ii) is Theorem 24.4.38 together with Corollary 24.7.10. (ii) $\Rightarrow$ (v) is Proposition 24.8.5. For (v) $\Rightarrow$ (i), if $g \geq 1$ then for distinct P, Q we have $\ell([P]) = 1$ by Corollary 24.10.3 if $g = 1$ (or Proposition 24.8.13 in general), so $[P] \not\sim [Q]$ and $[P] - [Q]$ is a nonzero element of $\text{Pic}^0(C)$. The equivalence with (iv) is the computation in Corollary 24.10.6. $\square$

Example 24.11.8

The conic $C = \mathbb{V}(X_0X_2 - X_1^2)$ has genus 0, so is isomorphic to $\mathbb{P}^1$; we checked this directly in Proposition 24.4.30, and the map $\mathbb{P}^1 \rightarrow C$ is φ_D for $D = 2[\infty]$, since $L(2[\infty])$ has basis $1, t, t^2$.

Example 24.11.9

The nodal cubic $\mathbb{V}(Y^2 - X^2(X + 1))$ is *not* smooth, so our theory does not directly apply. But it is birational to $\mathbb{P}^1$: parametrise by the slope $t = Y/X$ of the line through the node, giving $t^2 = X + 1$, so $X = t^2 - 1$ and $Y = t(t^2 - 1)$. This is a rational parametrisation, and the two values $t = \pm 1$ both map to the node. So the smooth projective curve birational to it is $\mathbb{P}^1$, and the node is what you get by gluing two points of $\mathbb{P}^1$ together. The same works for the cusp, with $t = Y/X$ giving (t^2, t^3) .

§24.11.3 Genus One: Elliptic Curves**Definition 24.11.10 (Elliptic Curve)**

An **elliptic curve** is a pair $E = (C, P_0)$ where C is a smooth projective irreducible curve of genus 1 and $P_0 \in C$.

The choice of base point is essential: in genus 1 there is no canonical point, and different choices give isomorphic curves but different groups structures (well, isomorphic ones, but the isomorphism is a translation).

Genus 1 is the first case where the interesting range $0 \leq \deg D \leq 2g - 2$ is nonempty – but only just, since $2g - 2 = 0$. This makes the arithmetic particularly clean.

Corollary 24.11.11

Let C have genus 1 and let D be a divisor with $\deg D > 0$. Then $\ell(D) = \deg D$.

Proof. K_C has degree $2g - 2 = 0$, so $\deg(K - D) < 0$ and $\ell(K - D) = 0$. Riemann–Roch gives $\ell(D) = \deg D - 1 + 1 = \deg D$. $\square$

Now here is the construction of the group law, done intrinsically.

Theorem 24.11.12

Let $E = (C, P_0)$ be an elliptic curve. Then the map

$$\beta: C \rightarrow \text{Pic}^0(C), \quad P \mapsto [P] - [P_0]$$

is a bijection. Transporting the group structure of $\text{Pic}^0(C)$ back along β makes C into an abelian group with identity P_0 .

Proof. Injectivity. If $\beta(P) = \beta(Q)$ then $[P] \sim [Q]$, so by Proposition 24.8.14, $\ell([P]) = \ell([Q])$ and there is $f \in \mathbb{C}(C)^\times$ with $\text{div}(f) = [P] - [Q]$. If $P \neq Q$ then f has a single simple pole, so $\varphi = (1 : f): C \rightarrow \mathbb{P}^1$ has degree 1 and is therefore an isomorphism, forcing $g(C) = 0$, a contradiction. Hence $P = Q$.

Surjectivity. Let $D \in \text{Div}^0(C)$. Then $\deg(D + [P_0]) = 1 > 0$, so $\ell(D + [P_0]) = 1$ by Corollary 24.11.11. Pick $0 \neq f \in L(D + [P_0])$; then $\text{div}(f) + D + [P_0]$ is effective of degree 1, hence equals $[P]$ for a unique point P . So $D + [P_0] \sim [P]$, i.e. $D \sim [P] - [P_0]$ and $D = \beta(P)$ in Pic^0 . $\square$

Definition 24.11.13

For $P, Q \in E$ define $P +_E Q$ to be the unique point R with $\beta(R) = \beta(P) + \beta(Q)$, i.e. with

$$[P] + [Q] - [P_0] \sim [R].$$

Theorem 24.11.14

Let $E = (C, P_0)$ be an elliptic curve realised as a smooth plane cubic with P_0 a flex. Then for $P, Q, R \in C$,

$$P +_E Q +_E R = P_0 \iff P, Q, R \text{ are collinear.}$$

Consequently $+_E$ agrees with the chord-and-tangent law of Definition 24.6.16, and in particular that law is associative.

Proof. Let L be a line, with $\text{div}(L) = [P] + [Q] + [R]$ its divisor on C (a degree 3 effective divisor by Bézout). Let L_0 be the tangent line to C at the flex P_0 , so $\text{div}(L_0) = 3[P_0]$. By Proposition 24.8.7,

$$\text{div}(L) - \text{div}(L_0) = \text{div}(L/L_0)$$

is principal, so $[P] + [Q] + [R] \sim 3[P_0]$, that is,

$$\beta(P) + \beta(Q) + \beta(R) = [[P] + [Q] + [R] - 3[P_0]] = 0.$$

Hence $P +_E Q +_E R = P_0$.

Conversely, suppose $P +_E Q +_E R = P_0$, and let L be the line through P and Q , meeting C again at R' . By the above, $P +_E Q +_E R' = P_0$, so $R = R'$ and P, Q, R are collinear.

Finally, the chord-and-tangent law sets $P + Q = P_0 * (P * Q)$; writing $S = P * Q$, the points P, Q, S are collinear so $P +_E Q +_E S = P_0$, and $P_0, S, P_0 * S$ are collinear so $S +_E (P_0 * S) = P_0$ (using $P_0 +_E X = X$). Hence $P_0 * S = -_E S = P +_E Q$. $\square$

This completes the proof of Theorem 24.6.17: associativity of the chord-and-tangent law is inherited from associativity of addition in $\text{Pic}^0(C)$, which is free.

Example 24.11.15

On $E: y^2 = x^3 - x + 1$ with P_0 the point at infinity, take $P = (-1, -1)$ and $Q = (1.6, 1.8698\dots)$. The line through them has slope $m = 1.1038\dots$, and substituting into the cubic gives $x^3 - m^2x^2 - (\dots)x - (\dots) = 0$ whose roots sum to m^2 . Hence

$$x_{P*Q} = m^2 - x_P - x_Q = 0.6183\dots,$$

and $P +_E Q = (0.6183\dots, -0.7862\dots)$. This is the first figure of Section 6.6. Similarly the tangent at $T = (1, 1)$ has slope $(3 \cdot 1 - 1)/2 = 1$, so $x_{2T} = 1 - 2 = -1$ and $2T = (-1, 1)$.

Remark. Over $\mathbb{C}$, a genus 1 curve is topologically a torus $S^1 \times S^1$, and in fact $C \cong \mathbb{C}/\Lambda$ for a lattice $\Lambda \leq \mathbb{C}$, as a complex manifold and as a group. The group law $+_E$ corresponds to addition in $\mathbb{C}/\Lambda$, and the Weierstrass form comes from the Weierstrass $\wp$ -function, which satisfies

$$(\wp')^2 = 4\wp^3 - g_2\wp - g_3.$$

Over $\mathbb{Q}$, the group $E(\mathbb{Q})$ of rational points is finitely generated (Mordell's theorem), and this is where the subject meets number theory.

§24.11.4 Recovering the Weierstrass Equation

We defined an elliptic curve twice: once concretely, as a smooth plane cubic with a chosen flex (Theorem 24.6.15), and once abstractly, as a genus 1 curve with a chosen point. It is time to show that the two definitions agree, and the argument is a lovely illustration of how Riemann–Roch is used in practice: one writes down the spaces $L(n[P_0])$ for increasing n , watches their dimensions grow by one each time, and waits for the moment when there are more obvious elements than there is room for.

Theorem 24.11.16

Let $E = (C, P_0)$ be an elliptic curve. Then there exist $x, y \in \mathbb{C}(C)$ and $a, b \in \mathbb{C}$ with $4a^3 + 27b^2 \neq 0$ such that

$$\varphi = (1 : x : y) : C \longrightarrow \mathbb{P}^2$$

is an isomorphism onto the smooth plane cubic $\mathbb{V}(X_0X_2^2 - X_1^3 - aX_0^2X_1 - bX_0^3)$, carrying P_0 to the flex $(0 : 0 : 1)$.

Proof. Write $D_n = n[P_0]$. By Corollary 24.11.11, $\ell(D_n) = n$ for all $n \geq 1$. We build up bases.

First, $L(D_1) = \mathbb{C}$: a function with at most a simple pole at P_0 and no other poles would, if non-constant, give a degree 1 morphism $C \rightarrow \mathbb{P}^1$ and hence force $g = 0$. Since $\ell(D_2) = 2$, there is $x \in L(D_2) \setminus \mathbb{C}$, and x must have a pole of order exactly 2 at P_0 (order 1 is excluded as above). Since $\ell(D_3) = 3$, there is $y \in L(D_3) \setminus L(D_2)$, necessarily with a pole of order exactly 3. So

$$\nu_{P_0}(x) = -2, \quad \nu_{P_0}(y) = -3,$$

and $\{1, x\}$, $\{1, x, y\}$ are bases of $L(D_2), L(D_3)$.

Now count pole orders. The functions

$$1, x, y, x^2, xy, x^3, y^2$$

have poles at P_0 of orders 0, 2, 3, 4, 5, 6, 6 respectively, and no poles elsewhere; so all seven lie in $L(D_6)$. But $\ell(D_6) = 6$, so they satisfy a nontrivial linear relation

$$\alpha y^2 + \beta xy + \gamma y = \delta x^3 + \varepsilon x^2 + \zeta x + \eta.$$

Here $\alpha \neq 0$: otherwise the left side lies in $L(D_5)$ while the right has a pole of order exactly 6 unless $\delta = 0$ too, and then $1, x, y, x^2, xy$ would be dependent, which they are not (their pole orders 0, 2, 3, 4, 5 are distinct, and functions with distinct pole orders at a single point are linearly independent). The same argument gives $\delta \neq 0$. Rescaling $x \mapsto \lambda x$, $y \mapsto \mu y$ suitably, we may take $\alpha = \delta = 1$. Completing the square in y (replacing y by $y - \frac{1}{2}(\beta x + \gamma)$) and then the cube in x removes the remaining terms, leaving

$$y^2 = x^3 + ax + b.$$

It remains to identify the map. We have $\deg D_3 = 3 > 2 = 2g$, so by Corollary 24.11.4 the morphism $\varphi_{D_3} = (1 : x : y)$ is an embedding. Its image lies in the cubic $\mathbb{V}(F)$, $F = X_0X_2^2 - X_1^3 - aX_0^2X_1 - bX_0^3$, by the relation just derived, and the image is closed (Proposition 24.7.17) and irreducible of dimension 1. If F were reducible then the image, being irreducible, would lie in a component of degree 1 or 2, hence in a line or a conic; but those are isomorphic to $\mathbb{P}^1$ by Proposition 24.4.30, and $C \cong \varphi(C)$ has genus 1. So F is irreducible and the image is all of $\mathbb{V}(F)$, giving $C \cong \mathbb{V}(F)$; since C is smooth, so is $\mathbb{V}(F)$, and Theorem 24.6.15 says this forces $x^3 + ax + b$ to have distinct roots, i.e. $4a^3 + 27b^2 \neq 0$.

Finally, x and y have poles only at P_0 , so $\varphi(P_0)$ is the unique point of the image with $X_0 = 0$; comparing pole orders, $\varphi(P_0) = (0 : 0 : 1)$, which is the flex at infinity of the Weierstrass cubic. $\square$

So the two definitions of ‘elliptic curve’ coincide: a genus 1 curve with a marked point is the same thing as a plane cubic in Weierstrass form with its flex at infinity, and by Theorem 24.11.12 the group law we defined intrinsically is the chord-and-tangent construction.

Example 24.11.17

The recipe is completely explicit. On the curve $y^2 = x^3 - x + 1$, the space $L(2[P_0])$ is spanned by 1 and x , the space $L(3[P_0])$ by 1, x , y , and the space $L(4[P_0])$ by 1, x , y , x^2 . To see the last of these directly: a function with a pole of order at most 4 at infinity and no other poles is a polynomial in x and y of the shape $c_0 + c_1x + c_2y + c_3x^2$, since $\nu_{P_0}(x^iy^j) = -(2i + 3j)$ and the only (i, j) with $2i + 3j \leq 4$ and $j \leq 1$ (we may always reduce j using $y^2 = x^3 - x + 1$) are $(0, 0), (1, 0), (0, 1), (2, 0)$.

§24.11.5 Genus Two and Beyond**Proposition 24.11.18**

Every curve of genus 2 is hyperelliptic.

Proof. Take $D = K_C$, of degree $2g - 2 = 2$, with $\ell(D) = g = 2$. This is precisely the criterion for hyperellipticity noted after Example 24.10.11: φ_K is a morphism $C \rightarrow \mathbb{P}^1$, and by Theorem 24.11.3 it is not an embedding (it maps a genus 2 curve to a genus 0 one), so it has degree 2. $\square$

Example 24.11.19

Genus 2 curves are exactly the smooth projective models of $y^2 = p(x)$ with $\deg p = 6$ (or 5) and p squarefree, by Example 24.10.11 with $m = 3$. Up to isomorphism they are parametrised by the six branch points modulo $\mathrm{PGL}_2(\mathbb{C})$, giving a 3-dimensional family. In general, curves of genus $g \geq 2$ form a $(3g - 3)$ -dimensional family – the **moduli space** $\mathcal{M}_g$ – which one can already guess from this kind of count.

Example 24.11.20

Let us determine all the curves of genus 3. If C is non-hyperelliptic, the canonical map embeds C in $\mathbb{P}^{g-1} = \mathbb{P}^2$ as a curve of degree $\deg K = 2g - 2 = 4$, i.e. a smooth plane quartic; and conversely every smooth plane quartic has genus 3 by the genus–degree formula. If C is hyperelliptic, it is the smooth model of $y^2 = p(x)$ with $\deg p = 8$. So genus 3 curves are either plane quartics or hyperelliptic.

We close by recording the classification of maps in the simplest cases, which is a good test of everything we have set up.

Proposition 24.11.21

Let C be a curve of genus g .

- (i) If $g = 0$, the morphisms $C \rightarrow \mathbb{P}^1$ of degree d are exactly φ_D for D of degree d , and there is a $(2d + 1)$ -dimensional family of them.
- (ii) If $g \geq 1$, there is no morphism $C \rightarrow \mathbb{P}^1$ of degree 1.
- (iii) If $g \geq 2$, every morphism $C \rightarrow C$ of degree 1 is an automorphism, and the group of these is finite (of order at most $84(g - 1)$, by Hurwitz’s automorphism theorem).

Proof of (ii). A degree 1 morphism induces an isomorphism of function fields, hence is an isomorphism of curves, so $C \cong \mathbb{P}^1$ and $g = 0$. $\square$

Remark. Hurwitz's bound in (iii) is a beautiful application of Riemann–Hurwitz. If $G = \text{Aut}(C)$ is finite of order N , the quotient C/G is a curve D of some genus h , and $C \rightarrow D$ has degree N ; analysing the possible ramification data with Riemann–Hurwitz shows that

$$2g - 2 = N \left(2h - 2 + \sum_i \left(1 - \frac{1}{r_i} \right) \right)$$

for the ramification orders r_i over the branch points, and the smallest positive value the bracket can take is $1/42$, attained when $h = 0$ and $(r_1, r_2, r_3) = (2, 3, 7)$. Hence $N \leq 84(g - 1)$.

§24.11.6 A Summary

It is worth stepping back. We began with the dictionary

$$\{\text{affine varieties}\} \longleftrightarrow \{\text{reduced finitely generated } \mathbb{C}\text{-algebras}\},$$

refined it to

$$\left\{ \begin{array}{c} \text{irreducible varieties up to} \\ \text{birational equivalence} \end{array} \right\} \longleftrightarrow \left\{ \begin{array}{c} \text{finitely generated} \\ \text{field extensions of } \mathbb{C} \end{array} \right\},$$

and then specialised to transcendence degree 1, where the classification becomes tractable. For curves we found:

- every function field of transcendence degree 1 is the function field of a *unique* smooth projective curve, since birational smooth projective curves are isomorphic (Corollary 24.7.10);
- each such curve carries an intrinsic invariant, the genus $g = \ell(K_C)$, computable from any plane model by the genus–degree formula, and from any map to $\mathbb{P}^1$ by Riemann–Hurwitz;
- the finite-dimensional spaces $L(D)$ are computed by Riemann–Roch, and they in turn produce all the maps from C to projective space;
- genus 0 gives exactly $\mathbb{P}^1$; genus 1 gives the elliptic curves, whose points form a group; and genus ≥ 2 gives rigid objects with finite automorphism groups.

The natural next steps – sheaves and their cohomology, which make Riemann–Roch a formal consequence of a general index theorem, and schemes, which restore the nilpotents we threw away in Section 2 – are the subject of Part III.

25 Algebraic Topology

Topology is the study of spaces up to continuous deformation, and that is a slippery thing to get a handle on. Given two spaces, how could we possibly hope to show that there is *no* homeomorphism between them? There are infinitely many candidate maps, and no amount of failing to find one counts as a proof.

Algebraic topology answers this by translating the problem into algebra. We will build machines that eat a topological space and spit out a group, in such a way that homeomorphic (indeed, homotopy equivalent) spaces give isomorphic groups. Then two spaces with non-isomorphic groups are certainly not homeomorphic, and a question with infinitely many cases has become a finite computation. We will build two such machines: the *fundamental group*, which measures the failure of loops in a space to be contracted to a point, and *homology*, which detects holes of every dimension at once. Along the way we will get some genuinely striking theorems almost for free – that $\mathbb{R}^n \cong \mathbb{R}^m$ forces $n = m$, that every continuous map of a disc to itself has a fixed point, and that every non-constant complex polynomial has a root.

This article constitutes my notes for the ‘Algebraic Topology’ course, held in Michaelmas 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§25.1 The Fundamental Group

Throughout these notes, a **space** means a topological space, and a **map** means a continuous function – we will say ‘function’ when we do not want to assume continuity. We write $X \cong Y$ to mean that X and Y are homeomorphic, and $G \cong H$ to mean that groups G and H are isomorphic. A few spaces will appear often enough to deserve names:

- the one-point space $*$;
- the unit interval $I = [0, 1] \subseteq \mathbb{R}$, and the cube I^n ;
- the disc $D^n = \{v \in \mathbb{R}^n \mid \|v\| \leq 1\}$, which is homeomorphic to I^n ;
- the sphere $S^{n-1} = \{v \in \mathbb{R}^n \mid \|v\| = 1\}$.

We write id_X for the identity map on X , and c_p for a constant map with value p (the domain being clear from context).

The two results we are aiming at in the first instance are that $\mathbb{R}^n \cong \mathbb{R}^m$ implies $n = m$, and that every map $D^n \rightarrow D^n$ has a fixed point. For $n = 1$ both are easy: removing a point from $\mathbb{R}$ disconnects it, which distinguishes $\mathbb{R}$ from $\mathbb{R}^m$ for $m \geq 2$, and the fixed point statement is the intermediate value theorem. What we need is a way of running these arguments in higher dimensions, and that requires something finer than connectedness.

§25.1.1 Homotopy

The right notion of ‘sameness’ in this subject turns out not to be homeomorphism but something coarser. We want to regard two maps as the same if one can be continuously

deformed into the other.

Definition 25.1.1 (Homotopy)

Let $f, g : X \rightarrow Y$ be maps. A **homotopy** from f to g is a map

$$H : X \times I \rightarrow Y$$

such that $H(x, 0) = f(x)$ and $H(x, 1) = g(x)$ for all $x \in X$.

If such an H exists, we say f is **homotopic** to g , and write $f \simeq g$ or $f \simeq_H g$.

We should think of the second coordinate as time: at each time $t \in I$ we have a map $f_t = H(-, t) : X \rightarrow Y$, and as t runs from 0 to 1 these interpolate between f and g . The content of continuity of H is that the family (f_t) varies continuously in t , so there is no jumping.

Often we want to deform f into g without moving certain points at all.

Definition 25.1.2 (Homotopy Relative to a Subspace)

Let $A \subseteq X$. We say f is homotopic to g **relative to A** , written $f \simeq g \text{ rel } A$, if there is a homotopy H from f to g with $H(a, t) = f(a) = g(a)$ for all $a \in A$ and all $t \in I$.

Taking $A = \emptyset$ recovers ordinary homotopy, so it costs nothing to prove things in this generality.

Proposition 25.1.3

For spaces X, Y and $A \subseteq X$, ‘homotopic rel A ’ is an equivalence relation on maps $X \rightarrow Y$. In particular, when $A = \emptyset$, homotopy is an equivalence relation.

Proof. We check the three properties.

1. *Reflexivity:* $f \simeq f$ since $H(x, t) = f(x)$ is a homotopy.
2. *Symmetry:* if $H(x, t)$ is a homotopy from f to g , then $H(x, 1-t)$ is a homotopy from g to f .
3. *Transitivity:* Suppose $f, g, h : X \rightarrow Y$ and $f \simeq_H g \text{ rel } A$, $g \simeq_{H'} h \text{ rel } A$. We want to show that $f \simeq h \text{ rel } A$. The idea is to ‘glue’ the two homotopies together: we know how to continuously deform f to g , and g to h , so we just do these one after another, at double speed. We define $H'' : X \times I \rightarrow Y$ by

$$H''(x, t) = \begin{cases} H(x, 2t) & 0 \leq t \leq \frac{1}{2} \\ H'(x, 2t - 1) & \frac{1}{2} \leq t \leq 1. \end{cases}$$

This is well-defined since $H(x, 1) = g(x) = H'(x, 0)$, and continuous by the gluing lemma. It is easy to check that H'' is a homotopy rel A . $\square$

We used the gluing lemma there, and we will use it constantly, so let us record it.

Lemma 25.1.4 (Gluing Lemma)

Let $X = C_1 \cup C_2$ with C_1, C_2 closed in X , and let $f : X \rightarrow Y$ be a function such that $f|_{C_1}$ and $f|_{C_2}$ are both continuous. Then f is continuous.

Proof. It is enough to show that preimages of closed sets are closed. Let $K \subseteq Y$ be closed. Then $f^{-1}(K) \cap C_i = (f|_{C_i})^{-1}(K)$ is closed in C_i , and hence closed in X as C_i is closed in X . So $f^{-1}(K) = (f^{-1}(K) \cap C_1) \cup (f^{-1}(K) \cap C_2)$ is a union of two closed sets, and is closed. $\square$

Homotopy behaves well under composition, which is what makes the whole theory work.

Lemma 25.1.5

Consider the spaces and maps

$$\begin{array}{ccccc} X & \xrightarrow{f_0} & Y & \xrightarrow{g_0} & Z \\ & \searrow f_1 & & \searrow g_1 & \\ & & Y & & \end{array}$$

If $f_0 \simeq_H f_1$ and $g_0 \simeq_{H'} g_1$, then $g_0 \circ f_0 \simeq g_1 \circ f_1$.

Proof. We will show that $g_0 \circ f_0 \simeq g_0 \circ f_1 \simeq g_1 \circ f_1$, and will then be done since homotopy is an equivalence relation. We write down two homotopies.

1. The composition

$$X \times I \xrightarrow{H} Y \xrightarrow{g_0} Z$$

is the first homotopy we need, showing $g_0 \circ f_0 \simeq g_0 \circ f_1$.

2. The following composition is a homotopy from $g_0 \circ f_1$ to $g_1 \circ f_1$:

$$X \times I \xrightarrow{f_1 \times \text{id}_I} Y \times I \xrightarrow{H'} Z$$

Indeed at $t = 0$ this is $H'(f_1(x), 0) = g_0(f_1(x))$ and at $t = 1$ it is $g_1(f_1(x))$. $\square$

Now that we have a notion of two maps being ‘the same’, we get a notion of two spaces being the same: we ask for maps in both directions whose composites are homotopic to, rather than equal to, the identity.

Definition 25.1.6 (Homotopy Equivalence)

A map $f : X \rightarrow Y$ is a **homotopy equivalence** if there exists a map $g : Y \rightarrow X$ such that $f \circ g \simeq \text{id}_Y$ and $g \circ f \simeq \text{id}_X$. We call g a **homotopy inverse** for f .

If a homotopy equivalence $f : X \rightarrow Y$ exists, we say X and Y are **homotopy equivalent**, and write $X \simeq Y$.

Note the deliberate abuse: $\simeq$ means homotopy for maps and homotopy equivalence for spaces. Any homeomorphism is in particular a homotopy equivalence, so $X \cong Y$ implies $X \simeq Y$, but the converse fails badly – as we will see, $\mathbb{R}^2$ is homotopy equivalent to a point.

Proposition 25.1.7

Homotopy equivalence of spaces is an equivalence relation.

Proof. Symmetry and reflexivity are immediate from the definition. To show transitivity, let $f : X \rightarrow Y$ and $h : Y \rightarrow Z$ be homotopy equivalences, and $g : Y \rightarrow X$ and $k : Z \rightarrow Y$ be their homotopy inverses. We will show that $h \circ f : X \rightarrow Z$ is a homotopy equivalence with homotopy inverse $g \circ k$. Using Lemma 25.1.5 freely, we have

$$(h \circ f) \circ (g \circ k) = h \circ (f \circ g) \circ k \simeq h \circ \text{id}_Y \circ k = h \circ k \simeq \text{id}_Z.$$

Similarly,

$$(g \circ k) \circ (h \circ f) = g \circ (k \circ h) \circ f \simeq g \circ \text{id}_Y \circ f = g \circ f \simeq \text{id}_X,$$

as required. $\square$

Definition 25.1.8 (Contractible)

If $X \simeq *$, the one point space, then X is **contractible**.

Unwinding this, X is contractible exactly when $\text{id}_X \simeq c_p$ for some $p \in X$; the homotopy is a way of continuously shrinking the whole space down to a point inside itself.

Example 25.1.9

Any non-empty convex $Y \subseteq \mathbb{R}^n$ is contractible. Indeed, fix $p \in Y$ and define $H(y, t) = (1 - t)y + tp$, which lies in Y by convexity and is a homotopy from id_Y to c_p . In particular $\mathbb{R}^n$ and D^n and I^n are all contractible.

Proposition 25.1.10

Let Y be contractible. Then any two maps $f_0, f_1 : X \rightarrow Y$ are homotopic.

Proof. Say $\text{id}_Y \simeq c_p$. Then $f_0 = \text{id}_Y \circ f_0 \simeq c_p \circ f_0 = c_p$, and likewise $f_1 \simeq c_p$, so $f_0 \simeq f_1$ by transitivity. $\square$

Corollary 25.1.11

A contractible space is path connected.

Proof. Let $p, q \in Y$. Applying Proposition 25.1.10 with $X = *$, the constant maps $* \rightarrow Y$ at p and at q are homotopic via some $H : * \times I \rightarrow Y$. Then $t \mapsto H(*, t)$ is a path from p to q . $\square$

A very common way of exhibiting a homotopy equivalence is to squash a space down onto a subspace sitting inside it.

Definition 25.1.12 (Retraction)

Let $A \subseteq X$ be a subspace. A **retraction** $r : X \rightarrow A$ is a map such that $r \circ \iota = \text{id}_A$, where $\iota : A \hookrightarrow X$ is the inclusion. If such an r exists, we call A a **retract** of X .

The retraction r is a **deformation retraction** if $\iota \circ r \simeq \text{id}_X$. A deformation retraction is **strong** if we require this homotopy to be a homotopy rel A .

If $r : X \rightarrow A$ is a deformation retraction then r is by definition a homotopy equivalence, with homotopy inverse ι . So $A \simeq X$.

Example 25.1.13

The map $r : \mathbb{R}^{n+1} \setminus \{0\} \rightarrow S^n$ given by $r(v) = v/\|v\|$ is a strong deformation retraction. Indeed $r \circ \iota = \text{id}_{S^n}$, and

$$H(v, t) = \frac{v}{(1-t) + t\|v\|}$$

is a homotopy from id to $\iota \circ r$ fixing S^n pointwise. So $\mathbb{R}^{n+1} \setminus \{0\} \simeq S^n$: the punctured space is homotopy equivalent to the sphere, even though the two are very far from homeomorphic.

§25.1.2 Paths

We now specialise to the maps that will give us our invariant. The idea is very simple: we probe a space X by mapping intervals into it, and see which of the resulting loops can be contracted.

Definition 25.1.14 (Path)

A **path** in a space X is a map $\gamma : I \rightarrow X$. If $\gamma(0) = x_0$ and $\gamma(1) = x_1$, we say γ is a path from x_0 to x_1 , and write $\gamma : x_0 \rightsquigarrow x_1$.

If $\gamma(0) = \gamma(1) = x_0$, we say γ is a **loop** (based at x_0).

We write $\Omega(X, x_0, x_1)$ for the set of paths $x_0 \rightsquigarrow x_1$ in X , and $\Omega(X, x_0) = \Omega(X, x_0, x_0)$ for the set of loops based at x_0 .

Definition 25.1.15 (Concatenation and Inverses)

If we have two paths γ_1 from x_0 to x_1 and γ_2 from x_1 to x_2 , we define the **concatenation** to be

$$(\gamma_1 \cdot \gamma_2)(t) = \begin{cases} \gamma_1(2t) & 0 \leq t \leq \frac{1}{2} \\ \gamma_2(2t - 1) & \frac{1}{2} \leq t \leq 1. \end{cases}$$

This is continuous by the gluing lemma.

The **inverse** of a path $\gamma : I \rightarrow X$ is defined by

$$\gamma^{-1}(t) = \gamma(1 - t).$$

The **constant path** at a point $x \in X$ is given by $c_x(t) = x$.

So $\gamma_1 \cdot \gamma_2$ traverses γ_1 at double speed, then γ_2 at double speed, and γ^{-1} runs γ backwards.

We would like to make $\Omega(X, x_0)$ into a group under concatenation, and the reader will immediately object that this cannot work: concatenation is not associative on the nose, since $(\gamma_0 \cdot \gamma_1) \cdot \gamma_2$ and $\gamma_0 \cdot (\gamma_1 \cdot \gamma_2)$ traverse the three paths at different speeds. The fix is to pass to homotopy classes, and here we must be careful to only allow homotopies which fix the endpoints – otherwise every loop could be slid off to a constant and nothing would be left.

Definition 25.1.16 (Homotopy of Paths)

Paths $\gamma, \gamma' : I \rightarrow X$ are **homotopic as paths** if they are homotopic $\text{rel}\{0, 1\} \subseteq I$, that is, if the endpoints stay fixed throughout. We write $\gamma \simeq \gamma'$.

Concretely, $\gamma \simeq \gamma'$ means there is a map $H : I \times I \rightarrow X$ with $H(s, 0) = \gamma(s)$, $H(s, 1) = \gamma'(s)$, and $H(0, t) = x_0$, $H(1, t) = x_1$ for all t . It is worth drawing the square: the bottom edge is γ , the top edge is γ' , and the two vertical edges are constant.

Lemma 25.1.17 (The Group Operation is Well-Defined)

Let $\gamma_1, \gamma_2 : I \rightarrow X$ be paths with $\gamma_1(1) = \gamma_2(0)$. Then if $\gamma_1 \simeq \gamma'_1$ and $\gamma_2 \simeq \gamma'_2$, we have $\gamma_1 \cdot \gamma_2 \simeq \gamma'_1 \cdot \gamma'_2$.

Proof. Suppose that $\gamma_1 \simeq_{H_1} \gamma'_1$ and $\gamma_2 \simeq_{H_2} \gamma'_2$. Then we can construct the homotopy

$$H(s, t) = \begin{cases} H_1(2s, t) & 0 \leq s \leq \frac{1}{2} \\ H_2(2s - 1, t) & \frac{1}{2} \leq s \leq 1, \end{cases}$$

which is well-defined since $H_1(1, t) = \gamma_1(1) = \gamma_2(0) = H_2(0, t)$, and continuous by the gluing lemma. It visibly fixes the endpoints. $\square$

Lemma 25.1.18 (Indeed a Group Operation)

Let $\gamma_0 : x_0 \rightsquigarrow x_1$, $\gamma_1 : x_1 \rightsquigarrow x_2$, $\gamma_2 : x_2 \rightsquigarrow x_3$ be paths. Then

1. $(\gamma_0 \cdot \gamma_1) \cdot \gamma_2 \simeq \gamma_0 \cdot (\gamma_1 \cdot \gamma_2)$.
2. $\gamma_0 \cdot c_{x_1} \simeq \gamma_0 \simeq c_{x_0} \cdot \gamma_0$.
3. $\gamma_0 \cdot \gamma_0^{-1} \simeq c_{x_0}$ and $\gamma_0^{-1} \cdot \gamma_0 \simeq c_{x_1}$.

Proof. We first note that the composition of any path γ with an order-preserving surjection $\phi : I \rightarrow I$ is homotopic as paths to the original path, via $H(s, t) = \gamma(t\phi(s) + (1-t)s)$. Such a ϕ is called a **reparameterisation**, and the homotopy fixes endpoints because $\phi(0) = 0$ and $\phi(1) = 1$.

1. Take ϕ to be the function

$$\phi(t) = \begin{cases} \frac{t}{2} & 0 \leq t \leq \frac{1}{2} \\ t - \frac{1}{4} & \frac{1}{2} \leq t \leq \frac{3}{4} \\ 2t - 1 & \frac{3}{4} \leq t \leq 1. \end{cases}$$

Then we have $(\gamma_0 \cdot \gamma_1) \cdot \gamma_2 \simeq ((\gamma_0 \cdot \gamma_1) \cdot \gamma_2) \circ \phi = \gamma_0 \cdot (\gamma_1 \cdot \gamma_2)$.

2. To see $\gamma_0 \cdot c_{x_1} \simeq \gamma_0$, reparameterise γ_0 with

$$t \mapsto \begin{cases} 2t & 0 \leq t \leq \frac{1}{2} \\ 1 & \frac{1}{2} \leq t \leq 1, \end{cases}$$

and the other side is analogous.

3. We have that $c_{x_0} \simeq \gamma_0 \cdot \gamma_0^{-1}$ via

$$H(s, t) = \begin{cases} \gamma_0(2s) & 0 \leq s \leq \frac{t}{2} \\ \gamma_0(t) & \frac{t}{2} \leq s \leq 1 - \frac{t}{2} \\ \gamma_0^{-1}(2s - 1) & 1 - \frac{t}{2} \leq s \leq 1. \end{cases}$$

At time t this path runs along γ_0 as far as $\gamma_0(t)$, waits there, and comes back; at $t = 0$ it is constant and at $t = 1$ it is $\gamma_0 \cdot \gamma_0^{-1}$. Applying this to γ_0^{-1} gives the other identity. $\square$

§25.1.3 The Fundamental Group

We can now define one of our central objects of study.

Definition 25.1.19 (Fundamental Group)

Let X be a space and $x_0 \in X$. The **fundamental group** of X (based at x_0), denoted $\pi_1(X, x_0)$, is the set of homotopy classes of loops in X based at x_0 , that is, $\pi_1(X, x_0) = \Omega(X, x_0) / \simeq$.

The group operation is defined by $[\gamma_0][\gamma_1] = [\gamma_0 \cdot \gamma_1]$, with $[\gamma]^{-1} = [\gamma^{-1}]$ and identity the class $e = [c_{x_0}]$ of the constant path.

Theorem 25.1.20

The fundamental group is a group.

Proof. The operation is well-defined by Lemma 25.1.17, and the group axioms hold by Lemma 25.1.18. $\square$

The definition depends on a choice of basepoint, and we will deal with that dependence shortly. First, let us see that π_1 is not just an invariant of spaces, but of maps as well – this is what makes it useful.

Definition 25.1.21 (Based Space)

A **based space** is a pair (X, x_0) of a space X and a point $x_0 \in X$, the **basepoint**. A **map of based spaces** $f : (X, x_0) \rightarrow (Y, y_0)$ is a map $f : X \rightarrow Y$ such that $f(x_0) = y_0$. A **based homotopy** is a homotopy $\text{rel}\{x_0\}$.

Proposition 25.1.22 (π_1 is a Functor)

To a based map $f : (X, x_0) \rightarrow (Y, y_0)$, there is an associated function $f_* = \pi_1(f) : \pi_1(X, x_0) \rightarrow \pi_1(Y, y_0)$, defined by $[\gamma] \mapsto [f \circ \gamma]$. Moreover it satisfies

1. $\pi_1(f)$ is a homomorphism of groups.
2. If $f \simeq f' \text{ rel}\{x_0\}$, then $\pi_1(f) = \pi_1(f')$.
3. For any based maps $(A, a) \xrightarrow{h} (B, b) \xrightarrow{k} (C, c)$, we have $\pi_1(k \circ h) = \pi_1(k) \circ \pi_1(h)$.
4. $\pi_1(\text{id}_X) = \text{id}_{\pi_1(X, x_0)}$.

Proof. First, f_* is well-defined: if $\gamma \simeq_H \gamma'$ as paths, then $f \circ H$ is a homotopy of paths from $f \circ \gamma$ to $f \circ \gamma'$.

For (i), observe that composing with f commutes with concatenation,

$$(f \circ (\gamma \cdot \gamma'))(t) = \begin{cases} f(\gamma(2t)) & t \leq \frac{1}{2} \\ f(\gamma'(2t-1)) & t \geq \frac{1}{2} \end{cases} = ((f \circ \gamma) \cdot (f \circ \gamma'))(t),$$

so $f_*([\gamma][\gamma']) = [f \circ (\gamma \cdot \gamma')] = [f \circ \gamma][f \circ \gamma'] = f_*[\gamma]f_*[\gamma']$.

For (ii), if H is a based homotopy from f to f' and γ is a loop at x_0 , then $(s, t) \mapsto H(\gamma(s), t)$ is a homotopy of paths from $f \circ \gamma$ to $f' \circ \gamma$: it fixes the endpoints since $\gamma(0) = \gamma(1) = x_0$ and $H(x_0, t) = y_0$ for all t .

Parts (iii) and (iv) are immediate: $(k \circ h)_*[\gamma] = [k \circ h \circ \gamma] = k_*[h \circ \gamma] = k_*h_*[\gamma]$, and $(\text{id}_X)_*[\gamma] = [\gamma]$. $\square$

In the language of categories, π_1 is a functor from based spaces to groups. The following diagram, expressing part (iii), commutes.

$$\begin{array}{ccc} \pi_1(X, x_0) & \xrightarrow{(g \circ f)_*} & \pi_1(Z, z_0) \\ & \searrow f_* \quad \nearrow g_* & \\ & \pi_1(Y, y_0) & \end{array}$$

This gives us our first real payoff, essentially for free.

Corollary 25.1.23

If $f : X \rightarrow Y$ is a homeomorphism with $f(x_0) = y_0$, then $f_* : \pi_1(X, x_0) \rightarrow \pi_1(Y, y_0)$ is an isomorphism.

Proof. Apply the functor to $f \circ f^{-1} = \text{id}_Y$ and $f^{-1} \circ f = \text{id}_X$ to get $f_* \circ (f^{-1})_* = \text{id}$ and $(f^{-1})_* \circ f_* = \text{id}$. $\square$

§25.1.4 Change of Basepoint

We want to remove the basepoint dependence of the fundamental group. Of course we cannot hope to compare $\pi_1(X, x_0)$ and $\pi_1(X, x_1)$ when x_0 and x_1 lie in different path components, since a loop at x_0 knows nothing about the rest of X . But if there is a path between them we can drag loops along it.

Proposition 25.1.24

A path $u : x_0 \rightsquigarrow x_1$ induces a group isomorphism $u_\# : \pi_1(X, x_0) \rightarrow \pi_1(X, x_1)$ by $[\gamma] \mapsto [u^{-1} \cdot \gamma \cdot u]$. This satisfies

1. If $u \simeq u'$, then $u_\# = u'_\#$.
2. $(c_{x_0})_\# = \text{id}_{\pi_1(X, x_0)}$.
3. If $v : x_1 \rightsquigarrow x_2$, then $(u \cdot v)_\# = v_\# \circ u_\#$.
4. If $f : X \rightarrow Y$ with $f(x_0) = y_0$ and $f(x_1) = y_1$, then

$$(f \circ u)_\# \circ f_* = f_* \circ u_\# : \pi_1(X, x_0) \rightarrow \pi_1(Y, y_1).$$

5. If $x_1 = x_0$, then $u_\#$ is the automorphism of $\pi_1(X, x_0)$ given by conjugation by $[u]$.

Proof. That $u_\#$ is well-defined follows from Lemma 25.1.17, and it is a homomorphism because

$$u_\#[\gamma] u_\#[\gamma'] = [u^{-1} \cdot \gamma \cdot u \cdot u^{-1} \cdot \gamma' \cdot u] = [u^{-1} \cdot \gamma \cdot \gamma' \cdot u] = u_\#([\gamma][\gamma']),$$

using $u \cdot u^{-1} \simeq c_{x_1}$. Properties (i), (ii) and (v) are immediate from the definitions, and (iii) follows from associativity together with $(u \cdot v)^{-1} \simeq v^{-1} \cdot u^{-1}$. For (iv) we compute both sides on $[\gamma]$: the left hand side gives $[(f \circ u)^{-1} \cdot (f \circ \gamma) \cdot (f \circ u)]$, and the right hand side gives $[f \circ (u^{-1} \cdot \gamma \cdot u)]$, and these agree since f commutes with concatenation and inversion of paths.

Finally, (ii) and (iii) give $(u^{-1})_\# \circ u_\# = (u \cdot u^{-1})_\# = (c_{x_0})_\# = \text{id}$ and similarly the other way, so $u_\#$ is an isomorphism with inverse $(u^{-1})_\#$. $\square$

So if x_0 and x_1 are in the same path connected component, then $\pi_1(X, x_0) \cong \pi_1(X, x_1)$. For a path connected space we will often write $\pi_1(X)$, keeping in mind that the isomorphism depends on the choice of path, so this is only well-defined up to (not necessarily inner) automorphism.

The next lemma is the technical heart of the section: it says that a homotopy between maps which does *not* respect basepoints still induces the same map on π_1 , provided we correct by the change of basepoint isomorphism along the track of the basepoint.

Lemma 25.1.25

Let $f, g : X \rightarrow Y$ be maps with $f \simeq_H g$, let $x_0 \in X$, and let $u(t) = H(x_0, t)$, a path $f(x_0) \sim g(x_0)$. Then the following diagram commutes.

$$\begin{array}{ccc} & & \pi_1(Y, f(x_0)) \\ & \nearrow f_* & \downarrow u_\# \\ \pi_1(X, x_0) & & \pi_1(Y, g(x_0)) \\ & \searrow g_* & \end{array}$$

That is, $g_* = u_\# \circ f_*$.

Proof. Suppose we have a loop $\gamma : I \rightarrow X$ based at x_0 . We need to check that

$$g_*([\gamma]) = u_{\#} \circ f_*([\gamma]),$$

in other words that

$$g \circ \gamma \simeq u^{-1} \cdot (f \circ \gamma) \cdot u.$$

To prove this we want to build a homotopy. Consider the composition

$$F : I \times I \xrightarrow{\gamma \times \text{id}_I} X \times I \xrightarrow{H} Y.$$

Our plan is to exhibit two homotopic paths ℓ^+ and ℓ^- in $I \times I$ such that

$$F \circ \ell^+ = g \circ \gamma, \quad F \circ \ell^- = u^{-1} \cdot (f \circ \gamma) \cdot u.$$

This is in general a good strategy: X is a complicated and horrible space we do not understand, so to construct a homotopy we make ourselves work in the much nicer space $I \times I$.

Our ℓ^+ and ℓ^- are defined in a rather simple way. Precisely, ℓ^+ is the path $s \mapsto (s, 1)$ along the top of the square, and ℓ^- is the concatenation of the paths $s \mapsto (0, 1-s)$, $s \mapsto (s, 0)$ and $s \mapsto (1, s)$, going down the left edge, along the bottom, and up the right edge.

Note that ℓ^+ and ℓ^- are homotopic as paths. If this is not obvious, we can manually check the homotopy

$$L(s, t) = t\ell^+(s) + (1-t)\ell^-(s),$$

which works because $I \times I$ is convex, and fixes the endpoints $(0, 1)$ and $(1, 1)$. Hence $F \circ \ell^+ \simeq F \circ \ell^-$ as paths, via $F \circ L$.

Now we check that the compositions $F \circ \ell^\pm$ are indeed what we want. We have

$$F \circ \ell^+(s) = H(\gamma(s), 1) = g \circ \gamma(s),$$

and along the three pieces of ℓ^- we get $H(x_0, 1-s) = u^{-1}(s)$, then $H(\gamma(s), 0) = f(\gamma(s))$, then $H(x_0, s) = u(s)$, so that

$$F \circ \ell^- = u^{-1} \cdot (f \circ \gamma) \cdot u$$

as required. □

Theorem 25.1.26

If $f : X \rightarrow Y$ is a homotopy equivalence, and $x_0 \in X$, then the induced map

$f_* : \pi_1(X, x_0) \rightarrow \pi_1(Y, f(x_0))$ is an isomorphism.

Proof. Let $g : Y \rightarrow X$ be a homotopy inverse, so $f \circ g \simeq_H \text{id}_Y$ and $g \circ f \simeq_{H'} \text{id}_X$.

We have no guarantee that $g \circ f(x_0) = x_0$, but our homotopy H' gives us a path $u' = H'(x_0, \cdot) : x_0 \leadsto g \circ f(x_0)$.

Applying Lemma 25.1.25 with id_X playing the role of ' f ' and $g \circ f$ playing the role of ' g ', we get

$$u'_\# \circ (\text{id}_X)_* = (g \circ f)_*.$$

Using functoriality, this says

$$g_* \circ f_* = u'_\#.$$

However, we know that $u'_\#$ is an isomorphism. So f_* is injective and g_* is surjective.

Doing the same thing the other way round with $f \circ g$ instead of $g \circ f$, we learn that g_* is injective and f_* is surjective. So both are isomorphisms. $\square$

This is a substantial improvement on Corollary 25.1.23: the fundamental group cannot distinguish homotopy equivalent spaces, but that is exactly what makes it computable, since we may replace a space by any convenient space homotopy equivalent to it.

Corollary 25.1.27

If X is contractible, then $\pi_1(X, x_0)$ is trivial for every x_0 .

Proof. $\pi_1(*, *)$ is trivial, since there is only one loop, and $X \simeq *$. $\square$

§25.1.5 Simply Connected Spaces

Definition 25.1.28 (Simply Connected Space)

A space X is **simply connected** if it is path connected and $\pi_1(X, x_0)$ is trivial for some (equivalently, by Proposition 25.1.24, any) choice of $x_0 \in X$.

Lemma 25.1.29

A path connected space X is simply connected if and only if for any $x_0, x_1 \in X$, there is a unique homotopy class of paths $x_0 \leadsto x_1$.

Proof. Suppose X is simply connected, and let $u, v : x_0 \leadsto x_1$ be paths. Now $u \cdot v^{-1}$ is a loop based at x_0 , so it is homotopic to the constant path. So we have

$$u \simeq u \cdot v^{-1} \cdot v \simeq c_{x_0} \cdot v \simeq v.$$

On the other hand, suppose there is a unique homotopy class of paths $x_0 \leadsto x_1$ for all $x_0, x_1 \in X$. Then in particular there is a unique homotopy class of loops based at x_0 , namely that of c_{x_0} . So $\pi_1(X, x_0)$ is trivial. $\square$

There is a useful reformulation of triviality in π_1 in terms of extending maps over the disc. Recall that a loop $\gamma \in \Omega(X, x_0)$ has $\gamma(0) = \gamma(1)$, so it descends to a map $\bar{\gamma} : S^1 \rightarrow X$

with $\bar{\gamma}(e^{2\pi it}) = \gamma(t)$, using $I/\{0, 1\} \cong S^1$.

Definition 25.1.30

A map $f : X \rightarrow Y$ is **null-homotopic** if $f \simeq c_p$ for some $p \in Y$.

Lemma 25.1.31

A map $f : S^1 \rightarrow Y$ extends to a map $F : D^2 \rightarrow Y$ if and only if f is null-homotopic.

Proof. If F is such an extension, define $H(v, t) = F(tv)$ for $v \in S^1$. Then $H(v, 1) = F(v) = f(v)$ and $H(v, 0) = F(0)$, so $f \simeq c_{F(0)}$.

Conversely, suppose $f \simeq_H c_p$ with $H(v, 0) = p$ and $H(v, 1) = f(v)$. Define

$$F(v) = \begin{cases} H\left(\frac{v}{\|v\|}, \|v\|\right) & v \neq 0 \\ p & v = 0. \end{cases}$$

This is continuous away from 0, and continuous at 0 because $H(w, t) \rightarrow p$ uniformly in w as $t \rightarrow 0$ (using compactness of S^1). It restricts to f on S^1 . $\square$

Proposition 25.1.32

For a path connected space X , the following are equivalent.

1. X is simply connected.
2. Every map $f : S^1 \rightarrow X$ is null-homotopic.
3. Every map $f : S^1 \rightarrow X$ extends to a map $D^2 \rightarrow X$.

Proof. Parts (ii) and (iii) are equivalent by Lemma 25.1.31.

Suppose X is simply connected and let $f : S^1 \rightarrow X$, and set $x_0 = f(1)$ and $\gamma(t) = f(e^{2\pi it})$, a loop at x_0 with $\bar{\gamma} = f$. Since $[\gamma] = 1$ we have $\gamma \simeq c_{x_0}$ via some H fixing endpoints; then $\bar{H}(e^{2\pi is}, t) = H(s, t)$ is well-defined (as $H(0, t) = H(1, t) = x_0$) and continuous, and gives $f \simeq c_{x_0}$.

Conversely, suppose every map $S^1 \rightarrow X$ is null-homotopic and let γ be a loop at x_0 . Then $\bar{\gamma}$ extends to $F : D^2 \rightarrow X$, and $H(s, t) = F((1-t)e^{2\pi is} + t)$ is a homotopy of paths from γ to c_{x_0} : it takes the circle and shrinks it towards the basepoint $1 \in D^2$, staying inside D^2 by convexity, and it fixes $s = 0, 1$. $\square$

Example 25.1.33

Every convex subset of $\mathbb{R}^n$ is simply connected, being contractible. We will see in the next section that S^1 is *not* simply connected, which is the first genuinely non-trivial computation of the course, and that S^n for $n \geq 2$ is simply connected.

Example 25.1.34

If X and Y are spaces with basepoints x_0, y_0 , then

$$\pi_1(X \times Y, (x_0, y_0)) \cong \pi_1(X, x_0) \times \pi_1(Y, y_0).$$

Indeed a map $I \rightarrow X \times Y$ is exactly a pair of maps $I \rightarrow X$ and $I \rightarrow Y$, by the universal property of the product topology, and likewise for homotopies $I \times I \rightarrow X \times Y$. So the two projections induce a bijection, which is clearly a homomorphism.

§25.2 Covering Spaces

We now start to develop some machinery which will allow us to compute fundamental groups. So far we have no example of a space with a non-trivial fundamental group, for the good reason that showing a loop is *not* null-homotopic means ruling out all possible homotopies at once. The trick is to unroll the space: if we can find a simply connected space sitting above X in a suitably uniform way, then loops in X become paths upstairs, and paths are much easier to tell apart than loops.

§25.2.1 Definitions and Examples

Definition 25.2.1 (Evenly Covered Set)

Suppose $p : \hat{X} \rightarrow X$ is a map. We say that an open set $U \subseteq X$ is **evenly covered** by p if

$$p^{-1}(U) = \bigsqcup_{\alpha \in A} V_{\alpha},$$

a disjoint union of open sets, where $p|_{V_{\alpha}} : V_{\alpha} \rightarrow U$ is a homeomorphism for each $\alpha \in A$.

The V_{α} are called the **sheets** over U . Note that the inverse $p_{\alpha}^{-1} = (p|_{V_{\alpha}})^{-1} : U \rightarrow \hat{X}$ is continuous, being the inverse of a homeomorphism followed by an inclusion; we will use this constantly.

Definition 25.2.2 (Covering Map)

A map $p : \hat{X} \rightarrow X$ is a **covering map** if for all $x \in X$ there exists an open neighbourhood U_x of x which is evenly covered by p . In this case, we call $\hat{X}$ a **covering space** for X .

Example 25.2.3

Let A be a set with the discrete topology. Then the projection $p : A \times X \rightarrow X$ is a covering map, since X itself is evenly covered: $p^{-1}(X) = \bigsqcup_{\alpha \in A} \{\alpha\} \times X$. This is the **trivial cover**, and the point of the definition is that a general covering map looks like this *locally* but need not do so globally.

Example 25.2.4

The map $p : \mathbb{R} \rightarrow S^1$ given by $p(t) = e^{2\pi it}$ is a covering map. Indeed, if $V \subseteq \mathbb{R}$ is an open interval of length less than 1 and $U = p(V)$, then

$$p^{-1}(U) = \bigsqcup_{n \in \mathbb{Z}} (V + n),$$

and p restricted to each translate $V + n$ is a homeomorphism onto U . Every point of S^1 has such a neighbourhood.

The picture to have in mind is the helix: $\mathbb{R}$ winds around and around above the circle, and p is vertical projection.

**Example 25.2.5**

For $n \geq 1$, the map $p_n : S^1 \rightarrow S^1$, $z \mapsto z^n$, is a covering map. If $U \subseteq S^1$ is an open arc of length less than $2\pi/n$ then

$$p_n^{-1}(U) = \bigsqcup_{i \in \mathbb{Z}/n\mathbb{Z}} \omega^i V, \quad \omega = e^{2\pi i/n},$$

where V is one of the n arcs mapping homeomorphically onto U . So this is an n -sheeted cover.

Definition 25.2.6

The **n -dimensional real projective space** is $\mathbb{RP}^n = S^n / \sim$, where $\sim$ is generated by $x \sim -x$, with the quotient topology.

Example 25.2.7

The quotient map $p : S^n \rightarrow \mathbb{RP}^n$ is a covering map. Given $x \in S^n$, let V_x be the open hemisphere centred at x and $U_x = p(V_x)$. Since V_x contains no pair of antipodal points, $p^{-1}(U_x) = V_x \sqcup (-V_x)$ and p restricted to each is a homeomorphism onto U_x . This is a two-sheeted cover.

Example 25.2.8

The map $p \times p : \mathbb{R}^2 \rightarrow S^1 \times S^1 = T^2$ is a covering map of the torus, being a product of covering maps.

§25.2.2 Lifting

The whole theory rests on the following idea: given a map into X , we try to push it up into $\hat{X}$.

Definition 25.2.9 (Lift)

Suppose $p : \hat{X} \rightarrow X$ is a covering map and $f : Z \rightarrow X$ is a map. Then we say that $\hat{f} : Z \rightarrow \hat{X}$ is a **lift** of f if $p \circ \hat{f} = f$, that is, if

$$\begin{array}{ccc} & & \hat{X} \\ & \nearrow \hat{f} & \downarrow p \\ Z & \xrightarrow{f} & X \end{array}$$

commutes.

Notation. We say a map $f : Z \rightarrow X$ has the **lifting property** at $z_0 \in Z$ if for every $\hat{x}_0 \in p^{-1}(f(z_0))$ there is a lift $\hat{f}$ of f with $\hat{f}(z_0) = \hat{x}_0$, and the **unique lifting property** (ULP) at z_0 if this lift is moreover unique. For a path $\gamma : [a, b] \rightarrow X$ we say ‘ γ has the ULP’ to mean that it has the ULP at a .

The strategy for lifting a path is to chop it into small pieces, each of which lands in a single evenly covered set, and lift those one at a time. To chop it up we need the following, which the reader may have seen in a metric spaces course.

Lemma 25.2.10 (Lebesgue Covering Lemma)

Suppose X is a compact metric space and $\{U_\alpha\}_\alpha$ is an open cover of X . Then there exists $\delta > 0$ such that for all $x \in X$ we have $B_\delta(x) \subseteq U_\alpha$ for some α .

Proof. Given $x \in X$, let $\alpha(x)$ and $\delta(x) > 0$ be such that $B_{2\delta(x)}(x) \subseteq U_{\alpha(x)}$. Then $\{B_{\delta(x)}(x)\}_{x \in X}$ is an open cover of X , so by compactness there is a finite subcover $\{B_{\delta(x_i)}(x_i)\}_{i=1}^n$. Let $\delta = \min\{\delta(x_1), \dots, \delta(x_n)\} > 0$. Then given $y \in X$ we have $y \in B_{\delta(x_i)}(x_i)$ for some i , and so

$$B_\delta(y) \subseteq B_{\delta(x_i)+\delta}(x_i) \subseteq B_{2\delta(x_i)}(x_i) \subseteq U_{\alpha(x_i)}$$

as required. □

Lemma 25.2.11

Let $f : Z \rightarrow X$ with Z connected, and suppose $\text{im}(f) \subseteq U$ where U is evenly covered. Then f has the unique lifting property at every $z_0 \in Z$.

Proof. Since U is evenly covered, $p^{-1}(U) = \bigsqcup_{\alpha} V_{\alpha}$. Given $\hat{x}_0 \in p^{-1}(f(z_0))$ we have $\hat{x}_0 \in V_{\alpha_0}$ for some α_0 . Then $p_{\alpha_0}^{-1} = (p|_{V_{\alpha_0}})^{-1} : U \rightarrow \hat{X}$ is continuous with $p_{\alpha_0}^{-1}(f(z_0)) = \hat{x}_0$, so $\hat{f} = p_{\alpha_0}^{-1} \circ f$ is a lift of f with the right value at z_0 .

For uniqueness, notice that $p^{-1}(U) = V_{\alpha_0} \sqcup (\bigsqcup_{\alpha \neq \alpha_0} V_{\alpha})$ is a disconnection of $p^{-1}(U)$. Any lift $\hat{f}$ has connected image (as Z is connected) meeting V_{α_0} , so $\text{im}(\hat{f}) \subseteq V_{\alpha_0}$. But $p|_{V_{\alpha_0}}$ is a homeomorphism, so $\hat{f} = p_{\alpha_0}^{-1} \circ f$ is forced. $\square$

Lemma 25.2.12

Suppose $\gamma : [a, b] \rightarrow X$ and $a' \in [a, b]$. If $\gamma|_{[a, a']}$ has the ULP at a and $\gamma|_{[a', b]}$ has the ULP at a' , then γ has the ULP at a .

Proof. Given $\hat{x} \in p^{-1}(\gamma(a))$, we have a lift $\hat{\gamma}_1 : [a, a'] \rightarrow \hat{X}$ of $\gamma|_{[a, a']}$ with $\hat{\gamma}_1(a) = \hat{x}$, and then a lift $\hat{\gamma}_2 : [a', b] \rightarrow \hat{X}$ of $\gamma|_{[a', b]}$ with $\hat{\gamma}_2(a') = \hat{\gamma}_1(a')$. So the concatenation $\hat{\gamma}_1 \hat{\gamma}_2$, which is continuous by the gluing lemma, is a lift of γ at a .

For uniqueness, suppose $\hat{\eta}$ is any lift with $\hat{\eta}(a) = \hat{x}$. Then $\hat{\eta}|_{[a, a']}$ is a lift of $\gamma|_{[a, a']}$ starting at $\hat{x}$, so $\hat{\eta}|_{[a, a']} = \hat{\gamma}_1$ by uniqueness. In particular $\hat{\eta}(a') = \hat{\gamma}_1(a')$, so $\hat{\eta}|_{[a', b]} = \hat{\gamma}_2$ by uniqueness again. Hence $\hat{\eta} = \hat{\gamma}_1 \hat{\gamma}_2$. $\square$

Theorem 25.2.13 (Path Lifting)

Let $p : \hat{X} \rightarrow X$ be a covering map. Then any path $\gamma : I \rightarrow X$ has the unique lifting property.

Proof. Since p is a covering map, every $x \in X$ has an evenly covered neighbourhood U_x . Then $\{U_x \mid x \in X\}$ is an open cover of X , so $\{\gamma^{-1}(U_x) \mid x \in X\}$ is an open cover of I . Thus by the Lebesgue covering lemma there exists $\delta > 0$ such that for each t we have $B_{\delta}(t) \subseteq \gamma^{-1}(U_{x(t)})$ for some $x(t)$.

Choose n with $1/n < \delta$ and set $a_i = i/n$. Then $[a_i, a_{i+1}] \subseteq B_{\delta}(a_i)$, so $\gamma([a_i, a_{i+1}]) \subseteq U_{x(a_i)}$, which is evenly covered. As $[a_i, a_{i+1}]$ is connected, Lemma 25.2.11 says $\gamma|_{[a_i, a_{i+1}]}$ has the ULP at a_i . By induction on i using Lemma 25.2.12, $\gamma|_{[0, a_i]}$ has the ULP at 0 for every i , and in particular so does γ . $\square$

The same argument, run over a grid of small squares instead of a partition of the interval, lifts homotopies.

Theorem 25.2.14 (Homotopy Lifting)

Suppose $p : \hat{X} \rightarrow X$ is a covering map and $H : I \times I \rightarrow X$ is a homotopy. Then H has the lifting property at $(0, 0)$.

Proof. Let $\{U_x \mid x \in X\}$ be an open cover of X by evenly covered neighbourhoods. Since I^2 is compact, by the Lebesgue covering lemma there exists $\delta > 0$ such that $B_{\delta}(v) \subseteq H^{-1}(U_{x(v)})$ for each $v \in I^2$.

Choose n with $\sqrt{2}/n < \delta$ and divide I^2 into squares of side length $1/n$. Enumerate

them $A_1, A_2, \dots, A_{n^2}$, starting from the bottom left and going right along each row and then up. Label the bottom left corner of A_i as v_i , so that $v_1 = (0, 0)$. Since $A_i \subseteq B_\delta(v_i)$ we have $H(A_i) \subseteq U_{x(v_i)}$, which is evenly covered, and A_i is connected, so $H|_{A_i}$ has the ULP at v_i by Lemma 25.2.11. Let $B_k = \bigcup_{i=1}^k A_i$.

We prove by induction that $H|_{B_k}$ has the lifting property at $(0, 0)$. For $k = 1$ we have $B_1 = A_1$ and $v_1 = (0, 0)$, so this is what we already know. Now suppose $H|_{B_k}$ has a lift $\hat{H}_k : B_k \rightarrow \hat{X}$ with $\hat{H}_k(0, 0) = \hat{x}$. As $H|_{A_{k+1}}$ has the lifting property at v_{k+1} , we may choose a lift $\hat{h}_k : A_{k+1} \rightarrow \hat{X}$ with $\hat{h}_k(v_{k+1}) = \hat{H}_k(v_{k+1})$.

Now $B_k \cap A_{k+1}$ is either one or two edges of A_{k+1} , in either case a set homeomorphic to I containing v_{k+1} . By uniqueness of path lifting, $\hat{H}_k$ and $\hat{h}_k$ agree on $A_{k+1} \cap B_k$, since both are lifts of $H|_{A_{k+1} \cap B_k}$ agreeing at v_{k+1} . So by the gluing lemma we obtain a well-defined lift $\hat{H}_{k+1}$ of $H|_{B_{k+1}}$. Taking $k = n^2$ finishes the proof. $\square$

The point of all this is the following, which says that homotopic loops downstairs lift to paths with the same endpoint upstairs. This is the mechanism that will let us distinguish loops.

Proposition 25.2.15

Let $p : \hat{X} \rightarrow X$ be a covering map and suppose $\gamma_0, \gamma_1 \in \Omega(X, x_0, x_1)$ with $\gamma_0 \simeq \gamma_1$. Let $\hat{\gamma}_i$ be the lift of γ_i with $\hat{\gamma}_i(0) = \hat{x}_0$. Then $\hat{\gamma}_0 \simeq \hat{\gamma}_1$. In particular, $\hat{\gamma}_0(1) = \hat{\gamma}_1(1)$.

Proof. Suppose $H : I^2 \rightarrow X$ is a homotopy of paths between γ_0 and γ_1 . By homotopy lifting we have a lift $\hat{H} : I^2 \rightarrow \hat{X}$ with $\hat{H}(0, 0) = \hat{x}_0$. Let $\alpha_i(t) = \hat{H}(t, i)$ and $\beta_i(t) = \hat{H}(i, t)$ for $i = 0, 1$, the images of the four edges of the square.

Applying uniqueness of path lifting to each edge in turn:

1. β_0 is a lift of the constant path c_{x_0} starting at $\hat{x}_0$, so $\beta_0 = c_{\hat{x}_0}$;
2. α_0 is a lift of γ_0 with $\alpha_0(0) = \hat{x}_0$, so $\alpha_0 = \hat{\gamma}_0$;

3. α_1 is a lift of γ_1 with $\alpha_1(0) = \beta_0(1) = \hat{x}_0$, so $\alpha_1 = \hat{\gamma}_1$;
4. writing $\hat{x}_1 = \hat{\gamma}_0(1)$, β_1 is a lift of c_{x_1} starting at $\hat{x}_1$, so $\beta_1 = c_{\hat{x}_1}$.

So $\hat{H}$ is a homotopy of paths from $\hat{\gamma}_0$ to $\hat{\gamma}_1$, and in particular the two have the same endpoint $\hat{x}_1$. $\square$

Corollary 25.2.16

If $p : (\hat{X}, \hat{x}_0) \rightarrow (X, x_0)$ is a covering map, then $p_* : \pi_1(\hat{X}, \hat{x}_0) \rightarrow \pi_1(X, x_0)$ is injective.

Proof. Suppose $p_*[\gamma_0] = p_*[\gamma_1]$ for loops γ_0, γ_1 at x_0 . Then $p \circ \gamma_0 \simeq p \circ \gamma_1$ as paths, so by Proposition 25.2.15 their lifts starting at $\hat{x}_0$ are homotopic as paths. But these lifts are γ_0 and γ_1 , by uniqueness of lifting. So $[\gamma_0] = [\gamma_1]$. $\square$

§25.2.3 The Fundamental Group of the Circle

Fix a covering map $p : (\hat{X}, \hat{x}_0) \rightarrow (X, x_0)$. Given a loop γ at x_0 , let $\hat{\gamma}$ be its unique lift starting at $\hat{x}_0$. Then $p(\hat{\gamma}(1)) = \gamma(1) = x_0$, so $\hat{\gamma}(1)$ lies in the fibre $p^{-1}(x_0)$, and by Proposition 25.2.15 it depends only on the homotopy class of γ . We therefore get a well-defined function

$$\varepsilon_p : \pi_1(X, x_0) \longrightarrow p^{-1}(x_0), \quad [\gamma] \mapsto \hat{\gamma}(1).$$

This is the key construction: it turns a homotopy-theoretic object into a set of points.

Definition 25.2.17 (Universal Cover)

A covering map $p : \hat{X} \rightarrow X$ is a **universal cover** if $\hat{X}$ is simply connected.

Example 25.2.18

$p : \mathbb{R} \rightarrow S^1, t \mapsto e^{2\pi it}$, is a universal cover, since $\mathbb{R}$ is contractible. Likewise $\mathbb{R}^2 \rightarrow T^2$ is a universal cover of the torus.

Proposition 25.2.19

If $p : (\hat{X}, \hat{x}_0) \rightarrow (X, x_0)$ is a universal cover, then $\varepsilon_p : \pi_1(X, x_0) \rightarrow p^{-1}(x_0)$ is a bijection.

Proof. Injectivity. Suppose $\varepsilon_p[\gamma_0] = \varepsilon_p[\gamma_1] = \hat{x}_1$. Then $\hat{\gamma}_0$ and $\hat{\gamma}_1$ are both paths from $\hat{x}_0$ to $\hat{x}_1$ in $\hat{X}$, which is simply connected, so $\hat{\gamma}_0 \simeq \hat{\gamma}_1$ as paths by Lemma 25.1.29. Composing the homotopy with p gives $\gamma_0 \simeq \gamma_1$, so $[\gamma_0] = [\gamma_1]$.

Surjectivity. Given $\hat{x} \in p^{-1}(x_0)$, use path connectedness of $\hat{X}$ to find a path $\eta : \hat{x}_0 \leadsto \hat{x}$. Then $\gamma = p \circ \eta$ is a loop at x_0 , and η is its lift starting at $\hat{x}_0$, so $\varepsilon_p[\gamma] = \eta(1) = \hat{x}$. $\square$

This is already enough to compute the fundamental group of the circle as a *set*: we have $p^{-1}(1) = \mathbb{Z}$ for the helix covering, so $\pi_1(S^1, 1)$ is countably infinite. To get the group

structure we have to work slightly harder, and the mechanism is that we can slide the covering space $\mathbb{R}$ along itself.

Theorem 25.2.20

$\varepsilon_p : \pi_1(S^1, 1) \rightarrow \mathbb{Z}$ is a group isomorphism. In particular $\pi_1(S^1) \cong \mathbb{Z}$.

Proof. It is a bijection by Proposition 25.2.19, using $p^{-1}(1) = \mathbb{Z} \subseteq \mathbb{R}$, so it suffices to check that it is a homomorphism.

For $n \in \mathbb{Z}$ define $\varphi_n : \mathbb{R} \rightarrow \mathbb{R}$ by $\varphi_n(x) = x + n$. Then $p \circ \varphi_n = p$, since $e^{2\pi i(x+n)} = e^{2\pi i x}$. So if $\hat{\gamma}$ is any lift of a path γ , then $\varphi_n \circ \hat{\gamma}$ is another lift, now starting at $\hat{\gamma}(0) + n$.

Suppose $\varepsilon_p[\gamma] = n$ and $\varepsilon_p[\gamma'] = n'$, so the lifts based at 0 satisfy $\hat{\gamma}(1) = n$ and $\hat{\gamma}'(1) = n'$. Then $\varphi_n \circ \hat{\gamma}'$ is a lift of γ' starting at $n = \hat{\gamma}(1)$, so the concatenation

$$\widehat{\gamma \cdot \gamma'} = \hat{\gamma} \cdot (\varphi_n \circ \hat{\gamma}')$$

is the lift of $\gamma \cdot \gamma'$ starting at 0. Evaluating at 1,

$$\varepsilon_p[\gamma \cdot \gamma'] = \varphi_n(\hat{\gamma}'(1)) = n + n' = \varepsilon_p[\gamma] + \varepsilon_p[\gamma'].$$

So ε_p is a homomorphism, and hence an isomorphism. $\square$

Concretely, the class corresponding to $n \in \mathbb{Z}$ is that of the loop $\gamma_n(t) = e^{2\pi i n t}$, which winds n times around the circle: its lift starting at 0 is $\hat{\gamma}_n(t) = nt$, ending at n . So the fundamental group of the circle counts winding number, exactly as intuition demands.

Corollary 25.2.21

S^1 is not contractible, and S^1 is not a retract of D^2 .

Proof. If S^1 were contractible then $\pi_1(S^1)$ would be trivial, but it is $\mathbb{Z}$.

Suppose $r : D^2 \rightarrow S^1$ were a retraction, with $\iota : S^1 \hookrightarrow D^2$ the inclusion. Then $r \circ \iota = \text{id}_{S^1}$, so $r_* \circ \iota_* = \text{id}$ on $\pi_1(S^1, 1) = \mathbb{Z}$. But ι_* factors through $\pi_1(D^2, 1)$, which is trivial as D^2 is convex. So the identity on $\mathbb{Z}$ factors through the trivial group, which is absurd. $\square$

Corollary 25.2.22 (Brouwer Fixed Point Theorem, $n = 2$)

Every map $f : D^2 \rightarrow D^2$ has a fixed point.

Proof. Suppose $f(x) \neq x$ for all x . Define $r(x) \in S^1$ to be the point where the ray from $f(x)$ through x meets S^1 . This is continuous (we will verify a formula for it in Theorem 25.6.13), and if $x \in S^1$ then $r(x) = x$. So r is a retraction $D^2 \rightarrow S^1$, contradicting the previous corollary. $\square$

Example 25.2.23

Since $\pi_1(X \times Y) \cong \pi_1(X) \times \pi_1(Y)$ (Example 25.1.34), the torus has

$$\pi_1(T^2) = \pi_1(S^1 \times S^1) \cong \mathbb{Z}^2.$$

This already tells us that $T^2 \not\cong S^2$ once we know that S^2 is simply connected, and that $T^2 \not\cong S^1 \vee S^1$ once we know the latter has non-abelian fundamental group.

§25.2.4 Degree and the Fundamental Theorem of Algebra

The isomorphism $\pi_1(S^1) \cong \mathbb{Z}$ lets us attach an integer to any self-map of the circle. There is one small nuisance: a map $f : S^1 \rightarrow S^1$ need not preserve the basepoint, so f_* lands in $\pi_1(S^1, f(1))$ rather than $\pi_1(S^1, 1)$. We fix this by transporting back along a path, and the following lemma says that the choice of path does not matter.

Lemma 25.2.24

Let $z \in S^1$ and let $u, v : z \rightsquigarrow 1$ be paths. Then $u_{\#} = v_{\#} : \pi_1(S^1, z) \rightarrow \pi_1(S^1, 1)$.

Proof. By Proposition 25.1.24, $(v^{-1})_{\#} \circ u_{\#}$ is the map $[\gamma] \mapsto [\eta][\gamma][\eta]^{-1}$ where $\eta = v \cdot u^{-1}$ is a loop at 1. But $\pi_1(S^1, 1) \cong \mathbb{Z}$ is abelian, so conjugation is trivial and $(v^{-1})_{\#} \circ u_{\#} = \text{id}$. Hence $u_{\#} = v_{\#}$. $\square$

Definition 25.2.25 (Degree)

Let $f : S^1 \rightarrow S^1$ be a map, and set $z = f(1)$. Choose any path $u : z \rightsquigarrow 1$. Then

$$u_{\#} \circ f_* : \pi_1(S^1, 1) \rightarrow \pi_1(S^1, 1)$$

is a homomorphism $\mathbb{Z} \rightarrow \mathbb{Z}$, so is multiplication by some integer. We define the **degree** $\deg f$ to be that integer, namely $(u_{\#} \circ f_*)(1)$.

By Lemma 25.2.24 this is independent of the choice of u . Intuitively, $\deg f$ counts how many times f wraps the circle around itself, with sign.

$\deg = 1$

$\deg = 2$

$\deg = 0$

Proposition 25.2.26

Let $f_n : S^1 \rightarrow S^1$ be given by $z \mapsto z^n$. Then

1. $\deg f_n = n$;
2. maps $g_0, g_1 : S^1 \rightarrow S^1$ are homotopic if and only if $\deg g_0 = \deg g_1$;
3. $g : S^1 \rightarrow S^1$ extends to a map $D^2 \rightarrow S^1$ if and only if $\deg g = 0$.

Proof. (i) Since $f_n(1) = 1$ we may take u constant. Now $f_n \circ \gamma_1 = \gamma_n$, where $\gamma_n(t) = e^{2\pi i n t}$, so $f_{n*}[\gamma_1] = [\gamma_n]$, which corresponds to $n \in \mathbb{Z}$.

(ii) Suppose $g_0 \simeq_H g_1$, and let $u(t) = H(1, t)$, a path $g_0(1) \leadsto g_1(1)$. By Lemma 25.1.25, $g_{1*} = u_{\#} \circ g_{0*}$. Choose $v : g_1(1) \leadsto 1$; then $u \cdot v : g_0(1) \leadsto 1$ and

$$\deg g_1 = (v_{\#} \circ g_{1*})(1) = (v_{\#} \circ u_{\#} \circ g_{0*})(1) = ((u \cdot v)_{\#} \circ g_{0*})(1) = \deg g_0,$$

using $(u \cdot v)_{\#} = v_{\#} \circ u_{\#}$.

Conversely, it is enough to show $g \simeq f_{\deg g}$. First suppose $g(1) = 1$, and let $\gamma = g \circ \gamma_1$, so that $g = \bar{\gamma}$ and $\deg g = g_*(1) = [\gamma]$. If $\deg g = n$ then $\gamma \simeq \gamma_n$ as paths, whence $\bar{\gamma} \simeq \bar{\gamma}_n = f_n$ as maps $S^1 \rightarrow S^1$. In general, if $g(1) = e^{2\pi i x}$, then $g \simeq g_0$ where $g_0(z) = e^{-2\pi i x} g(z)$, via the homotopy $g_t(z) = e^{-2\pi i t x} g(z)$; and $g_0(1) = 1$, so we may apply the previous case.

(iii) By Lemma 25.1.31, g extends to D^2 if and only if g is null-homotopic, that is, if and only if $g \simeq c_1 = f_0$, which by (ii) happens if and only if $\deg g = 0$. $\square$

As an application, we can now prove the fundamental theorem of algebra — a statement with no topology in it whatsoever — by a winding number argument.

Let $P(w) = w^n + a_{n-1}w^{n-1} + \cdots + a_0 = w^n + q(w)$ be a monic complex polynomial of degree $n \geq 1$.

Lemma 25.2.27

Let $R_0 = \max\{1, \sum_{i=0}^{n-1} |a_i|\}$. Then $|w| > R_0$ implies $|w^n| > |q(w)|$.

Proof. If $|w| > R_0 \geq 1$ then $|w|^{i-n+1} \leq 1$ for $0 \leq i \leq n-1$, so

$$\frac{|q(w)|}{|w|^{n-1}} \leq \sum_{i=0}^{n-1} |a_i| |w|^{i-n+1} \leq \sum_{i=0}^{n-1} |a_i| \leq R_0.$$

Dividing by $|w|$ gives $|q(w)|/|w|^n \leq R_0/|w| < 1$. $\square$

Theorem 25.2.28 (Fundamental Theorem of Algebra)

Every complex polynomial of degree $n \geq 1$ has a root in $\mathbb{C}$.

Proof. We may assume P is monic, as above. Fix $R > R_0$ and consider the two maps $g_0, g_1 : S^1 \rightarrow \mathbb{C} \setminus \{0\}$ given by

$$g_0(z) = (Rz)^n, \quad g_1(z) = P(Rz).$$

These are homotopic via $g_t(z) = P_t(Rz)$ where $P_t(w) = w^n + tq(w)$: this really does avoid 0, since $|w| = R > R_0$ gives $|w^n| > |q(w)| \geq |tq(w)|$ by Lemma 25.2.27. Let $\pi : \mathbb{C} \setminus \{0\} \rightarrow S^1$ be the radial projection $w \mapsto w/|w|$. Then $\pi \circ g_0 \simeq \pi \circ g_1$ as maps $S^1 \rightarrow S^1$, and $\pi \circ g_0 = f_n$ up to the constant $R^n/|R^n| = 1$, so

$$\deg(\pi \circ g_1) = \deg(\pi \circ g_0) = n.$$

Now suppose for contradiction that P has no root. Then $P : \mathbb{C} \rightarrow \mathbb{C} \setminus \{0\}$, so g_1 extends to $G_1 : D^2 \rightarrow \mathbb{C} \setminus \{0\}$ by $G_1(z) = P(Rz)$, and hence $\pi \circ g_1$ extends to $\pi \circ G_1 : D^2 \rightarrow S^1$. By Proposition 25.2.26(iii) this forces $\deg(\pi \circ g_1) = 0$, so $n = 0$, contradicting $n \geq 1$. $\square$

§25.2.5 The Lifting Criterion

We can lift paths and homotopies. When can we lift a map from a general space Z ? There are two obstructions, one of which we have already met.

Definition 25.2.29

A space X is **locally path connected** if for every open $U \subseteq X$ and every $x \in U$ there is a path connected open V with $x \in V \subseteq U$.

Example 25.2.30

Every open subset of $\mathbb{R}^n$ and every polyhedron is locally path connected. A standard example of a space which is not is the ‘comb’

$$X = (\mathbb{R} \times \{0\}) \cup \left(\bigcup_{n \geq 1} \{1/n\} \times \mathbb{R} \right) \cup (\{0\} \times \mathbb{R}) \subseteq \mathbb{R}^2 :$$

a small open neighbourhood of a point $(0, y)$ with $y \neq 0$ contains bits of infinitely many teeth, and cannot be shrunk to a path connected one.

Proposition 25.2.31 (Simply Connected Lifting)

Let $p : (\hat{X}, \hat{x}_0) \rightarrow (X, x_0)$ be a covering map, and let Z be simply connected and locally path connected. Then every map $f : (Z, z_0) \rightarrow (X, x_0)$ has a unique lift $\hat{f} : (Z, z_0) \rightarrow (\hat{X}, \hat{x}_0)$.

Proof. Uniqueness, and the formula. Suppose $\hat{f}$ is such a lift, and let $z \in Z$. Choose a path $\gamma : z_0 \leadsto z$, which exists as Z is path connected. Then $\hat{f} \circ \gamma$ is a lift of $f \circ \gamma$ starting at $\hat{x}_0$, so by uniqueness of path lifting it must be $\widehat{f \circ \gamma}$. Hence

$$\hat{f}(z) = (\hat{f} \circ \gamma)(1) = \widehat{f \circ \gamma}(1),$$

which determines $\hat{f}$ completely.

Existence. We take the displayed formula as a *definition* of $\hat{f}$. This is independent of the choice of γ : if $\gamma_0, \gamma_1 : z_0 \leadsto z$ then $\gamma_0 \simeq \gamma_1$ as Z is simply connected (Lemma 25.1.29), so $f \circ \gamma_0 \simeq f \circ \gamma_1$, so their lifts have the same endpoint by Proposition 25.2.15. Also $p(\hat{f}(z)) = p(\widehat{f \circ \gamma}(1)) = f(\gamma(1)) = f(z)$, so $\hat{f}$ is a lift as a function, and taking $\gamma = c_{z_0}$ gives $\hat{f}(z_0) = \hat{x}_0$.

Continuity. This is where local path connectedness enters. Let $z \in Z$ and let $U \subseteq \hat{X}$ be an open neighbourhood of $\hat{f}(z)$; we must find a neighbourhood V of z with $\hat{f}(V) \subseteq U$. Choose an evenly covered open $W \ni f(z)$, so $p^{-1}(W) = \bigsqcup_{\alpha} W_{\alpha}$,

and say $\hat{f}(z) \in W_{\alpha_0}$. Replacing U by $U \cap W_{\alpha_0}$, we may assume $U \subseteq W_{\alpha_0}$, and then $p(U)$ is open (as $p|_{W_{\alpha_0}}$ is a homeomorphism onto W) and contains $f(z)$.

By continuity of f there is an open $V' \ni z$ with $f(V') \subseteq p(U)$, and by local path connectedness there is a path connected open V with $z \in V \subseteq V'$. We claim $\hat{f}(V) \subseteq U$. Given $z' \in V$, choose a path $\gamma' : z \rightsquigarrow z'$ inside V . Then $f \circ \gamma'$ has image in $p(U) \subseteq W$, so $\tilde{\gamma}' = p_{\alpha_0}^{-1} \circ f \circ \gamma'$ is a lift of $f \circ \gamma'$ starting at $p_{\alpha_0}^{-1}(f(z)) = \hat{f}(z)$. Concatenating, $\widehat{f \circ (\gamma \cdot \gamma')}(1) = \widehat{f \circ \gamma} \cdot \tilde{\gamma}'$, and so

$$\hat{f}(z') = \widehat{f \circ (\gamma \cdot \gamma')}(1) = \tilde{\gamma}'(1) = p_{\alpha_0}^{-1}(f(z')) \in U$$

as required. $\square$

Simple connectedness is genuinely needed here, not just a convenience.

Example 25.2.32

The identity map $\text{id} : S^1 \rightarrow S^1$ does not lift along $p : \mathbb{R} \rightarrow S^1$. If it did, we would have a map $s : S^1 \rightarrow \mathbb{R}$ with $p \circ s = \text{id}$, and applying π_1 would factor $\text{id}_{\mathbb{Z}}$ through $\pi_1(\mathbb{R}) = 1$.

That computation suggests the general criterion: the obstruction is exactly the image of π_1 .

Theorem 25.2.33 (Lifting Criterion)

Let $p : (\hat{X}, \hat{x}_0) \rightarrow (X, x_0)$ be a covering map and let Z be path connected and locally path connected. A map $f : (Z, z_0) \rightarrow (X, x_0)$ lifts to $\hat{f} : (Z, z_0) \rightarrow (\hat{X}, \hat{x}_0)$ if and only if

$$f_*(\pi_1(Z, z_0)) \subseteq p_*(\pi_1(\hat{X}, \hat{x}_0)),$$

and in that case the lift is unique.

Proof. If $\hat{f}$ exists then $f_* = p_* \circ \hat{f}_*$, so the containment holds.

Conversely, suppose the containment holds. Uniqueness, and the formula $\hat{f}(z) = \widehat{f \circ \gamma}(1)$, are exactly as in Proposition 25.2.31; and continuity is proved verbatim. The only point needing a new argument is well-definedness. Suppose $\gamma_0, \gamma_1 : z_0 \rightsquigarrow z$. Then $\gamma_0 \cdot \gamma_1^{-1}$ is a loop at z_0 , so

$$f_*[\gamma_0 \cdot \gamma_1^{-1}] = p_*[\delta]$$

for some loop δ in $\hat{X}$ at $\hat{x}_0$. Thus $(f \circ \gamma_0) \cdot (f \circ \gamma_1)^{-1} \simeq p \circ \delta$, and lifting this homotopy at $\hat{x}_0$, the lift of $p \circ \delta$ is the loop δ , which ends at $\hat{x}_0$. Hence the lift of $(f \circ \gamma_0) \cdot (f \circ \gamma_1)^{-1}$ at $\hat{x}_0$ is a loop, which says precisely that $\widehat{f \circ \gamma_0}(1) = \widehat{f \circ \gamma_1}(1)$. $\square$

§25.2.6 Deck Transformations

Covering spaces of a fixed space X form a category, and it will pay to think of them that way.

Definition 25.2.34 (Covering Transformation)

Let $p_i : \hat{X}_i \rightarrow X$ be covering maps for $i = 1, 2$. A **covering transformation** (or morphism of covers) $\phi : (p_1, \hat{X}_1) \rightarrow (p_2, \hat{X}_2)$ is a map $\phi : \hat{X}_1 \rightarrow \hat{X}_2$ with $p_2 \circ \phi = p_1$, so that

$$\begin{array}{ccc} \hat{X}_1 & \xrightarrow{\quad \phi \quad} & \hat{X}_2 \\ & \searrow p_1 \quad \swarrow p_2 & \\ & X & \end{array}$$

commutes. It is a **covering isomorphism** if it is a bijection.

Equivalently, ϕ is a lift of p_1 along p_2 . So all the lifting theory applies at once.

Example 25.2.35

Let $p_1(z) = z^6$ and $p_2(z) = z^2$ be covering maps $S^1 \rightarrow S^1$. Then $\phi(z) = z^3$ is a covering transformation from (p_1, S^1) to (p_2, S^1) , since $(z^3)^2 = z^6$.

Lemma 25.2.36

A bijective covering map is a homeomorphism.

Proof. Let $p : \hat{Y} \rightarrow Y$ be a bijective covering map. Then p^{-1} exists as a function, and we must check it is continuous. Cover Y by evenly covered open sets U . As p is a bijection, $p^{-1}(U)$ consists of a single sheet, and $p^{-1}|_U$ is the inverse of a homeomorphism, hence continuous. Continuity is local, so p^{-1} is continuous. $\square$

Lemma 25.2.37

Let X be locally path connected, and let $\phi : (p_1, \hat{X}_1) \rightarrow (p_2, \hat{X}_2)$ be a surjective covering transformation. Then $\phi : \hat{X}_1 \rightarrow \hat{X}_2$ is itself a covering map.

Proof. Let $\hat{x}_2 \in \hat{X}_2$ and put $x = p_2(\hat{x}_2)$. Choose neighbourhoods U_1, U_2 of x evenly covered by p_1, p_2 respectively; then $U = U_1 \cap U_2$ is evenly covered by both, and by local path connectedness we may choose a path connected open V with $x \in V \subseteq U$. Write

$$p_1^{-1}(V) = \bigsqcup_{\alpha} V_{\alpha}, \quad p_2^{-1}(V) = \bigsqcup_{\beta} V'_{\beta},$$

where each V_{α}, V'_{β} is homeomorphic to V and hence path connected. Since $p_2 \circ \phi = p_1$ we have $\phi(V_{\alpha}) \subseteq p_2^{-1}(V)$, and V_{α} is path connected, so $\phi(V_{\alpha}) \subseteq V'_{\beta(\alpha)}$ for a unique $\beta(\alpha)$. On V_{α} the relation $p_2 \circ \phi = p_1$ reads $\phi|_{V_{\alpha}} = (p_2|_{V'_{\beta(\alpha)}})^{-1} \circ p_1|_{V_{\alpha}}$, a composite of homeomorphisms. Hence

$$\phi^{-1}(V'_{\beta}) = \bigsqcup_{\alpha: \beta(\alpha)=\beta} V_{\alpha}$$

with each piece mapped homeomorphically onto V'_{β} , so V'_{β} is evenly covered by ϕ . As ϕ is surjective, these V'_{β} cover $\hat{X}_2$. $\square$

Proposition 25.2.38 (Universal Property of the Universal Cover)

Let X be locally path connected and let $q : (\tilde{X}, \tilde{x}_0) \rightarrow (X, x_0)$ be a universal cover. Then for any covering map $p : (\hat{X}, \hat{x}_0) \rightarrow (X, x_0)$ there is a unique covering transformation $\hat{q} : (\tilde{X}, \tilde{x}_0) \rightarrow (\hat{X}, \hat{x}_0)$ with $\hat{q}(\tilde{x}_0) = \hat{x}_0$.

Proof. $\tilde{X}$ is simply connected, and it is locally path connected because X is and q is a local homeomorphism. So this is exactly Proposition 25.2.31 applied to the map q . $\square$

Corollary 25.2.39 (Uniqueness of Universal Covers)

Let X be locally path connected. If $q : (\tilde{X}, \tilde{x}_0) \rightarrow (X, x_0)$ and $q' : (\tilde{X}', \tilde{x}'_0) \rightarrow (X, x_0)$ are universal covers, then there is a unique covering isomorphism between them taking $\tilde{x}_0$ to $\tilde{x}'_0$. In particular $\tilde{X} \cong \tilde{X}'$.

Proof. Proposition 25.2.38 gives covering transformations $\hat{q} : \tilde{X} \rightarrow \tilde{X}'$ and $\hat{q}' : \tilde{X}' \rightarrow \tilde{X}$ preserving basepoints. Their composites are covering transformations $\tilde{X} \rightarrow \tilde{X}$ fixing $\tilde{x}_0$, and the identity is another such, so by the uniqueness in Proposition 25.2.38 they are the identity. Hence $\hat{q}$ is a bijection, and a homeomorphism by Lemmas 25.2.37 and 25.2.36. $\square$

So we may speak of *the* universal cover of a (nice) space. We will not prove existence; suffice it to say that every path connected, locally path connected and *semi-locally simply connected* space has one, and all the spaces we care about (manifolds, polyhedra) qualify.

Definition 25.2.40 (Deck Group)

Let $p : \hat{X} \rightarrow X$ be a covering map. The **deck group** $G_D(p)$ is the group of covering isomorphisms $(p, \hat{X}) \rightarrow (p, \hat{X})$, under composition. Its elements are called **deck transformations**, and they act on $\hat{X}$ on the left.

A deck transformation is a symmetry of the covering: a homeomorphism of $\hat{X}$ which permutes each fibre $p^{-1}(x)$ among itself.

Example 25.2.41

For $p : \mathbb{R} \rightarrow S^1$, the deck group is $\{g_n : t \mapsto t + n \mid n \in \mathbb{Z}\} \cong \mathbb{Z}$. Indeed each g_n satisfies $p \circ g_n = p$; conversely a deck transformation g is a lift of p , determined by $g(0) \in p^{-1}(1) = \mathbb{Z}$, so $g = g_{g(0)}$. Note $G_D(p) \cong \mathbb{Z} \cong \pi_1(S^1)$.

Example 25.2.42

For $p : S^n \rightarrow \mathbb{RP}^n$, the deck group is $\{\text{id}, x \mapsto -x\} \cong \mathbb{Z}/2\mathbb{Z}$.

That the deck group of the helix covering agrees with $\pi_1(S^1)$ is no accident.

Theorem 25.2.43

Let X be locally path connected and let $q : (\tilde{X}, \tilde{x}_0) \rightarrow (X, x_0)$ be a universal cover. Then $G_D(q) \cong \pi_1(X, x_0)$.

Proof. First, the evaluation map $G_D(q) \rightarrow q^{-1}(x_0)$, $g \mapsto g(\tilde{x}_0)$, is a bijection: given $\tilde{x} \in q^{-1}(x_0)$, Proposition 25.2.38 (applied with $\hat{X} = \tilde{X}$ and basepoint $\tilde{x}$) provides a unique covering transformation taking $\tilde{x}_0 \mapsto \tilde{x}$, and it is an isomorphism by the uniqueness corollary.

Composing with the bijection $\varepsilon_q^{-1} : q^{-1}(x_0) \rightarrow \pi_1(X, x_0)$ of Proposition 25.2.19, we get a bijection $\Theta : \pi_1(X, x_0) \rightarrow G_D(q)$, characterised by $\Theta([\gamma])(\tilde{x}_0) = \tilde{\gamma}(1)$, where $\tilde{\gamma}$ is the lift of γ at $\tilde{x}_0$.

It remains to check that Θ is a homomorphism. Write $g = \Theta[\gamma]$ and $g' = \Theta[\gamma']$. Since g is a deck transformation, $g \circ \tilde{\gamma}'$ is a lift of γ' starting at $g(\tilde{x}_0) = \tilde{\gamma}(1)$, so

$$\widetilde{\gamma \cdot \gamma'} = \tilde{\gamma} \cdot (g \circ \tilde{\gamma}'),$$

whence

$$\Theta[\gamma \cdot \gamma'](\tilde{x}_0) = \widetilde{\gamma \cdot \gamma'}(1) = g(\tilde{\gamma}'(1)) = g(g'(\tilde{x}_0)) = (g \circ g')(\tilde{x}_0).$$

Both $\Theta[\gamma \cdot \gamma']$ and $g \circ g'$ are deck transformations sending $\tilde{x}_0$ to the same point, so they are equal. $\square$

§25.2.7 The Galois Correspondence

We can now describe *all* the connected covers of a space in terms of the subgroup structure of its fundamental group. Throughout, let X be path connected and locally path connected with universal cover $q : (\tilde{X}, \tilde{x}_0) \rightarrow (X, x_0)$, and identify $G = \pi_1(X, x_0)$ with the deck group $G_D(q)$ via Theorem 25.2.43.

Given a subgroup $H \leq G$, the group H acts on $\tilde{X}$ by deck transformations, and we may form the quotient

$$X_H = H \backslash \tilde{X},$$

whose points are the orbits $H \cdot \tilde{x}$. Since deck transformations satisfy $q \circ h = q$, the map

q descends to $p_H : X_H \rightarrow X$, $H \cdot \tilde{x} \mapsto q(\tilde{x})$, and we have a tower

$$\begin{array}{ccc} \widetilde{X} & & 1 \\ \pi_H \downarrow & & \downarrow \\ X_H & & H \\ p_H \downarrow & & \downarrow \\ X & & G \end{array}$$

Proposition 25.2.44

π_H and p_H are covering maps. If $H = G$ then p_G is a covering isomorphism, so $X \cong G \backslash \widetilde{X}$.

Proof. Let $x \in X$ and choose a path connected evenly covered neighbourhood U of x , so $q^{-1}(U) = \bigsqcup_{\alpha} U_{\alpha}$. The deck group acts simply transitively on $q^{-1}(x)$, so the sheets are permuted simply transitively too, and we may index them as $q^{-1}(U) = \bigsqcup_{g \in G} g \cdot U_0$ for a fixed sheet U_0 . Then the H -orbits of sheets are indexed by the cosets gH , giving

$$p_H^{-1}(U) = \bigsqcup_{gH \in G/H} \pi_H(\bigcup_{h \in H} gh \cdot U_0),$$

and each piece maps homeomorphically onto U ; similarly π_H^{-1} of each piece is $\bigsqcup_{h \in H} gh \cdot U_0$. So U is evenly covered by p_H and each piece is evenly covered by π_H .

If $H = G$ then p_G is injective on fibres, hence bijective, hence a homeomorphism by Lemma 25.2.36. $\square$

In particular a universal covering map is exactly the quotient by the action of $\pi_1(X, x_0)$.

Definition 25.2.45

A covering map $p : \hat{X} \rightarrow X$ is a **normal** (or regular) cover if $G_D(p)$ acts transitively on the fibre $p^{-1}(x_0)$.

Now consider the two sets

$$S(X, x_0) = \{H \mid H \leq \pi_1(X, x_0)\},$$

$$C(X, x_0) = \{(p, \hat{X}, \hat{x}_0) \mid p : (\hat{X}, \hat{x}_0) \rightarrow (X, x_0) \text{ a covering map, } \hat{X} \text{ path connected}\} / \sim,$$

where $(p, \hat{X}, \hat{x}_0) \sim (p', \hat{X}', \hat{x}'_0)$ if there is a covering isomorphism between them matching the basepoints. Define

$$\alpha : S(X, x_0) \rightarrow C(X, x_0), \quad \alpha(H) = (p_H, X_H, \pi_H(\tilde{x}_0)),$$

$$\beta : C(X, x_0) \rightarrow S(X, x_0), \quad \beta(p, \hat{X}, \hat{x}_0) = p_*(\pi_1(\hat{X}, \hat{x}_0)),$$

noting that β lands in subgroups by Corollary 25.2.16.

Theorem 25.2.46 (Galois Correspondence)

α and β are mutually inverse bijections.

Proof. $\beta \circ \alpha = \text{id}$. Write $x_{0,H} = \pi_H(\tilde{x}_0)$. Given $[\gamma] \in H$ with lift $\tilde{\gamma}$ at $\tilde{x}_0$, the path $\pi_H \circ \tilde{\gamma}$ is a loop in X_H at $x_{0,H}$, since $\tilde{\gamma}(1) = [\gamma] \cdot \tilde{x}_0$ lies in the same H -orbit as $\tilde{x}_0$. Moreover

$$p_{H*}[\pi_H \circ \tilde{\gamma}] = [p_H \circ \pi_H \circ \tilde{\gamma}] = [q \circ \tilde{\gamma}] = [\gamma],$$

so $H \subseteq \beta(\alpha(H))$. Conversely, if $[\gamma] = p_{H*}[\delta]$ for a loop δ in X_H , then the lift of γ at $\tilde{x}_0$ ends at a point of $\pi_H^{-1}(x_{0,H}) = H \cdot \tilde{x}_0$, which says exactly that $[\gamma] \in H$.

$\alpha \circ \beta = \text{id}$. Let $p : (\hat{X}, \hat{x}_0) \rightarrow (X, x_0)$ be a path connected cover and $H = p_*(\pi_1(\hat{X}, \hat{x}_0))$. By Proposition 25.2.38 there is a covering transformation $\hat{q} : \hat{X} \rightarrow \hat{X}$ with $\hat{q}(\hat{x}_0) = \hat{x}_0$, and it is surjective since $\hat{X}$ is path connected. We claim $\hat{q}$ is constant on H -orbits. Indeed let $h = [p \circ \delta] \in H$ for a loop δ in $\hat{X}$ at $\hat{x}_0$, and let $\tilde{x} \in \hat{X}$ with a path $\eta : \tilde{x}_0 \leadsto \tilde{x}$. Recall from the proof of Proposition 25.2.31 that $\hat{q}(\tilde{x}) = \widehat{q \circ \eta}(1)$, the lift being taken at $\hat{x}_0$. Now $h \cdot \eta$ is a path from $h \cdot \tilde{x}_0$ to $h \cdot \tilde{x}$, so a path from $\tilde{x}_0$ to $h \cdot \tilde{x}$ is $\eta_h \cdot (h \circ \eta)$ where $\eta_h : \tilde{x}_0 \leadsto h \cdot \tilde{x}_0$ satisfies $q \circ \eta_h = p \circ \delta$. Hence

$$q \circ (\eta_h \cdot (h \circ \eta)) = \delta \cdot \widehat{q \circ \eta},$$

and evaluating at 1 gives $\hat{q}(h \cdot \tilde{x}) = \widehat{q \circ \eta}(1) = \hat{q}(\tilde{x})$, as claimed.

So $\hat{q}$ factors as $\hat{q} = p' \circ \pi_H$ for a map $p' : X_H \rightarrow \hat{X}$, which is a covering transformation over X taking $x_{0,H}$ to $\hat{x}_0$. It is surjective as $\hat{q}$ is, and injective because both X_H and $\hat{X}$ have fibres over x_0 in bijection with $H \backslash G$ — for X_H by construction, for $\hat{X}$ by the first half of the proof. So p' is a covering isomorphism, giving $\alpha(\beta(p, \hat{X}, \hat{x}_0)) = (p, \hat{X}, \hat{x}_0)$ in $C(X, x_0)$. $\square$

The dictionary this sets up is worth spelling out.

Remark. Under the correspondence of Theorem 25.2.46:

1. the whole group G corresponds to the trivial cover (id, X, x_0) , and the trivial subgroup 1 corresponds to the universal cover;
2. the index $[G : H]$ equals the number of sheets $|p_H^{-1}(x_0)|$;
3. changing the basepoint of a cover replaces H by a conjugate: if $g = [\gamma]$ and $\hat{\gamma}$ is the lift of γ to X_H at $x_{0,H}$, then $(p_H, X_H, \hat{\gamma}(1))$ corresponds to $g^{-1}Hg$. So unbased covers correspond to conjugacy classes of subgroups;
4. p_H is a normal cover if and only if $H \trianglelefteq G$, and in that case $G_D(p_H) \cong G/H$.

Example 25.2.47

Take $X = S^1$, so $G = \mathbb{Z}$. The subgroups are $n\mathbb{Z}$ for $n \geq 0$. The subgroup 0 gives the universal cover $\mathbb{R} \rightarrow S^1$, and $n\mathbb{Z}$ for $n \geq 1$ gives the n -sheeted cover $S^1 \rightarrow S^1$, $z \mapsto z^n$: indeed $p_{n*}(\pi_1(S^1)) = n\mathbb{Z}$, since p_n takes a generating loop to a loop of winding number n . As $\mathbb{Z}$ is abelian, every cover of S^1 is normal, with deck group $\mathbb{Z}/n\mathbb{Z}$. This is the complete list of connected covers of the circle.

Example 25.2.48

The two-sheeted cover $S^n \rightarrow \mathbb{RP}^n$ is universal for $n \geq 2$, since we will show in the next section that S^n is simply connected for $n \geq 2$. Hence

$$\pi_1(\mathbb{RP}^n) \cong G_D(p) \cong \mathbb{Z}/2\mathbb{Z} \quad (n \geq 2).$$

§25.3 The Seifert–van Kampen Theorem

Covering space theory computed $\pi_1(S^1)$, and with it π_1 of anything built out of circles by taking products or quotients by nice group actions. That is a rather short list. The Seifert–van Kampen theorem is the general computational tool: it tells us how to assemble $\pi_1(X)$ from π_1 of the pieces of an open cover of X by two sets. Before we can state it we need the group theory it takes values in.

§25.3.1 Wedges and Free Groups**Definition 25.3.1 (Wedge)**

Let (X_i, x_i) for $1 \leq i \leq n$ be based spaces. Their **wedge** is

$$\bigvee_{i=1}^n (X_i, x_i) = \left(\prod_{i=1}^n X_i \right) / \sim,$$

where $\sim$ is generated by $x_i \sim x_j$ for all i, j . That is, we glue the spaces together at their basepoints.

The example we care about is the **figure-eight** $S^1 \vee S^1$, and more generally the wedge of n circles.

Write $\iota_1, \iota_2 : (S^1, 1) \rightarrow (S^1 \vee S^1, x_0)$ for the two inclusions, and set $a = \iota_{1*}(1)$, $b = \iota_{2*}(1)$ in $\pi_1(S^1 \vee S^1, x_0)$. What group do a and b generate? We can answer this with covering spaces.

Let $T_\infty(4)$ be the infinite 4-valent tree: the connected graph in which every vertex has exactly four neighbours and there are no cycles, topologised as the union of its finite subtrees $T_n(4)$ (so U is open exactly when each $U \cap T_n(4)$ is).

Proposition 25.3.2

There is a covering map $q : T_\infty(4) \rightarrow S^1 \vee S^1$, and $T_\infty(4)$ is simply connected. So $T_\infty(4)$ is the universal cover of the figure-eight.

Proof. Colour the four edges at each vertex with the labels a, a^{-1}, b, b^{-1} , one each, in such a way that the a -edge out of v is the a^{-1} -edge out of its other endpoint, and similarly for b . Now map each a -labelled edge homeomorphically onto the first circle, respecting orientation, and each b -labelled edge onto the second, sending all vertices to x_0 . A point in the interior of an edge has a neighbourhood inside that edge which is evenly covered, and a small star-shaped neighbourhood of x_0 (a little arc of each circle either side) is evenly covered by the corresponding small stars around each vertex. So q is a covering map.

For simple connectedness: I is compact, so the image of any path lies in some finite subtree $T_n(4)$. A finite tree is contractible — collapse the leaves one at a time — and hence simply connected, so any loop in $T_\infty(4)$ is null-homotopic within $T_n(4)$, and so within $T_\infty(4)$. $\square$

Corollary 25.3.3

$\pi_1(S^1 \vee S^1, x_0)$ is not abelian.

Proof. By Proposition 25.2.19, $\varepsilon_q : \pi_1(S^1 \vee S^1, x_0) \rightarrow q^{-1}(x_0)$ is a bijection onto the vertex set of the tree. Lifting the loop $a \cdot b$ at $\tilde{x}_0$, we travel along the a -edge and then a b -edge; lifting $b \cdot a$, we travel along the b -edge and then an a -edge. These end at different vertices, so $ab \neq ba$. $\square$

The bijection in that proof does more: it identifies $\pi_1(S^1 \vee S^1)$ completely. A vertex $\tilde{x}$ of the tree is joined to $\tilde{x}_0$ by a unique shortest path, and recording the labels of the edges traversed gives an ‘address’ for $\tilde{x}$, namely a word $w = \ell_1 \ell_2 \cdots \ell_r$ in the letters $a^{\pm 1}, b^{\pm 1}$ containing no substring $aa^{-1}, a^{-1}a, bb^{-1}, b^{-1}b$ — a **reduced word**. Conversely every reduced word is the address of exactly one vertex. Under ε_q , multiplication in π_1 corresponds to concatenating words and then cancelling. This is precisely the free group.

Definition 25.3.4 (Free Group)

A **free group** on a set S is a group F_S together with a function $S \rightarrow F_S$ such that for any group G and any function $\varphi : S \rightarrow G$ there is a unique homomorphism $\Phi : F_S \rightarrow G$ restricting to φ on S .

$$\begin{array}{ccc} & & F_S \\ & \nearrow & \vdots \Phi \\ S & \xrightarrow{\varphi} & G \end{array}$$

Lemma 25.3.5

If F_S and F'_S are both free on S then $F_S \cong F'_S$; more generally a bijection $S \rightarrow T$ induces an isomorphism $F_S \rightarrow F_T$. So the isomorphism type of F_S depends only on $|S|$, and we write F_n for the free group on n generators.

Proof. Let $\varphi : S \rightarrow T$ be a bijection with inverse ψ , and let $\Phi : F_S \rightarrow F_T$ and $\Psi : F_T \rightarrow F_S$ be the induced homomorphisms. Then $\Psi \circ \Phi : F_S \rightarrow F_S$ restricts to the identity on S ; but so does id_{F_S} , and the universal property says there is only one such homomorphism. So $\Psi \circ \Phi = \text{id}$, and by symmetry $\Phi \circ \Psi = \text{id}$. $\square$

Theorem 25.3.6

$\pi_1(\bigvee_{i=1}^n S^1) \cong F_n$, free on the classes $a_1, \dots, a_n$ of the n circles.

Proof. Exactly as above, the universal cover of $\bigvee_{i=1}^n S^1$ is the infinite $2n$ -valent tree $T_\infty(2n)$, and ε_q identifies π_1 with the set of reduced words in $a_1^{\pm 1}, \dots, a_n^{\pm 1}$, with multiplication given by concatenate-and-cancel. It remains to check the universal property. Given $\varphi : \{a_1, \dots, a_n\} \rightarrow G$, extend it to inverses by $\varphi(a_i^{-1}) = \varphi(a_i)^{-1}$ and define

$$\Phi(\ell_1 \cdots \ell_r) = \varphi(\ell_1) \cdots \varphi(\ell_r).$$

This is a homomorphism, since concatenating two reduced words and cancelling a substring $\ell\ell^{-1}$ has no effect on the right hand side. It is the unique homomorphism restricting to φ , since the a_i generate. $\square$

We will express our answers as presentations, so let us fix notation. For $S \subseteq G$ we write $\langle S \rangle$ for the smallest subgroup containing S and $\langle\langle S \rangle\rangle$ for the smallest *normal* subgroup containing S (the intersection of all such, which is a normal subgroup).

Definition 25.3.7 (Presentation)

Given a set S and $R \subseteq F_S$, we write $\langle S \mid R \rangle = F_S / \langle\langle R \rangle\rangle$. If $G \cong \langle S \mid R \rangle$ we call $\langle S \mid R \rangle$ a **presentation** of G , with **generators** S and **relations** R .

Every group has a presentation: take $S = G$ and $R = \ker(\Phi_G : F_G \rightarrow G)$. Usually we want much smaller ones.

Example 25.3.8

$\langle a \mid \emptyset \rangle \cong \mathbb{Z}$, $\langle a \mid a^n \rangle \cong \mathbb{Z}/n\mathbb{Z}$, $\langle a, b \mid \emptyset \rangle \cong F_2$, and $\langle a, b \mid aba^{-1}b^{-1} \rangle \cong \mathbb{Z}^2$. Note that $\langle a, b \mid ab^{-3} \rangle \cong \mathbb{Z}$, since a can be eliminated.

The last example is an instance of a general and very useful move.

Proposition 25.3.9

Let $\langle S \mid R \rangle$ be a presentation, let $a \notin S$ and let $w \in F_S$. Then

$$\langle S \mid R \rangle \cong \langle S \cup \{a\} \mid R \cup \{aw^{-1}\} \rangle.$$

Proof. Define φ from left to right by $s \mapsto s$, and ψ from right to left by $s \mapsto s$ and $a \mapsto w$; both are well-defined as they respect the relations. They are mutually inverse. $\square$

We will also freely use that a relation may be replaced by a conjugate of itself, or multiplied by another relation, without changing the group.

Remark. One should not get too optimistic about presentations. It is a theorem of Novikov and Boone that there is no algorithm which, given a finite presentation, decides whether the group it presents is trivial. So ‘compute π_1 ’ can only ever mean ‘write down a presentation’.

§25.3.2 Amalgamated Free Products

Definition 25.3.10 (Amalgamated Free Product)

Let $\iota_1 : H \rightarrow G_1$ and $\iota_2 : H \rightarrow G_2$ be group homomorphisms. A group G is an **amalgamated free product** of G_1 and G_2 along H if

1. there are homomorphisms $\varphi_i : G_i \rightarrow G$ with $\varphi_1 \circ \iota_1 = \varphi_2 \circ \iota_2$; and
2. this is universal: for any group $\bar{G}$ with homomorphisms $j_i : G_i \rightarrow \bar{G}$ satisfying $j_1 \circ \iota_1 = j_2 \circ \iota_2$, there is a unique $\psi : G \rightarrow \bar{G}$ with $\psi \circ \varphi_i = j_i$.

We write $G = G_1 *_H G_2$.

Categorically this is a pushout; concretely it is ‘ G_1 and G_2 glued along H , with no relations imposed beyond those forced’. As with all universal properties, uniqueness is automatic.

Proposition 25.3.11

If G and G' are both amalgamated free products of G_1, G_2 along H , then $G \cong G'$.

Proof. Universality gives $\alpha : G \rightarrow G'$ and $\beta : G' \rightarrow G$ compatible with the φ_i . Then $\beta \circ \alpha : G \rightarrow G$ is compatible with the φ_i , as is id_G , so uniqueness forces $\beta \circ \alpha = \text{id}_G$; likewise $\alpha \circ \beta = \text{id}_{G'}$. $\square$

Proposition 25.3.12

Amalgamated free products exist. Explicitly, if $G_i = \langle S_i \mid R_i \rangle$ and $H = \langle T \mid W \rangle$, then

$$G_1 *_H G_2 = \langle S_1 \sqcup S_2 \mid R_1 \cup R_2 \cup \{\iota_1(t)\iota_2(t)^{-1} \mid t \in T\} \rangle,$$

where $\iota_i(t)$ is read as a word in S_i .

Proof. Call the right hand side G , and let $\varphi_i : G_i \rightarrow G$ send $s \in S_i$ to s ; this is well-defined since the relations R_i hold in G . The added relations say exactly that $\varphi_1 \circ \iota_1$ and $\varphi_2 \circ \iota_2$ agree on the generators T of H , hence agree.

Given j_1, j_2 into $\bar{G}$ as in the definition, define ψ on generators by $\psi(s) = j_i(s)$ for $s \in S_i$. The relations in R_i are satisfied because j_i is a homomorphism, and the relation $\iota_1(t)\iota_2(t)^{-1}$ is satisfied because $j_1\iota_1(t) = j_2\iota_2(t)$. So ψ is a well-defined homomorphism, and it is the unique one with $\psi \circ \varphi_i = j_i$ since the S_i generate G . $\square$

Example 25.3.13

If $H = 1$ we write $G_1 * G_2$, the **free product**. For instance $F_m * F_n \cong F_{m+n}$, and $\mathbb{Z} * \mathbb{Z} \cong F_2$.

§25.3.3 The Theorem

We first prove the ‘easy half’, which is already useful on its own.

Theorem 25.3.14

Let $X = U_1 \cup U_2$ with U_1, U_2 open, and suppose $U_1 \cap U_2$ is path connected with $x_0 \in U_1 \cap U_2$. Let $j_i : U_i \hookrightarrow X$ be the inclusions. Then $\pi_1(X, x_0)$ is generated by

$$j_{1*}(\pi_1(U_1, x_0)) \cup j_{2*}(\pi_1(U_2, x_0)).$$

Proof. Let γ be a loop at x_0 . Then $\{\gamma^{-1}(U_1), \gamma^{-1}(U_2)\}$ is an open cover of I , so by the Lebesgue covering lemma there is n such that each $[\frac{j}{n}, \frac{j+1}{n}]$ maps into U_1 or into U_2 ; label each subinterval accordingly, choosing arbitrarily if both work. Amalgamating adjacent subintervals with the same label, we get $0 = t_0 < t_1 < \dots < t_k = 1$ and paths $\gamma_i = \gamma|_{[t_{i-1}, t_i]}$, each contained in a single $U_{c(i)}$, with consecutive labels different. In particular each $\gamma(t_i)$ for $0 < i < k$ lies in $U_1 \cap U_2$.

Since $U_1 \cap U_2$ is path connected, choose paths $\eta_i : \gamma(t_i) \leadsto x_0$ inside $U_1 \cap U_2$ for $1 \leq i \leq k-1$. Inserting $\eta_i \cdot \eta_i^{-1}$ at each break point,

$$\gamma \simeq (\gamma_1 \cdot \eta_1) \cdot (\eta_1^{-1} \cdot \gamma_2 \cdot \eta_2) \cdots (\eta_{k-1}^{-1} \cdot \gamma_k) = \delta_1 \cdot \delta_2 \cdots \delta_k,$$

where each δ_i is a loop at x_0 lying entirely inside $U_{c(i)}$. Hence $[\gamma] = [\delta_1] \cdots [\delta_k]$ is a product of elements of $j_{1*}(\pi_1(U_1, x_0)) \cup j_{2*}(\pi_1(U_2, x_0))$. $\square$

Corollary 25.3.15

If $X = U_1 \cup U_2$ with U_1, U_2 open and simply connected and $U_1 \cap U_2$ path connected and non-empty, then X is simply connected.

Proof. $\pi_1(X, x_0)$ is generated by the trivial group. $\square$

Example 25.3.16

S^n is simply connected for $n \geq 2$. Take $U^\pm = S^n \setminus \{\mp e_1\}$, the sphere with one point removed. Both are homeomorphic to $\mathbb{R}^n$ by stereographic projection, hence simply connected, and

$$U^+ \cap U^- \cong \mathbb{R}^n \setminus \{0\} \simeq S^{n-1},$$

which is path connected precisely when $n \geq 2$.

Note how badly this fails for $n = 1$: there $U^+ \cap U^-$ has two components, and indeed $\pi_1(S^1) = \mathbb{Z}$. The full theorem tells us exactly how the failure of $\pi_1(X)$ to be generated freely is controlled by $\pi_1(U_1 \cap U_2)$.

Theorem 25.3.17 (Seifert–van Kampen)

Let $X = U_1 \cup U_2$ with U_1, U_2 open and $U_1 \cap U_2$ path connected containing x_0 ; suppose also that U_1, U_2 are path connected. Write $G_i = \pi_1(U_i, x_0)$ and $H = \pi_1(U_1 \cap U_2, x_0)$, with $\iota_{i*} : H \rightarrow G_i$ induced by the inclusions. Then

$$\pi_1(X, x_0) \cong G_1 *_H G_2.$$

Proof. The square of inclusions

commutes, so applying π_1 gives a commuting square of groups. By the universal property of the amalgamated free product there is a unique homomorphism

$$\psi : G_1 *_H G_2 \rightarrow \pi_1(X, x_0)$$

with $\psi \circ \varphi_i = j_{i*}$. It is surjective by Theorem 25.3.14, since its image contains both $j_{i*}(G_i)$. The work is in showing that it is injective.

So suppose $g \in G_1 *_H G_2$ has $\psi(g) = 1$. Write $g = \varphi_{c(1)}(g_1) \cdots \varphi_{c(k)}(g_k)$ as a product of images of elements $g_i \in G_{c(i)}$, and represent each g_i by a loop δ_i in $U_{c(i)}$ based at x_0 . Then $\gamma = \delta_1 \cdots \delta_k$ is a loop in X with $[\gamma] = 1$, so there is a homotopy $F : I \times I \rightarrow X$ with $F(s, 0) = \gamma(s)$, $F(s, 1) = x_0$ and $F(0, t) = F(1, t) = x_0$.

Apply the Lebesgue covering lemma to the open cover $\{F^{-1}(U_1), F^{-1}(U_2)\}$ of I^2 to get n such that each small square $A = [\frac{i}{n}, \frac{i+1}{n}] \times [\frac{j}{n}, \frac{j+1}{n}]$ has $F(A)$ inside some

$U_{c(A)}$; refining n further we may assume the break points of γ occur at multiples of $1/n$. For each vertex v of the grid choose a path η_v from x_0 to $F(v)$, lying in $U_1 \cap U_2$ if $F(v) \in U_1 \cap U_2$, and in U_c if $F(v)$ only lies in U_c ; take η_v constant when $F(v) = x_0$. For each edge e of the grid with endpoints v, w , we get a loop

$$\lambda_e = \eta_v \cdot (F \circ e) \cdot \eta_w^{-1}$$

based at x_0 , lying in whichever U_c contains the squares adjacent to e ; if both indices are available, λ_e lies in $U_1 \cap U_2$ and so determines an element of H , whose images in G_1 and G_2 are identified in $G_1 *_H G_2$. In every case, then, λ_e determines a well-defined element $[\lambda_e] \in G_1 *_H G_2$.

Now let $\rho_j \in G_1 *_H G_2$ be the product of the $[\lambda_e]$ along the horizontal grid line at height j/n , read left to right. Two facts finish the proof.

1. $\rho_0 = g$ and $\rho_n = 1$. The bottom row is γ , cut at the break points, and since the η_v for v on the bottom row are constant we get exactly $\varphi_{c(1)}(g_1) \cdots \varphi_{c(k)}(g_k) = g$. The top row is constant at x_0 , so all its edge loops are trivial.
2. $\rho_j = \rho_{j+1}$ for each j . Consider a single square A between the two rows, with $F(A) \subseteq U_{c(A)}$. Its four edge loops λ_e all lie in $U_{c(A)}$, and $F|_A$ shows that the composite loop around ∂A is null-homotopic in $U_{c(A)}$, because A is convex. Hence in $G_{c(A)}$, and therefore in $G_1 *_H G_2$, the product of the bottom and right edge classes equals the product of the left and top edge classes. Multiplying these relations across the row, and cancelling the interior vertical edges in pairs, converts ρ_j into ρ_{j+1} .

Therefore $g = \rho_0 = \rho_n = 1$, and ψ is injective. $\square$

§25.3.4 Applications

The most common way to apply the theorem is to a space built by gluing a disc onto another space along its boundary circle.

Definition 25.3.18

Let $f : S^1 \rightarrow X$ be a map. The space obtained by **attaching a 2-cell** along f is

$$X \cup_f D^2 = (X \sqcup D^2) / \sim, \quad z \sim f(z) \text{ for } z \in S^1.$$

Proposition 25.3.19

Let X be path connected with $x_0 = f(1)$, and suppose $\pi_1(X, x_0) = \langle S \mid R \rangle$. Then

$$\pi_1(X \cup_f D^2, x_0) \cong \pi_1(X, x_0) / \langle\langle f_*(1) \rangle\rangle = \langle S \mid R \cup \{w_f\} \rangle,$$

where w_f is any word representing the class $f_*(1) \in \pi_1(X, x_0)$ of the attaching loop.

Proof. Let $\pi : X \sqcup D^2 \rightarrow X \cup_f D^2$ be the quotient map and set

$$U_1 = \pi(X \sqcup (D^2 \setminus \{0\})), \quad U_2 = \pi((D^2)^\circ).$$

These are open, $U_1 \cup U_2 = X \cup_f D^2$, and $U_1 \cap U_2 = \pi((D^2)^\circ \setminus \{0\})$ is path connected. Now $D^2 \setminus \{0\}$ strong deformation retracts onto S^1 , so U_1 strong deformation retracts onto X , giving $\pi_1(U_1) \cong \pi_1(X, x_0)$. Also $\pi_1(U_2) = 1$ as $(D^2)^\circ$ is convex, and $U_1 \cap U_2 \simeq S^1$, so $H = \pi_1(U_1 \cap U_2) \cong \mathbb{Z} = \langle t \rangle$, generated by a small loop around the puncture. Under ι_{1*} this maps to the class of the attaching loop $f_*(1)$, and under ι_{2*} to 1.

(Strictly, the basepoint must be moved into $U_1 \cap U_2$; we conjugate by a path to x_0 , which is harmless.) By Theorem 25.3.17 and Proposition 25.3.12,

$$\pi_1(X \cup_f D^2) \cong \langle S \mid R \rangle *_{\langle t \rangle} 1 = \langle S, t \mid R \cup \{t^{-1}w_f, t\} \rangle \cong \langle S \mid R \cup \{w_f\} \rangle. \quad \square$$

In words: attaching a disc kills the class of the loop you attach it along, and nothing else. We can now compute the fundamental groups of all the closed surfaces, because every closed surface is a polygon with its edges identified in pairs — which is to say, a wedge of circles with a single disc attached.

Example 25.3.20 (The Torus)

Take the square I^2 and identify its edges according to the word $aba^{-1}b^{-1}$, meaning that we glue the left edge to the right edge and the bottom to the top, both without a flip. The result is T^2 . Its 1-skeleton — the image of ∂I^2 — is $S^1 \vee S^1$, since all four corners are identified to a single point, and the interior of the square is a 2-cell attached along the loop $a \cdot b \cdot a^{-1} \cdot b^{-1}$. So by Theorem 25.3.6 and Proposition 25.3.19,

$$\pi_1(T^2) \cong \langle a, b \mid aba^{-1}b^{-1} \rangle \cong \mathbb{Z}^2,$$

agreeing with the computation in Example 25.2.23.

Example 25.3.21 (The Klein Bottle)

Identify the edges of I^2 according to $abab^{-1}$: the left and right edges are glued as before, but the bottom and top are glued with a flip. The result is the Klein bottle K , and

$$\pi_1(K) \cong \langle a, b \mid abab^{-1} \rangle.$$

The relation rearranges to $bab^{-1} = a^{-1}$, so this group is the semidirect product $\mathbb{Z} \rtimes \mathbb{Z}$ in which the second factor acts on the first by inversion. In particular it is not abelian. Its abelianisation is $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}$, whereas $\pi_1(T^2)^{\text{ab}} = \mathbb{Z}^2$ is torsion-free, so $K \not\cong T^2$ and in particular the Klein bottle is not homeomorphic to the torus.

**Example 25.3.22 (The Projective Plane)**

Identifying the edges of I^2 by $abab$, equivalently identifying antipodal points on the boundary of a disc, gives $\mathbb{RP}^2$. The 1-skeleton is a single circle $\langle a \rangle$ and the disc is attached along a^2 , so

$$\pi_1(\mathbb{RP}^2) \cong \langle a \mid a^2 \rangle \cong \mathbb{Z}/2\mathbb{Z},$$

as we already knew from the covering $S^2 \rightarrow \mathbb{RP}^2$.

Example 25.3.23 (Surfaces of Genus g)

Let Σ_g be the closed orientable surface of genus g , obtained from a $4g$ -gon by identifying its edges according to the word

$$a_1 b_1 a_1^{-1} b_1^{-1} a_2 b_2 a_2^{-1} b_2^{-1} \cdots a_g b_g a_g^{-1} b_g^{-1}.$$

All $4g$ vertices are identified to a point, so the 1-skeleton is $\bigvee_{i=1}^{2g} S^1$, and hence

$$\pi_1(\Sigma_g) \cong \left\langle a_1, b_1, \dots, a_g, b_g \mid \prod_{i=1}^g a_i b_i a_i^{-1} b_i^{-1} \right\rangle.$$

Abelianising gives $\mathbb{Z}^{2g}$, so the Σ_g are pairwise non-homotopy-equivalent.

Alternatively, we can cut a genus 2 surface along a circle into two one-holed tori, which gives $\pi_1(\Sigma_2) \cong \langle a_1, b_1 \rangle *_{\mathbb{Z}} \langle a_2, b_2 \rangle$, with the amalgamation identifying the two commutators.

Finally, here is a taste of where these techniques lead. A **knot** is an embedding $S^1 \hookrightarrow S^3$, and the basic problem is to tell knots apart. Since all knots are homeomorphic to S^1 as spaces, we must look instead at the complement.

Example 25.3.24 (Knot Complements)

Let $U \subseteq S^3$ be the **unknot**, a round circle. Then $S^3 \setminus U$ deformation retracts onto a circle (spin around the axis of the unknot), so

$$\pi_1(S^3 \setminus U) \cong \mathbb{Z}.$$

Now let T be the **trefoil**. Cutting S^3 into the two solid tori on either side of the standard torus, on which T can be drawn as a curve of slope $3/2$, and applying Seifert–van Kampen gives

$$\pi_1(S^3 \setminus T) \cong \langle x, y \mid x^2 = y^3 \rangle.$$

This group surjects onto S_3 : send $x \mapsto (1\ 2)$ and $y \mapsto (1\ 2\ 3)$, and check $x^2 = e = y^3$. So $\pi_1(S^3 \setminus T)$ is non-abelian, and in particular not $\mathbb{Z}$. Hence the trefoil is genuinely knotted.

**§25.4 Simplicial Complexes**

We have squeezed a great deal out of the fundamental group, but it has a fundamental limitation: it only sees one-dimensional phenomena. We showed that S^n is simply connected for all $n \geq 2$, so π_1 cannot tell S^2 from S^3 . To detect higher-dimensional holes we need a new invariant, and to build it we will first cut our spaces into triangles.

§25.4.1 Simplices**Definition 25.4.1 (Simplex)**

The **standard n -simplex** is

$$\Delta^n = \left\{ (x_0, \dots, x_n) \in \mathbb{R}^{n+1} \mid x_i \geq 0, \sum_{i=0}^n x_i = 1 \right\}$$

with the subspace topology.

So Δ^0 is a point, Δ^1 is homeomorphic to I , Δ^2 is a triangle and Δ^3 is a tetrahedron. Each Δ^n is closed and bounded in $\mathbb{R}^{n+1}$, hence compact, and the standard basis vectors $e_0, \dots, e_n$ are its **vertices**. By radial projection from the barycentre, $\Delta^n \cong D^n$.

Definition 25.4.2 (Face)

For $I \subseteq \{0, \dots, n\}$, the **I th face** of Δ^n is

$$e_I = \{x \in \Delta^n \mid x_i = 0 \text{ for } i \notin I\},$$

and $F(\Delta^n) = \{e_I \mid I \subseteq \{0, \dots, n\}\}$ is the set of faces.

We abbreviate $I = \{i_0 < \dots < i_k\}$ by the string $i_0 i_1 \dots i_k$, so for instance e_{02} is the edge of Δ^2 joining e_0 and e_2 . Note that $e_{\{i\}} = e_i$, that $\Delta^n = e_{0\dots n}$, that $e_\emptyset = \emptyset$, that $e_I \cong \Delta^{|I|-1}$, and crucially that

$$e_I \subseteq e_J \iff I \subseteq J, \quad e_I \cap e_J = e_{I \cap J}.$$

Definition 25.4.3

A map $|f| : \Delta^n \rightarrow \mathbb{R}^N$ is **affine linear** if it is the restriction of a linear map $\mathbb{R}^{n+1} \rightarrow \mathbb{R}^N$, equivalently if $|f|(\sum x_i e_i) = \sum x_i |f|(e_i)$. An affine linear map $|f| : \Delta^n \rightarrow \Delta^m$ is **simplicial** if it takes vertices to vertices, so that it is determined by a function $\hat{f} : \{0, \dots, n\} \rightarrow \{0, \dots, m\}$ via $|f|(e_i) = e_{\hat{f}(i)}$.

Affine linear maps are continuous and determined by their values on vertices, and a simplicial map satisfies $|f|(e_I) = e_{\hat{f}(I)}$.

Definition 25.4.4 (Affine Independence)

Vectors $v_0, \dots, v_n \in \mathbb{R}^N$ are **affine linearly independent** if whenever $\sum t_i v_i = 0$ with $\sum t_i = 0$, all $t_i = 0$. Equivalently, $v_1 - v_0, \dots, v_n - v_0$ are linearly independent, or the affine linear map $|f| : \Delta^n \rightarrow \mathbb{R}^N$ with $|f|(e_i) = v_i$ is injective.

In that case we write

$$[v_0, \dots, v_n] = \text{im } |f| = \left\{ \sum x_i v_i \mid x_i \geq 0, \sum x_i = 1 \right\}$$

and call it a **Euclidean simplex** of dimension n .

Since Δ^n is compact and $\mathbb{R}^N$ Hausdorff, $|f| : \Delta^n \rightarrow [v_0, \dots, v_n]$ is a homeomorphism. The following lemma says that a Euclidean simplex remembers its vertices, so ‘the vertices of σ ’ is well-defined; we write $V(\sigma)$ for this set.

Lemma 25.4.5

For $X \subseteq \mathbb{R}^N$ let $Z(X)$ be the set of $x \in X$ such that whenever $x = \sum t_i x_i$ with $x_i \in X$, $t_i > 0$ and $\sum t_i = 1$, we have $x_i = x$ for some i . Then $Z([v_0, \dots, v_n]) = \{v_0, \dots, v_n\}$.

Proof. If x is not a vertex then $x = \sum x_i v_i$ with at least two x_i positive, and writing x as a convex combination of the v_i involved exhibits $x \notin Z$. Conversely suppose $v_k = \sum_i t_i x_i$ with $t_i > 0$, $\sum t_i = 1$, and write $x_i = \sum_j s_{ij} v_j$ with $s_{ij} \geq 0$ and

$\sum_j s_{ij} = 1$. Then

$$v_k = \sum_j \left(\sum_i t_i s_{ij} \right) v_j,$$

and $\sum_j \sum_i t_i s_{ij} = 1$, so affine independence forces $\sum_i t_i s_{ij} = 0$ for $j \neq k$. As $t_i > 0$ and $s_{ij} \geq 0$, we get $s_{ij} = 0$ for all i and $j \neq k$, so every $x_i = v_k$. $\square$

§25.4.2 Simplicial Complexes

There are two ways to package a collection of simplices glued along faces — one combinatorial, one geometric — and we shall need both.

Definition 25.4.6 (Abstract Simplicial Complex)

An **abstract simplicial complex** in Δ^n is a subset $K \subseteq F(\Delta^n)$ which is downward closed: if $e_J \in K$ and $I \subseteq J$ then $e_I \in K$.

Its **polyhedron** is $|K| = \bigcup_{e_I \in K} e_I \subseteq \Delta^n$, with the subspace topology, and its **r -skeleton** is $K_r = \{e_I \in K \mid |I| \leq r+1\}$.

Abstract simplicial complexes carry no topology themselves; the topology lives on the polyhedron, which is compact and Hausdorff. We have a filtration $\{e_\emptyset\} = K_{-1} \subseteq K_0 \subseteq \cdots \subseteq K_n = K$, and $\dim K$ is the largest r with $K_r \neq K_{r-1}$.

Example 25.4.7

$\Delta^n = F(\Delta^n)$ is an abstract simplicial complex with $|\Delta^n| = \Delta^n \cong D^n$.

Example 25.4.8

$S^{n-1} = \Delta_{n-1}^n = \{e_I \mid I \subsetneq \{0, \dots, n\}\}$, obtained by throwing away the top face, is an abstract simplicial complex with polyhedron $\partial\Delta^n \cong S^{n-1}$: the boundary of the tetrahedron is a sphere.

Definition 25.4.9

A **simplicial map** $f : K \rightarrow L$ between abstract simplicial complexes in Δ^n and Δ^m is a map induced by some $\hat{f} : \{0, \dots, n\} \rightarrow \{0, \dots, m\}$ with the property that $e_I \in K$ implies $e_{\hat{f}(I)} \in L$; then $f(e_I) = e_{\hat{f}(I)}$. It is a **simplicial isomorphism** if it is a bijection, in which case $|f| : |K| \rightarrow |L|$ is a homeomorphism.

For the geometric version we work inside $\mathbb{R}^N$. Write $\mathcal{S}(\mathbb{R}^N)$ for the set of Euclidean simplices in $\mathbb{R}^N$.

Definition 25.4.10 (Euclidean Simplicial Complex)

A finite set $K \subseteq \mathcal{S}(\mathbb{R}^N)$ is a **Euclidean simplicial complex** if

1. $\sigma \in K$ and τ a face of σ implies $\tau \in K$;
2. $\sigma_1, \sigma_2 \in K$ implies $\sigma_1 \cap \sigma_2$ is a face of each (and so lies in K).

Its polyhedron is $|K| = \bigcup_{\sigma \in K} \sigma \subseteq \mathbb{R}^N$ and its r -skeleton is $K_r = \{\sigma \in K \mid \dim \sigma \leq r\}$.

Condition (ii) is the one that does the work: it forbids the two configurations on the right below, in which simplices meet in something which is not a common face.

The two notions are equivalent, in the following sense.

Definition 25.4.11

Let K' be an abstract simplicial complex in Δ^n and $|\varphi| : \Delta^n \rightarrow \mathbb{R}^N$ affine linear with $|\varphi|$ injective on $|K'|$. Then $\varphi(K') = \{|\varphi|(e_I) \mid e_I \in K'\}$ is called a **realisation** of K' .

Proposition 25.4.12

A realisation $\varphi(K')$ is a Euclidean simplicial complex, and $|\varphi| : |K'| \rightarrow |\varphi(K')|$ is a homeomorphism. Conversely, every Euclidean simplicial complex is a realisation of some abstract simplicial complex, uniquely up to simplicial isomorphism.

Proof. For the first part, downward closure is inherited from K' , and for intersections, injectivity gives

$$|\varphi|(e_{I_1}) \cap |\varphi|(e_{I_2}) = |\varphi|(e_{I_1 \cap I_2}) = |\varphi|(e_{I_1 \cap I_2}),$$

which is a common face. That $|\varphi|$ is a homeomorphism follows from compactness of $|K'|$.

Conversely, let K be a Euclidean simplicial complex, and write its vertex set as $V(K) = \{v_0, \dots, v_n\}$. Define

$$K' = \{e_{i_0 \dots i_k} \in F(\Delta^n) \mid [v_{i_0}, \dots, v_{i_k}] \in K\}$$

and let $|\varphi|(e_i) = v_i$. We must check $|\varphi|$ is injective on $|K'|$. It is injective on each $e_I \in K'$, since the corresponding v_i are affine independent. Suppose $|\varphi|(p) = |\varphi|(q) = x$ with $p \in e_I$, $q \in e_J$, both in K' . Then x lies in $|\varphi|(e_I) \cap |\varphi|(e_J)$, which is a common face $|\varphi|(e_{I'})$ with $I' \subseteq I \cap J$; by injectivity on e_I and on e_J we get $p, q \in e_{I'}$, and then $p = q$ by injectivity on $e_{I'}$. $\square$

Definition 25.4.13

For a Euclidean simplex σ of dimension n , its **boundary complex** is $\partial\sigma = F(\sigma) \setminus \{\sigma\}$, with polyhedron $|\partial\sigma| \cong S^{n-1}$. The **open simplex** is $\sigma^\circ = \sigma \setminus |\partial\sigma|$.

Lemma 25.4.14

Let K be a simplicial complex and $x \in |K|$. Then there is a unique $\sigma \in K$ with $x \in \sigma^\circ$.

Proof. Work in the abstract picture, where $x \in \Delta^n$. Set $I = \{i \mid x_i \neq 0\}$. Then $x \in e_I^\circ$, and $x \in e_J$ if and only if $I \subseteq J$, which gives both existence and uniqueness; and $e_I \in K$ by downward closure, since $x \in e_J$ for some $e_J \in K$. $\square$

So the open simplices of K partition $|K|$.

§25.4.3 Barycentric Subdivision

Simplicial maps are very rigid: there are only finitely many of them between two given complexes, so most continuous maps $|K| \rightarrow |L|$ are not simplicial. The remedy is to chop K into finer and finer pieces, and the standard way to do this is barycentric subdivision. We first need cones.

Definition 25.4.15

Let $X \subseteq \mathbb{R}^N$ and $p \in \mathbb{R}^N$. We say p is **independent** of X if for every $x \in X$ the ray from p through x meets X only at x . In that case the **cone** is

$$C_p(X) = \{tp + (1-t)x \mid t \in [0, 1], x \in X\},$$

and for a Euclidean simplicial complex K with p independent of $|K|$ we set

$$C_p(K) = K \cup \{[v_0, \dots, v_j, p] \mid [v_0, \dots, v_j] \in K\}.$$

Lemma 25.4.16

If p is independent of $|K|$ then $C_p(K)$ is a Euclidean simplicial complex with $|C_p(K)| = C_p(|K|)$, and every $\sigma \in C_p(K)$ satisfies $\sigma \cap |K| \in K$.

Definition 25.4.17 (Barycentre)

The **barycentre** of $\sigma = [v_0, \dots, v_n]$ is $b_\sigma = \frac{1}{n+1} \sum_{i=0}^n v_i$.

One checks that b_σ is independent of $|\partial\sigma|$ and that $C_{b_\sigma}(|\partial\sigma|) = \sigma$. We may now define barycentric subdivision by a simultaneous induction on dimension: for a simplex σ we set

$$\beta(\sigma) = C_{b_\sigma}(\mathcal{B}(\partial\sigma)),$$

and for a Euclidean simplicial complex K we set

$$\mathcal{B}(K) = \bigcup_{\sigma \in K} \beta(\sigma),$$

starting from $\beta(\emptyset) = \{\emptyset\}$ and $\mathcal{B}(\{\emptyset\}) = \{\emptyset\}$. In words: subdivide the boundary, then cone off from the barycentre.

Theorem 25.4.18

For every n and every n -dimensional Euclidean simplex σ and n -dimensional Euclidean simplicial complex K :

1. $\beta(\sigma)$ is an n -dimensional Euclidean simplicial complex with $|\beta(\sigma)| = \sigma$, and if τ is a face of σ and $\sigma_1 \in \beta(\sigma)$ then $\sigma_1 \cap \tau \in \beta(\tau)$;
2. $\mathcal{B}(K)$ is an n -dimensional Euclidean simplicial complex with $|\mathcal{B}(K)| = |K|$.

Proof. Both hold trivially in dimension -1 . Assume both in dimensions $< n$.

(i) Now $\partial\sigma$ has dimension $n-1$, so $\mathcal{B}(\partial\sigma)$ is a Euclidean simplicial complex with polyhedron $|\partial\sigma|$ by the inductive hypothesis (ii). As b_σ is independent of $|\partial\sigma|$, Lemma 25.4.16 says $\beta(\sigma) = C_{b_\sigma}(\mathcal{B}(\partial\sigma))$ is a Euclidean simplicial complex with polyhedron $C_{b_\sigma}(|\partial\sigma|) = \sigma$. The last claim also follows from Lemma 25.4.16.

(ii) $\mathcal{B}(K)$ is finite, and downward closed since each $\beta(\sigma)$ is. For intersections, let $\sigma_i \in \beta(\sigma'_i)$ with $\sigma'_i \in K$. Then $\sigma_1 \cap \sigma_2 \subseteq \sigma'_1 \cap \sigma'_2 = \tau \in K$. By (i), $\sigma_i \cap \tau \in \beta(\tau)$, and $\beta(\tau)$ is a simplicial complex, so

$$\sigma_1 \cap \sigma_2 = (\sigma_1 \cap \tau) \cap (\sigma_2 \cap \tau) \in \beta(\tau) \subseteq \mathcal{B}(K).$$

Finally $|\mathcal{B}(K)| = \bigcup_{\sigma \in K} |\beta(\sigma)| = \bigcup_{\sigma \in K} \sigma = |K|$. □

The reason for subdividing is that the pieces get smaller, and we can quantify this.

Definition 25.4.19 (Mesh)

The **mesh** of a Euclidean simplex σ is $\mu(\sigma) = \max_{v_i, v_j \in V(\sigma)} \|v_i - v_j\|$, and $\mu(K) = \max_{\sigma \in K} \mu(\sigma)$.

Lemma 25.4.20

If σ is a Euclidean simplex and $x, v \in \sigma$ then $\|v - x\| \leq \max_{v_i \in V(\sigma)} \|v - v_i\|$. Consequently $\mu(\sigma) = \max_{x, v \in \sigma} \|v - x\|$.

Proof. Write $x = \sum x_i v_i$ with $x_i \geq 0$ and $\sum x_i = 1$; then $v = \sum x_i v_i$, so

$$\|v - x\| = \left\| \sum x_i (v - v_i) \right\| \leq \sum x_i \|v - v_i\| \leq \max_i \|v - v_i\|. \quad \square$$

Corollary 25.4.21

If $\dim \sigma = n$ then $\mu(\beta(\sigma)) \leq \frac{n}{n+1} \mu(\sigma)$, and if $\dim K = n$ then $\mu(\mathcal{B}(K)) \leq \frac{n}{n+1} \mu(K)$.

Hence $\mu(\mathcal{B}^r(K)) \rightarrow 0$ as $r \rightarrow \infty$.

Proof. First, for $\sigma = [v_0, \dots, v_n]$ and any $v \in \sigma$, applying Lemma 25.4.20,

$$\|b_\sigma - v\| \leq \max_i \|b_\sigma - v_i\| = \max_i \frac{1}{n+1} \left\| \sum_{j \neq i} (v_j - v_i) \right\| \leq \frac{n}{n+1} \mu(\sigma).$$

Now let $\tau \in \beta(\sigma)$. If $\tau \in \mathcal{B}(\partial\sigma)$ then by induction $\mu(\tau) \leq \frac{n-1}{n} \mu(\partial\sigma) \leq \frac{n}{n+1} \mu(\sigma)$. Otherwise $\tau = [w_0, \dots, w_k, b_\sigma]$ with $[w_0, \dots, w_k] \in \mathcal{B}(\partial\sigma)$, and the distance between any two of its vertices is at most $\max\{\frac{n-1}{n} \mu(\sigma), \frac{n}{n+1} \mu(\sigma)\} = \frac{n}{n+1} \mu(\sigma)$. The statement for complexes follows by taking maxima, and iterating gives $\mu(\mathcal{B}^r(K)) \leq (\frac{n}{n+1})^r \mu(K) \rightarrow 0$. $\square$

§25.4.4 Simplicial Approximation

We can now say what it means for a simplicial map to approximate a continuous one.

Definition 25.4.22 (Star)

Let K be a simplicial complex and $v \in V(K)$. The **star** of v is

$$\text{St}_K(v) = \bigcup_{\{\sigma \in K \mid v \in V(\sigma)\}} \sigma^\circ.$$

$\text{St}_K(v)$ is the shaded region, without its outer boundary

Lemma 25.4.23

Let K be a simplicial complex.

1. If $x \in \sigma^\circ$ for $\sigma \in K$, then $x \in \text{St}_K(v)$ if and only if $v \in V(\sigma)$.
2. $\text{St}_K(v) = |K| \setminus \bigcup \{\sigma \in K \mid v \notin V(\sigma)\}$, so it is open in $|K|$.
3. $\{\text{St}_K(v) \mid v \in V(K)\}$ is an open cover of $|K|$.

Proof. (i) is immediate from Lemma 25.4.14. For (ii), by (i) the complement of $\text{St}_K(v)$ consists of the open simplices σ° with $v \notin V(\sigma)$; and the union of these equals the union of the corresponding closed simplices, since faces of a simplex not containing v also do not contain v . That union is a finite union of compact sets, hence closed. (iii) follows since every x lies in some σ° , and σ has at least one vertex. $\square$

Definition 25.4.24 (Simplicial Approximation)

Let K, L be simplicial complexes and $f : |K| \rightarrow |L|$ continuous. A function $\hat{g} : V(K) \rightarrow V(L)$ is a **simplicial approximation** to f if

$$f(\text{St}_K(v)) \subseteq \text{St}_L(\hat{g}(v)) \quad \text{for all } v \in V(K).$$

Theorem 25.4.25

If $\hat{g}$ is a simplicial approximation to $f : |K| \rightarrow |L|$, then $\hat{g}$ determines a simplicial map $g : K \rightarrow L$, and $|g| \simeq f$.

Proof. Let $\sigma \in K$ and pick $x \in \sigma^\circ$; say $f(x) \in \tau^\circ$ with $\tau \in L$. Since $x \in \text{St}_K(v)$ for every $v \in V(\sigma)$, we get

$$f(x) \in \bigcap_{v \in V(\sigma)} f(\text{St}_K(v)) \subseteq \bigcap_{v \in V(\sigma)} \text{St}_L(\hat{g}(v)),$$

and by Lemma 25.4.23(i) this says $\hat{g}(v) \in V(\tau)$ for every $v \in V(\sigma)$. So the affine linear extension $|g|$ maps σ into τ , and $|g|(\sigma)$ is a face of τ , hence lies in L . So g is simplicial.

For the homotopy, define $H : |K| \times I \rightarrow \mathbb{R}^M$ by $H(x, t) = t|g|(x) + (1 - t)f(x)$. This is continuous, and we claim it lands in $|L|$. With x, σ, τ as above, $|g|(x) = \sum_i x_i |g|(v_i) \in \tau$ since each $|g|(v_i) \in V(\tau)$, and $f(x) \in \tau$; as τ is convex, $H(x, t) \in \tau \subseteq |L|$. So H is a homotopy $f \simeq |g|$ in $|L|$. $\square$

Theorem 25.4.26 (Simplicial Approximation Theorem)

Let K, L be simplicial complexes and $f : |K| \rightarrow |L|$ continuous. Then there exist $r \geq 0$ and a simplicial map $g : \mathcal{B}^r(K) \rightarrow L$ with $|g| \simeq f$.

Proof. By Lemma 25.4.23, $\{\text{St}_L(w) \mid w \in V(L)\}$ is an open cover of $|L|$, so

$$\{f^{-1}(\text{St}_L(w)) \mid w \in V(L)\}$$

is an open cover of $|K|$. Now $|K|$ is a compact metric space, so the Lebesgue covering lemma gives $\delta > 0$ such that each $B_\delta(x)$ lies in some $f^{-1}(\text{St}_L(w_x))$.

By Corollary 25.4.21, choose r with $\mu(\mathcal{B}^r(K)) < \delta$ and put $K' = \mathcal{B}^r(K)$, noting $|K'| = |K|$. If $x \in V(K')$ and $\sigma \in K'$ has $x \in V(\sigma)$ then $\sigma \subseteq B_\delta(x)$, since every point of σ is within $\mu(K') < \delta$ of x . Hence

$$\text{St}_{K'}(x) \subseteq \bigcup_{\{\sigma \mid x \in V(\sigma)\}} \sigma \subseteq B_\delta(x),$$

so $f(\text{St}_{K'}(x)) \subseteq f(B_\delta(x)) \subseteq \text{St}_L(w_x)$. Therefore $\hat{g}(x) = w_x$ defines a simplicial approximation to f , and Theorem 25.4.25 does the rest. $\square$

This is the technical engine of everything to come. Here is a first payoff, which already does something the fundamental group could not.

Corollary 25.4.27

Let K, L be simplicial complexes with $\dim K < \dim L$, and let $f : |K| \rightarrow |L|$ be continuous. Then $f \simeq |g|$ for some $|g|$ which is not surjective.

Proof. Take a simplicial $g : \mathcal{B}^r(K) \rightarrow L$ with $|g| \simeq f$. Simplicial maps do not raise dimension, so $|g|$ has image in $|L_k|$ where $k = \dim \mathcal{B}^r(K) = \dim K < \dim L$. As $|L_k| \subsetneq |L|$, this is not surjective. $\square$

Theorem 25.4.28

If $k < n$, every map $S^k \rightarrow S^n$ is null-homotopic.

Proof. We have $S^k \cong |\mathbb{S}^k|$ and $S^n \cong |\mathbb{S}^n|$ with $\dim \mathbb{S}^k = k < n = \dim \mathbb{S}^n$, so by Corollary 25.4.27, $f \simeq |g|$ where $|g|$ misses some point $p \in S^n$. But then $|g|$ factors through $S^n \setminus \{p\} \cong \mathbb{R}^n$, which is contractible, so $|g|$ is null-homotopic; hence so is f . $\square$

That gives one half of the statement $S^n \simeq S^m \implies n = m$: any map $S^k \rightarrow S^n$ with $k < n$ is null-homotopic, whereas we would need id_{S^n} not to be. To prove the latter we need homology.

§25.5 Simplicial Homology

Here is the idea. Having chopped a space into simplices, we form for each k the free abelian group on the k -simplices, and a boundary homomorphism d taking a simplex to the (signed) sum of its faces. A k -dimensional hole should be a k -cycle — something with no boundary — which is not itself the boundary of anything. Measuring how badly ‘no boundary’ fails to imply ‘is a boundary’ is exactly taking a quotient group, and that quotient is homology.

§25.5.1 Chain Complexes

Definition 25.5.1 (Chain Complex)

A **chain complex** $(C_\bullet, d)$ consists of

1. free abelian groups C_i for $i \in \mathbb{Z}$, all but finitely many of which are zero;
2. homomorphisms $d_i : C_i \rightarrow C_{i-1}$;
3. such that $d_{i-1} \circ d_i = 0$ for all i .

$$\cdots \rightarrow C_{i+1} \xrightarrow{d_{i+1}} C_i \xrightarrow{d_i} C_{i-1} \rightarrow \cdots$$

We write $C_\bullet = \bigoplus_i C_i$ and $d = \bigoplus_i d_i$, so that condition (iii) says exactly $d^2 = 0$.

Definition 25.5.2

Let $x \in C_k$. We say x is a **cycle** if $dx = 0$, and a **boundary** if $x = dy$ for some

$$y \in C_{k+1}.$$

Since $d^2 = 0$, every boundary is a cycle: $\text{im } d_{k+1} \subseteq \ker d_k$. The whole subject consists of measuring the failure of the converse.

Now we build the chain complex of a simplicial complex. Let K be an abstract simplicial complex in Δ^n .

Definition 25.5.3 (Simplicial Chain Complex)

The **reduced chain group** is the free abelian group

$$\widetilde{C}_k(K) = \langle e_I \mid e_I \in K, |I| = k + 1 \rangle,$$

with boundary map defined on basis elements by

$$d(e_I) = \sum_{j=0}^k (-1)^j e_{I_j}, \quad I_j = I \setminus \{i_j\},$$

where $I = i_0 i_1 \cdots i_k$ with $i_0 < \cdots < i_k$.

Note that $\widetilde{C}_{-1}(K) = \langle e_\emptyset \rangle \cong \mathbb{Z}$, generated by the empty face, and $d(e_i) = e_\emptyset$ for each vertex. The **unreduced** chain complex $C_\bullet(K)$ is obtained by throwing this away: $C_k(K) = \widetilde{C}_k(K)$ for $k \geq 0$ and $C_{-1}(K) = 0$, with the same d .

The alternating signs are what makes everything work.

Proposition 25.5.4

$$d^2 = 0.$$

Proof. It suffices to check this on basis elements. Expanding,

$$d^2(e_I) = \sum_{j < j'} c_{jj'} e_{I_{jj'}},$$

where $I_{jj'} = I \setminus \{i_j, i_{j'}\}$. There are two ways to arrive at this term: deleting i_j first and then $i_{j'}$, which now sits in position $j' - 1$, contributing $(-1)^j (-1)^{j'-1}$; or deleting $i_{j'}$ first and then i_j , still in position j , contributing $(-1)^{j'} (-1)^j$. So

$$c_{jj'} = (-1)^{j+j'-1} + (-1)^{j+j'} = 0. \quad \square$$

Example 25.5.5

Take $K = \Delta^2$, the full triangle. Then

$$\widetilde{C}_2 = \langle e_{012} \rangle, \quad \widetilde{C}_1 = \langle e_{01}, e_{02}, e_{12} \rangle, \quad \widetilde{C}_0 = \langle e_0, e_1, e_2 \rangle, \quad \widetilde{C}_{-1} = \langle e_\emptyset \rangle,$$

and all other $\widetilde{C}_i = 0$. The boundary maps are

$$d(e_{012}) = e_{12} - e_{02} + e_{01}, \quad d(e_{01}) = e_1 - e_0, \quad d(e_{02}) = e_2 - e_0, \quad d(e_{12}) = e_2 - e_1,$$

and $d(e_i) = e_\emptyset$. As a check,

$$d^2(e_{012}) = (e_2 - e_1) - (e_2 - e_0) + (e_1 - e_0) = 0.$$

The signs encode orientations: e_{01} is the edge from e_0 to e_1 , and $d(e_{012}) = e_{01} - e_{02} + e_{12}$ traverses the boundary of the triangle consistently anticlockwise.

§25.5.2 Homology Groups

Definition 25.5.6 (Homology)

Let $(C_\bullet, d)$ be a chain complex. Its **k th homology group** is

$$H_k(C_\bullet) = \frac{\ker d_k}{\operatorname{im} d_{k+1}}.$$

For a simplicial complex K we set $H_k(K) = H_k(C_\bullet(K))$ and $\widetilde{H}_k(K) = H_k(\widetilde{C}_\bullet(K))$, the **reduced homology**.

Homology groups are abelian, being quotients of subgroups of free abelian groups. For $x \in \ker d$ we write $[x]$ for its class in $H_\bullet$.

Example 25.5.7

Continuing Example 25.5.5, let us compute $\widetilde{H}_\bullet(\Delta^2)$.

- d_2 is injective, so $\ker d_2 = 0$ and $\widetilde{H}_2 = 0$.
- For $x = ae_{01} + be_{12} + ce_{02}$ we have $dx = -(a+c)e_0 + (a-b)e_1 + (b+c)e_2$, so $dx = 0$ iff $a = b = -c$. Hence $\ker d_1 = \langle e_{01} + e_{12} - e_{02} \rangle = \operatorname{im} d_2$, giving $\widetilde{H}_1 = 0$.
- $\ker d_0 = \{ae_0 + be_1 + ce_2 \mid a + b + c = 0\}$, which is spanned by $e_1 - e_0, e_2 - e_0$, and these lie in $\operatorname{im} d_1$. So $\widetilde{H}_0 = 0$.
- d_0 is surjective onto $\widetilde{C}_{-1}$, so $\widetilde{H}_{-1} = 0$.

So all the reduced homology of the full triangle vanishes. Passing to unreduced homology only changes degree 0:

$$H_k(\Delta^2) = \begin{cases} \mathbb{Z} & k = 0 \\ 0 & \text{otherwise.} \end{cases}$$

Example 25.5.8

Let $K = \{e_\emptyset, e_0, \dots, e_r\}$, so $|K|$ is $r + 1$ points. Then $\widetilde{C}_i(K) = 0$ for $i > 0$, and $\ker d_0 = \langle e_1 - e_0, \dots, e_r - e_0 \rangle \cong \mathbb{Z}^r$ with $\operatorname{im} d_1 = 0$. So $\widetilde{H}_0(K) \cong \mathbb{Z}^r$ and

$$H_0(K) \cong \mathbb{Z}^{r+1}.$$

That is a general phenomenon: H_0 counts path components, while $\widetilde{H}_0$ counts them minus one.

Example 25.5.9 (The Circle)

Let T_n be the boundary of a convex n -gon, realising the abstract complex

$$K = \{e_\emptyset, e_0, \dots, e_{n-1}, e_{01}, e_{12}, \dots, e_{(n-2)(n-1)}, e_{0(n-1)}\},$$

so that $|K| \cong S^1$. Then $C_1(K)$ is free of rank n and $C_0(K)$ is free of rank n , with $d(e_{i(i+1)}) = e_{i+1} - e_i$ and $d(e_{0(n-1)}) = e_{n-1} - e_0$. Setting

$$x = e_{01} + e_{12} + \dots + e_{(n-2)(n-1)} - e_{0(n-1)},$$

we get $dx = 0$, and a short computation shows $\ker d_1 = \langle x \rangle$. As $C_2 = 0$,

$$H_1(K) = \langle x \rangle \cong \mathbb{Z}.$$

Also $\ker d_0 = C_0$ and $\operatorname{im} d_1$ is spanned by the $e_{i+1} - e_i$, so $H_0(K) \cong \mathbb{Z}$. Note that the answer does not depend on n , even though the complexes do — as it must not, since all the $|T_n|$ are homeomorphic. That homology depends only on $|K|$ is a theorem we will prove in the next section.

§25.5.3 Chain Maps

We want simplicial maps to induce maps on homology, and for that we need the notion of a map of chain complexes.

Definition 25.5.10 (Chain Map)

Let $(C_\bullet, d)$ and $(C'_\bullet, d')$ be chain complexes. A **chain map** $f : C_\bullet \rightarrow C'_\bullet$ is a collection of homomorphisms $f_i : C_i \rightarrow C'_i$ with $f_{i-1} \circ d_i = d'_i \circ f_i$, that is, with $fd = d'f$.

Proposition 25.5.11

A chain map f induces a homomorphism $f_* : H_\bullet(C) \rightarrow H_\bullet(C')$ by $f_*[x] = [f(x)]$, and $(f \circ g)_* = f_* \circ g_*$.

Proof. If $dx = 0$ then $d'f(x) = f(dx) = 0$, so $f(\ker d) \subseteq \ker d'$; and if $x = dy$ then $f(x) = d'f(y)$, so $f(\operatorname{im} d) \subseteq \operatorname{im} d'$. Hence f descends to the quotients. Functoriality is immediate. $\square$

Now let $f : K \rightarrow L$ be a simplicial map, determined by $\hat{f} : \{0, \dots, n\} \rightarrow \{0, \dots, m\}$. The obvious guess is to define $f_\#(e_I) = e_{\hat{f}(I)}$, and this fails for two reasons.

First, if $\hat{f}$ is not injective on I then $e_{\hat{f}(I)}$ has smaller dimension than e_I : for $f : \Delta^1 \rightarrow \Delta^1$ with $e_0, e_1 \mapsto e_0$ we would need $f_\#(e_{01}) = e_0$, which does not preserve grading.

Second, the signs go wrong. For $f : \Delta^1 \rightarrow \Delta^1$ swapping e_0 and e_1 , we would have $f_\#(e_{01}) = e_{01}$, so $df_\#(e_{01}) = e_1 - e_0$, while $f_\#d(e_{01}) = f_\#(e_1 - e_0) = e_0 - e_1$.

The fix for both is to allow *ordered* index tuples and to build the signs in.

Definition 25.5.12

For $I = (i_0, \dots, i_k) \in \{0, \dots, n\}^{k+1}$, define $e_I \in \widetilde{C}_k(\Delta^n)$ by

$$e_I = \begin{cases} 0 & \text{if } I \text{ has a repeated entry,} \\ (-1)^{S(I)} e_{I'} & \text{otherwise,} \end{cases}$$

where I' is the increasing rearrangement of I and $(-1)^{S(I)}$ is the sign of the permutation taking I to I' .

So $e_{102} = -e_{012} = e_{210}$ and $e_{001} = 0$. With this convention the boundary formula holds in general.

Proposition 25.5.13

For any $I \in \{0, \dots, n\}^{k+1}$ we have $d(e_I) = \sum_{j=0}^k (-1)^j e_{I_j}$, where I_j omits the j th entry of the tuple.

Proof. If I has a repeated entry the claim is a direct check: if the repeat is at positions $j_1 \neq j_2$, all terms e_{I_j} with $j \notin \{j_1, j_2\}$ vanish, and the remaining two terms cancel by the sign rule. Otherwise let σ take I to I' ; if i_j sits in position j' in I' then removing it changes the number of inversions by $j - j'$, so $S(I_j) \equiv S(I) + j - j' \pmod{2}$. Hence

$$\begin{aligned} \sum_j (-1)^j e_{I_j} &= \sum_j (-1)^j (-1)^{S(I) + j - j'} e_{(I')_{j'}} \\ &= (-1)^{S(I)} \sum_{j'} (-1)^{j'} e_{(I')_{j'}} = (-1)^{S(I)} d(e_{I'}) = d(e_I). \quad \square \end{aligned}$$

Definition 25.5.14

For a simplicial map $f : K \rightarrow L$ define $f_\# : C_k(K) \rightarrow C_k(L)$ on basis elements by

$$f_\#(e_{i_0 \dots i_k}) = e_{\hat{f}(i_0) \dots \hat{f}(i_k)}.$$

This preserves grading, and collapses degenerate images to zero rather than dropping dimension.

Proposition 25.5.15

$f_\#$ is a chain map.

Proof. Using Proposition 25.5.13 twice,

$$d(f_{\#}(e_I)) = d(e_{f(I)}) = \sum_{j=0}^k (-1)^j e_{(f(I))_j} = f_{\#} \left(\sum_{j=0}^k (-1)^j e_{I_j} \right) = f_{\#}(d(e_I)). \quad \square$$

Example 25.5.16

For $f : \Delta^1 \rightarrow \Delta^1$ with $e_0, e_1 \mapsto e_0$ we get $f_{\#}(e_{01}) = e_{00} = 0$, and for f the swap we get $f_{\#}(e_{01}) = e_{10} = -e_{01}$, so $df_{\#}(e_{01}) = -(e_1 - e_0) = e_0 - e_1 = f_{\#}(de_{01})$. Both problems are fixed.

We write $f_* : H_{\bullet}(K) \rightarrow H_{\bullet}(L)$ for the induced map on homology.

§25.5.4 Chain Homotopies

Homotopic maps of spaces should induce the same map on homology. The algebraic shadow of a homotopy is the following.

Definition 25.5.17 (Chain Homotopy)

Chain maps $f_0, f_1 : (C, d) \rightarrow (C', d')$ are **chain homotopic**, written $f_0 \simeq f_1$, if there are homomorphisms $h_i : C_i \rightarrow C'_{i+1}$ with

$$d'h + hd = f_0 - f_1.$$

We call h a **chain homotopy**.

The formula looks unmotivated until one draws the picture. If $f_0, f_1 : X \rightarrow Y$ are homotopic via H , then H sweeps each simplex σ out into a prism $\sigma \times I$, and the boundary of that prism consists of the two ends $f_0(\sigma)$ and $f_1(\sigma)$ together with the prism on $\partial\sigma$. Writing h for ‘sweep out into a prism’, that reads $dh + hd = f_1 - f_0$, up to signs.

Lemma 25.5.18

If $f_0 \simeq f_1$ then $f_{0*} = f_{1*} : H_{\bullet}(C) \rightarrow H_{\bullet}(C')$.

Proof. Let $[x] \in H_{\bullet}(C)$, so $dx = 0$. Then

$$f_{0*}[x] - f_{1*}[x] = [(f_0 - f_1)x] = [(d'h + hd)x] = [d'h(x)] = 0,$$

since $d'h(x) \in \text{im } d'$. □

Definition 25.5.19

A chain complex (C, d) is **contractible** if $\text{id}_C \simeq 0$.

Lemma 25.5.20

If (C, d) is contractible then $H_\bullet(C) = 0$.

Proof. $[x] = (\text{id})_*[x] = 0_*[x] = 0$ for every class. □

The basic example of a contractible chain complex comes from coning off.

Definition 25.5.21

Let K be an abstract simplicial complex in Δ^n not containing the vertex e_0 . Its **cone** is $C_{e_0}(K) = K \cup \{e_{0I} \mid e_I \in K\}$, an abstract simplicial complex.

Proposition 25.5.22

$\widetilde{C}_\bullet(C_{e_0}(K))$ is contractible, and hence $\widetilde{H}_\bullet(C_{e_0}(K)) = 0$.

Proof. Define $h : \widetilde{C}_k \rightarrow \widetilde{C}_{k+1}$ on basis elements by $h(e_I) = e_{0I}$, noting that this is zero when $0 \in I$. We check $dh + hd = \text{id}$.

If $0 \notin I$ then by Proposition 25.5.13,

$$dh(e_I) = d(e_{0I}) = e_I + \sum_{j=0}^k (-1)^{j+1} e_{0I_j} = e_I - h(de_I),$$

so $dh(e_I) + hd(e_I) = e_I$. If $0 \in I$, say $I = 0J$ with $0 \notin J$, then $h(e_I) = 0$ so $dh(e_I) = 0$, while

$$hd(e_{0J}) = h\left(e_J - \sum_j (-1)^j e_{0J_j}\right) = e_{0J} - 0 = e_I,$$

using $h(e_{0J_j}) = e_{00J_j} = 0$. So $dh + hd = \text{id}$ in both cases. □

Corollary 25.5.23

$H_i(C_{e_0}(K)) = \mathbb{Z}$ for $i = 0$ and 0 otherwise. In particular this holds for $\Delta^n = C_{e_0}(\Delta^n \text{ on } \{1, \dots, n\})$, so a simplex has the homology of a point.

Proof. Write $(\widetilde{C}, \widetilde{d})$ and (C, d) for the reduced and unreduced complexes. For $i > 0$ we have $\ker \widetilde{d}_i = \ker d_i$ and $\text{im } \widetilde{d}_{i+1} = \text{im } d_{i+1}$, so $H_i(C) = \widetilde{H}_i = 0$. In degree 0, $\widetilde{H}_{-1} = 0$ says $\widetilde{d}_0 : \widetilde{C}_0 \rightarrow \langle e_\emptyset \rangle \cong \mathbb{Z}$ is surjective, and $\widetilde{H}_0 = 0$ says $\ker \widetilde{d}_0 = \text{im } \widetilde{d}_1$. Hence

$$\mathbb{Z} \cong \widetilde{C}_0 / \ker \widetilde{d}_0 = \widetilde{C}_0 / \text{im } \widetilde{d}_1 = C_0 / \text{im } d_1 = \ker d_0 / \text{im } d_1 = H_0(C). \quad \square$$

§25.5.5 Exact Sequences

To compute anything beyond cones we need a way of relating the homology of a space to that of its pieces. The algebra behind this is the theory of exact sequences.

Definition 25.5.24 (Exact Sequence)

A sequence of abelian groups and homomorphisms

$$\cdots \rightarrow A_{k+1} \xrightarrow{f_{k+1}} A_k \xrightarrow{f_k} A_{k-1} \rightarrow \cdots$$

is **exact at A_k** if $\ker f_k = \operatorname{im} f_{k+1}$, and **exact** if it is exact everywhere. A **short exact sequence** is an exact sequence of the form

$$0 \rightarrow A \xrightarrow{f} B \xrightarrow{g} C \rightarrow 0.$$

Unwinding: $0 \rightarrow A \rightarrow B$ is exact at A iff f is injective; $B \rightarrow C \rightarrow 0$ is exact at C iff g is surjective; and a short exact sequence says exactly that f is injective, g is surjective, and $C \cong B/f(A)$.

Definition 25.5.25

A **short exact sequence of chain complexes** is a pair of chain maps

$$0 \rightarrow A_\bullet \xrightarrow{f} B_\bullet \xrightarrow{g} C_\bullet \rightarrow 0$$

such that $0 \rightarrow A_k \rightarrow B_k \rightarrow C_k \rightarrow 0$ is exact for every k .

The following is the engine of every homology computation we will do.

Lemma 25.5.26 (Snake Lemma)

Given a short exact sequence of chain complexes as above, there are homomorphisms $\partial_k : H_k(C) \rightarrow H_{k-1}(A)$, the **connecting homomorphisms**, such that the sequence

$$\cdots \rightarrow H_k(A) \xrightarrow{f_*} H_k(B) \xrightarrow{g_*} H_k(C) \xrightarrow{\partial_k} H_{k-1}(A) \xrightarrow{f_*} \cdots$$

is exact. This is the **long exact sequence** of the short exact sequence.

Proof. Construction of ∂_k . Let $[c] \in H_k(C)$, so $dc = 0$.

1. g is surjective, so choose $b \in B_k$ with $g(b) = c$.
2. $g(db) = dg(b) = dc = 0$, so $db \in \ker g = \operatorname{im} f$; choose $a \in A_{k-1}$ with $f(a) = db$.
3. $f(da) = df(a) = d^2b = 0$, and f is injective, so $da = 0$.

We set $\partial_k[c] = [a]$.

$$\begin{array}{ccccccc}
0 & \longrightarrow & A_k & \xrightarrow{f} & B_k & \xrightarrow{g} & C_k \longrightarrow 0 \\
& & \downarrow d & & \downarrow d & \nearrow \partial_k & \downarrow d \\
0 & \longrightarrow & A_{k-1} & \xrightarrow{f} & B_{k-1} & \xrightarrow{g} & C_{k-1} \longrightarrow 0
\end{array}$$

Well-definedness. Suppose $g(b') = c$ too. Then $b - b' \in \ker g = \operatorname{im} f$, say $b - b' = f(\alpha)$. Then $f(a) - f(a') = db - db' = f(d\alpha)$, so $a - a' = d\alpha$ by injectivity of f , and $[a] = [a']$. Now suppose $[c] = [c']$, so $c - c' = d\gamma$ with $\gamma = g(\beta)$ by surjectivity. Replacing b by $b - d\beta$ we may assume b maps to c' , and $d(b - d\beta) = db$, so we get the same a .

Exactness at $H_k(C)$. If $\partial_k[c] = 0$ then $a = d\alpha$ for some $\alpha \in A_k$, and then $d(b - f(\alpha)) = db - f(d\alpha) = db - f(a) = 0$, so $[b - f(\alpha)] \in H_k(B)$ and $g_*[b - f(\alpha)] = [g(b)] = [c]$. Conversely if $[c] = g_*[b]$ with $db = 0$ then in the construction we may take $a = 0$.

Exactness at $H_k(B)$. Certainly $g_*f_* = (gf)_* = 0$. Conversely if $g_*[b] = 0$ then $g(b) = d\gamma$ for some $\gamma \in C_{k+1}$, and choosing β with $g(\beta) = \gamma$ we get $g(b - d\beta) = 0$, so $b - d\beta = f(\alpha)$ for some $\alpha \in A_k$. Then $f(d\alpha) = d(b - d\beta) = 0$, so $d\alpha = 0$ and $[b] = [b - d\beta] = f_*[\alpha]$.

Exactness at $H_{k-1}(A)$. If $[a] = \partial_k[c]$ then $f_*[a] = [db] = 0$. Conversely if $f_*[a] = 0$ then $f(a) = db$ for some $b \in B_k$, and $dg(b) = g(db) = g(f(a)) = 0$, so $[g(b)] \in H_k(C)$ and by construction $\partial_k[g(b)] = [a]$. $\square$

§25.5.6 The Mayer–Vietoris Sequence

Let K_1, K_2 be abstract simplicial complexes in Δ^n . Then $K_1 \cap K_2$ and $K_1 \cup K_2$ are also abstract simplicial complexes, and the inclusions give a commuting square, hence a commuting square of chain maps.

Proposition 25.5.27

The sequence

$$0 \longrightarrow C_\bullet(K_1 \cap K_2) \xrightarrow{i} C_\bullet(K_1) \oplus C_\bullet(K_2) \xrightarrow{j} C_\bullet(K_1 \cup K_2) \longrightarrow 0,$$

with $i(x) = (i_{1\#}x, i_{2\#}x)$ and $j(x, y) = j_{1\#}x - j_{2\#}y$, is a short exact sequence of chain complexes.

Proof. Each $C_\bullet(K)$ has as basis the $e_I \in K$, and the maps $i_\#, j_\#$ send basis elements to basis elements, so we may argue basiswise.

i is injective since $i_{1\#}$ is. Next, $ji = j_{1\#}i_{1\#} - j_{2\#}i_{2\#} = 0$ as the square commutes, so $\operatorname{im} i \subseteq \ker j$. Conversely if $j(x, y) = 0$ then $x = y$ as elements of $C_\bullet(K_1 \cup K_2)$, so all the simplices occurring lie in both K_1 and K_2 , giving $x = y \in C_\bullet(K_1 \cap K_2)$ and $(x, y) = i(x)$.

Finally, if $e_I \in K_1 \cup K_2$ then $e_I \in K_1$ or $e_I \in K_2$, and correspondingly $e_I = j(e_I, 0)$ or $e_I = j(0, -e_I)$. So j is surjective. $\square$

Theorem 25.5.28 (Mayer–Vietoris)

Let K_1, K_2 be abstract simplicial complexes in Δ^n . Then there is a long exact sequence

$$\begin{aligned} \cdots \rightarrow H_k(K_1 \cap K_2) &\xrightarrow{i_*} H_k(K_1) \oplus H_k(K_2) \xrightarrow{j_*} H_k(K_1 \cup K_2) \\ &\xrightarrow{\partial_k} H_{k-1}(K_1 \cap K_2) \xrightarrow{i_*} H_{k-1}(K_1) \oplus H_{k-1}(K_2) \rightarrow \cdots \end{aligned}$$

Proof. Apply the snake lemma to Proposition 25.5.27. $\square$

Example 25.5.29 (Disjoint Unions)

If K_1 and K_2 are disjoint complexes inside a common Δ^n , so that $K_1 \cap K_2 = \{e_\emptyset\}$ and hence $C_\bullet(K_1 \cap K_2) = 0$, the Mayer–Vietoris sequence degenerates to

$$0 \rightarrow H_k(K_1) \oplus H_k(K_2) \rightarrow H_k(K_1 \sqcup K_2) \rightarrow 0,$$

so $H_k(K_1 \sqcup K_2) \cong H_k(K_1) \oplus H_k(K_2)$: homology of a disjoint union is the direct sum.

We can already compute the homology of spheres, using nothing but the long exact sequence.

Theorem 25.5.30

For $n \geq 1$,

$$H_k(\mathbb{S}^n) = \begin{cases} \mathbb{Z} & k = 0, n \\ 0 & \text{otherwise.} \end{cases}$$

Proof. Recall $\mathbb{S}^n = \Delta^{n+1} \setminus \{e_{0\dots(n+1)}\}$ has polyhedron S^n . We induct on n . For $n = 1$ this is Example 25.5.9, since $|\mathbb{S}^1|$ is the boundary of a triangle.

For the inductive step, write $\mathbb{S}^n = K_1 \cup K_2$ where

$$K_1 = \{e_I \mid I \subseteq \{0, \dots, n\}\}, \quad K_2 = \{e_I \mid I \subsetneq \{0, \dots, n+1\}, I \neq \{0, \dots, n\}\}.$$

Both are downward closed, and their union is all of $\mathbb{S}^n$. Now $K_1 = \Delta^n$ is a simplex, while $K_2 = C_{e_{n+1}}(\mathbb{S}^{n-1})$ is a cone on the vertex e_{n+1} , so both have the homology of a point by Corollary 25.5.23; geometrically these are the two hemispheres. Their intersection is $\{e_I \mid I \subsetneq \{0, \dots, n\}\} = \mathbb{S}^{n-1}$, the equator. For $k \geq 2$ the Mayer–Vietoris sequence gives

$$0 \rightarrow H_k(\mathbb{S}^n) \xrightarrow{\partial_k} H_{k-1}(\mathbb{S}^{n-1}) \rightarrow 0,$$

using $H_k(K_1) = H_k(K_2) = H_{k-1}(K_1) = H_{k-1}(K_2) = 0$ for $k \geq 2$. So $H_k(\mathbb{S}^n) \cong H_{k-1}(\mathbb{S}^{n-1})$, which by induction is $\mathbb{Z}$ if $k = n$ and 0 otherwise. For $k = 1$ and $n \geq 2$

the sequence reads

$$0 \rightarrow H_1(\mathbb{S}^n) \rightarrow H_0(\mathbb{S}^{n-1}) \xrightarrow{i_*} H_0(K_1) \oplus H_0(K_2),$$

and $i_* : \mathbb{Z} \rightarrow \mathbb{Z} \oplus \mathbb{Z}$ is injective (it is $x \mapsto (x, x)$), so $H_1(\mathbb{S}^n) = 0$. Finally $H_0(\mathbb{S}^n) = \mathbb{Z}$ since $|\mathbb{S}^n|$ is connected. $\square$

§25.6 The Topological Invariance of Homology

So far homology is an invariant of a *simplicial complex*, not of a space: we have computed $H_\bullet(K)$, and we noticed in Example 25.5.9 that the answer for the n -gon did not depend on n , but we have not shown that this is a general phenomenon. In this section we show that $H_\bullet(K)$ depends only on the homotopy type of $|K|$, and that continuous maps induce homomorphisms. The tool is simplicial approximation.

§25.6.1 Approximations are Chain Homotopic

Lemma 25.6.1

Let $f_0, f_1 : K \rightarrow L$ be simplicial approximations to the same continuous map $F : |K| \rightarrow |L|$. Then for every $\sigma \in K$ there is a simplex $\tau \in L$ containing $f_0(v)$ and $f_1(v)$ for every vertex v of σ .

Proof. Pick $x \in \sigma^\circ$ and let $\tau \in L$ be the unique simplex with $F(x) \in \tau^\circ$. For each vertex v of σ we have $x \in \text{St}_K(v)$, so $F(x) \in \text{St}_L(f_i(v))$ for $i = 0, 1$; and by Lemma 25.4.23(i) this says $f_i(v) \in V(\tau)$. $\square$

Theorem 25.6.2

Let $f_0, f_1 : K \rightarrow L$ be simplicial approximations to the same $F : |K| \rightarrow |L|$. Then $f_{0\#} \simeq f_{1\#}$, and hence $f_{0*} = f_{1*} : H_\bullet(K) \rightarrow H_\bullet(L)$.

Proof. Define the **prism operator** $h : C_k(K) \rightarrow C_{k+1}(L)$ on basis elements by

$$h(e_{i_0 \dots i_k}) = \sum_{j=0}^k (-1)^j e_{\hat{f}_0(i_0) \dots \hat{f}_0(i_j) \hat{f}_1(i_j) \dots \hat{f}_1(i_k)}.$$

Each term is a legitimate element of $C_{k+1}(L)$: by Lemma 25.6.1 all the indices appearing lie in the vertex set of a single simplex $\tau \in L$, so the corresponding face of τ lies in L (or the term is zero, if an index repeats).

It is now a direct computation with the formula of Proposition 25.5.13 that

$$dh + hd = f_{1\#} - f_{0\#}.$$

Indeed, expanding $dh(e_I)$, the terms in which one deletes an index other than the two ‘middle’ ones $\hat{f}_0(i_j), \hat{f}_1(i_j)$ are precisely the terms of $-h(de_I)$, with matching signs. The terms where one of the middle indices is deleted telescope: deleting $\hat{f}_1(i_j)$ from the j th summand cancels against deleting $\hat{f}_0(i_{j+1})$ from the $(j+1)$ st, leaving only the two extreme terms, namely $e_{\hat{f}_1(i_0)\dots\hat{f}_1(i_k)} = f_{1\#}(e_I)$ from $j=0$ and $-e_{\hat{f}_0(i_0)\dots\hat{f}_0(i_k)} = -f_{0\#}(e_I)$ from $j=k$.

So h is a chain homotopy, and Lemma 25.5.18 gives $f_{0*} = f_{1*}$. $\square$

The picture is the same prism as before: $h(\sigma)$ is the simplicial subdivision of $\sigma \times I$, with $f_0(\sigma)$ at the bottom and $f_1(\sigma)$ at the top.

§25.6.2 Induced Maps

To define F_* for a continuous F , we approximate; but the approximation lives on a subdivision of K , so we need to know that subdividing does not change homology.

Theorem 25.6.3

Let K be a simplicial complex. Any simplicial approximation $g : \mathcal{B}(K) \rightarrow K$ to the identity map on $|K| = |\mathcal{B}(K)|$ induces an isomorphism

$$\nu_K = g_* : H_\bullet(\mathcal{B}(K)) \longrightarrow H_\bullet(K),$$

and ν_K does not depend on the choice of g .

Proof sketch. Independence of the choice is Theorem 25.6.2, since any two such g are simplicial approximations to the same map id . (Note that such a g exists: for each vertex w of $\mathcal{B}(K)$ we have $w \in \sigma^\circ$ for a unique $\sigma \in K$, and we may take $\hat{g}(w)$ to be any vertex of σ .)

For the isomorphism, one induces on the skeleta of K . For K a single simplex both $H_\bullet(\mathcal{B}(K))$ and $H_\bullet(K)$ are the homology of a point, by Corollary 25.5.23, and g_* is easily checked to be an isomorphism there. For the inductive step one writes K as the union of its $(n-1)$ -skeleton and its n -simplices, compares the two Mayer–Vietoris sequences using the fact that g is compatible with the decomposition, and applies the five lemma. $\square$

Writing $\nu_{K,r} : H_\bullet(\mathcal{B}^r(K)) \rightarrow H_\bullet(K)$ for the composite $\nu_K \circ \nu_{\mathcal{B}(K)} \circ \dots$, we can now make the key definition.

Definition 25.6.4

Let $F : |K| \rightarrow |L|$ be continuous. By the simplicial approximation theorem there is a simplicial $f : \mathcal{B}^r(K) \rightarrow L$ with $|f| \simeq F$. Define

$$F_* = f_* \circ \nu_{K,r}^{-1} : H_\bullet(K) \longrightarrow H_\bullet(L).$$

Theorem 25.6.5

F_* is well-defined, independent of the choice of r and f . Moreover $(\text{id})_* = \text{id}$ and $(F \circ G)_* = F_* \circ G_*$.

Proof sketch. If $f : \mathcal{B}^r(K) \rightarrow L$ and $f' : \mathcal{B}^{r'}(K) \rightarrow L$ are two simplicial approximations to F , with $r \leq r'$ say, choose a simplicial approximation $g : \mathcal{B}^{r'}(K) \rightarrow \mathcal{B}^r(K)$ to the identity. Then $f \circ g$ and f' are both simplicial approximations to F , so $f_*g_* = f'_*$ by Theorem 25.6.2; and $g_* = \nu_{\mathcal{B}^r(K), r'-r}$, so $f'_*\nu_{K, r'}^{-1} = f_*\nu_{K, r}^{-1}$.

Functoriality follows similarly: if f approximates F and g approximates G (after enough subdivision that the composite makes sense), then $f \circ g$ approximates $F \circ G$. $\square$

Theorem 25.6.6 (Homotopy Invariance)

If $F_0, F_1 : |K| \rightarrow |L|$ are continuous with $F_0 \simeq F_1$, then $F_{0*} = F_{1*}$.

Proof sketch. Let $H : |K| \times I \rightarrow |L|$ be a homotopy. Triangulate $|K| \times I$, which is the polyhedron of a simplicial complex M containing two copies K^0, K^1 of K at the ends. Applying simplicial approximation to H gives a simplicial map $\mathcal{B}^r(M) \rightarrow L$ restricting on the two ends to approximations of F_0 and F_1 ; the inclusions of the ends are homotopy equivalences onto $|M|$ inducing the same map on homology, by the argument of Theorem 25.6.2 applied to the prism. Hence $F_{0*} = F_{1*}$. $\square$

Corollary 25.6.7

If $|K| \simeq |L|$ then $H_\bullet(K) \cong H_\bullet(L)$.

Proof. Let $F : |K| \rightarrow |L|$ and $G : |L| \rightarrow |K|$ with $F \circ G \simeq \text{id}$ and $G \circ F \simeq \text{id}$. Then by Theorems 25.6.5 and 25.6.6, $F_*G_* = \text{id}$ and $G_*F_* = \text{id}$, so F_* is an isomorphism. $\square$

Definition 25.6.8

A space X is **triangulable** if $X \cong |K|$ for some simplicial complex K . In that case we define $H_\bullet(X) = H_\bullet(K)$, which by Corollary 25.6.7 is well-defined.

Not every space is triangulable, or even homotopy equivalent to a triangulable space — the infinite wedge $\bigvee_{i=1}^\infty S^1$ is an example — but every compact manifold and every CW complex we shall meet is.

§25.6.3 First Consequences**Proposition 25.6.9**

If $|K|$ is path connected then $H_0(K) \cong \mathbb{Z}$. In general $H_0(K) \cong \mathbb{Z}^k$ where k is the number of path components of $|K|$.

Proof. $C_0(K)$ is free on the vertices e_i , and every e_i is a cycle. For vertices e_i, e_j , let $F_i : \Delta^0 \rightarrow |K|$ be the map hitting e_i ; then $F_{i*}[e_0] = [e_i]$. If $|K|$ is path connected then $F_i \simeq F_j$, so $[e_i] = [e_j]$ by homotopy invariance. Hence $H_0(K)$ is generated by the single class $[e_0]$. It is non-trivial: the homomorphism $C_0(K) \rightarrow \mathbb{Z}$ sending each $e_i \mapsto 1$ kills $\text{im } d_1$ (as $d(e_{ij}) = e_j - e_i$), so it descends to a surjection $H_0(K) \rightarrow \mathbb{Z}$. Hence $H_0(K) \cong \mathbb{Z}$.

In general $|K|$ is the disjoint union of its path components, each of which is the polyhedron of a subcomplex, and Example 25.5.29 gives the direct sum decomposition. $\square$

Theorem 25.6.10

For $n \geq 1$,

$$H_k(S^n) = \begin{cases} \mathbb{Z} & k = 0, n \\ 0 & \text{otherwise,} \end{cases}$$

and $H_k(D^n) = \mathbb{Z}$ for $k = 0$, zero otherwise. Consequently $S^n \simeq S^m$ implies $n = m$.

Proof. We have $S^n \cong |\mathbb{S}^n|$ and $D^n \cong |\Delta^n|$, so this is Theorem 25.5.30 and Corollary 25.5.23. If $S^n \simeq S^m$ with $n \neq m$, comparing H_n gives $\mathbb{Z} \cong 0$ (taking $n \geq 1$; the case $n = 0$ is clear as S^0 is disconnected). $\square$

Corollary 25.6.11 (Invariance of Dimension)

If $\mathbb{R}^n \cong \mathbb{R}^m$ then $n = m$.

Proof. Take $n, m \geq 1$. A homeomorphism $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$ restricts to a homeomorphism $\mathbb{R}^n \setminus \{0\} \rightarrow \mathbb{R}^m \setminus \{f(0)\}$. By Example 25.1.13 these are homotopy equivalent to S^{n-1} and S^{m-1} respectively, so $S^{n-1} \simeq S^{m-1}$ and hence $n = m$ by Theorem 25.6.10. $\square$

Corollary 25.6.12

For $n \geq 1$ there is no retraction $r : D^n \rightarrow S^{n-1}$.

Proof. Let $j : S^{n-1} \hookrightarrow D^n$ be the inclusion. If r were a retraction then $r \circ j = \text{id}$, so $r_* j_* = \text{id}$ on $H_{n-1}(S^{n-1})$. For $n \geq 2$ this is $\mathbb{Z}$, while $H_{n-1}(D^n) = 0$, so the identity on $\mathbb{Z}$ factors through 0, which is absurd. For $n = 1$ use H_0 : $H_0(S^0) = \mathbb{Z}^2$ and $H_0(D^1) = \mathbb{Z}$, and $\mathbb{Z}^2 \rightarrow \mathbb{Z} \rightarrow \mathbb{Z}^2$ cannot compose to the identity. $\square$

Theorem 25.6.13 (Brouwer Fixed Point Theorem)

Every continuous $F : D^n \rightarrow D^n$ has a fixed point.

Proof. Suppose not, so $F(x) \neq x$ for all x . Define $G : D^n \rightarrow S^{n-1}$ by letting $G(x)$ be the point where the ray from $F(x)$ through x meets S^{n-1} ; we must check this is continuous.

For $p \in D^n$ and $v \in S^{n-1}$, the ray $\{p + tv \mid t \geq 0\}$ meets S^{n-1} where $\|p + tv\|^2 = 1$, that is

$$t^2 + 2t\langle p, v \rangle + \|p\|^2 - 1 = 0, \quad t = -\langle p, v \rangle \pm \sqrt{\langle p, v \rangle^2 + 1 - \|p\|^2},$$

and the discriminant is non-negative since $\|p\| \leq 1$. Taking the larger root,

$$\tau(p, v) = -\langle p, v \rangle + \sqrt{\langle p, v \rangle^2 + 1 - \|p\|^2}$$

is continuous in (p, v) , and so is $P(p, v) = p + \tau(p, v)v$. Hence

$$G(x) = P\left(F(x), \frac{x - F(x)}{\|x - F(x)\|}\right)$$

is continuous, using $x \neq F(x)$. If $x \in S^{n-1}$ then x itself lies on the ray and on the sphere with $t > 0$, so $G(x) = x$. Thus G is a retraction $D^n \rightarrow S^{n-1}$, contradicting Corollary 25.6.12. $\square$

§25.7 Homology Calculations and Applications

We now have a working invariant. In this final section we put it to work: we define the degree of a map of spheres, compute the homology of all the closed surfaces, and establish the Euler characteristic and the Lefschetz fixed point theorem.

§25.7.1 Degree

Since $H_n(S^n) \cong \mathbb{Z}$ for $n \geq 1$, any map $f : S^n \rightarrow S^n$ induces a homomorphism $\mathbb{Z} \rightarrow \mathbb{Z}$, which is multiplication by an integer.

Definition 25.7.1 (Degree)

For $n \geq 1$ and $f : S^n \rightarrow S^n$, the **degree** $\deg f \in \mathbb{Z}$ is defined by

$$f_*(x) = (\deg f) x \quad \text{for all } x \in H_n(S^n) \cong \mathbb{Z}.$$

Note that this is independent of the choice of generator, since -1 times a generator gives the same multiplier.

Proposition 25.7.2

For maps $f, g : S^n \rightarrow S^n$:

1. $\deg \text{id} = 1$ and $\deg(g \circ f) = \deg g \cdot \deg f$;
2. if $f \simeq g$ then $\deg f = \deg g$;
3. if f is constant then $\deg f = 0$;
4. if f is a homotopy equivalence then $\deg f = \pm 1$.

Proof. (i) is functoriality (Theorem 25.6.5) and (ii) is homotopy invariance (Theorem 25.6.6). For (iii), a constant map factors through a point, and $H_n(*) = 0$ for

$n \geq 1$. For (iv), if g is a homotopy inverse then $\deg g \deg f = \deg \text{id} = 1$ in $\mathbb{Z}$. $\square$

Corollary 25.7.3

id_{S^n} is not null-homotopic, so S^n is not contractible.

Proof. $\deg \text{id} = 1 \neq 0 = \deg(\text{constant})$. $\square$

Together with Theorem 25.4.28 this completes the story we began in Section 25.4: for $k < n$ every map $S^k \rightarrow S^n$ is null-homotopic, whereas id_{S^n} is not, so $S^k \not\cong S^n$.

For $n = 1$ this notion of degree agrees with the one we defined via π_1 in Section 2, since both are computed by the winding number of the image loop — for instance, $z \mapsto z^m$ has degree m in both senses.

Example 25.7.4

Let $r : S^n \rightarrow S^n$ be the reflection $(x_0, \dots, x_n) \mapsto (-x_0, x_1, \dots, x_n)$. Then $\deg r = -1$. To see this, triangulate S^n as $|\mathbb{S}^n|$ so that r is simplicial and swaps two vertices $e_0 \leftrightarrow e_1$, fixing the rest; then $r_\#$ acts on the top cycle by transposing two indices, hence by -1 . Consequently the antipodal map $a = (-1)^{\text{all coordinates}}$, being a composite of $n + 1$ reflections, has $\deg a = (-1)^{n+1}$.

§25.7.2 The Homology of Surfaces

We first record a splitting lemma, which lets us read off answers from short exact sequences.

Proposition 25.7.5

If $0 \rightarrow A \rightarrow B \rightarrow \mathbb{Z}^r \rightarrow 0$ is exact, then $B \cong A \oplus \mathbb{Z}^r$.

Proof. Choose $b_i \in B$ mapping to the standard basis vectors of $\mathbb{Z}^r$; this defines a homomorphism $s : \mathbb{Z}^r \rightarrow B$ splitting the surjection, since $\mathbb{Z}^r$ is free. Then $b \mapsto (b - s(g(b)), g(b))$ is an isomorphism $B \rightarrow A \oplus \mathbb{Z}^r$. $\square$

Example 25.7.6 (The Torus)

Triangulate T^2 as $|K|$ and write $K = K_1 \cup K_2$, where $|K_1|$ and $|K_2|$ are the two cylinders obtained by cutting the torus along two parallel circles. Then $|K_i| \simeq S^1$ and $|K_1 \cap K_2| \cong S^1 \sqcup S^1$.

Both inclusions $S^1 \hookrightarrow |K_i|$ of the two boundary circles are homotopy equivalences, and they are homotopic to each other. So on H_1 , writing c_1, c_2 for the classes of the two circles of the intersection, the map $\alpha_1 = i_*$ has matrix

$$\alpha_1 = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} : \mathbb{Z}^2 \rightarrow \mathbb{Z}^2,$$

and the same is true of α_0 on H_0 . Hence $\ker \alpha_k \cong \mathbb{Z}$ and $\text{coker } \alpha_k \cong \mathbb{Z}$ for $k = 0, 1$.

Since $H_2(K_i) = H_2(S^1) = 0$, the Mayer–Vietoris sequence

$$\begin{aligned} 0 \rightarrow H_2(K) \xrightarrow{\partial} H_1(K_1 \cap K_2) \xrightarrow{\alpha_1} H_1(K_1) \oplus H_1(K_2) \rightarrow H_1(K) \\ \xrightarrow{\partial} H_0(K_1 \cap K_2) \xrightarrow{\alpha_0} H_0(K_1) \oplus H_0(K_2) \rightarrow H_0(K) \rightarrow 0 \end{aligned}$$

breaks into short exact sequences

$$\begin{aligned} 0 \rightarrow H_2(K) \rightarrow \ker \alpha_1 \rightarrow 0, \quad 0 \rightarrow \operatorname{coker} \alpha_0 \rightarrow H_0(K) \rightarrow 0, \\ 0 \rightarrow \operatorname{coker} \alpha_1 \rightarrow H_1(K) \rightarrow \ker \alpha_0 \rightarrow 0. \end{aligned}$$

Therefore $H_2(T^2) \cong \mathbb{Z}$, and $H_1(T^2) \cong \mathbb{Z} \oplus \mathbb{Z}$ by Proposition 25.7.5, and $H_0(T^2) \cong \mathbb{Z}$. In summary

$$H_k(T^2) = \begin{cases} \mathbb{Z} & k = 0, 2 \\ \mathbb{Z}^2 & k = 1 \\ 0 & \text{otherwise.} \end{cases}$$

a triangulation of T^2

For higher genus it is cleanest to build the surface out of a wedge of circles and a single disc, exactly as in Example 25.3.23. Write $\Sigma_{g,1}$ for the surface Σ_g with an open disc removed.

Lemma 25.7.7

$\Sigma_{g,1} \simeq \bigvee_{i=1}^{2g} S^1$, and hence

$$H_k(\Sigma_{g,1}) = \begin{cases} \mathbb{Z} & k = 0 \\ \mathbb{Z}^{2g} & k = 1 \\ 0 & \text{otherwise.} \end{cases}$$

Proof. Realise Σ_g as a $4g$ -gon with its boundary identified, and remove an open disc from the interior. What is left deformation retracts radially onto the boundary of the polygon, which after the identifications is $\bigvee_{i=1}^{2g} S^1$. The homology of a wedge of m circles is $H_0 = \mathbb{Z}$, $H_1 = \mathbb{Z}^m$ and 0 above — by induction on m using Mayer–Vietoris with K_1 the first circle and K_2 the rest (thickened slightly so as to intersect in a contractible set). $\square$

Theorem 25.7.8

For the closed orientable surface of genus $g \geq 0$,

$$H_k(\Sigma_g) = \begin{cases} \mathbb{Z} & k = 0, 2 \\ \mathbb{Z}^{2g} & k = 1 \\ 0 & \text{otherwise.} \end{cases}$$

Proof. Write $\Sigma_g = K_1 \cup K_2$ with $|K_1| = \Sigma_{g,1}$ and $|K_2| = D^2$ the disc we removed, so $|K_1 \cap K_2| \cong S^1$. Mayer–Vietoris gives

$$\begin{aligned} 0 \rightarrow H_2(\Sigma_g) &\xrightarrow{\partial} H_1(S^1) \xrightarrow{\iota_*} H_1(\Sigma_{g,1}) \rightarrow H_1(\Sigma_g) \\ &\xrightarrow{\partial} H_0(S^1) \xrightarrow{\alpha_0} H_0(K_1) \oplus H_0(K_2), \end{aligned}$$

using $H_2(K_i) = 0$ from Lemma 25.7.7 and Corollary 25.5.23.

The key point is that $\iota_* : \mathbb{Z} \rightarrow \mathbb{Z}^{2g}$ is the zero map. Under the identification of Lemma 25.7.7, the boundary circle is the loop

$$a_1 b_1 a_1^{-1} b_1^{-1} \cdots a_g b_g a_g^{-1} b_g^{-1},$$

whose class in $H_1(\bigvee S^1) = \mathbb{Z}^{2g}$ is obtained by adding up the signed number of times it traverses each circle. Each generator occurs once forwards and once backwards, so the total is 0.

Hence $\partial : H_2(\Sigma_g) \rightarrow \mathbb{Z}$ is an isomorphism onto $\ker \iota_* = \mathbb{Z}$, giving $H_2(\Sigma_g) \cong \mathbb{Z}$. Also $\mathbb{Z}^{2g} = \text{coker } \iota_* \hookrightarrow H_1(\Sigma_g)$, and $\alpha_0 : \mathbb{Z} \rightarrow \mathbb{Z}^2$ is injective (both components send a point to a point), so $\partial = 0$ on H_1 and the map $\mathbb{Z}^{2g} \rightarrow H_1(\Sigma_g)$ is onto. So $H_1(\Sigma_g) \cong \mathbb{Z}^{2g}$. Finally $H_0(\Sigma_g) \cong \mathbb{Z}$ by connectedness. For $g = 0$ this reduces to $H_\bullet(S^2)$, as it should. $\square$

The same argument handles the non-orientable surfaces. Let N_r be the closed surface obtained from a $2r$ -gon by identifying the edges according to the word $a_1^2 a_2^2 \cdots a_r^2$; equivalently, N_r is the connected sum of r copies of $\mathbb{RP}^2$. So $N_1 = \mathbb{RP}^2$ and $N_2 = K$, the Klein bottle, and $N_{r,1}$, the surface with an open disc removed, is homotopy equivalent to $\bigvee_{i=1}^r S^1$. For $r = 1$ the punctured surface $N_{1,1}$ is the Möbius band, and its boundary circle wraps *twice* around the core.

the Möbius band $N_{1,1}$

Theorem 25.7.9

For $r \geq 1$,

$$H_k(N_r) = \begin{cases} \mathbb{Z} & k = 0 \\ \mathbb{Z}^{r-1} \oplus \mathbb{Z}/2\mathbb{Z} & k = 1 \\ 0 & \text{otherwise.} \end{cases}$$

In particular $H_2(N_r) = 0$ and $H_1(\mathbb{RP}^2) = \mathbb{Z}/2\mathbb{Z}$.

Proof. As before, $N_r = N_{r,1} \cup D^2$ with $N_{r,1} \simeq \bigvee_{i=1}^r S^1$ and intersection S^1 . This time the attaching loop is $a_1^2 \cdots a_r^2$, whose class in $H_1 = \mathbb{Z}^r$ is $(2, 2, \dots, 2)$. So $\iota_* : \mathbb{Z} \rightarrow \mathbb{Z}^r$ is injective, whence $H_2(N_r) = \ker \iota_* = 0$, and

$$H_1(N_r) \cong \text{coker } \iota_* = \mathbb{Z}^r / \langle (2, \dots, 2) \rangle.$$

Changing basis to $u_1 = e_1 + \cdots + e_r$, $u_2 = e_2, \dots, u_r = e_r$, this is $\mathbb{Z}^r / \langle 2u_1 \rangle \cong \mathbb{Z}/2\mathbb{Z} \oplus \mathbb{Z}^{r-1}$, as claimed. (As in the orientable case, α_0 is injective so the sequence terminates correctly.) $\square$

Notice that homology detects non-orientability through torsion, and through the vanishing of H_2 : a closed orientable surface has a fundamental class in H_2 , and a non-orientable one does not. In particular the Σ_g and N_r are pairwise non-homotopy-equivalent, which together with the classification of surfaces says that homology is a complete invariant for closed surfaces.

§25.7.3 The Euler Characteristic

Definition 25.7.10 (Euler Characteristic)

Let K be a simplicial complex. Its **Euler characteristic** is

$$\chi(K) = \sum_k (-1)^k \text{rank } C_k(K),$$

the alternating sum of the numbers of simplices in each dimension.

For a two-dimensional complex this is ‘vertices – edges + faces’, the classical Euler formula. It is not at all obvious from the definition that this depends only on $|K|$, but homology makes it so.

Theorem 25.7.11

$\chi(K) = \sum_k (-1)^k \text{rank } H_k(K)$. In particular $\chi(K)$ depends only on the homotopy type of $|K|$.

Proof. Write $Z_k = \ker d_k$ and $B_k = \text{im } d_{k+1}$, both subgroups of the free abelian group C_k , hence free. Rank-nullity applied to $d_k : C_k \rightarrow C_{k-1}$, whose image is B_{k-1} , gives

$$\text{rank } C_k = \text{rank } Z_k + \text{rank } B_{k-1},$$

and $H_k = Z_k/B_k$ gives $\text{rank } Z_k = \text{rank } H_k + \text{rank } B_k$. Hence

$$\sum_k (-1)^k \text{rank } C_k = \sum_k (-1)^k (\text{rank } H_k + \text{rank } B_k + \text{rank } B_{k-1}),$$

and the B terms cancel in pairs, leaving $\sum_k (-1)^k \text{rank } H_k$. $\square$

Example 25.7.12

From Theorems 25.7.8 and 25.7.9,

$$\chi(\Sigma_g) = 1 - 2g + 1 = 2 - 2g, \quad \chi(N_r) = 1 - (r - 1) + 0 = 2 - r,$$

using that $\mathbb{Z}/2\mathbb{Z}$ has rank 0. So $\chi(S^2) = 2$, $\chi(T^2) = 0$, $\chi(\mathbb{RP}^2) = 1$ and $\chi(K) = 0$ for the Klein bottle. Also $\chi(S^n) = 1 + (-1)^n$.

§25.7.4 The Lefschetz Fixed Point Theorem

Brouwer's theorem said that a self-map of a disc has a fixed point. There is a beautiful generalisation, which computes an obstruction to being fixed-point-free out of the induced maps on homology. For this it is convenient to work with rational coefficients: replacing each $C_k(K) \cong \mathbb{Z}^{n_k}$ by $\mathbb{Q}^{n_k}$ with the same boundary matrices gives a chain complex of $\mathbb{Q}$ -vector spaces, and all the theory goes through verbatim, with $H_k(K; \mathbb{Q})$ a vector space of dimension rank $H_k(K)$.

Definition 25.7.13 (Lefschetz Number)

Let $f : C \rightarrow C$ be a chain map of a finitely generated chain complex of $\mathbb{Q}$ -vector spaces. Its **Lefschetz number** is

$$L(f) = \sum_k (-1)^k \operatorname{tr}(f_k : C_k \rightarrow C_k),$$

and likewise $L(f_*) = \sum_k (-1)^k \operatorname{tr}(f_{k*} : H_k(C) \rightarrow H_k(C))$.

Proposition 25.7.14

$L(f) = L(f_*)$.

Proof. Write $U_k = \operatorname{im} d_{k+1} \subseteq \ker d_k \subseteq C_k$, and choose complements so that $\ker d_k = U_k \oplus V_k$ and $C_k = U_k \oplus V_k \oplus U'_k$. Then d maps U'_k isomorphically onto U_{k-1} and kills $U_k \oplus V_k$, so in block form

$$d = \begin{pmatrix} 0 & 0 & I \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Since f is a chain map it preserves $\ker d$ and $\operatorname{im} d$, so

$$f_k = \begin{pmatrix} A_k & X_k & * \\ 0 & B_k & * \\ 0 & 0 & A'_k \end{pmatrix},$$

and comparing $df = fd$ in the top-right block gives $A_{k-1} = A'_k$. Now $H_k(C) = (U_k \oplus V_k)/U_k \cong V_k$, on which f_{k*} acts by B_k . Hence

$$L(f) = \sum_k (-1)^k (\operatorname{tr} A_k + \operatorname{tr} B_k + \operatorname{tr} A_{k-1}) = \sum_k (-1)^k \operatorname{tr} B_k = L(f_*),$$

because the A terms cancel in consecutive pairs. □

Corollary 25.7.15

$\chi(K) = L(\text{id}) = L(\text{id}_{H_\bullet})$, recovering Theorem 25.7.11.

Definition 25.7.16

For a continuous $F : |K| \rightarrow |K|$, its **Lefschetz number** is $L(F) = L(F_*)$, where $F_* : H_\bullet(K; \mathbb{Q}) \rightarrow H_\bullet(K; \mathbb{Q})$.

Theorem 25.7.17 (Lefschetz Fixed Point Theorem)

Let K be a simplicial complex and $F : |K| \rightarrow |K|$ continuous. If $L(F) \neq 0$ then F has a fixed point.

Proof sketch. Suppose F has no fixed point. As $|K|$ is compact and $x \mapsto \|F(x) - x\|$ is continuous and positive, there is $\varepsilon > 0$ with $\|F(x) - x\| \geq \varepsilon$ for all x .

Subdivide until $\mu(\mathcal{B}^r K) < \varepsilon/3$, and take a simplicial approximation $f : \mathcal{B}^{r+s}(K) \rightarrow \mathcal{B}^r(K)$ to F for suitable s . Then for each simplex σ of $\mathcal{B}^{r+s}(K)$, the image $f(\sigma)$ is at distance at least $\varepsilon/3$ from σ , so $f(\sigma) \neq \sigma$; that is, no basis element of the chain complex is sent to a multiple of itself. Hence every diagonal entry of every matrix f_k vanishes, so $L(f) = 0$, and by Proposition 25.7.14 and the identification of f_* with F_* we get $L(F) = 0$. $\square$

Example 25.7.18

If $|K|$ is contractible then $H_0 = \mathbb{Q}$ and $H_k = 0$ for $k > 0$, and $F_{0*} = \text{id}$ on H_0 since $|K|$ is connected. So $L(F) = 1 \neq 0$ for every F , and every self-map of a contractible polyhedron has a fixed point. Taking $|K| = D^n$ recovers the Brouwer fixed point theorem.

Example 25.7.19

Let $F : S^n \rightarrow S^n$. Then $L(F) = 1 + (-1)^n \deg F$. So if $\deg F \neq (-1)^{n+1}$ then F has a fixed point. In particular any map $S^n \rightarrow S^n$ without a fixed point has the degree of the antipodal map, and any map of S^{2n} of degree 1 — for instance any orientation-preserving homeomorphism — has a fixed point.

Example 25.7.20

Let $F : \Sigma_g \rightarrow \Sigma_g$ with $g \geq 2$, and suppose F acts as the identity on H_1 . Then

$$L(F) = 1 - 2g + \text{tr}(F_{2*}),$$

where F_{2*} is multiplication by the degree d of F . So $L(F) = 1 - 2g + d$, and F has a fixed point unless d happens to equal $2g - 1$. For example, any such F of degree 1 has a fixed point once $g \geq 2$.

We finish with a remark on where all this goes. Simplicial homology is concrete, and that is its virtue for a first course, but the price is the enormous labour of the invariance

theorems: we had to subdivide, approximate, and compare, simply to know that $H_\bullet(K)$ depends only on $|K|$. *Singular* homology, in which one takes the free abelian group on *all* continuous maps $\Delta^n \rightarrow X$, is manifestly a topological invariant and is defined for every space; the price there is that the chain groups are enormous and nothing can be computed directly. The two theories agree on triangulable spaces, and the modern approach is to use singular homology for the theory and simplicial (or cellular) homology for the computations — which is, in effect, what we have been doing all along.

26 Analysis of Functions

Analysis of functions is the study of *spaces* of functions, and of the operations that act on them. The change of viewpoint is a small one to state and an enormous one to work with: instead of asking what a single function does at a single point, we regard a function as one point in an infinite-dimensional space, and we ask about the geometry and topology of that space.

Once we do this, a great deal becomes possible. Questions about partial differential equations turn into questions about linear operators between Banach spaces. Questions about convergence of Fourier series turn into questions about orthonormal bases in a Hilbert space. And the classical obstruction that non-differentiable functions cannot be differentiated simply dissolves: we enlarge the notion of a function until every distribution has derivatives of every order, and then we work out afterwards which of our generalised objects were honest functions all along.

The unifying technique of the course is *compactness by weakening*. In infinite dimensions the closed unit ball is never compact in the norm topology, so bounded sequences need not have convergent subsequences and the classical method of extracting limits fails. The remedy is to weaken the topology until compactness returns, at the price that the limits we obtain are much worse behaved. Recovering the good behaviour afterwards – through convexity, lower semicontinuity, elliptic regularity – is the real work, and the pay-off is the existence of solutions to nonlinear partial differential equations that no explicit formula will ever reach.

This article constitutes my notes for the ‘Analysis of Functions’ course, held in Lent 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§26.1 Introduction

Let me try to say in slightly more detail what the plan is.

We begin, in Section 26.2, with a review of measure and integration. Almost none of this is new – it is the Probability and Measure course, with the probabilistic language stripped out – but we do need it in a hurry and in a slightly different key, so it is worth setting down. The one genuinely new item is Littlewood’s three principles, which are the informal slogans that make measure theory feel like analysis rather than bookkeeping.

Section 26.3 builds the spaces L^p . These are our first examples of Banach spaces made of functions, and essentially everything later in the course is a statement about them or about their relatives. We prove Hölder’s and Minkowski’s inequalities, completeness, and – most importantly for what follows – a collection of density theorems, culminating in the fact that any L^p function ($p < \infty$) can be approximated in norm by smooth compactly supported functions. The tool that does this is *mollification*: convolution with a shrinking bump. It is worth understanding it thoroughly, since it is used on almost every subsequent page.

Section 26.5 is about duality. We compute the dual of L^p , prove the Radon–Nikodým theorem (a measure-theoretic statement, via a Hilbert space argument – an early sign

of how the subject works), and state the Riesz representation theorem which identifies measures as functionals on continuous functions. Section 26.6 then introduces the weak and weak-* topologies, proves Hahn–Banach and Banach–Alaoglu, and so gets us the compactness we were after.

With compactness in hand, Section 26.7 sets out the direct method of the calculus of variations in the abstract: a coercive, lower semicontinuous functional on a suitable space attains its infimum. The delicate point is that coercivity wants a weak topology and lower semicontinuity wants a strong one, and *convexity* is what reconciles them.

Sections 26.8 and 26.9 develop the Fourier transform and distribution theory in parallel, since each is much improved by the other. The Fourier transform is an isometry (up to constants) of L^2 , an isomorphism of the Schwartz space, and – once we have tempered distributions – a bijection of a class of objects large enough to include every polynomial, every bounded function, and the Dirac delta.

Finally Sections 26.10 and 26.11 put everything to work. Sobolev spaces are the function spaces adapted to differential operators; the Sobolev embedding theorem says that enough weak differentiability forces classical differentiability, and the Rellich–Kondrachov theorem provides the compactness that lets the direct method run. We finish by solving the Dirichlet problem, describing the eigenvalues of the Laplacian on a bounded domain, and proving existence of minimisers for a class of variational problems whose Euler–Lagrange equations we could not hope to solve by hand.

§26.2 Measure and Integration

We assume the reader has met the Lebesgue integral. This section is a review: it fixes notation, records the results we shall use constantly, and adds the three theorems of Littlewood that describe how far measurable objects are from classical ones. Everything up to and including the convergence theorems is proved in my Probability and Measure notes, and I shall not repeat those proofs here; the same applies to the relations between the various modes of convergence (almost everywhere, in measure, in L^p), which are set out there in detail and which we use without comment.

§26.2.1 Measure spaces

We recall the basic framework.

Definition 26.2.1 (σ -algebra)

Let E be a set. A collection $\mathcal{E}$ of subsets of E is a **σ -algebra** on E if

- (i) $\emptyset \in \mathcal{E}$;
- (ii) $A \in \mathcal{E} \implies A^c = E \setminus A \in \mathcal{E}$;
- (iii) if $(A_n)_{n \in \mathbb{N}}$ is a sequence in $\mathcal{E}$ then $\bigcup_{n \in \mathbb{N}} A_n \in \mathcal{E}$.

The pair $(E, \mathcal{E})$ is a **measurable space**, and elements of $\mathcal{E}$ are **measurable sets**.

Definition 26.2.2 (Measure)

A **measure** on a measurable space $(E, \mathcal{E})$ is a function $\mu : \mathcal{E} \rightarrow [0, \infty]$ with $\mu(\emptyset) = 0$ which is **countably additive**: if $(A_n)_{n \in \mathbb{N}}$ are disjoint elements of $\mathcal{E}$ then

$$\mu\left(\bigcup_{n \in \mathbb{N}} A_n\right) = \sum_{n \in \mathbb{N}} \mu(A_n).$$

We call $(E, \mathcal{E}, \mu)$ a **measure space**.

Countable additivity is the whole content of the definition; everything else about measures is a consequence of it, together with the elementary manipulations of set theory. In particular a measure is monotone, countably subadditive, and continuous along increasing and (given finiteness) decreasing sequences of sets.

Example 26.2.3

On any set E we may take $\mathcal{E} = 2^E$ and $\mu(A) = \text{card}(A) \in [0, \infty]$, the counting measure. This is not a frivolous example: with $E = \mathbb{N}$ the L^p spaces of the counting measure are the sequence spaces ℓ^p , and every theorem we prove about L^p spaces has a sequence space avatar which is usually easier to think about.

Definition 26.2.4 (Generated σ -algebra)

Given a collection $\mathcal{A}$ of subsets of E , the σ -algebra **generated** by $\mathcal{A}$ is

$$\sigma(\mathcal{A}) = \bigcap_{\substack{\mathcal{E} \supseteq \mathcal{A} \\ \mathcal{E} \text{ a } \sigma\text{-algebra}}} \mathcal{E},$$

the smallest σ -algebra containing $\mathcal{A}$. If $(E, \mathcal{T})$ is a topological space then $\mathcal{B}(E) = \sigma(\mathcal{T})$ is the **Borel σ -algebra**.

The example we care about above all others is Lebesgue measure. Its existence was the main construction of the measure theory course, and we simply quote it.

Theorem 26.2.5 (Lebesgue measure)

There is a σ -algebra $\mathcal{M}$ of subsets of $\mathbb{R}^n$ and a measure λ on $(\mathbb{R}^n, \mathcal{M})$ such that

- (i) $\mathcal{B}(\mathbb{R}^n) \subseteq \mathcal{M}$;
- (ii) if $A = (a_1, b_1] \times \cdots \times (a_n, b_n]$ is a box, with $-\infty < a_i \leq b_i < \infty$, then

$$\lambda(A) = (b_1 - a_1) \cdots (b_n - a_n);$$

- (iii) (**Borel regularity**) $A \in \mathcal{M}$ if and only if for every $\varepsilon > 0$ there are a closed set C and an open set O with $C \subseteq A \subseteq O$ and $\lambda(O \setminus C) < \varepsilon$.

These conditions determine $\mathcal{M}$ and λ uniquely.

We write dx for $d\lambda$ and $|A|$ for $\lambda(A)$ when no confusion can arise. Property (iii) deserves emphasis, because it is the one we shall reach for repeatedly and it is easy to forget that it is available. It says that a Lebesgue measurable set is, up to arbitrarily small error, both an open set and a closed set. This is the rigorous form of Littlewood's first principle, and

it is the engine behind almost every approximation argument in the course: if we want to prove something for all measurable sets, it is usually enough to prove it for boxes and then turn the handle.

Definition 26.2.6 (Measurable function)

Let $(E, \mathcal{E})$ and $(G, \mathcal{G})$ be measurable spaces. A function $f : E \rightarrow G$ is **measurable** if $f^{-1}(A) \in \mathcal{E}$ for all $A \in \mathcal{G}$.

When $(G, \mathcal{G}) = (\mathbb{R}, \mathcal{B}(\mathbb{R}))$ or $(\mathbb{C}, \mathcal{B}(\mathbb{C}))$ we just say ‘ f is measurable on E ’; when $(G, \mathcal{G}) = ([0, \infty], \mathcal{B}([0, \infty]))$ we say f is a non-negative measurable function. Recall that measurability is preserved by the vector space operations, by products, by countable suprema and infima, and by pointwise (indeed almost everywhere) limits. This last stability property is exactly what the Riemann theory lacks and is the reason we work with the Lebesgue integral at all.

§26.2.2 The integral

Definition 26.2.7 (Simple function)

A **simple function** on $(E, \mathcal{E})$ is a function of the form $f = \sum_{k=1}^N a_k \mathbb{1}_{A_k}$ with a_k scalars and $A_k \in \mathcal{E}$.

For a non-negative simple function (which we may always write with $a_k \in [0, \infty]$ and A_k disjoint) we define

$$\mu(f) = \int_E f \, d\mu = \sum_{k=1}^N a_k \mu(A_k),$$

with the convention $0 \cdot \infty = \infty \cdot 0 = 0$. For general non-negative measurable f we set

$$\mu(f) = \int_E f \, d\mu = \sup\{\mu(g) : 0 \leq g \leq f, \, g \text{ simple}\},$$

and finally a measurable f is **integrable** if $\mu(|f|) < \infty$, in which case writing $f = f^+ - f^-$ with $f^\pm \geq 0$ we set $\mu(f) = \mu(f^+) - \mu(f^-)$. Complex-valued f are handled by taking real and imaginary parts.

The integral so defined is linear, monotone, and additive over disjoint sets. The two theorems that make it usable are the following.

Theorem 26.2.8 (Monotone convergence)

If f_n are non-negative measurable with $f_n \uparrow f$ almost everywhere, then $\int_E f_n \, d\mu \uparrow \int_E f \, d\mu$.

Theorem 26.2.9 (Dominated convergence)

Suppose $f_n \rightarrow f$ almost everywhere and $|f_n| \leq g$ almost everywhere for some integrable g . Then f is integrable and $\int_E f_n \, d\mu \rightarrow \int_E f \, d\mu$.

We shall also use Fatou’s lemma ($\int \liminf f_n \leq \liminf \int f_n$ for non-negative f_n) and Fubini–Tonelli, which lets us exchange the order of a double integral provided either the

integrand is non-negative or the double integral converges absolutely. These will be used without comment.

Remark. A remark on the meaning of ' $f \in L^p$ ' that is worth making early. Two functions agreeing almost everywhere have the same integral against everything, and there is no measure-theoretic way to tell them apart. We therefore work throughout with equivalence classes of functions modulo equality almost everywhere, while continuing to write $f(x)$ as though f were a function. This costs us nothing until we want to restrict f to a set of measure zero – for instance to a hypersurface, when solving a boundary value problem – and then it costs us a whole theorem (the trace theorem, Section 26.10).

§26.2.3 Littlewood's three principles

Littlewood wrote in 1944 that there are three principles, roughly expressible as follows: *every measurable set is nearly a finite union of intervals; every measurable function is nearly continuous; every convergent sequence of measurable functions is nearly uniformly convergent.* The word 'nearly' means 'up to a set of arbitrarily small measure'. Each principle is a theorem, and it is instructive to see them proved, both because we use them and because their proofs are a compendium of the standard tricks.

The first principle is Borel regularity, essentially by definition of Lebesgue measure.

Proposition 26.2.10

Let $A \subseteq \mathbb{R}^n$ be measurable with $|A| < \infty$. Then for every $\varepsilon > 0$ there is a finite union B of boxes with $|A \Delta B| < \varepsilon$.

Proof. By Theorem 26.2.5(iii) choose an open $O \supseteq A$ with $|O \setminus A| < \varepsilon/2$. Every open subset of $\mathbb{R}^n$ is a countable disjoint union of half-open dyadic boxes $\bigcup_k Q_k$; since $|O| \leq |A| + \varepsilon/2 < \infty$, the tail $\sum_{k>N} |Q_k|$ can be made smaller than $\varepsilon/2$. Taking $B = \bigcup_{k \leq N} Q_k$ gives

$$|A \Delta B| \leq |O \setminus A| + |O \setminus B| < \varepsilon. \quad \square$$

The third principle is Egorov's theorem. Note that some hypothesis of finite measure is necessary: on $\mathbb{R}$ the functions $f_n = \mathbb{1}_{[n, n+1]}$ converge pointwise to 0 but not uniformly off any set of finite measure.

Theorem 26.2.11 (Egorov)

Let $E \subseteq \mathbb{R}^d$ be measurable with $|E| < \infty$, and let $f_n, f : E \rightarrow \mathbb{C}$ be measurable with $f_n \rightarrow f$ almost everywhere on E . Then for every $\varepsilon > 0$ there is a closed set $A_\varepsilon \subseteq E$ with $|E \setminus A_\varepsilon| < \varepsilon$ and $f_n \rightarrow f$ uniformly on A_ε .

Proof. Discarding a null set, we may assume $f_n \rightarrow f$ everywhere on E . For $n, k \in \mathbb{N}$ put

$$E_k^n = \{x \in E : |f_j(x) - f(x)| < 1/n \text{ for all } j > k\}.$$

For fixed n these increase in k , and their union over k is all of E by pointwise convergence. Since $|E| < \infty$ we have $|E_k^n| \uparrow |E|$, so we may choose k_n with $|E \setminus E_{k_n}^n| < 2^{-n}\varepsilon$.

Set $A' = \bigcap_{n \geq 1} E_{k_n}^n$. Then

$$|E \setminus A'| \leq \sum_{n \geq 1} |E \setminus E_{k_n}^n| < \varepsilon,$$

after replacing ε by $\varepsilon/2$ if we like. And the convergence is uniform on A' : given $\delta > 0$ pick $n > 1/\delta$; then for every $x \in A' \subseteq E_{k_n}^n$ and every $j > k_n$ we have $|f_j(x) - f(x)| < 1/n < \delta$, and the choice of k_n did not depend on x . Finally, Borel regularity lets us shrink A' to a closed A_ε with $|A' \setminus A_\varepsilon|$ as small as we please. $\square$

The second principle is Lusin's theorem, and its proof uses the third.

Theorem 26.2.12 (Lusin)

Let $E \subseteq \mathbb{R}^d$ be measurable with $|E| < \infty$ and let f be measurable and almost everywhere finite on E . Then for every $\varepsilon > 0$ there is a closed $F_\varepsilon \subseteq E$ with $|E \setminus F_\varepsilon| < \varepsilon$ such that $f|_{F_\varepsilon}$ is continuous.

Proof. Suppose first that $f = \sum_{n=1}^m a_n \mathbb{1}_{A_n}$ is simple, with the A_n a partition of E . By Borel regularity choose compact $K_n \subseteq A_n$ with $|A_n \setminus K_n| < \varepsilon/m$, and set $B = \bigcup_{n=1}^m K_n$, so that $|E \setminus B| < \varepsilon$. The sets K_n are compact and disjoint, hence pairwise at positive distance; as f is constant on each K_n it is continuous on B .

For general f , choose simple $f_n \rightarrow f$ almost everywhere, and by the previous paragraph choose measurable C_n with $|C_n| < 2^{-n}$ and f_n continuous on $E \setminus C_n$. By Egorov there is $A \subseteq E$ with $|E \setminus A| < \varepsilon/3$ and $f_n \rightarrow f$ uniformly on A . Pick N with $\sum_{n \geq N} 2^{-n} < \varepsilon/3$ and set

$$F' = A \setminus \bigcup_{n \geq N} C_n,$$

so $|E \setminus F'| < 2\varepsilon/3$. On F' each f_n ($n \geq N$) is continuous and $f_n \rightarrow f$ uniformly, so $f|_{F'}$ is continuous. Borel regularity again produces a closed $F_\varepsilon \subseteq F'$ of nearly the same measure. $\square$

Remark. A word of warning, because this trips up everyone at least once. To say ' $f|_F$ is continuous' is a statement about f restricted to F with its subspace topology; it is emphatically *not* the statement that f , as a function on E , is continuous at each point of F . For a spectacular example take $f = \mathbb{1}_{\mathbb{Q}}$ on $\mathbb{R}$. Then f is continuous at no point whatever, but $f|_{\mathbb{R} \setminus \mathbb{Q}} \equiv 0$ is as continuous as one could wish.

§26.3 L^p Spaces

Every measure space carries with it a family of Banach spaces, one for each $p \in [1, \infty]$, and these are the spaces in which we shall spend the rest of the course. Their theory is a rare thing in analysis: it is genuinely uniform in p , so that a single argument handles a continuum of spaces, and yet the endpoints $p = 1$ and $p = \infty$ are always exceptional, and the exceptions are always interesting.

§26.3.1 Definitions

Definition 26.3.1 (L^p norm)

Let $(E, \mathcal{E}, \mu)$ be a measure space and $f : E \rightarrow \mathbb{C}$ measurable. For $1 \leq p < \infty$ we define

$$\|f\|_{L^p} = \left(\int_E |f|^p d\mu \right)^{1/p},$$

and we define the **essential supremum**

$$\|f\|_{L^\infty} = \operatorname{ess\,sup}_E |f| = \inf \{K \geq 0 : |f| \leq K \text{ almost everywhere}\}.$$

For $1 \leq p \leq \infty$, the L^p **space** over E is

$$L^p(E, \mu) = \{f : E \rightarrow \mathbb{C} \text{ measurable} : \|f\|_{L^p} < \infty\} / \sim,$$

where $f \sim g$ if $f = g$ almost everywhere.

When $(E, \mathcal{E}, \mu) = (\mathbb{R}^n, \mathcal{M}, \lambda)$ we write simply $L^p(\mathbb{R}^n)$, and when $\Omega \subseteq \mathbb{R}^n$ is measurable, $L^p(\Omega)$ means $L^p(\Omega, \lambda|_\Omega)$. The quotient by almost-everywhere equality is not a technicality we can dispense with: without it $\|\cdot\|_{L^p}$ is only a seminorm, since a function supported on a null set has norm zero.

Note that the infimum in the definition of $\operatorname{ess\,sup}$ is attained – if $|f| \leq K_n$ a.e. and $K_n \downarrow K$ then $|f| \leq K$ off the union of countably many null sets – so $|f| \leq \|f\|_{L^\infty}$ almost everywhere, as one would hope.

Example 26.3.2

Let $E = \mathbb{N}$ with counting measure. Then $L^p(\mathbb{N})$ is the sequence space ℓ^p of sequences (a_n) with $\sum |a_n|^p < \infty$ (with the obvious modification at $p = \infty$). Since no non-empty set has measure zero, there is no quotient to take, and ‘almost everywhere’ means ‘everywhere’.

Example 26.3.3

Let $E = [0, 1]$ with Lebesgue measure and $f(x) = x^{-\alpha}$ for $\alpha > 0$. Then $\int_0^1 x^{-\alpha p} dx < \infty$ if and only if $\alpha p < 1$, so $f \in L^p([0, 1])$ exactly when $p < 1/\alpha$. Thus by varying α we can produce a function lying in L^p for all p below any prescribed threshold and in no L^p above it. The spaces really are different.

§26.3.2 Hölder and Minkowski

The two fundamental inequalities both come from convexity. We say $p, q \in [1, \infty]$ are **conjugate exponents** if

$$\frac{1}{p} + \frac{1}{q} = 1,$$

with the convention $1/\infty = 0$; so 1 and ∞ are conjugate, and 2 is self-conjugate.

Lemma 26.3.4 (Young’s inequality)

Let $p, q \in (1, \infty)$ be conjugate and $a, b \geq 0$. Then

$$ab \leq \frac{a^p}{p} + \frac{b^q}{q},$$

with equality if and only if $a^p = b^q$.

Proof. If a or b is zero this is clear, so assume both positive. The logarithm is strictly concave, so

$$\log\left(\frac{a^p}{p} + \frac{b^q}{q}\right) \geq \frac{1}{p} \log(a^p) + \frac{1}{q} \log(b^q) = \log a + \log b = \log(ab),$$

using $1/p + 1/q = 1$, and strict concavity gives equality precisely when $a^p = b^q$. Exponentiating gives the result. $\square$

Theorem 26.3.5 (Hölder's inequality)

Let $p, q \in [1, \infty]$ be conjugate and let $f \in L^p(E, \mu)$, $g \in L^q(E, \mu)$. Then $fg \in L^1(E, \mu)$ and

$$\|fg\|_{L^1} \leq \|f\|_{L^p} \|g\|_{L^q}.$$

Proof. The cases $p = 1, q = \infty$ (and its mirror) are immediate from $|fg| \leq |f| \|g\|_{L^\infty}$ almost everywhere. So suppose $1 < p < \infty$. If either norm is zero the corresponding function vanishes a.e. and there is nothing to prove; and if either is infinite there is nothing to prove either. So normalise: let $F = |f|/\|f\|_{L^p}$ and $G = |g|/\|g\|_{L^q}$, so that $\|F\|_{L^p} = \|G\|_{L^q} = 1$. By Lemma 26.3.4 applied pointwise,

$$FG \leq \frac{F^p}{p} + \frac{G^q}{q},$$

and integrating,

$$\int_E FG \, d\mu \leq \frac{1}{p} \int_E F^p \, d\mu + \frac{1}{q} \int_E G^q \, d\mu = \frac{1}{p} + \frac{1}{q} = 1.$$

Multiplying through by $\|f\|_{L^p} \|g\|_{L^q}$ gives the claim. $\square$

Hölder's inequality is the reason conjugate exponents are worth naming. It says the pairing $(f, g) \mapsto \int fg$ is bounded on $L^p \times L^q$, and we shall see in Section 26.5 that it accounts for *all* bounded linear functionals on L^p when $p < \infty$.

Theorem 26.3.6 (Minkowski's inequality)

Let $1 \leq p \leq \infty$ and $f, g \in L^p(E, \mu)$. Then $f + g \in L^p(E, \mu)$ and

$$\|f + g\|_{L^p} \leq \|f\|_{L^p} + \|g\|_{L^p}.$$

Proof. The cases $p = 1$ and $p = \infty$ are immediate from the pointwise triangle inequality, so take $1 < p < \infty$. Since $|f + g|^p \leq (2 \max(|f|, |g|))^p \leq 2^p(|f|^p + |g|^p)$,

the left-hand side is finite. Now write

$$\int_E |f + g|^p \, d\mu \leq \int_E |f| |f + g|^{p-1} \, d\mu + \int_E |g| |f + g|^{p-1} \, d\mu,$$

and apply Hölder to each term, noting that $|f + g|^{p-1} \in L^q$ with

$$\| |f + g|^{p-1} \|_{L^q} = \left(\int_E |f + g|^{(p-1)q} \, d\mu \right)^{1/q} = \|f + g\|_{L^p}^{p/q}$$

since $(p-1)q = p$. This gives

$$\|f + g\|_{L^p}^p \leq (\|f\|_{L^p} + \|g\|_{L^p}) \|f + g\|_{L^p}^{p/q}.$$

If $\|f + g\|_{L^p} = 0$ we are done; otherwise divide by $\|f + g\|_{L^p}^{p/q}$ and use $p - p/q = 1$. $\square$

So $L^p(E, \mu)$ is a normed vector space. We will also want the following integral form of Minkowski's inequality, which says that 'the norm of an integral is at most the integral of the norms' – a continuous version of the triangle inequality, with the sum replaced by an integral.

Lemma 26.3.7 (Minkowski's integral inequality)

Let $F : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{C}$ be measurable with $F(\cdot, y) \in L^p$ for a.e. y , and let $1 \leq p < \infty$. Then

$$\left(\int_{\mathbb{R}^n} \left| \int_{\mathbb{R}^n} F(x, y) \, dy \right|^p \, dx \right)^{1/p} \leq \int_{\mathbb{R}^n} \left(\int_{\mathbb{R}^n} |F(x, y)|^p \, dx \right)^{1/p} \, dy.$$

Proof. For $p = 1$ this is exactly Tonelli's theorem, so suppose $1 < p < \infty$, and write $G(x) = \int_{\mathbb{R}^n} |F(x, y)| \, dy$, which dominates the modulus of the inner integral on the left. Suppose first that $\|G\|_{L^p} < \infty$. Then, using Tonelli to exchange the order of integration and then Hölder in the x variable,

$$\begin{aligned} \int_{\mathbb{R}^n} G(x)^p \, dx &= \int_{\mathbb{R}^n} G(x)^{p-1} \int_{\mathbb{R}^n} |F(x, y)| \, dy \, dx \\ &= \int_{\mathbb{R}^n} \left(\int_{\mathbb{R}^n} G(x)^{p-1} |F(x, y)| \, dx \right) \, dy \\ &\leq \int_{\mathbb{R}^n} \|G^{p-1}\|_{L^q} \|F(\cdot, y)\|_{L^p} \, dy = \|G\|_{L^p}^{p/q} \int_{\mathbb{R}^n} \|F(\cdot, y)\|_{L^p} \, dy, \end{aligned}$$

since $(p-1)q = p$. If $\|G\|_{L^p} = 0$ there is nothing to prove; otherwise divide by $\|G\|_{L^p}^{p/q}$ and use $p - p/q = 1$.

It remains to remove the assumption $\|G\|_{L^p} < \infty$. Replace F by $F \mathbb{1}_{K \times K'}$ for compact sets K, K' and by $\min(|F|, m)$: for the truncated function G is bounded with bounded support, so the above applies, and the right-hand side only increases if we untruncate. Letting $m \rightarrow \infty$ and $K, K' \uparrow \mathbb{R}^n$, monotone convergence gives the general case. $\square$

§26.3.3 Completeness

The next theorem is the reason L^p spaces are useful rather than merely definable.

Theorem 26.3.8 (Riesz–Fischer)

For every $1 \leq p \leq \infty$, the space $(L^p(E, \mu), \|\cdot\|_{L^p})$ is a Banach space.

Proof. Recall that a normed space is complete if and only if every absolutely convergent series converges. So let (f_k) be a sequence in L^p with $\sum_k \|f_k\|_{L^p} = M < \infty$.

Take first $p < \infty$. Set $g_N = \sum_{k=1}^N |f_k|$ and $g = \sum_{k=1}^\infty |f_k| \in [0, \infty]$, so $g_N \uparrow g$ pointwise. By Minkowski $\|g_N\|_{L^p} \leq M$ for every N , and by monotone convergence applied to $g_N^p \uparrow g^p$,

$$\int_E g^p \, d\mu = \lim_N \int_E g_N^p \, d\mu \leq M^p.$$

In particular $g < \infty$ almost everywhere, so the series $\sum_k f_k(x)$ converges absolutely for almost every x ; call its sum $f(x)$ (and set $f = 0$ on the null set where it does not converge). Then $|f| \leq g$, so $f \in L^p$. Moreover

$$\left| f - \sum_{k=1}^N f_k \right|^p \leq \left(\sum_{k>N} |f_k| \right)^p \leq g^p \in L^1,$$

and the left-hand side tends to 0 pointwise a.e., so dominated convergence gives $\left\| f - \sum_{k \leq N} f_k \right\|_{L^p} \rightarrow 0$ as required.

For $p = \infty$, let $A_k = \{|f_k| > \|f_k\|_{L^\infty}\}$, a null set, and let $A = \bigcup_k A_k$, also null. Off A the series $\sum_k f_k$ converges uniformly by the Weierstrass M -test, to a bounded limit f , and uniform convergence off a null set is exactly convergence in L^∞ . $\square$

The $p = 2$ case is special, because the norm comes from an inner product

$$\langle f, g \rangle_{L^2} = \int_E \bar{f} g \, d\mu,$$

which is finite by Hölder (this is Cauchy–Schwarz). So $L^2(E, \mu)$ is a Hilbert space, and we may use all the geometry – orthogonal projection, orthonormal bases, the Riesz representation theorem – that Hilbert space affords. Much of what we do later works only for $p = 2$ for exactly this reason.

§26.3.4 Inclusions between L^p spaces

It is natural to ask how the spaces $L^p(E, \mu)$ sit relative to one another as p varies. The answer depends entirely on the measure space, and the two extreme cases are worth having clearly in mind.

Proposition 26.3.9

Suppose $\mu(E) < \infty$ and $1 \leq p \leq q \leq \infty$. Then $L^q(E, \mu) \subseteq L^p(E, \mu)$, and

$$\|f\|_{L^p} \leq \mu(E)^{\frac{1}{p} - \frac{1}{q}} \|f\|_{L^q}.$$

Proof. If $q = \infty$ then $\int |f|^p \leq \|f\|_{L^\infty}^p \mu(E)$ directly. Otherwise apply Hölder to the pair $|f|^p \in L^{q/p}$ and $1 \in L^r$ where r is conjugate to q/p :

$$\int_E |f|^p d\mu \leq \left(\int_E |f|^q d\mu \right)^{p/q} \mu(E)^{1-p/q},$$

and take p -th roots. □

On a space of infinite measure the situation is completely different: there are *no* inclusions at all between distinct $L^p(\mathbb{R}^n)$. A function can fail to be in L^p for two quite different reasons – it can be too singular locally, or it can decay too slowly at infinity – and raising p helps with one while hurting the other.

Example 26.3.10

Work on $\mathbb{R}$, and let $1 \leq p < q < \infty$. Then

$$f(x) = |x|^{-1/q} \mathbb{1}_{\{|x|<1\}} \in L^p \setminus L^q, \quad g(x) = |x|^{-1/p} \mathbb{1}_{\{|x|>1\}} \in L^q \setminus L^p.$$

Indeed $\int_0^1 x^{-p/q} dx < \infty$ since $p/q < 1$, while $\int_0^1 x^{-1} dx = \infty$; and $\int_1^\infty x^{-q/p} dx < \infty$ since $q/p > 1$, while $\int_1^\infty x^{-1} dx = \infty$.

The following picture summarises the two situations. On the left, a finite measure space, where the L^p spaces are nested and higher exponents mean smaller spaces; on the right, $\mathbb{R}^n$, where the spaces genuinely overlap and neither contains the other.

There is one general statement that survives on any measure space, and it is a useful one: the L^p norms are logarithmically convex in $1/p$.

Proposition 26.3.11 (Interpolation)

Let $1 \leq p < r < q \leq \infty$ and write $\frac{1}{r} = \frac{\theta}{p} + \frac{1-\theta}{q}$ for some $\theta \in (0, 1)$. Then for measurable f ,

$$\|f\|_{L^r} \leq \|f\|_{L^p}^\theta \|f\|_{L^q}^{1-\theta}.$$

In particular $L^p \cap L^q \subseteq L^r$.

Proof. Suppose that $q < \infty$; the case $q = \infty$ is a similar but easier variant. We factorise $|f|^r = |f|^{\theta r} |f|^{(1-\theta)r}$ and apply Hölder with the pair $p/(\theta r)$ and $q/((1-\theta)r)$,

which are indeed conjugate by the definition of θ :

$$\int |f|^r \leq \left(\int |f|^p \right)^{\theta r/p} \left(\int |f|^q \right)^{(1-\theta)r/q}.$$

Taking r -th roots gives the result. $\square$

§26.3.5 Density of simple functions

Every approximation theorem in this course begins with simple functions, so let us record the basic statement.

Proposition 26.3.12

Let $1 \leq p < \infty$. The set of simple functions s with $\mu(\{s \neq 0\}) < \infty$ is dense in $L^p(E, \mu)$. For $p = \infty$, the simple functions are dense, but the finite-support condition cannot be imposed.

Proof. Let $f \in L^p$ and, splitting into real and imaginary and then positive and negative parts, assume $f \geq 0$. Choose simple $0 \leq s_n \uparrow f$ pointwise (the standard dyadic approximation does this). Then $|f - s_n|^p \leq f^p \in L^1$ and $|f - s_n|^p \rightarrow 0$ pointwise, so $\|f - s_n\|_{L^p} \rightarrow 0$ by dominated convergence. Each s_n has $\mu(\{s_n \neq 0\}) < \infty$: indeed $s_n \leq f$, so on $\{s_n \geq \varepsilon\}$ we have $\mu(\{s_n \geq \varepsilon\}) \leq \varepsilon^{-p} \|f\|_{L^p}^p < \infty$ by Chebyshev, and s_n takes finitely many values.

For $p = \infty$ the dyadic approximation converges uniformly on the set where f is bounded, which is almost everything; but a simple function of finite support cannot approximate the constant function 1 on $\mathbb{R}^n$ in L^∞ . $\square$

Simple functions are, as their name suggests, simple, but they are not *pleasant*: they are discontinuous, and one cannot differentiate them. In Section 26.4 we shall upgrade this density statement dramatically, to smooth compactly supported functions. That is a much more useful statement, and the mechanism which produces it – mollification – is one of the central tools of the course.

§26.3.6 Separability

Definition 26.3.13

A metric space is **separable** if it has a countable dense subset.

Separability is a smallness condition, and we shall need it in two places: to run a diagonal argument in the proof of Banach–Alaoglu, and to know that L^2 has a countable orthonormal basis.

Proposition 26.3.14

For $1 \leq p < \infty$, the space $L^p(\mathbb{R}^n)$ is separable. The space $L^\infty(\mathbb{R}^n)$ is not.

Proof. For separability, consider the countable family $\mathcal{C}$ of finite rational linear combinations of indicators of boxes with rational vertices. Given $f \in L^p$ and $\varepsilon > 0$,

Proposition 26.3.12 produces a simple $s = \sum_{k \leq N} a_k \mathbb{1}_{A_k}$ with finite-measure A_k and $\|f - s\|_{L^p} < \varepsilon/2$. Each $\mathbb{1}_{A_k}$ is approximated in L^p by an indicator of a finite union of rational boxes, by Proposition 26.2.10 together with $\|\mathbb{1}_A - \mathbb{1}_B\|_{L^p} = |A \triangle B|^{1/p}$; and each a_k may be replaced by a nearby rational. So $\mathcal{C}$ is dense.

For L^∞ , note that $\|\mathbb{1}_{B_r(0)} - \mathbb{1}_{B_s(0)}\|_{L^\infty} = 1$ whenever $r \neq s$. This is an uncountable family of points pairwise at distance 1, and no countable set can be dense in such a space (each point of the family needs its own approximant). $\square$

§26.4 Convolution and Mollification

We now come to the single most useful technique in the course. The idea is very simple. Averaging a function against a small smooth bump produces a smooth function, and if the bump is small enough the average is close to the original. So every L^p function ($p < \infty$) is a limit of smooth functions, and any statement which is stable under L^p limits need only be checked for smooth functions.

§26.4.1 Convolution

Definition 26.4.1 (Convolution)

For measurable $f, g : \mathbb{R}^n \rightarrow \mathbb{C}$ we define the **convolution**

$$(f * g)(x) = \int_{\mathbb{R}^n} f(y)g(x - y) \, dy,$$

whenever the integral exists.

The integral certainly exists for every x when, say, $f \in L^1(\mathbb{R}^n)$ and $g \in L^\infty(\mathbb{R}^n)$, or when $f, g \in C_c(\mathbb{R}^n)$; we shall see in a moment exactly how much integrability is needed. The following bookkeeping lemma records the algebraic properties.

Lemma 26.4.2

For $f, g, h \in C_c^\infty(\mathbb{R}^n)$ we have $f * g = g * f$ and $(f * g) * h = f * (g * h)$. Moreover

$$\int_{\mathbb{R}^n} f * g = \left(\int_{\mathbb{R}^n} f \right) \left(\int_{\mathbb{R}^n} g \right).$$

Proof. Commutativity is the substitution $z = x - y$; associativity and the last identity are Fubini together with a change of variables, all of which is justified since everything in sight is continuous and compactly supported. (The hypotheses can be weakened considerably – for instance the last identity holds for $f, g \in L^1$ – but this version suffices for us.) $\square$

Before turning to regularity we should record when the defining integral converges, and in which space the answer lives. The following is the basic estimate, and the case $q = 1$ of it is the one we shall use on almost every subsequent page.

Theorem 26.4.3 (Young's convolution inequality)

Let $1 \leq p \leq \infty$.

- (i) If $f \in L^p(\mathbb{R}^n)$ and $g \in L^1(\mathbb{R}^n)$ then $(f * g)(x)$ converges absolutely for almost every x , and $f * g \in L^p(\mathbb{R}^n)$ with

$$\|f * g\|_{L^p} \leq \|f\|_{L^p} \|g\|_{L^1}.$$

- (ii) If $f \in L^p(\mathbb{R}^n)$ and $g \in L^q(\mathbb{R}^n)$ with q conjugate to p , then $(f * g)(x)$ converges absolutely for every x , and $f * g \in L^\infty(\mathbb{R}^n)$ with $\|f * g\|_{L^\infty} \leq \|f\|_{L^p} \|g\|_{L^q}$.

Proof. (i) For $p = \infty$ this is immediate, so take $p < \infty$ and set $F(x, y) = f(x - y)g(y)$. Then for each fixed y ,

$$\|F(\cdot, y)\|_{L^p} = |g(y)| \left(\int_{\mathbb{R}^n} |f(x - y)|^p dx \right)^{1/p} = |g(y)| \|f\|_{L^p}$$

by translation invariance of Lebesgue measure. Minkowski's integral inequality (Lemma 26.3.7) applied to $|F|$ gives

$$\left(\int_{\mathbb{R}^n} \left(\int_{\mathbb{R}^n} |f(x - y)g(y)| dy \right)^p dx \right)^{1/p} \leq \int_{\mathbb{R}^n} |g(y)| \|f\|_{L^p} dy = \|f\|_{L^p} \|g\|_{L^1}.$$

In particular the inner integral is finite for almost every x , which is the absolute convergence, and the resulting function dominates $|f * g|$.

- (ii) This is Hölder applied at each fixed x , using that $y \mapsto f(x - y)$ has the same L^p norm as f . $\square$

Remark. The two cases are the endpoints of the general statement: if $1 \leq p, q, r \leq \infty$ satisfy $\frac{1}{p} + \frac{1}{q} = 1 + \frac{1}{r}$ then $\|f * g\|_{L^r} \leq \|f\|_{L^p} \|g\|_{L^q}$. One can deduce this from the two cases above by interpolation, or prove it directly by splitting $|f(x - y)g(y)|$ into three factors and applying Hölder with three exponents. We shall not need it.

Convolution is very much a smoothing operation, in a sense the next result makes precise: $f * g$ inherits the *best* regularity of its two factors, not the worst. To state it we need the standard notation for higher derivatives.

Definition 26.4.4 (Multi-index)

An (n) -**multi-index** is an element $\alpha = (\alpha_1, \dots, \alpha_n) \in \mathbb{Z}_{\geq 0}^n$. We write $|\alpha| = \alpha_1 + \dots + \alpha_n$ and $\alpha! = \alpha_1! \dots \alpha_n!$, and for $x \in \mathbb{R}^n$ we write $x^\alpha = x_1^{\alpha_1} \dots x_n^{\alpha_n}$. For $f \in C^k(\mathbb{R}^n)$ with $k \geq |\alpha|$ we write

$$D^\alpha f = \frac{\partial^{|\alpha|} f}{\partial x_1^{\alpha_1} \dots \partial x_n^{\alpha_n}}.$$

Definition 26.4.5

We say $f \in L_{\text{loc}}^p(\mathbb{R}^n)$ if $f \mathbb{1}_K \in L^p(\mathbb{R}^n)$ for every compact $K \subseteq \mathbb{R}^n$.

Theorem 26.4.6

Suppose $f \in L^1_{\text{loc}}(\mathbb{R}^n)$ and $g \in C^k_c(\mathbb{R}^n)$ for some $k \geq 0$. Then $f * g \in C^k(\mathbb{R}^n)$, and $D^\alpha(f * g) = f * D^\alpha g$ for every multi-index α with $|\alpha| \leq k$.

Proof. Write $\tau_\xi f(x) = f(x - \xi)$ for translation. Note that $\tau_\xi(f * g) = f * (\tau_\xi g)$ straight from the definition.

Take $k = 0$ first. Choose R so large that $\text{supp } g \subseteq B_{R-1}(0)$. As $|\xi| \rightarrow 0$ we have $\tau_\xi g \rightarrow g$ pointwise, and $|\tau_\xi g| \leq (\sup |g|)\mathbb{1}_{B_R(0)}$ for $|\xi| < 1$; since f is locally integrable, $|f|(\sup |g|)\mathbb{1}_{B_R(0)}$ is an integrable dominating function on the region that matters. Dominated convergence therefore gives $\tau_\xi(f * g) \rightarrow f * g$ pointwise, i.e. $f * g$ is continuous.

Take $k = 1$. Let $\Delta_i^h g(x) = h^{-1}(g(x + he_i) - g(x))$, so $\Delta_i^h g \rightarrow D_i g$ pointwise as $h \rightarrow 0$. By the mean value theorem $\Delta_i^h g(x) = D_i g(x + te_i)$ for some $|t| \leq |h|$, so $|\Delta_i^h g| \leq (\sup |D_i g|)\mathbb{1}_{B_R(0)}$ for $|h| < 1$, again a legitimate dominating function. Hence, by dominated convergence,

$$\frac{(f * g)(x + he_i) - (f * g)(x)}{h} = (f * \Delta_i^h g)(x) \rightarrow (f * D_i g)(x).$$

So $f * g$ has partial derivatives $f * D_i g$, and these are continuous by the case $k = 0$; hence $f * g \in C^1$. Induction on k finishes the proof. $\square$

The picture to have in mind is that of a fixed bump g being slid across f : the value $(f * g)(x)$ is a weighted average of f over a window centred at x , and moving the window moves the average smoothly, no matter how badly behaved f is inside it.

**§26.4.2 Approximate identities****Definition 26.4.7 (Mollifier)**

Fix $\phi \in C^\infty_c(\mathbb{R}^n)$ with $\phi \geq 0$ and $\int_{\mathbb{R}^n} \phi = 1$, supported in the unit ball. For $\varepsilon > 0$ set

$$\phi_\varepsilon(y) = \varepsilon^{-n} \phi(y/\varepsilon).$$

The family $(\phi_\varepsilon)_{\varepsilon > 0}$ is called a **mollifier**, or an **approximate identity**.

Each ϕ_ε is smooth, non-negative, supported in $B_\varepsilon(0)$, and has integral 1 (the factor ε^{-n} is exactly what is needed for this). So as $\varepsilon \downarrow 0$ the graphs become taller and narrower, converging in a sense we will make precise later to the Dirac delta.

Of course we should check such a ϕ exists, and the standard construction is worth seeing because the same function will reappear when we build test functions in Section 26.9.

Example 26.4.8 (The standard bump)

Define $\psi : \mathbb{R} \rightarrow \mathbb{R}$ by

$$\psi(x) = \begin{cases} \exp\left(\frac{-1}{1-x^2}\right) & |x| < 1, \\ 0 & |x| \geq 1. \end{cases}$$

This is smooth. Away from $x = \pm 1$ this is clear. At $x = \pm 1$, every derivative of ψ on $(-1, 1)$ is of the form $R(x)(1-x^2)^{-m}e^{-1/(1-x^2)}$ for a polynomial R and integer m , and $t^{-m}e^{-1/t} \rightarrow 0$ as $t \downarrow 0$ since the exponential beats every power. So every derivative extends continuously by 0, and $\psi \in C_c^\infty(\mathbb{R})$ with $\text{supp } \psi = [-1, 1]$.

Normalising, $\phi = \psi / \int_{\mathbb{R}} \psi$ is a legitimate mollifier on $\mathbb{R}$; in $\mathbb{R}^n$ one takes $\psi(|x|^2)$ suitably scaled, or simply a product of one-dimensional bumps. The rescaled family ϕ_ε concentrates as $\varepsilon \downarrow 0$:

Each of these has the same area, namely 1.

Before proving that mollification converges, we need one lemma, which says that translation acts continuously on L^p . It is intuitively obvious and genuinely needs proof.

Lemma 26.4.9 (Continuity of translation)

Let $1 \leq p < \infty$ and $g \in L^p(\mathbb{R}^n)$. Then $\|\tau_z g - g\|_{L^p} \rightarrow 0$ as $z \rightarrow 0$.

Proof. This is a density argument of exactly the shape we shall use again and again. First suppose $g = \mathbb{1}_R$ for a box R . Then $\|\tau_z \mathbb{1}_R - \mathbb{1}_R\|_{L^p}^p = |R \Delta (R+z)| \rightarrow 0$ as $z \rightarrow 0$, by direct computation with the side lengths. By linearity the result follows for finite disjoint unions of boxes.

Next let B be measurable with $|B| < \infty$. Given $\varepsilon > 0$, Proposition 26.2.10 gives a finite union of boxes A with $\|\mathbb{1}_A - \mathbb{1}_B\|_{L^p} = |A \Delta B|^{1/p} < \varepsilon$. Since translation is an isometry of L^p ,

$$\|\tau_z \mathbb{1}_B - \mathbb{1}_B\|_{L^p} \leq \|\tau_z \mathbb{1}_B - \tau_z \mathbb{1}_A\|_{L^p} + \|\tau_z \mathbb{1}_A - \mathbb{1}_A\|_{L^p} + \|\mathbb{1}_A - \mathbb{1}_B\|_{L^p} < 3\varepsilon$$

for $|z|$ small enough. Hence the result holds for indicators of finite-measure sets, so for simple functions of finite support, so – again by the isometry of translation and a three-term estimate – for all of L^p by Proposition 26.3.12. $\square$

Remark. This fails for $p = \infty$: take $g = \mathbb{1}_{[0,\infty)}$, for which $\|\tau_z g - g\|_{L^\infty} = 1$ for every $z \neq 0$. The failure is the same one that will prevent us from approximating L^∞ functions by continuous ones.

Theorem 26.4.10 (Mollification)

Let (ϕ_ε) be a mollifier and let $g \in L^p(\mathbb{R}^n)$ with $1 \leq p < \infty$. Then $\phi_\varepsilon * g \in C^\infty(\mathbb{R}^n)$, $\|\phi_\varepsilon * g\|_{L^p} \leq \|g\|_{L^p}$, and

$$\phi_\varepsilon * g \rightarrow g \quad \text{in } L^p(\mathbb{R}^n) \text{ as } \varepsilon \rightarrow 0.$$

Proof. Smoothness is Theorem 26.4.6: the convolution is defined at every point because $\int_{B_\varepsilon(x)} |g| \leq \|g\|_{L^p} \|\mathbb{1}_{B_\varepsilon(x)}\|_{L^q} < \infty$ by Hölder, so $g \in L^1_{\text{loc}}$, and $\phi_\varepsilon \in C_c^\infty$.

For the convergence, we estimate pointwise. Substituting $y = \varepsilon z$ and using $\int \phi = 1$,

$$\begin{aligned} |(\phi_\varepsilon * g)(x) - g(x)| &= \left| \int_{\mathbb{R}^n} \phi_\varepsilon(y) g(x - y) \, dy - g(x) \right| \\ &= \left| \int_{\mathbb{R}^n} \phi(z) (g(x - \varepsilon z) - g(x)) \, dz \right| \\ &\leq \int_{\mathbb{R}^n} \phi(z) |\tau_{\varepsilon z} g(x) - g(x)| \, dz. \end{aligned}$$

Now take L^p norms in x and apply Minkowski's integral inequality (Lemma 26.3.7) to move the norm inside the z -integral:

$$\|\phi_\varepsilon * g - g\|_{L^p} \leq \int_{\mathbb{R}^n} \phi(z) \|\tau_{\varepsilon z} g - g\|_{L^p} \, dz.$$

The integrand is bounded by $2\phi(z) \|g\|_{L^p} \in L^1$ and tends to 0 pointwise in z as $\varepsilon \rightarrow 0$, by Lemma 26.4.9. So the integral tends to 0 by dominated convergence. The norm bound $\|\phi_\varepsilon * g\|_{L^p} \leq \|g\|_{L^p}$ follows from the same application of Minkowski's integral inequality without the subtraction. $\square$

Here is the picture. Convolving a rough function with ϕ_ε rounds off its corners and jumps on the scale ε , and leaves it alone where it was already smooth on that scale.

Corollary 26.4.11

For $1 \leq p < \infty$, the space $C_c^\infty(\mathbb{R}^n)$ is dense in $L^p(\mathbb{R}^n)$.

Proof. Given $g \in L^p$ and $\varepsilon > 0$, first truncate: $g \mathbb{1}_{B_R(0)} \rightarrow g$ in L^p as $R \rightarrow \infty$ by dominated convergence, so we may assume g has compact support. Now $\phi_\delta * g \rightarrow g$ in L^p by Theorem 26.4.10, and $\phi_\delta * g$ is smooth with support contained in the δ -neighbourhood of $\text{supp } g$, hence compact. $\square$

This is not true for $p = \infty$, and the reason is worth stating: a uniform limit of continuous functions is continuous, so no sequence in $C(\mathbb{R}^n)$ can converge in L^∞ to a function with a genuine jump. The space L^∞ is simply too big – it is not separable either – and this is the first of several places where it will have to be treated separately.

Corollary 26.4.12

Suppose $f \in L^1_{\text{loc}}(\Omega)$ for $\Omega \subseteq \mathbb{R}^n$ open and

$$\int_{\Omega} f \varphi \, dx = 0 \quad \text{for all } \varphi \in C_c^\infty(\Omega).$$

Then $f = 0$ almost everywhere.

Proof. Fix a ball B with $\overline{B} \subseteq \Omega$; it suffices to show $f = 0$ a.e. on B . For $x \in B$ and ε smaller than the distance from B to $\partial\Omega$, the function $y \mapsto \phi_\varepsilon(x - y)$ lies in $C_c^\infty(\Omega)$, so the hypothesis gives $(\phi_\varepsilon * f)(x) = 0$. But $f \mathbb{1}_B \in L^1$, so $\phi_\varepsilon * (f \mathbb{1}_B) \rightarrow f \mathbb{1}_B$ in L^1 by Theorem 26.4.10, and for x well inside B these agree. Hence $f = 0$ a.e. on B . $\square$

This innocuous corollary – often called the fundamental lemma of the calculus of variations – is what will allow us to pass from ‘the equation holds when tested against every smooth function’ to ‘the equation holds’. It is used every time we solve a PDE weakly.

§26.4.3 The Lebesgue differentiation theorem

Mollification says that averages of f over small balls converge to f in L^p . It is natural to ask whether they converge *pointwise*, and the answer is yes, almost everywhere. This is a genuinely non-trivial theorem, and the standard proof introduces a tool – the maximal function – which is the beginning of a whole subject.

Definition 26.4.13 (Hardy–Littlewood maximal function)

For $f \in L^1(\mathbb{R}^n)$, define $Mf : \mathbb{R}^n \rightarrow [0, \infty]$ by

$$Mf(x) = \sup_{r>0} \frac{1}{|B_r(x)|} \int_{B_r(x)} |f(y)| \, dy.$$

The maximal function is never in L^1 unless $f = 0$ (it decays like $|x|^{-n}$ at infinity, which is not integrable), so the best we can hope for is the following *weak type* bound.

Lemma 26.4.14

Let $f \in L^1(\mathbb{R}^n)$. Then Mf is measurable and finite almost everywhere, and there

is a constant C_n depending only on n with

$$|\{Mf > \lambda\}| \leq \frac{C_n \|f\|_{L^1}}{\lambda} \quad \text{for all } \lambda > 0.$$

Proof. Write $A_\lambda = \{Mf > \lambda\}$. For each $x \in A_\lambda$ there is $r_x > 0$ with

$$\frac{1}{|B_{r_x}(x)|} \int_{B_{r_x}(x)} |f| > \lambda.$$

We first check A_λ is open (which gives measurability of Mf , since A_λ is a superlevel set). If $x_m \rightarrow x$ with $x \in A_\lambda$, then $\mathbb{1}_{B_{r_x}(x_m)} \rightarrow \mathbb{1}_{B_{r_x}(x)}$ almost everywhere and dominated convergence gives

$$\frac{1}{|B_{r_x}(x_m)|} \int_{B_{r_x}(x_m)} |f| \rightarrow \frac{1}{|B_{r_x}(x)|} \int_{B_{r_x}(x)} |f| > \lambda,$$

so $x_m \in A_\lambda$ for large m . Thus the complement of A_λ is closed under limits, i.e. A_λ is open.

Now let $K \subseteq A_\lambda$ be compact. The balls $\{B_{r_x}(x) : x \in A_\lambda\}$ cover K , so finitely many $B_1, \dots, B_N$ do. By the Wiener covering lemma there is a disjoint subcollection $B_{i_1}, \dots, B_{i_k}$ with $|\bigcup_{i \leq N} B_i| \leq 3^n \sum_{j \leq k} |B_{i_j}|$. Hence

$$|K| \leq 3^n \sum_{j=1}^k |B_{i_j}| \leq \frac{3^n}{\lambda} \sum_{j=1}^k \int_{B_{i_j}} |f| \leq \frac{3^n}{\lambda} \int_{\mathbb{R}^n} |f| = \frac{3^n \|f\|_{L^1}}{\lambda},$$

using disjointness in the last inequality. Taking the supremum over compact $K \subseteq A_\lambda$ and using inner regularity gives $|A_\lambda| \leq 3^n \|f\|_{L^1} / \lambda$. Finally $\{Mf = \infty\} \subseteq A_\lambda$ for every λ , so it is null. $\square$

Theorem 26.4.15 (Lebesgue differentiation theorem)

Let $f \in L^1(\mathbb{R}^n)$. Then for almost every $x \in \mathbb{R}^n$,

$$\lim_{r \rightarrow 0} \frac{1}{|B_r(x)|} \int_{B_r(x)} |f(y) - f(x)| \, dy = 0.$$

Such x are called **Lebesgue points** of f .

The idea of the proof is a beautiful one and is used throughout analysis: the statement is trivially true for continuous functions, continuous functions are dense, and the maximal inequality controls the error made in passing to the limit. This last ingredient is essential – density alone is never enough for a pointwise statement.

Proof. For $\lambda > 0$ let

$$A_\lambda = \left\{ x \in \mathbb{R}^n : \limsup_{r \rightarrow 0} \frac{1}{|B_r(x)|} \int_{B_r(x)} |f(y) - f(x)| \, dy > 2\lambda \right\};$$

it is enough to show $|A_\lambda| = 0$ for every $\lambda > 0$.

Fix $\varepsilon > 0$ and, by Corollary 26.4.11, choose $g \in C_c^\infty(\mathbb{R}^n)$ with $\|f - g\|_{L^1} < \varepsilon$. For any x and r , the triangle inequality gives

$$\begin{aligned} \frac{1}{|B_r(x)|} \int_{B_r(x)} |f(y) - f(x)| \, dy &\leq \frac{1}{|B_r(x)|} \int_{B_r(x)} |f(y) - g(y)| \, dy \\ &\quad + \frac{1}{|B_r(x)|} \int_{B_r(x)} |g(y) - g(x)| \, dy + |g(x) - f(x)|. \end{aligned}$$

The first term is at most $M_{f-g}(x)$ by definition, and the second tends to 0 as $r \rightarrow 0$ by continuity of g . So

$$\limsup_{r \rightarrow 0} \frac{1}{|B_r(x)|} \int_{B_r(x)} |f(y) - f(x)| \, dy \leq M_{f-g}(x) + |f(x) - g(x)|.$$

Consequently, if $x \in A_\lambda$ then either $M_{f-g}(x) > \lambda$ or $|f(x) - g(x)| > \lambda$. By Lemma 26.4.14 the first set has measure at most $C_n \varepsilon / \lambda$, and by Chebyshev's inequality the second has measure at most ε / λ . Hence

$$|A_\lambda| \leq \frac{(1 + C_n)\varepsilon}{\lambda},$$

and since $\varepsilon > 0$ was arbitrary, $|A_\lambda| = 0$. $\square$

Corollary 26.4.16

For $f \in L^1(\mathbb{R}^n)$ and any mollifier (ϕ_ε) , we have $\phi_\varepsilon * f \rightarrow f$ almost everywhere as $\varepsilon \rightarrow 0$.

Proof. At a Lebesgue point x , bounding $\phi_\varepsilon \leq \|\phi\|_{L^\infty} \varepsilon^{-n} \mathbb{1}_{B_\varepsilon(0)}$ gives

$$|(\phi_\varepsilon * f)(x) - f(x)| \leq \int \phi_\varepsilon(y) |f(x - y) - f(x)| \, dy \leq \frac{C}{|B_\varepsilon(x)|} \int_{B_\varepsilon(x)} |f(y) - f(x)| \, dy,$$

which tends to 0. $\square$

Corollary 26.4.17

Let $g \in L^1(\mathbb{R})$ and set $G(x) = \int_{-\infty}^x g(t) \, dt$. Then G is differentiable at almost every x , with $G'(x) = g(x)$.

Proof. At a Lebesgue point x of g we have, for $h > 0$,

$$\begin{aligned} \left| \frac{G(x+h) - G(x)}{h} - g(x) \right| &= \left| \frac{1}{h} \int_x^{x+h} (g(t) - g(x)) \, dt \right| \\ &\leq \frac{2}{|B_h(x)|} \int_{B_h(x)} |g - g(x)| \rightarrow 0, \end{aligned}$$

and similarly for $h < 0$. $\square$

Example 26.4.18

Take $g = \mathbb{1}_{(0,\infty)}$ on $\mathbb{R}$ (which is in L^1_{loc} , and the theorem applies locally). Every $x \neq 0$ is a Lebesgue point, and indeed

$$G(x) = \int_{-\infty}^x g = \begin{cases} 0 & x \leq 0 \\ x & x > 0 \end{cases}$$

is differentiable exactly off 0, with $G' = g$ there. The point $x = 0$ is not a Lebesgue point, and this single bad point is the seed from which the whole theory of distributions grows: we would very much like to say that $G' = g$ and $g' = \delta_0$, and presently we shall.

§26.5 Hilbert Space and Duality

We turn now to the linear structure. The spaces L^p are Banach spaces, and L^2 is a Hilbert space; the point of this section is to see what that buys us. The headline results are a complete description of the dual space of L^p for $p < \infty$, and – as a by-product of the Hilbert space geometry – a proof of the Radon–Nikodým theorem, which is a theorem of measure theory obtained by functional-analytic means. That last is characteristic of the subject: once the spaces are set up correctly, hard-looking measure theory becomes soft linear algebra.

§26.5.1 Orthogonal systems of functions

Throughout, $\mathcal{H}$ denotes a Hilbert space over $\mathbb{C}$ with inner product $\langle \cdot, \cdot \rangle$, conjugate-linear in the first variable. The model to keep in mind is $\mathcal{H} = L^2(E, \mu)$ with $\langle f, g \rangle = \int_E \bar{f}g \, d\mu$.

Definition 26.5.1

A subset $S = \{u_j\}_{j \in J} \subseteq \mathcal{H}$ is **orthogonal** if $\langle u_i, u_j \rangle = 0$ whenever $i \neq j$, and **orthonormal** if in addition $\|u_j\| = 1$ for all j . We say S is **complete** if $\overline{\text{span } S} = \mathcal{H}$, and an orthonormal complete set is an **orthonormal basis**. A Hilbert space is **separable** exactly when it admits a countable orthonormal basis.

If $\{e_n\}_{n \in \mathbb{N}}$ is a countable orthonormal basis then every $x \in \mathcal{H}$ has the expansion

$$x = \sum_{n \in \mathbb{N}} \langle e_n, x \rangle e_n, \quad \|x\|^2 = \sum_{n \in \mathbb{N}} |\langle e_n, x \rangle|^2,$$

the series converging in norm; this is Parseval's identity, and it says that $\mathcal{H} \cong \ell^2$ as soon as $\mathcal{H}$ is separable and infinite-dimensional. Abstractly, then, there is only one separable infinite-dimensional Hilbert space. What makes the subject non-trivial is that the *same* space carries many different natural bases, and that choosing a good one is often the whole problem.

Example 26.5.2

Some orthonormal bases worth knowing.

- (i) The trigonometric system $\{x \mapsto e^{-2\pi i n x} : n \in \mathbb{Z}\}$ is an orthonormal basis of

$L^2((0, 1))$. Orthonormality is a computation; completeness follows either from Stone–Weierstrass (the trigonometric polynomials are dense in the continuous periodic functions in the uniform norm) or from Corollary 26.4.11. This is the classical theory of Fourier series, in one line.

(ii) Let

$$\psi(x) = \begin{cases} 1 & 0 \leq x < 1/2, \\ -1 & 1/2 \leq x < 1, \\ 0 & \text{otherwise,} \end{cases}$$

and set $\psi_{n,k}(x) = 2^{n/2}\psi(2^n x - k)$. Then $\{\psi_{n,k} : n, k \in \mathbb{Z}\}$ is an orthonormal basis of $L^2(\mathbb{R})$, the **Haar system**. It is the simplest example of a wavelet basis, and unlike the trigonometric system its elements are localised in space as well as in frequency.

(iii) Let $\mathcal{H} = L^2(\mathbb{R}, e^{-x^2} dx)$, with inner product $\langle f, g \rangle = \int_{\mathbb{R}} \bar{f} g e^{-x^2} dx$. Applying Gram–Schmidt to the linearly independent family $1, x, x^2, \dots$ produces orthogonal polynomials H_k with $\deg H_k = k$; normalised so that the coefficient of x^k in H_k is 2^k , these are the **Hermite polynomials**, and they form a complete orthogonal set.

The result from Linear Analysis we shall use over and over is the following.

Theorem 26.5.3 (Riesz representation, Hilbert space form)

Let $\mathcal{H}$ be a Hilbert space and $\Lambda : \mathcal{H} \rightarrow \mathbb{C}$ a bounded linear functional. Then there is a unique $w \in \mathcal{H}$ with

$$\Lambda u = \langle w, u \rangle \quad \text{for all } u \in \mathcal{H},$$

and $\|\Lambda\|_{\mathcal{H}'} = \|w\|$.

Proof. We recall the argument. If $\Lambda = 0$ take $w = 0$. Otherwise $K = \ker \Lambda$ is a proper closed subspace, so there is $v \in K^\perp$ with $\|v\| = 1$ (take any $z \notin K$ and subtract its orthogonal projection onto K , which exists because K is closed and convex). For any u , the vector $u - \frac{\Lambda u}{\Lambda v} v$ lies in K , hence is orthogonal to v , so $\langle v, u \rangle = \frac{\Lambda u}{\Lambda v}$. Thus $w = \overline{\Lambda v} v$ works. Uniqueness and the norm identity are immediate. $\square$

§26.5.2 The Radon–Nikodým theorem

Here is a first illustration of the power of Theorem 26.5.3.

Definition 26.5.4

Let μ, ν be measures on a measurable space $(E, \mathcal{E})$. We say ν is **absolutely continuous** with respect to μ , written $\nu \ll \mu$, if $\mu(A) = 0 \implies \nu(A) = 0$ for all $A \in \mathcal{E}$. We say μ and ν are **mutually singular**, written $\mu \perp \nu$, if there is a measurable Z with $\mu(Z) = 0 = \nu(Z^c)$.

Theorem 26.5.5 (Radon–Nikodým)

Let μ, ν be finite measures on $(E, \mathcal{E})$ with $\nu \ll \mu$. Then there is a non-negative $w \in L^1(E, \mu)$ such that

$$\nu(A) = \int_A w \, d\mu \quad \text{for all } A \in \mathcal{E};$$

equivalently, $\int_E F \, d\nu = \int_E Fw \, d\mu$ for every measurable $F : E \rightarrow [0, \infty]$.

Proof. The trick is to introduce two auxiliary measures which are comparable to both μ and ν . Set $\alpha = \mu + 2\nu$ and $\beta = \nu + 2\mu$, both finite. Since $\mu \leq \alpha$ and $\nu \leq \alpha$, we have

$$\mathcal{H} := L^2(E, \alpha) \subseteq L^2(E, \mu) \cap L^2(E, \nu),$$

and every $f \in \mathcal{H}$ is β -integrable. Consider the linear functional

$$\Lambda(f) = \int_E f \, d\beta, \quad f \in \mathcal{H}.$$

It is bounded, since

$$|\Lambda(f)| \leq \int_E |f| \, d\beta = 2 \int_E |f| \, d\mu + \int_E |f| \, d\nu \leq 2 \int_E |f| \, d\alpha \leq 2\sqrt{\alpha(E)} \|f\|_{L^2(\alpha)}$$

by Cauchy–Schwarz. By Theorem 26.5.3 there is $g \in \mathcal{H}$ with

$$\int_E f \, d\beta = \int_E gf \, d\alpha \quad \text{for all } f \in \mathcal{H}.$$

Unwinding the definitions of α and β , this says

$$\int_E (2g - 1)f \, d\nu = \int_E (2 - g)f \, d\mu \quad \text{for all } f \in \mathcal{H}. \quad (*)$$

We claim $\frac{1}{2} \leq g \leq 2$ almost everywhere with respect to both μ and ν . Indeed, let $A_j = \{g < \frac{1}{2} - \frac{1}{j}\}$ and put $f = \mathbb{1}_{A_j}$ in (*):

$$\frac{3}{2}\mu(A_j) \leq \int_E (2 - g)\mathbb{1}_{A_j} \, d\mu = \int_E (2g - 1)\mathbb{1}_{A_j} \, d\nu \leq -\frac{2}{j}\nu(A_j) \leq 0,$$

forcing $\mu(A_j) = 0$ and then $\nu(A_j) = 0$. Letting $j \rightarrow \infty$ gives $g \geq 1/2$ a.e.; the argument at the other end, with $A_j = \{g > 2 + 1/j\}$, gives $g \leq 2$ a.e.

Now let $Z = \{g = 1/2\}$. Putting $f = \mathbb{1}_Z$ in (*) gives $0 = \int_Z (2 - g) \, d\mu \geq \frac{3}{2}\mu(Z)$, so $\mu(Z) = 0$, and hence $\nu(Z) = 0$ by absolute continuity. Given measurable $F : E \rightarrow [0, \infty]$, define on Z^c

$$f = \frac{F}{2g - 1}, \quad w = \frac{2 - g}{2g - 1},$$

and $f = w = 0$ on Z . Both are well defined and bounded multiples of F and 1 respectively, since $2g - 1 \in [0, 3]$ is bounded away from 0 off Z after a further

exhaustion, and applying $(*)$ (first for bounded F , then in general by monotone convergence) gives

$$\int_E F \, d\nu = \int_{Z^c} (2g - 1)f \, d\nu = \int_{Z^c} (2 - g)f \, d\mu = \int_E Fw \, d\mu$$

as required. Taking $F = 1$ shows $w \in L^1(E, \mu)$, and taking $F = \mathbb{1}_A$ gives the stated form. $\square$

§26.5.3 Dual spaces

Definition 26.5.6 (Dual space)

Let X be a topological vector space over $\mathbb{F} = \mathbb{R}$ or $\mathbb{C}$. The **(topological) dual** X' is the vector space of continuous linear functionals $\Lambda : X \rightarrow \mathbb{F}$. If X is normed, we norm X' by

$$\|\Lambda\|_{X'} = \sup_{\|x\|_X \leq 1} |\Lambda(x)|.$$

The space X' is always a Banach space, complete regardless of whether X is, since completeness is inherited from the target field. What is not at all obvious is that X' contains anything: the definition alone does not produce a single non-zero functional. That is the business of the Hahn–Banach theorem, which we prove in Section 26.6; for now we record what we shall need.

Lemma 26.5.7

Let X be a normed space and $x \neq y$ in X . Then there is $\Lambda \in X'$ with $\Lambda(x) \neq \Lambda(y)$.

We defer the proof to Corollary 26.6.9. Granting it, for each $x \in X$ the evaluation map $f_x : X' \rightarrow \mathbb{F}$, $\Lambda \mapsto \Lambda(x)$, is linear and bounded (with $|f_x(\Lambda)| \leq \|x\| \|\Lambda\|$), hence $f_x \in X'' = (X')'$; and Lemma 26.5.7 says $x \mapsto f_x$ is injective. In fact it is isometric, again by Hahn–Banach.

Definition 26.5.8 (Reflexive)

A Banach space X is **reflexive** if the canonical map $X \rightarrow X''$, $x \mapsto f_x$, is surjective (hence an isometric isomorphism), in which case we write $X = X''$.

For a Hilbert space, Theorem 26.5.3 gives a conjugate-linear isometry $\mathcal{H} \rightarrow \mathcal{H}'$; applying it twice shows that every Hilbert space is reflexive. This will matter enormously later: reflexivity is what makes bounded sequences have weakly convergent subsequences.

§26.5.4 The dual of L^p

Fix a measure space $(E, \mathcal{E}, \mu)$ and conjugate exponents p, q . Hölder's inequality says that for $g \in L^q$ the map

$$\Lambda_g(f) = \int_E gf \, d\mu$$

is a bounded linear functional on L^p with $\|\Lambda_g\|_{(L^p)'} \leq \|g\|_{L^q}$. In fact equality holds.

Lemma 26.5.9

For $1 \leq p \leq \infty$ and $g \in L^q$ we have $\|\Lambda_g\|_{(L^p)'} = \|g\|_{L^q}$. Hence $\kappa : L^q \rightarrow (L^p)'$, $g \mapsto \Lambda_g$, is a linear isometry.

Proof. Only ' $\geq$ ' needs proof. Suppose $1 < q < \infty$ and $g \neq 0$; take

$$f = \frac{|g|^{q-1} \overline{\text{sgn } g}}{\|g\|_{L^q}^{q-1}}, \quad \text{so that} \quad \|f\|_{L^p}^p = \frac{\int |g|^{(q-1)p}}{\|g\|_{L^q}^{(q-1)p}} = 1$$

since $(q-1)p = q$. Then $\Lambda_g(f) = \|g\|_{L^q}$. For $q = 1$ take $f = \overline{\text{sgn } g}$, of L^∞ norm 1. For $q = \infty$, given $\varepsilon > 0$ let $A = \{|g| > \|g\|_{L^\infty} - \varepsilon\}$, which has positive measure; assuming μ σ -finite we may shrink it to have finite positive measure, and $f = \mu(A)^{-1} \mathbb{1}_A \overline{\text{sgn } g}$ has $\|f\|_{L^1} = 1$ and $\Lambda_g(f) \geq \|g\|_{L^\infty} - \varepsilon$. $\square$

So L^q sits isometrically inside $(L^p)'$. The theorem is that for $p < \infty$ it is everything.

Theorem 26.5.10

Let $(E, \mathcal{E}, \mu)$ be σ -finite, let $1 \leq p < \infty$ and let q be conjugate to p . Then $\kappa : L^q(E, \mu) \rightarrow L^p(E, \mu)'$ is an isometric isomorphism. We write $L^p(E, \mu)' = L^q(E, \mu)$.

Proof. By Lemma 26.5.9 it remains to prove surjectivity, and by Lemma 26.5.9 again it is enough to produce, for each $\Lambda \in (L^p)'$, some $g \in L^q$ with $\Lambda = \Lambda_g$.

Reduction to real scalars and positive functionals. Writing $f = f_r + if_i$ and $\Lambda_r(f) = \text{Re } \Lambda(f)$, $\Lambda_i(f) = \text{Im } \Lambda(f)$ for real f , a complex functional is determined by a pair of real ones, so we may take the scalars real. A real-linear bounded $\Lambda : L^p(E; \mathbb{R}) \rightarrow \mathbb{R}$ is called **positive** if $\Lambda(f) \geq 0$ whenever $f \geq 0$; one checks (this is on the example sheet, and is the Jordan decomposition in disguise) that every bounded real-linear functional is a difference $\Lambda = \Lambda^+ - \Lambda^-$ of positive bounded ones. So assume Λ positive.

The finite measure case. Suppose first $\mu(E) < \infty$. Define $\nu(A) = \Lambda(\mathbb{1}_A)$ for $A \in \mathcal{E}$. Then $\nu \geq 0$ by positivity, $\nu(\emptyset) = 0$, and ν is finitely additive by linearity. It is countably additive: if $B = \bigcup_{n \geq 1} A_n$ with the A_n disjoint, and $B_k = \bigcup_{n \leq k} A_n$, then

$$\|\mathbb{1}_B - \mathbb{1}_{B_k}\|_{L^p} = \mu(B \setminus B_k)^{1/p} \rightarrow 0,$$

so $\nu(B) - \nu(B_k) = \Lambda(\mathbb{1}_B - \mathbb{1}_{B_k}) \rightarrow 0$ by continuity of Λ . The same computation shows $\mu(A) = 0 \implies \nu(A) = 0$, i.e. $\nu \ll \mu$. By Theorem 26.5.5 there is a non-negative $g \in L^1(E, \mu)$ with $\Lambda(\mathbb{1}_A) = \int_A g \, d\mu$ for all A ; by linearity $\Lambda(f) = \int_E fg \, d\mu$ for all simple f , and hence for all bounded measurable f by dominated convergence.

g lies in L^q . Suppose $1 < p < \infty$. For $N > 0$ let $g_N = \min(g, N)$ and $f_N = g_N^{q-1}$, a bounded function. Then

$$\int_E g_N^q \, d\mu \leq \int_E f_N g \, d\mu = \Lambda(f_N) \leq \|\Lambda\| \|f_N\|_{L^p} = \|\Lambda\| \left(\int_E g_N^q \, d\mu \right)^{1/p},$$

using $(q-1)p = q$. Dividing (the integral is finite as g_N is bounded and $\mu(E) < \infty$) gives $\|g_N\|_{L^q} \leq \|\Lambda\|$, and monotone convergence as $N \rightarrow \infty$ gives $\|g\|_{L^q} \leq \|\Lambda\| < \infty$. For $p = 1$ one argues instead that $\mu(\{g > \|\Lambda\| + \varepsilon\}) = 0$, directly from $\Lambda(\mathbb{1}_A) \leq \|\Lambda\| \mu(A)$, so $g \in L^\infty$. Finally, since $g \in L^q$ the functional Λ_g is bounded on L^p and agrees with Λ on the dense set of simple functions (Proposition 26.3.12), so $\Lambda = \Lambda_g$.

The σ -finite case. Write $E = \bigcup_k E_k$ with $E_k \uparrow$ and $\mu(E_k) < \infty$. Applying the above on each E_k produces $g_k \in L^q(E_k)$ representing Λ on functions supported in E_k ; by uniqueness these are consistent, so they patch to a measurable g on E with $\|g\mathbb{1}_{E_k}\|_{L^q} \leq \|\Lambda\|$ for every k . Monotone convergence gives $g \in L^q$ with $\|g\|_{L^q} \leq \|\Lambda\|$, and $\Lambda = \Lambda_g$ on the dense set of functions supported in some E_k , hence everywhere. $\square$

Corollary 26.5.11

For $1 < p < \infty$, $L^p(\mathbb{R}^n)$ is reflexive.

Proof. $(L^p)'' = (L^q)' = L^p$, and one checks that the composite isomorphism is the canonical embedding. $\square$

The theorem genuinely fails at $p = \infty$: the dual of L^∞ is much larger than L^1 . To see this, note that $C([0, 1]) \subseteq L^\infty([0, 1])$ and $f \mapsto f(0)$ is a bounded functional on $C([0, 1])$; Hahn–Banach extends it to L^∞ , and no $g \in L^1$ can represent it (it vanishes on every f vanishing near 0, which forces $g = 0$ a.e., but the functional is not zero). Correspondingly neither L^1 nor L^∞ is reflexive. This is not a technicality to be regretted: it is why the natural home for many variational problems is L^p with $1 < p < \infty$, and why problems formulated in L^1 (or in the space of measures) are genuinely harder.

§26.5.5 The Riesz representation theorem for measures

There is one more duality worth recording, and it goes the other way: instead of describing functionals in terms of functions, it describes them in terms of *measures*. This is the sense in which a measure ‘is’ a way of integrating continuous functions.

Definition 26.5.12

Let E be a topological space and $\mathcal{E} \supseteq \mathcal{B}(E)$ a σ -algebra. A measure μ on $(E, \mathcal{E})$ is **regular** if for every $A \in \mathcal{E}$ and $\varepsilon > 0$ there are a closed C and an open O with $C \subseteq A \subseteq O$ and $\mu(O \setminus C) < \varepsilon$.

Lebesgue measure on $(\mathbb{R}^n, \mathcal{M})$ is regular, by Theorem 26.2.5(iii). Now if μ is a finite regular measure on $\mathbb{R}^n$, then every $f \in C_c^0(\mathbb{R}^n; \mathbb{R})$ is measurable and bounded, so

$$\Lambda(f) = \int_{\mathbb{R}^n} f \, d\mu$$

defines a positive bounded linear functional on $C_c^0(\mathbb{R}^n; \mathbb{R})$. The question is whether μ can be recovered from Λ , and whether every such Λ arises this way.

Lemma 26.5.13

A finite regular measure μ on $\mathbb{R}^n$ is determined by the functional $\Lambda(f) = \int f \, d\mu$ on $C_c^0(\mathbb{R}^n; \mathbb{R})$.

Proof. We would like to take $f = \mathbb{1}_O$, but indicators are not continuous, so we approximate. Let O be open, and for $k \in \mathbb{N}$ set $O_k = O \cap \{|x| < k\}$ and

$$\chi_k(x) = \begin{cases} 1 & x \in O_k, \text{ dist}(x, O_k^c) \geq 1/k, \\ k \text{ dist}(x, O_k^c) & x \in O_k, \text{ dist}(x, O_k^c) < 1/k, \\ 0 & x \notin O_k. \end{cases}$$

Each χ_k is continuous with compact support (distance functions are 1-Lipschitz) and $\chi_k \uparrow \mathbb{1}_O$ pointwise. By monotone convergence $\Lambda(\chi_k) \rightarrow \mu(O)$. So Λ determines μ on open sets, and hence on all of $\mathcal{E}$ by regularity. $\square$

Theorem 26.5.14 (Riesz–Markov)

Let $\Lambda : C_c^0(\mathbb{R}^n; \mathbb{R}) \rightarrow \mathbb{R}$ be a positive bounded linear functional. Then there is a σ -algebra $\mathcal{M} \supseteq \mathcal{B}(\mathbb{R}^n)$ and a unique finite regular measure μ on it with

$$\Lambda(f) = \int_{\mathbb{R}^n} f \, d\mu \quad \text{for all } f \in C_c^0(\mathbb{R}^n; \mathbb{R}).$$

The proof is a construction of μ from Λ by an outer measure argument – one defines $\mu(O) = \sup\{\Lambda(f) : 0 \leq f \leq 1, \text{supp } f \subseteq O\}$ for open O and extends by regularity – and it is genuinely technical. We shall take it on trust.

Example 26.5.15

Take $\Lambda(f) = f(0)$. This is positive and bounded, and the measure it represents is $\mu = \delta_0$, the Dirac point mass at the origin. The reader who feels that δ_0 ‘should’ be a function will be pleased to know that in Section 26.9 it becomes a perfectly respectable distribution, and that this example is the prototype.

§26.6 Weak Topologies and Compactness

In finite dimensions, the Bolzano–Weierstrass theorem says that bounded sequences have convergent subsequences, and this single fact underlies most existence proofs in analysis: to produce an object with a desired property, construct a bounded sequence of approximations and pass to a limit. In infinite dimensions this fails completely. In ℓ^2 the orthonormal sequence (e_n) is bounded but $\|e_n - e_m\| = \sqrt{2}$ for $n \neq m$, so no subsequence is Cauchy; indeed the closed unit ball of a normed space is compact if and only if the space is finite-dimensional.

The remedy is to keep the sequence and change the topology. If we declare fewer sets to be open, more sets become compact, and with luck we can weaken the topology enough to restore Bolzano–Weierstrass while keeping enough separation to make the limits useful. This section carries that out. We need the Hahn–Banach theorem first, because a weak topology is built from linear functionals and is useless unless there are plenty of them.

§26.6.1 The Hahn–Banach theorem

Hahn–Banach is an extension theorem: a bounded functional defined on a subspace extends to the whole space with the same bound. We work over $\mathbb{R}$; the complex case follows by taking real parts, since a complex-linear Λ is determined by $\ell = \operatorname{Re} \Lambda$ via $\Lambda(x) = \ell(x) - i\ell(ix)$.

For the sake of generality we replace the norm bound by something weaker.

Definition 26.6.1 (Sublinear functional)

A **sublinear functional** on a real vector space X is a map $p : X \rightarrow \mathbb{R}$ with

$$p(x + y) \leq p(x) + p(y), \quad p(tx) = tp(x)$$

for all $x, y \in X$ and $t \geq 0$.

Example 26.6.2

Every seminorm is sublinear, and so is $|\ell|$ for any linear ℓ . But sublinear functionals need not be non-negative or symmetric: on $\mathbb{R}$, $p(x) = x$ is sublinear.

Note that a one-sided bound $\ell(x) \leq p(x)$ automatically gives a two-sided one, since $-\ell(x) = \ell(-x) \leq p(-x)$, whence $-p(-x) \leq \ell(x) \leq p(x)$.

Lemma 26.6.3 (Banach extension lemma)

Let X be a real vector space, p a sublinear functional on X , $M \leq X$ a subspace, and $\ell : M \rightarrow \mathbb{R}$ linear with $\ell \leq p$ on M . Then for any $x \in X \setminus M$ there is a linear $\tilde{\ell}$ on $\widetilde{M} = \operatorname{span}(M \cup \{x\})$ extending ℓ with $\tilde{\ell} \leq p$ on $\widetilde{M}$.

Proof. Every $w \in \widetilde{M}$ is uniquely $w = \lambda x + y$ with $y \in M$, $\lambda \in \mathbb{R}$, so $\tilde{\ell}$ is determined by the single number $a = \tilde{\ell}(x)$, and the problem is to choose a compatibly.

For $y, z \in M$ we have

$$\ell(y) + \ell(z) = \ell(y + z) \leq p(y + z) \leq p(y - x) + p(z + x),$$

so that $\ell(y) - p(y - x) \leq p(z + x) - \ell(z)$ for all $y, z \in M$. Hence

$$a := \sup_{y \in M} (\ell(y) - p(y - x)) \leq \inf_{z \in M} (p(z + x) - \ell(z)) < \infty,$$

and both bounds are finite. By construction $\ell(y) - a \leq p(y - x)$ and $\ell(z) + a \leq p(z + x)$ for all $y, z \in M$. Now take $w = \lambda x + y$. For $\lambda > 0$, apply the second inequality with $z = \lambda^{-1}y$ and multiply by λ ; for $\lambda < 0$, apply the first with $y' = -\lambda^{-1}y$ and multiply by $-\lambda$; for $\lambda = 0$ there is nothing to prove. In each case we get $\tilde{\ell}(w) \leq p(w)$. $\square$

If X/M is finite-dimensional we can now finish by induction, and if X is separable we can finish by a countable induction plus a limiting argument. In general we need a form of the axiom of choice.

Proposition 26.6.4 (Zorn's lemma)

Let $(S, \leq)$ be a non-empty partially ordered set in which every totally ordered subset has an upper bound. Then S has a maximal element.

Theorem 26.6.5 (Hahn–Banach)

Let X be a real vector space, p a sublinear functional on X , $M \leq X$ and $\ell : M \rightarrow \mathbb{R}$ linear with $\ell \leq p$ on M . Then there is a linear $\tilde{\ell} : X \rightarrow \mathbb{R}$ extending ℓ with $\tilde{\ell} \leq p$ on X .

Proof. Let S be the set of pairs (N, ℓ^*) where $M \leq N \leq X$ and $\ell^* : N \rightarrow \mathbb{R}$ is linear, extends ℓ , and satisfies $\ell^* \leq p$ on N . Order S by $(N_1, \ell_1^*) \leq (N_2, \ell_2^*)$ if $N_1 \leq N_2$ and ℓ_2^* extends ℓ_1^* . Then $S \neq \emptyset$ (it contains (M, ℓ)), and any chain $T \subseteq S$ has the upper bound (N_T, ℓ_T) with $N_T = \bigcup_{(N, \ell^*) \in T} N$ – a subspace because T is totally ordered – and ℓ_T the common value. By Proposition 26.6.4 there is a maximal $(\tilde{N}, \tilde{\ell})$; and if $\tilde{N} \neq X$ then Lemma 26.6.3 would extend it further, contradicting maximality. So $\tilde{N} = X$. $\square$

Corollary 26.6.6

Let X be a normed space over $\mathbb{F} = \mathbb{R}$ or $\mathbb{C}$, $M \leq X$, and $\Lambda : M \rightarrow \mathbb{F}$ a bounded linear functional. Then there is $\tilde{\Lambda} \in X'$ extending Λ with $\|\tilde{\Lambda}\|_{X'} = \|\Lambda\|_{M'}$.

Proof. For $\mathbb{F} = \mathbb{R}$ apply Theorem 26.6.5 with $p(x) = \|\Lambda\|_{M'} \|x\|$. For $\mathbb{F} = \mathbb{C}$, write $\Lambda(x) = \ell(x) - i\ell(ix)$ with $\ell = \operatorname{Re} \Lambda$ real-linear; since for each x we may pick θ with $|\Lambda(x)| = \ell(e^{i\theta}x)$, the real and complex norms agree, and extending ℓ then setting $\tilde{\Lambda}(x) = \tilde{\ell}(x) - i\tilde{\ell}(ix)$ does the job. $\square$

Corollary 26.6.7

For any $x \neq 0$ in a normed space X there is $\Lambda \in X'$ with $\|\Lambda\|_{X'} = 1$ and $\Lambda(x) = \|x\|$. Consequently $\|x\| = \sup_{\|\Lambda\|_{X'} \leq 1} |\Lambda(x)|$, and the canonical map $X \rightarrow X''$ is isometric.

Proof. Define $\Lambda(tx) = t\|x\|$ on $M = \mathbb{F}x$, of norm 1, and extend by Corollary 26.6.6. $\square$

§26.6.2 Geometric forms

Hahn–Banach has a geometric face which is often more useful. Recall that $A \subseteq X$ is **convex** if $tx + (1-t)y \in A$ for all $x, y \in A$ and $t \in [0, 1]$. In $\mathbb{R}^n$ one knows that disjoint compact convex sets can be separated by a hyperplane; Hahn–Banach extends this to infinite dimensions, with the linear functional playing the role of the hyperplane.

Theorem 26.6.8 (Geometric Hahn–Banach)

Let A, B be disjoint, non-empty, convex subsets of a real or complex Banach space

X .

(a) If A is open, there are $\Lambda \in X'$ and $\gamma \in \mathbb{R}$ with

$$\operatorname{Re} \Lambda(x) < \gamma \leq \operatorname{Re} \Lambda(y) \quad \text{for all } x \in A, y \in B.$$

If B is also open, the second inequality is strict too.

(b) If A is compact and B is closed, there are $\Lambda \in X'$ and $\gamma_1 < \gamma_2$ with

$$\operatorname{Re} \Lambda(x) < \gamma_1 < \gamma_2 < \operatorname{Re} \Lambda(y) \quad \text{for all } x \in A, y \in B.$$

Proof. We may take X real.

(a) Pick $a_0 \in A$, $b_0 \in B$ and set $x_0 = b_0 - a_0$, and let $C = A - B + x_0$. Then C is convex (a sum of convex sets), open (a union of translates of the open A), and contains 0; and $x_0 \notin C$ since $A \cap B = \emptyset$. Define the **Minkowski gauge**

$$p(x) = \inf\{t > 0 : t^{-1}x \in C\}.$$

One checks (example sheet) that p is sublinear, that $p(x) \leq k\|x\|$ for some $k > 0$ (because C contains a ball about 0), and that $p(y) < 1$ for $y \in C$; since $x_0 \notin C$ we get $p(x_0) \geq 1$.

On $M = \mathbb{R}x_0$ define $f(tx_0) = t$. Then $f \leq p$ on M : for $t > 0$, $f(tx_0) = t \leq tp(x_0) = p(tx_0)$, and for $t \leq 0$, $f(tx_0) = t \leq 0 \leq p(tx_0)$. By Theorem 26.6.5 extend f to a linear Λ on X with $\Lambda \leq p$; then $-k\|x\| \leq -p(-x) \leq \Lambda(x) \leq p(x) \leq k\|x\|$, so $\Lambda \in X'$.

For $a \in A$, $b \in B$ we have $a - b + x_0 \in C$, so

$$\Lambda(a) - \Lambda(b) + 1 = \Lambda(a - b + x_0) \leq p(a - b + x_0) < 1,$$

giving $\Lambda(a) < \Lambda(b)$. Thus $\Lambda(A)$ and $\Lambda(B)$ are convex subsets of $\mathbb{R}$ (that is, intervals) with $\sup \Lambda(A) \leq \inf \Lambda(B)$. As Λ is a non-zero continuous linear map it is open, so $\Lambda(A)$ is an open interval and $\gamma = \sup \Lambda(A)$ is not attained; this is the claim.

(b) Since A is compact, B closed and they are disjoint, $d = \inf\{\|a - b\| : a \in A, b \in B\} > 0$. Let $V = B_{d/2}(0)$; then $A + V$ is open, convex, and disjoint from B , so (a) provides Λ with $\sup \Lambda(A + V) \leq \inf \Lambda(B)$. Since $\Lambda(A)$ is a compact subset of the open set $\Lambda(A + V)$ we may insert the two constants $\gamma_1 < \gamma_2$. $\square$

Pictorially: a point outside a closed convex set can be cut off from it by a hyperplane, with room to spare.

Corollary 26.6.9

For distinct x, y in a normed space X there is $\Lambda \in X'$ with $\Lambda(x) \neq \Lambda(y)$.

Proof. Apply Theorem 26.6.8(b) with $A = \{x\}$ and $B = \{y\}$ (or Corollary 26.6.7 to $x - y$). $\square$

Corollary 26.6.10

Let $M \leq X$ be a subspace with $\overline{M} \neq X$, and let $x_0 \in X \setminus \overline{M}$. Then there is $\Lambda \in X'$ with $\Lambda(x_0) = 1$ and $\Lambda|_M = 0$.

Proof. Take $A = \{x_0\}$, $B = \overline{M}$ in Theorem 26.6.8(b) to get Λ_0 with $\operatorname{Re} \Lambda_0(x_0) < \gamma_1 < \gamma_2 < \operatorname{Re} \Lambda_0(y)$ for $y \in \overline{M}$. Since $\overline{M}$ is a subspace, $\Lambda_0(\overline{M})$ is a subspace of $\mathbb{F}$ bounded away from $\operatorname{Re} \Lambda_0(x_0)$, which forces $\Lambda_0|_M = 0$; then rescale. $\square$

Remark. Corollary 26.6.10 is the standard tool for proving *density*: to show a subspace M is dense in X , it suffices to show that the only $\Lambda \in X'$ vanishing on M is $\Lambda = 0$. This is usually much easier, because we have a concrete description of X' to work with. We shall use exactly this manoeuvre when studying Sobolev spaces.

§26.6.3 Consequences of Baire category

We record, without proof, three theorems from Linear Analysis which all follow from the Baire category theorem (a complete metric space is not a countable union of nowhere dense sets). Their common feature is that they turn a pointwise or algebraic hypothesis into a uniform or topological conclusion. Proofs of all three, and of Baire's theorem itself, are in my Linear Analysis notes; the same is true of the Hilbert space material of Section 26.5 and of the spectral theorem for compact self-adjoint operators, which we shall borrow in Section 26.11.

Theorem 26.6.11 (Principle of uniform boundedness)

Let X be a Banach space, Y a normed space, and $\mathcal{T} \subseteq \mathcal{B}(X, Y)$ a family of bounded operators with $\sup_{T \in \mathcal{T}} \|Tx\| < \infty$ for every $x \in X$. Then $\sup_{T \in \mathcal{T}} \|T\| < \infty$.

Theorem 26.6.12 (Open mapping theorem)

A surjective bounded linear map between Banach spaces is open. In particular a bijective bounded linear map has bounded inverse.

Theorem 26.6.13 (Closed graph theorem)

A linear map between Banach spaces whose graph is closed is bounded.

The consequence we need immediately is the following, which says that weak convergence – defined in a moment – cannot produce unbounded sequences.

Proposition 26.6.14

Let X be a Banach space and (x_n) a sequence with $\Lambda(x_n)$ convergent for every $\Lambda \in X'$. Then $(\|x_n\|)$ is bounded.

Proof. View each x_n as an element f_{x_n} of $X'' = \mathcal{B}(X', \mathbb{F})$, noting X' is a Banach space. For each Λ the sequence $f_{x_n}(\Lambda) = \Lambda(x_n)$ is convergent, hence bounded. By Theorem 26.6.11, $\sup_n \|f_{x_n}\|_{X''} < \infty$; and $\|f_{x_n}\|_{X''} = \|x_n\|$ by Corollary 26.6.7. $\square$

§26.6.4 Seminorms and locally convex spaces

To define the weak topologies properly we need topologies generated not by a norm but by a family of seminorms.

Definition 26.6.15 (Seminorm)

A **seminorm** on a vector space X over $\mathbb{F}$ is a map $p : X \rightarrow \mathbb{R}$ with $p(x + y) \leq p(x) + p(y)$ and $p(\lambda x) = |\lambda|p(x)$.

Taking $\lambda = 0$ gives $p(0) = 0$, and then $0 = p(0) \leq 2p(x)$ shows $p \geq 0$. So a seminorm is a norm except that $p(x) = 0$ need not force $x = 0$. A single seminorm is therefore too coarse to separate points; the idea is to use many of them.

Definition 26.6.16

A family $\mathcal{P}$ of seminorms on X is **separating** if for every $x \neq 0$ there is $p \in \mathcal{P}$ with $p(x) \neq 0$.

Given a separating family $\mathcal{P}$, set $V(p, n) = \{x : p(x) < 1/n\}$ for $p \in \mathcal{P}$ and $n \in \mathbb{N}$, let $\dot{\beta}$ be the collection of finite intersections of such sets, and let $\beta = \{x + B : x \in X, B \in \dot{\beta}\}$.

Theorem 26.6.17

β is a base for a Hausdorff topology $\tau_{\mathcal{P}}$ on X , with respect to which addition, scalar multiplication and every $p \in \mathcal{P}$ are continuous.

Definition 26.6.18

A space of the form $(X, \tau_{\mathcal{P}})$ is a **locally convex topological vector space**, or LCTVS. If $\mathcal{P} = \{p_n\}_{n \in \mathbb{N}}$ is countable, $\tau_{\mathcal{P}}$ is metrisable by

$$d(x, y) = \sum_{n=1}^{\infty} 2^{-n} \frac{p_n(x - y)}{1 + p_n(x - y)},$$

and if this metric is complete we call X a **Fréchet space**.

‘Locally convex’ refers to the fact that the basic neighbourhoods $V(p, n)$ are convex, which is exactly the hypothesis needed for Hahn–Banach separation arguments to work. All the spaces in this course are locally convex; we shall meet Fréchet spaces again when we build test functions.

§26.6.5 Weak and weak-* topologies

Let X be a Banach space. Taking $\mathcal{P} = \{\|\cdot\|\}$ recovers the norm topology, which for contrast we now call the **strong topology** τ_s ; convergence in it, written $x_n \rightarrow x$, means $\|x_n - x\| \rightarrow 0$.

Definition 26.6.19 (Weak topology)

For $\Lambda \in X'$ the map $p_\Lambda(x) = |\Lambda(x)|$ is a seminorm, and the family $\{p_\Lambda : \Lambda \in X'\}$ is separating by Corollary 26.6.9. The topology it generates is the **weak topology** τ_w on X . Thus $x_n \rightharpoonup x$ (x_n converges weakly to x) if and only if

$$\Lambda(x_n) \rightarrow \Lambda(x) \quad \text{for all } \Lambda \in X'.$$

Definition 26.6.20 (Weak-* topology)

The dual X' carries its own strong and weak topologies, but also a third: the family of seminorms $\{p_x : \Lambda \mapsto |\Lambda(x)| : x \in X\}$ generates the **weak-* topology** τ_{w*} on X' . Thus $\Lambda_n \xrightarrow{*} \Lambda$ if and only if $\Lambda_n(x) \rightarrow \Lambda(x)$ for every $x \in X$: weak-* convergence is pointwise convergence of functionals.

Since $X \subseteq X''$, the weak-* topology on X' is coarser than its weak topology, and the two coincide exactly when X is reflexive. Strong convergence implies weak convergence implies weak-* convergence, and none of the implications reverses.

Example 26.6.21

Two examples of weak convergence to 0 without strong convergence, which between them illustrate the two mechanisms available.

- (i) (*Oscillation.*) In $L^2((0, 2\pi))$ let $f_n(x) = \sin(nx)$. Then $\|f_n\|_{L^2} = \sqrt{\pi}$ for all n , so $f_n \not\rightarrow 0$ strongly. But $\int_0^{2\pi} g(x) \sin(nx) \, dx \rightarrow 0$ for every $g \in L^2$: this is true for g in the dense set of trigonometric polynomials by orthogonality, hence for all g by density and uniform boundedness. So $f_n \rightharpoonup 0$. The mass does not go away; it is redistributed into ever higher frequencies, and every fixed test function averages it out.
- (ii) (*Escape to infinity.*) In $L^2(\mathbb{R})$ let $g_n(x) = \phi(x-n)$ for a fixed non-zero bump ϕ . Again $\|g_n\|_{L^2} = \|\phi\|_{L^2}$ is constant, but for $h \in C_c(\mathbb{R})$ the supports eventually separate, so $\int h g_n = 0$ for large n , and density gives $g_n \rightharpoonup 0$. The mass is neither destroyed nor spread out – it simply escapes to infinity.

**Example 26.6.22**

Specialising to our spaces: for $1 \leq p < \infty$ and $f_i, f \in L^p(\mathbb{R}^n)$, we have $f_i \rightharpoonup f$ if and only if

$$\int_{\mathbb{R}^n} g f_i \longrightarrow \int_{\mathbb{R}^n} g f \quad \text{for all } g \in L^q(\mathbb{R}^n),$$

by Theorem 26.5.10. When $1 < p < \infty$ the space is reflexive and this is the same as weak-* convergence. For $f_i \in L^\infty(\mathbb{R}^n) = L^1(\mathbb{R}^n)'$, weak-* convergence means testing against all $g \in L^1$, which is strictly weaker than weak convergence, since $(L^\infty)'$ is strictly bigger than L^1 .

Oscillation is by far the more common of the two mechanisms, and it is worth having a general statement. The following says that a rapidly oscillating periodic function converges weakly to its mean – the oscillations are not damped, they are simply averaged out by any fixed test function.

Proposition 26.6.23 (Oscillating sequences)

Let $g \in L^\infty(\mathbb{R})$ be 1-periodic with mean $\bar{g} = \int_0^1 g(t) \, dt$, and set $g_m(x) = g(mx)$. Then $g_m \xrightarrow{*} \bar{g}$ in $L^\infty(\mathbb{R}) = L^1(\mathbb{R})'$; that is,

$$\int_{\mathbb{R}} h(x) g(mx) \, dx \longrightarrow \bar{g} \int_{\mathbb{R}} h(x) \, dx \quad \text{for every } h \in L^1(\mathbb{R}).$$

Proof. Each g_m has $\|g_m\|_{L^\infty} = \|g\|_{L^\infty}$, so the functionals $\Lambda_m(h) = \int h g_m$ have uniformly bounded norms on $L^1(\mathbb{R})$. A uniformly bounded family of functionals which converges on a dense subset converges everywhere: if $\|\Lambda_m\| \leq C$ and $\Lambda_m(h_0)$ converges for h_0 in a dense set, then for general h and $\varepsilon > 0$ we may pick h_0 with $\|h - h_0\|_{L^1} < \varepsilon$ and estimate $|\Lambda_m(h) - \Lambda_{m'}(h)| \leq 2C\varepsilon + |\Lambda_m(h_0) - \Lambda_{m'}(h_0)|$, so $(\Lambda_m(h))$ is Cauchy.

So it is enough to treat $h = \mathbb{1}_{[a,b]}$, since finite linear combinations of such indicators are dense in $L^1(\mathbb{R})$. Substituting $t = mx$,

$$\int_a^b g(mx) \, dx = \frac{1}{m} \int_{ma}^{mb} g(t) \, dt.$$

The interval $[ma, mb]$ has length $m(b-a)$ and so contains $N_m = \lfloor m(b-a) \rfloor$ complete periods of g , each contributing $\bar{g}$, together with a leftover interval of length at most 1 on which the integral is at most $\|g\|_{L^\infty}$ in modulus. Hence

$$\left| \frac{1}{m} \int_{ma}^{mb} g - \frac{N_m}{m} \bar{g} \right| \leq \frac{\|g\|_{L^\infty}}{m} \rightarrow 0,$$

and $N_m/m \rightarrow b-a$, giving the claim. $\square$

Example 26.6.24

Take $g(x) = \sin(2\pi x)$, so $\bar{g} = 0$ and $u_m(x) = \sin(2\pi mx) \xrightarrow{*} 0$. But now consider $u_m^2 = \sin^2(2\pi mx)$: this is again of the form $G(mx)$ for the 1-periodic $G = \sin^2(2\pi \cdot)$, whose mean is $1/2$, so

$$u_m \xrightarrow{*} 0 \quad \text{while} \quad u_m^2 \xrightarrow{*} \frac{1}{2} \neq 0 = (\text{weak limit of } u_m)^2.$$

This little computation deserves to be remembered, because it is the whole difficulty of the last third of the course in miniature. Weak limits do not commute with nonlinear operations. Any functional built by integrating a nonlinear function of u will therefore fail to be weakly *continuous*, and the best we can hope for is an inequality in one direction. Note which direction we got here: $\frac{1}{2} > 0$, so the limit of $\int u_m^2$ is *larger* than $\int u^2$. That is lower semicontinuity, and Section 26.7 explains why convexity of the integrand always makes it fall this way.

Remark. Two warnings. First, the weak topology is *not* metrisable on an infinite-dimensional space (though it is metrisable on bounded sets when X' is separable), so one must be careful with sequential arguments; we shall always be in the situation where sequences suffice. Second, weak convergence is strictly weaker than strong convergence, but by Proposition 26.6.14 a weakly convergent sequence is still bounded, and one always has

$$\|x\| \leq \liminf_{n \rightarrow \infty} \|x_n\| \quad \text{when } x_n \rightharpoonup x,$$

since $\|x\| = \sup_{\|\Lambda\| \leq 1} |\Lambda(x)| = \sup_{\Lambda} \lim_n |\Lambda(x_n)| \leq \liminf_n \|x_n\|$. The norm can drop in the limit – it did in both parts of Example 26.6.21, from a positive constant to 0 – but it cannot jump up. This inequality, **weak lower semicontinuity of the norm**, is the single most useful property of weak convergence, and everything in Section 26.7 is built on it.

§26.6.6 Banach–Alaoglu

Now the pay-off. It is worth recalling first the one compactness theorem for function spaces that we already have, from the topology of $C(K)$: it buys strong (uniform) convergence, but at the price of a hypothesis – equicontinuity – that is much too strong to verify in practice.

Theorem 26.6.25 (Arzelà–Ascoli, a weak form)

Let (f_i) be a sequence of functions $[0, 1] \rightarrow \mathbb{C}$ which is bounded and equicontinuous. Then (f_i) has a uniformly convergent subsequence.

What follows is the trade we advertised: we drop equicontinuity entirely, keep only boundedness, and accept a much weaker form of convergence in exchange.

Theorem 26.6.26 (Banach–Alaoglu)

Let X be a normed space and $\overline{B}' = \{\Lambda \in X' : \|\Lambda\|_{X'} \leq 1\}$ the closed unit ball of the dual. Then $\overline{B}'$ is compact in the weak-* topology.

The general statement is proved by embedding $\overline{B}'$ into the product $\prod_{x \in X} \{z : |z| \leq \|x\|\}$ and applying Tychonoff's theorem, and therefore uses the axiom of choice in an essential way. For our purposes a sequential version on separable spaces is enough, and it can be proved by hand with a diagonal argument.

Theorem 26.6.27 (Banach–Alaoglu, sequential form)

Let X be a separable Banach space and let $(\Lambda_j)_{j=1}^\infty$ be a sequence in $\overline{B}' \subseteq X'$. Then there is a subsequence (Λ_{j_k}) and $\Lambda \in \overline{B}'$ with $\Lambda_{j_k} \xrightarrow{*} \Lambda$.

Proof. Let $D = \{x_1, x_2, \dots\}$ be a countable dense subset of X .

Diagonal extraction. The sequence $(\Lambda_j(x_1))_j$ is bounded in $\mathbb{F}$, since $|\Lambda_j(x_1)| \leq \|x_1\|$. By Bolzano–Weierstrass some subsequence converges, to a limit we call $\Lambda(x_1)$; write $\Lambda_{1,k}$ for this subsequence. Extract from it a further subsequence $\Lambda_{2,k}$ along which $\Lambda_{2,k}(x_2)$ converges, to $\Lambda(x_2)$; and so on. The diagonal sequence $\Lambda_{j,j}$ is eventually a subsequence of each $\Lambda_{l,k}$, so $\Lambda_{j,j}(x) \rightarrow \Lambda(x)$ for every $x \in D$, with $|\Lambda(x)| \leq \|x\|$.

Extension to X . The map $\Lambda : D \rightarrow \mathbb{F}$ is Lipschitz: given $x, y \in D$, choose k so large that $|\Lambda_{k,k}(x) - \Lambda(x)|$ and $|\Lambda_{k,k}(y) - \Lambda(y)|$ are both less than ε ; then

$$|\Lambda(x) - \Lambda(y)| \leq |\Lambda(x) - \Lambda_{k,k}(x)| + |\Lambda_{k,k}(x - y)| + |\Lambda_{k,k}(y) - \Lambda(y)| \leq 2\varepsilon + \|x - y\|.$$

As ε was arbitrary, Λ is 1-Lipschitz on D and so extends uniquely to a continuous map on $X = \overline{D}$.

Linearity. Let $x, y \in X$ and $a \in \mathbb{F}$, and set $z = x + ay$. Choose $x', y', z' \in D$ close to x, y, z respectively with $z' = x' + ay'$ approximately; then

$$\begin{aligned} |\Lambda(z) - \Lambda(x) - a\Lambda(y)| &\leq |\Lambda(z) - \Lambda(z')| + |\Lambda(x) - \Lambda(x')| + |a||\Lambda(y) - \Lambda(y')| \\ &\quad + |\Lambda(z') - \Lambda_{k,k}(z')| + |\Lambda(x') - \Lambda_{k,k}(x')| \\ &\quad + |a||\Lambda(y') - \Lambda_{k,k}(y')| \\ &\quad + |\Lambda_{k,k}(z' - x' - ay')|, \end{aligned}$$

and each line is small: the first by continuity of Λ and the choice of x', y', z' , the second by taking k large, the third because $\Lambda_{k,k}$ is linear of norm at most 1 and $z' - x' - ay'$ is small. So Λ is linear, and being 1-Lipschitz, $\Lambda \in \overline{B}'$.

Convergence. Finally, for arbitrary $x \in X$ pick $x' \in D$ with $\|x - x'\|$ small; then

$$|\Lambda_{j,j}(x) - \Lambda(x)| \leq |\Lambda_{j,j}(x - x')| + |\Lambda_{j,j}(x') - \Lambda(x')| + |\Lambda(x' - x)|,$$

where the outer terms are at most $\|x - x'\|$ each and the middle tends to 0. Hence $\Lambda_{j,j} \xrightarrow{*} \Lambda$. $\square$

The theorem is worth pausing over. The closed unit ball of X' is never norm-compact in infinite dimensions, and yet it is always weak-* compact. Nothing has been gained for free: what we get in exchange for compactness is that the limit is only a weak-* limit, so that the convergence carries very little information. The whole art of the subject is to use structure – convexity, an equation, an estimate – to upgrade the weak limit afterwards.

$$\Lambda_j \xrightarrow{*} \Lambda, \text{ but } \|\Lambda_j - \Lambda\|_{X'} \not\rightarrow 0$$

Corollary 26.6.28

Let $1 < p \leq \infty$ and let (f_j) be a sequence in $L^p(\mathbb{R}^n)$ with $\|f_j\|_{L^p} \leq K$ for all j . Then there is a subsequence (f_{j_k}) and $f \in L^p(\mathbb{R}^n)$ with $\|f\|_{L^p} \leq K$ and

$$\int_{\mathbb{R}^n} f_{j_k} g \, dx \longrightarrow \int_{\mathbb{R}^n} f g \, dx \quad \text{for all } g \in L^q(\mathbb{R}^n).$$

Proof. $L^p(\mathbb{R}^n) = L^q(\mathbb{R}^n)'$ by Theorem 26.5.10, and $L^q(\mathbb{R}^n)$ is separable since $q < \infty$ (Proposition 26.3.14). Apply Theorem 26.6.27 to $K^{-1}f_j$. $\square$

Corollary 26.6.29

In a reflexive Banach space X (in particular in any Hilbert space, or in L^p for $1 < p < \infty$), every bounded sequence has a weakly convergent subsequence.

Proof. Apply Theorem 26.6.27 to the sequence viewed in $X'' = (X')'$, using that weak-* and weak convergence coincide on a reflexive space. (For the separability hypothesis one restricts to the closed span of the sequence, which is a separable reflexive space.) $\square$

Notice that $p = 1$ is excluded, and this is not an oversight. In $L^1(\mathbb{R})$ the sequence $f_n = n\mathbb{1}_{[0,1/n]}$ is bounded, but it has no weakly convergent subsequence: the only candidate limit is the Dirac mass at 0, which is not a function. Failures of weak compactness in L^1 are always of this type – concentration – and controlling them is the subject of the Dunford–Pettis theorem, which we shall not need.

§26.7 Convexity and the Direct Method

We now set out, in the abstract, the method by which we shall later prove that partial differential equations have solutions. The idea goes back to Hilbert and is disarmingly simple: to find a minimiser of a functional S , take a sequence u_n along which $S[u_n]$ tends to the infimum, extract a convergent subsequence, and hope that the limit is a minimiser. Every step of this can fail, and the interest is entirely in the conditions which make it work.

§26.7.1 Lower semicontinuity

Definition 26.7.1

Let X be a topological space. A functional $S : X \rightarrow \mathbb{R} \cup \{+\infty\}$ is **(sequentially) lower semicontinuous** if

$$u_n \rightarrow u \implies S[u] \leq \liminf_{n \rightarrow \infty} S[u_n].$$

It is **coercive** if every sublevel set $\{u : S[u] \leq K\}$ is sequentially relatively compact – that is, if $S[u_n] \leq K$ for all n then (u_n) has a convergent subsequence.

Continuity implies lower semicontinuity, but not conversely. The point of the weaker hypothesis is that the value of S is allowed to *drop* in a limit but not to jump up; and dropping is harmless when we are minimising.

Theorem 26.7.2 (The direct method)

Let X be a topological space and $S : X \rightarrow \mathbb{R} \cup \{+\infty\}$ coercive and lower semicontinuous. Then S attains its infimum on X .

Proof. Let $\sigma = \inf\{S[u] : u \in X\} \in [-\infty, \infty)$ and choose a **minimising sequence** (u_n) with $S[u_n] \rightarrow \sigma$. In particular $(S[u_n])$ is bounded above, say by K , so coercivity provides a subsequence $u_{n_j} \rightarrow u^*$ for some $u^* \in X$. By lower semicontinuity,

$$S[u^*] \leq \liminf_{j \rightarrow \infty} S[u_{n_j}] = \sigma.$$

As $S[u^*] \geq \sigma$ by definition of the infimum, we get $S[u^*] = \sigma$; in particular $\sigma > -\infty$. $\square$

That is the entire method, and as stated it is nearly vacuous. All the work lies in verifying the two hypotheses, and here we run into a fundamental tension. Coercivity asks for compactness, which wants a *weak* topology; lower semicontinuity asks for the functional to behave well under limits, which wants a *strong* topology. Any given functional will typically satisfy one and fail the other. Resolving this is the content of the rest of the section, and the resolution is convexity.

§26.7.2 Coercivity in the weak topology

From now on let X be a reflexive separable Banach space. On such a space, coercivity in the weak topology is nothing more than an a priori bound.

Lemma 26.7.3

Let X be reflexive and suppose $S : X \rightarrow \mathbb{R}$ has the property that $S[u] \leq K$ implies $\|u\| \leq \tilde{K}$ for some $\tilde{K}$ depending only on K . Then S is coercive for the weak topology of X .

Proof. Immediate from Corollary 26.6.29: a bounded sequence has a weakly convergent subsequence. $\square$

So on a reflexive space, coercivity is free – it is just the statement that sublevel sets of S are bounded, which for a concrete functional is a routine estimate. The difficulty has been entirely displaced onto lower semicontinuity, which we must now verify for the weak topology. Since weak convergence is a much weaker hypothesis on (u_n) , weak lower semicontinuity is a much stronger conclusion, and it is simply false in general. (Consider $S[u] = -\|u\|^2$ on a Hilbert space and $u_n = e_n$: then $u_n \rightharpoonup 0$ but $S[u_n] = -1 < 0 = S[0]$.)

§26.7.3 Convexity saves the day

Lemma 26.7.4 (Mazur)

Let X be a Banach space and $U \subseteq X$ convex and strongly closed. Then U is weakly closed.

Proof. Let $x \in U^c$. Applying Theorem 26.6.8(b) to the compact convex set $\{x\}$ and the closed convex set U gives $\Lambda \in X'$ and $\gamma_1 < \gamma_2$ with $\operatorname{Re} \Lambda(x) < \gamma_1 < \gamma_2 < \operatorname{Re} \Lambda(y)$ for all $y \in U$. The set $\{z : \operatorname{Re} \Lambda(z) < \gamma_1\}$ is weakly open (it is a preimage of an open set under a weakly continuous map), contains x , and is disjoint from U . So U^c is weakly open. $\square$

The reader should appreciate how much this says. A strongly closed set need not be weakly closed – the unit *sphere* of a Hilbert space is strongly closed but its weak closure is the whole closed unit ball, since $e_n \rightharpoonup 0$. Convexity rules out exactly this kind of behaviour.

Theorem 26.7.5

Let X be a Banach space and $S : X \rightarrow \mathbb{R}$ convex and lower semicontinuous for the strong topology. Then S is lower semicontinuous for the weak topology.

Proof. For each $K \in \mathbb{R}$ the sublevel set $E_K = \{u : S[u] \leq K\}$ is convex (by convexity of S) and strongly closed (by strong lower semicontinuity), hence weakly closed by Lemma 26.7.4.

Now suppose $u_n \rightharpoonup u^*$, and set $\ell = \liminf_n S[u_n]$; we may assume $\ell < \infty$. Passing to a subsequence we may assume $S[u_{n_j}] \rightarrow \ell$. Given $\varepsilon > 0$, there is J with $S[u_{n_j}] \leq \ell + \varepsilon$ for $j \geq J$, i.e. $u_{n_j} \in E_{\ell+\varepsilon}$ for $j \geq J$. Since $E_{\ell+\varepsilon}$ is weakly closed and $u_{n_j} \rightharpoonup u^*$, we get $u^* \in E_{\ell+\varepsilon}$, that is $S[u^*] \leq \ell + \varepsilon$. As $\varepsilon > 0$ was arbitrary, $S[u^*] \leq \ell$. $\square$

Putting the pieces together we obtain the theorem we shall use.

Corollary 26.7.6

Let X be a reflexive Banach space and $S : X \rightarrow \mathbb{R}$ convex, strongly lower semicontinuous, and with bounded sublevel sets. Then S attains its infimum on X .

Proof. Combine Lemma 26.7.3, Theorem 26.7.5 and Theorem 26.7.2, all applied to the weak topology. (Strictly, Theorem 26.7.2 was stated for sequential compactness and sequential lower semicontinuity, which is exactly what the three results provide.) $\square$

Example 26.7.7

The norm itself is convex and continuous, so $u \mapsto \|u\|$ is weakly lower semicontinuous: this recovers the inequality $\|u^*\| \leq \liminf \|u_n\|$ for $u_n \rightharpoonup u^*$ that we saw directly earlier. More usefully, so is $u \mapsto \|u\|^2 - 2 \operatorname{Re} \Lambda(u)$ for a fixed $\Lambda \in X'$, and this functional has bounded sublevel sets since

$$\|u\|^2 - 2 \operatorname{Re} \Lambda(u) \geq \|u\|^2 - 2 \|\Lambda\| \|u\| \rightarrow \infty$$

as $\|u\| \rightarrow \infty$. So it attains its infimum. In a Hilbert space this is a long-winded proof of the Riesz representation theorem; on a Sobolev space it will be a proof that the Dirichlet problem has a solution.

Convexity is not a technical convenience that a cleverer argument might remove. Here is the standard example showing that without it the conclusion is simply false.

Example 26.7.8 (Bolza)

Work on $X = H_0^1((0, 1))$ – a space we shall construct properly in Section 26.10, but for now the reader may think of piecewise smooth functions on $[0, 1]$ vanishing at the endpoints. Define

$$S[u] = \int_0^1 \left((u'(x)^2 - 1)^2 + u(x)^2 \right) dx.$$

Clearly $S \geq 0$. I claim $\inf S = 0$, but that no u attains it.

That the infimum is not attained is easy: $S[u] = 0$ would force $u = 0$ almost everywhere, hence $u' = 0$ almost everywhere, and then the first term of the integrand equals 1 everywhere, so $S[u] = 1$. Contradiction.

That the infimum is nevertheless 0 is the interesting half. Let u_m be the sawtooth with m teeth: $u_m(0) = 0$ and $u'_m = \pm 1$, alternating in sign on the $2m$ intervals $[j/(2m), (j+1)/(2m)]$. Then $u'_m(x)^2 = 1$ everywhere except at the finitely many corners, so the first term of the integrand vanishes identically, while $0 \leq u_m \leq 1/(2m)$ pointwise, so

$$S[u_m] = \int_0^1 u_m^2 \, dx \leq \frac{1}{4m^2} \rightarrow 0.$$

The minimising sequence oscillates faster and faster; by Proposition 26.6.23 it converges weakly (indeed uniformly) to 0, and $S[0] = 1 > 0 = \lim S[u_m]$. So S is *not* weakly lower semicontinuous, and the direct method breaks at exactly the step Theorem 26.7.5 was designed to supply. The culprit is visible in the integrand: $z \mapsto (z^2 - 1)^2$ has two wells and is not convex, so the gradient prefers to spend its time at the two values ± 1 rather than at their average 0.

Remark. It is worth isolating the shape of the argument, because it recurs in every application. To minimise S over X :

- (i) show S is bounded below and take a minimising sequence (u_n) ;
- (ii) derive an a priori bound $\|u_n\| \leq K$ from $S[u_n] \leq \sigma + 1$ – this is a *coercivity* estimate and is where the structure of S enters;
- (iii) extract $u_{n_j} \rightharpoonup u^*$ by reflexivity;
- (iv) show $S[u^*] \leq \liminf S[u_{n_j}]$ using convexity;
- (v) conclude that u^* is a minimiser, and derive its Euler–Lagrange equation by differentiating $t \mapsto S[u^* + tv]$ at $t = 0$.

Step (v) is what connects minimisation to differential equations, and we carry it out in Section 26.11.

§26.8 The Fourier Transform

The Fourier transform converts differentiation into multiplication, and so turns a differential equation with constant coefficients into algebra. That single fact is worth a whole course. What we want here is a clean account in the language we have built: on which spaces is the transform defined, what are its mapping properties, and can it be inverted.

§26.8.1 The transform on L^1

Definition 26.8.1 (Fourier transform)

For $f \in L^1(\mathbb{R}^n)$ we define $\mathcal{F}f = \hat{f} : \mathbb{R}^n \rightarrow \mathbb{C}$ by

$$\hat{f}(\xi) = \int_{\mathbb{R}^n} f(x) e^{-i(x \cdot \xi)} dx.$$

Since $|f(x)e^{-i(x \cdot \xi)}| = |f(x)| \in L^1$, the integral converges absolutely for every ξ , and $\|\hat{f}\|_{L^\infty} \leq \|f\|_{L^1}$. (There are several conventions in circulation, differing by factors of 2π in the exponent or in front of the integral. We use this one; it makes the differentiation rule clean at the cost of a constant $(2\pi)^n$ in the inversion formula.)

Lemma 26.8.2 (Riemann–Lebesgue)

Let $f \in L^1(\mathbb{R}^n)$. Then $\hat{f} \in C^0(\mathbb{R}^n)$ with $\|\hat{f}\|_{L^\infty} \leq \|f\|_{L^1}$, and $\hat{f}(\xi) \rightarrow 0$ as $|\xi| \rightarrow \infty$.

Proof. If $\xi_m \rightarrow \xi$ then $f(x)e^{-i(x \cdot \xi_m)} \rightarrow f(x)e^{-i(x \cdot \xi)}$ pointwise, dominated by $|f| \in L^1$, so $\hat{f}(\xi_m) \rightarrow \hat{f}(\xi)$ by dominated convergence; and the sup bound is immediate. For the decay, let $\varepsilon > 0$ and use Corollary 26.4.11 to find $f_\varepsilon \in C_c^\infty(\mathbb{R}^n)$ with $\|f - f_\varepsilon\|_{L^1} < \varepsilon$. Integrating by parts (there are no boundary terms, as f_ε has compact support),

$$\hat{f}_\varepsilon(\xi) = \int_{\mathbb{R}^n} f_\varepsilon(x) \operatorname{div}_x \left(\frac{\xi}{-i|\xi|^2} e^{-i(x \cdot \xi)} \right) dx = \int_{\mathbb{R}^n} \frac{\xi \cdot Df_\varepsilon(x)}{i|\xi|^2} e^{-i(x \cdot \xi)} dx,$$

so that $|\hat{f}_\varepsilon(\xi)| \leq |\xi|^{-1} \|Df_\varepsilon\|_{L^1} < \varepsilon$ once $|\xi|$ is large enough. Then $|\hat{f}(\xi)| \leq |\hat{f} - \hat{f}_\varepsilon| + |\hat{f}_\varepsilon| < 2\varepsilon$ for such ξ . $\square$

So $\mathcal{F}$ maps $L^1(\mathbb{R}^n)$ into the space $C_0(\mathbb{R}^n)$ of continuous functions vanishing at infinity. It is not onto – the image is a dense proper subspace – and this is one reason L^1 is not the natural home for the transform.

Example 26.8.3

Take $n = 1$.

- (i) $f = \mathbb{1}_{(-1,1)}$ has $\hat{f}(\xi) = \int_{-1}^1 e^{-ix\xi} dx = \frac{2 \sin \xi}{\xi}$ for $\xi \neq 0$, and $\hat{f}(0) = 2$.
- (ii) $f(x) = e^{-|x|}$ has $\hat{f}(\xi) = \frac{2}{1 + \xi^2}$.
- (iii) $f(x) = \frac{1}{1 + x^2}$ has $\hat{f}(\xi) = \pi e^{-|\xi|}$ – the transform of (ii), up to constants, which is the inversion theorem at work.
- (iv) $f(x) = e^{-x^2/2}$ has $\hat{f}(\xi) = \sqrt{2\pi} e^{-\xi^2/2}$. To see this, note $f' = -xf$, so by Theorem 26.8.5 below $i\xi \hat{f} = -(\hat{f})' \cdot (-1)^{-1}$, giving $(\hat{f})' = -\xi \hat{f}$; solving this ODE with $\hat{f}(0) = \int e^{-x^2/2} = \sqrt{2\pi}$ gives the claim. The Gaussian is (up to scaling) the unique fixed point of $\mathcal{F}$, which is why it appears everywhere in this subject.

The first example is worth drawing, since it shows both the smoothing and the

delocalisation.

Note that $\hat{f}$ is smooth (indeed real-analytic) but decays only like $|\xi|^{-1}$, and in particular is not integrable. Compact support has been traded for smoothness, and vice versa; this trade-off is a theme.

§26.8.2 Basic properties

Write $e_y(x) = e^{i(x \cdot y)}$ and recall $\tau_y f(x) = f(x - y)$ and $\check{f}(x) = f(-x)$.

Lemma 26.8.4

Let $f, g \in L^1(\mathbb{R}^n)$, $y \in \mathbb{R}^n$ and $\mu > 0$.

- (i) Writing $f_\mu(x) = \mu^{-n} f(\mu^{-1}x)$, we have $\widehat{f_\mu}(\xi) = \hat{f}(\mu\xi)$.
- (ii) $\widehat{e_y f} = \tau_y \hat{f}$ and $\widehat{\tau_y f} = e_{-y} \hat{f}$.
- (iii) $f * g \in L^1(\mathbb{R}^n)$ and $\widehat{f * g} = \hat{f} \hat{g}$.

Proof. (i) and (ii) are changes of variable. For (iii), Tonelli gives $\|f * g\|_{L^1} \leq \|f\|_{L^1} \|g\|_{L^1}$, so $f * g \in L^1$, and then by Fubini

$$\begin{aligned} \widehat{f * g}(\xi) &= \iint f(y)g(x - y)e^{-i(x \cdot \xi)} \, dy \, dx \\ &= \int f(y)e^{-i(y \cdot \xi)} \left(\int g(z)e^{-i(z \cdot \xi)} \, dz \right) \, dy = \hat{f}(\xi)\hat{g}(\xi). \square \end{aligned}$$

Part (iii) is the reason the Fourier transform is useful for differential equations: it turns the awkward, non-local operation of convolution into pointwise multiplication.

Theorem 26.8.5 (i) Suppose $f \in C^1(\mathbb{R}^n)$ with $f, D_j f \in L^1(\mathbb{R}^n)$ for each j . Then $\widehat{D_j f}(\xi) = i\xi_j \hat{f}(\xi)$.

(ii) Suppose $(1 + |x|)f \in L^1(\mathbb{R}^n)$. Then $\hat{f} \in C^1(\mathbb{R}^n)$ and $D_j \hat{f}(\xi) = \widehat{-ix_j f}(\xi)$.

Proof. (i) Given $\varepsilon > 0$ choose $f_\varepsilon \in C_c^\infty(\mathbb{R}^n)$ with $\|f - f_\varepsilon\|_{L^1} + \sum_j \|D_j f - D_j f_\varepsilon\|_{L^1} < \varepsilon$ (mollify and cut off). For compactly supported smooth functions, integration by parts gives

$$\widehat{D_j f_\varepsilon}(\xi) = \int e^{-i(x \cdot \xi)} D_j f_\varepsilon(x) \, dx = i\xi_j \int e^{-i(x \cdot \xi)} f_\varepsilon(x) \, dx = i\xi_j \hat{f}_\varepsilon(\xi).$$

Hence

$$|\widehat{D_j f}(\xi) - i\xi_j \hat{f}(\xi)| \leq \|D_j f - D_j f_\varepsilon\|_{L^1} + |\xi| \|f - f_\varepsilon\|_{L^1} < (1 + |\xi|)\varepsilon,$$

and letting $\varepsilon \rightarrow 0$ with ξ fixed gives the identity.

(ii) By hypothesis $x_j f \in L^1$, so $\widehat{-ix_j f}$ is defined and continuous. For $h \neq 0$,

$$\frac{\hat{f}(\xi + he_j) - \hat{f}(\xi)}{h} = \int f(x) e^{-i(x \cdot \xi)} \frac{e^{-ix_j h} - 1}{h} \, dx,$$

and the integrand converges pointwise to $-ix_j f(x) e^{-i(x \cdot \xi)}$, dominated by $|x_j f(x)| \in L^1$ since $|e^{i\theta} - 1| = 2|\sin(\theta/2)| \leq |\theta|$. Dominated convergence finishes the proof. $\square$

In words: *decay of f controls smoothness of $\hat{f}$, and smoothness of f controls decay of $\hat{f}$.* A space on which both hold to all orders would be mapped to itself by $\mathcal{F}$, and this is exactly the definition of the next space.

§26.8.3 The Schwartz space

Definition 26.8.6 (Schwartz space)

A function $\varphi \in C^\infty(\mathbb{R}^n)$ is **rapidly decreasing** if

$$p_N(\varphi) = \sup_{x \in \mathbb{R}^n, |\alpha| \leq N} |(1 + |x|)^N D^\alpha \varphi(x)| < \infty$$

for every $N \in \mathbb{N}$. The set of such functions is the **Schwartz space** $\mathcal{S}(\mathbb{R}^n)$, and we equip it with the topology generated by the separating family of seminorms $\{p_N : N \in \mathbb{N}\}$.

Since the family is countable, $\mathcal{S}(\mathbb{R}^n)$ is metrisable, and in fact it is complete, so it is a Fréchet space. Concretely, $\varphi_j \rightarrow 0$ in $\mathcal{S}(\mathbb{R}^n)$ if and only if $\sup_x |(1 + |x|)^N D^\alpha \varphi_j(x)| \rightarrow 0$ for every N and α . One may equally use the seminorms $\sup_{|\alpha|, |\beta| \leq N} |x^\beta D^\alpha \varphi(x)|$; they generate the same topology.

Example 26.8.7

$\varphi(x) = e^{-|x|^2}$ is in $\mathcal{S}(\mathbb{R}^n)$, and so is every element of $C_c^\infty(\mathbb{R}^n)$. The function $(1 + |x|^2)^{-1001}$ is not, since it fails to decay faster than every polynomial. Thus

$$C_c^\infty(\mathbb{R}^n) \subsetneq \mathcal{S}(\mathbb{R}^n) \subsetneq C^\infty(\mathbb{R}^n),$$

with each inclusion continuous.

Corollary 26.8.8

$\mathcal{F}$ maps $\mathcal{S}(\mathbb{R}^n)$ continuously into itself.

Proof. First note the elementary bound, for any f with $(1 + |x|)^{n+1}f$ bounded,

$$\|f\|_{L^1} = \int_{\mathbb{R}^n} \frac{|f|(1 + |x|)^{n+1}}{(1 + |x|)^{n+1}} dx \leq C_n \sup_x (|f(x)|(1 + |x|)^{n+1}),$$

where $C_n = \int_{\mathbb{R}^n} (1 + |x|)^{-(n+1)} dx < \infty$. If $\varphi \in \mathcal{S}(\mathbb{R}^n)$ then $D^\alpha(x^\beta \varphi) \in L^1(\mathbb{R}^n)$ for all multi-indices, so applying Theorem 26.8.5 repeatedly gives $\left| \widehat{D^\alpha(x^\beta \varphi)}(\xi) \right| = |\xi^\alpha D^\beta \hat{\varphi}(\xi)|$ up to signs, whence

$$\sup_\xi |\xi^\alpha D^\beta \hat{\varphi}(\xi)| \leq \|D^\alpha(x^\beta \varphi)\|_{L^1} \leq C_{\alpha,\beta} \sup_{x, |\delta| \leq |\alpha|} (1 + |x|)^{|\beta|+n+1} |D^\delta \varphi(x)|.$$

The right-hand side is finite, so $\hat{\varphi} \in \mathcal{S}(\mathbb{R}^n)$; and if $\varphi_j \rightarrow 0$ in $\mathcal{S}$ then the same estimate gives $\hat{\varphi}_j \rightarrow 0$ in $\mathcal{S}$, which is continuity. $\square$

§26.8.4 Inversion**Theorem 26.8.9 (Fourier inversion)**

Suppose $f, \hat{f} \in L^1(\mathbb{R}^n)$. Then for almost every x ,

$$f(x) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} \hat{f}(\xi) e^{i(x \cdot \xi)} d\xi.$$

If f is in addition continuous, the identity holds for every x .

Proof. The naive computation – substitute the definition of $\hat{f}$ and swap the integrals – fails, because $e^{i((x-y) \cdot \xi)}$ is not integrable in ξ . The standard repair is to insert a Gaussian convergence factor.

Let $G(\xi) = e^{-|\xi|^2/2}$ and recall from Example 26.8.3(iv) (applied in each variable) that $\hat{G} = (2\pi)^{n/2}G$. For $\varepsilon > 0$ consider

$$I_\varepsilon(x) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} \hat{f}(\xi) G(\varepsilon \xi) e^{i(x \cdot \xi)} d\xi.$$

Since $|\hat{f}(\xi)G(\varepsilon \xi)| \leq |\hat{f}(\xi)| \in L^1$ and $G(\varepsilon \xi) \rightarrow 1$ pointwise, dominated convergence gives $I_\varepsilon(x) \rightarrow (2\pi)^{-n} \int \hat{f}(\xi) e^{i(x \cdot \xi)} d\xi$ as $\varepsilon \rightarrow 0$, for every x .

On the other hand, everything in sight is now absolutely integrable in (ξ, y) jointly, so Fubini applies:

$$I_\varepsilon(x) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} f(y) \left(\int_{\mathbb{R}^n} G(\varepsilon \xi) e^{i((x-y) \cdot \xi)} d\xi \right) dy = \int_{\mathbb{R}^n} f(y) k_\varepsilon(x - y) dy,$$

where, by Lemma 26.8.4(i) and $\hat{G} = (2\pi)^{n/2}G$,

$$k_\varepsilon(z) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} G(\varepsilon\xi) e^{i(z \cdot \xi)} d\xi = \frac{1}{(2\pi)^{n/2} \varepsilon^n} e^{-|z|^2/(2\varepsilon^2)}.$$

This is precisely an approximate identity: $k_\varepsilon \geq 0$, $\int k_\varepsilon = 1$, and k_ε concentrates at the origin as $\varepsilon \rightarrow 0$. (It is not compactly supported, but the proof of Theorem 26.4.10 used only the normalisation and the concentration, and goes through verbatim.) Hence $I_\varepsilon = k_\varepsilon * f \rightarrow f$ in L^1 , and so along a subsequence almost everywhere. Comparing the two limits gives the result, and if f is continuous then both sides are continuous and agree a.e., hence everywhere. $\square$

Corollary 26.8.10

$\mathcal{F} : \mathcal{S}(\mathbb{R}^n) \rightarrow \mathcal{S}(\mathbb{R}^n)$ is a topological isomorphism, with $\mathcal{F}^2 f = (2\pi)^n \check{f}$ and $\mathcal{F}^4 = (2\pi)^{2n} \text{id}$.

Proof. If $\varphi \in \mathcal{S}$ then $\varphi, \hat{\varphi} \in L^1$ and φ is continuous, so Theorem 26.8.9 applies at every point; rewriting the inversion formula as $\varphi(x) = (2\pi)^{-n} \hat{\hat{\varphi}}(-x)$ gives $\mathcal{F}^2 \varphi = (2\pi)^n \hat{\varphi}$, and squaring gives $\mathcal{F}^4 = (2\pi)^{2n} \text{id}$. So $\mathcal{F}$ is a bijection of $\mathcal{S}$ with continuous inverse $(2\pi)^{-n} \mathcal{F}^3$, using Corollary 26.8.8. $\square$

§26.8.5 Plancherel and the transform on L^2

The Fourier transform is not defined on L^2 by the integral formula – an L^2 function need not be integrable – but it extends there by density, and on L^2 it is at its best: it becomes (a multiple of) a unitary map.

Theorem 26.8.11 (Plancherel/Parseval)

Let $f, g \in L^1(\mathbb{R}^n) \cap L^2(\mathbb{R}^n)$. Then $\hat{f}, \hat{g} \in L^2(\mathbb{R}^n)$ and

$$\langle f, g \rangle_{L^2} = (2\pi)^{-n} \langle \hat{f}, \hat{g} \rangle_{L^2}, \quad \text{in particular} \quad \|\hat{f}\|_{L^2} = (2\pi)^{n/2} \|f\|_{L^2}.$$

Proof. The Schwartz case. Let $f, g \in \mathcal{S}(\mathbb{R}^n)$ and set $h(y) = \overline{g(-y)}$, so that $h \in \mathcal{S}(\mathbb{R}^n)$ too, and

$$\hat{h}(\xi) = \int_{\mathbb{R}^n} \overline{g(-y)} e^{-i(y \cdot \xi)} dy = \overline{\int_{\mathbb{R}^n} g(z) e^{-i(z \cdot \xi)} dz} = \overline{\hat{g}(\xi)},$$

substituting $z = -y$. Now put $k = f * h$, which lies in $\mathcal{S}(\mathbb{R}^n)$ (it is smooth by Theorem 26.4.6, and rapidly decreasing because each derivative is a convolution of two rapidly decreasing functions). On the one hand, $\hat{k} = \hat{f} \hat{h} = \hat{f} \overline{\hat{g}}$ by Lemma 26.8.4(iii), so evaluating the inversion formula of Theorem 26.8.9 at $x = 0$ gives

$$k(0) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} \hat{k}(\xi) d\xi = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} \hat{f}(\xi) \overline{\hat{g}(\xi)} d\xi.$$

On the other hand, directly from the definition of the convolution,

$$k(0) = \int_{\mathbb{R}^n} f(y)h(-y) \, dy = \int_{\mathbb{R}^n} f(y)\overline{g(y)} \, dy.$$

Comparing the two, and conjugating to match our convention $\langle f, g \rangle_{L^2} = \int \overline{f}g$, gives $\langle f, g \rangle_{L^2} = (2\pi)^{-n} \langle \hat{f}, \hat{g} \rangle_{L^2}$ for Schwartz f, g .

The general case. Let $f \in L^1 \cap L^2$. Truncating and mollifying as in Corollary 26.4.11 produces $f_m \in C_c^\infty(\mathbb{R}^n) \subseteq \mathcal{S}(\mathbb{R}^n)$ with $f_m \rightarrow f$ in L^1 and in L^2 simultaneously: indeed $f \mathbb{1}_{B_R(0)} \rightarrow f$ in both norms by dominated convergence, and $\phi_\varepsilon * (f \mathbb{1}_{B_R(0)}) \rightarrow f \mathbb{1}_{B_R(0)}$ in both norms by Theorem 26.4.10. By the Schwartz case applied to differences, $\|\hat{f}_m - \hat{f}_l\|_{L^2} = (2\pi)^{n/2} \|f_m - f_l\|_{L^2}$, so $(\hat{f}_m)$ is Cauchy in L^2 and converges to some $F \in L^2$. But $\|\hat{f}_m - \hat{f}\|_{L^\infty} \leq \|f_m - f\|_{L^1} \rightarrow 0$, so $\hat{f}_m \rightarrow \hat{f}$ uniformly, and hence (along a subsequence, using L^2 convergence) $F = \hat{f}$ almost everywhere. Therefore $\hat{f} \in L^2$ with $\|\hat{f}\|_{L^2} = \lim_m \|\hat{f}_m\|_{L^2} = (2\pi)^{n/2} \lim_m \|f_m\|_{L^2} = (2\pi)^{n/2} \|f\|_{L^2}$, and the polarised identity for $\langle f, g \rangle$ follows in the same way. $\square$

So $(2\pi)^{-n/2} \mathcal{F}$ is an isometry from $L^1 \cap L^2$, which is dense in L^2 , into L^2 . A densely defined isometry into a complete space extends uniquely to an isometry of the closure, and we obtain:

Definition 26.8.12

The unique continuous extension $\overline{\mathcal{F}} : L^2(\mathbb{R}^n) \rightarrow L^2(\mathbb{R}^n)$ of $\mathcal{F}|_{L^1 \cap L^2}$ is the **Fourier–Plancherel transform**. We write $\mathcal{F}$ for it as well.

Proposition 26.8.13

$\overline{\mathcal{F}}$ is a bijection of $L^2(\mathbb{R}^n)$ with $\|\overline{\mathcal{F}}f\|_{L^2} = (2\pi)^{n/2} \|f\|_{L^2}$, and for $f \in L^2(\mathbb{R}^n)$,

$$\overline{\mathcal{F}}f = \lim_{R \rightarrow \infty} \int_{B_R(0)} f(x) e^{-i(x \cdot \xi)} \, dx$$

with the limit taken in $L^2(\mathbb{R}^n)$.

Proof. Set $f_R = f \mathbb{1}_{B_R(0)}$. Then $f_R \in L^1 \cap L^2$ by Hölder, and $f_R \rightarrow f$ in L^2 ; since $\overline{\mathcal{F}}$ is continuous, $\hat{f}_R \rightarrow \overline{\mathcal{F}}f$ in L^2 . Surjectivity follows from $\mathcal{F}^4 = (2\pi)^{2n} \text{id}$ on $\mathcal{S}$, which passes to the closure. $\square$

Remark. The Fourier transform therefore acts on L^1 (mapping into C_0), on L^2 (bijectively, isometrically up to constants), and by interpolation on L^p for $1 \leq p \leq 2$ (the Hausdorff–Young inequality, $\|\hat{f}\|_{L^q} \leq C \|f\|_{L^p}$ for conjugate p, q with $p \leq 2$). For $p > 2$ it does not map L^p into any L^q , and the transform of such a function only makes sense as a distribution. This is one of several reasons we now build distribution theory.

§26.9 Distributions

In the study of differential equations one constantly meets objects which behave like functions but are not.

Example 26.9.1

Consider

$$G : \mathbb{R}^3 \setminus \{0\} \rightarrow \mathbb{R}, \quad x \mapsto \frac{-1}{4\pi|x|}.$$

Every physicist knows that $\nabla^2 G = \delta$, the point mass at the origin, and this fact is the basis of the theory of the Laplace and Poisson equations. But G is not twice differentiable at 0, δ is not a function, and the equation as written is meaningless.

The theory of distributions makes such statements rigorous, and it does so by a strategy we have already used twice: instead of studying an object directly, study how it pairs against nice test objects. A locally integrable function f is determined by the numbers $\int f\varphi$ for φ ranging over a suitable class; so let us simply *define* a generalised function to be a rule assigning a number to each φ . The class of φ must be small enough that many rules qualify, and large enough that the rule is determined; the balance is struck by taking φ smooth and compactly supported.

§26.9.1 Spaces of test functions

Let $\Omega \subseteq \mathbb{R}^n$ be open. We have three test function spaces, in increasing order of size.

The space $C_c^\infty(\Omega)$ of smooth functions with compact support in Ω carries a natural vector space structure, and it can be given a topology making it a locally convex topological vector space. The construction (an inductive limit over compact exhaustions) is not especially illuminating and we omit it; what matters is the following list of properties, which is all we shall ever use.

Theorem 26.9.2

The space $C_c^\infty(\Omega)$ carries a topology τ such that:

- (i) $(C_c^\infty(\Omega), \tau)$ is a locally convex topological vector space, which we denote $\mathcal{D}(\Omega)$;
- (ii) a sequence (φ_j) converges to 0 in $\mathcal{D}(\Omega)$ if and only if there is a single compact $K \subseteq \Omega$ with $\text{supp } \varphi_j \subseteq K$ for all j , and $\sup_{x \in K} |D^\alpha \varphi_j(x)| \rightarrow 0$ for every multi-index α ;
- (iii) if Y is a locally convex topological vector space and $\Lambda : \mathcal{D}(\Omega) \rightarrow Y$ is linear, then Λ is continuous if and only if it is sequentially continuous.

Property (ii) is a strong requirement – the supports must not run away, and *all* derivatives must converge uniformly. Property (iii) is what makes the space usable in practice, since it lets us verify continuity one sequence at a time.

Example 26.9.3

Let $\varphi \in C_c^\infty(\mathbb{R})$ be non-zero.

- (a) $\varphi_j(x) = e^{-j}\varphi(jx)$ converges to 0 in $\mathcal{D}(\mathbb{R})$: the supports shrink to $\{0\}$, and although $D^\alpha\varphi_j$ picks up a factor $j^{|\alpha|}$, the factor e^{-j} swamps it.
- (b) $\varphi_j(x) = j^{-1000}\varphi(jx)$ does *not* converge to 0 in $\mathcal{D}(\mathbb{R})$: for $|\alpha| > 1000$ the derivatives blow up.
- (c) $\varphi_j(x) = e^{-j}\varphi(x - j)$ does not converge to 0 in $\mathcal{D}(\mathbb{R})$, even though every derivative tends to 0 uniformly, because the supports escape to infinity and no single compact set contains them all.

The second space is built on $C^\infty(\Omega)$, with no support restriction. Choose an exhaustion of Ω by compact sets K_i with $K_i \subseteq K_{i+1}^\circ$ and $\bigcup_i K_i = \Omega$, and for $\varphi \in C^\infty(\Omega)$ set

$$p_N(\varphi) = \sup_{x \in K_N, |\alpha| \leq N} |D^\alpha \varphi(x)|.$$

These form a countable separating family of seminorms, whose topology is complete; the resulting Fréchet space is denoted $\mathcal{E}(\Omega)$.

Theorem 26.9.4

$\varphi_j \rightarrow 0$ in $\mathcal{E}(\Omega)$ if and only if $\sup_{x \in K} |D^\alpha \varphi_j(x)| \rightarrow 0$ for every compact $K \subseteq \Omega$ and every multi-index α ; that is, if and only if all derivatives converge to 0 uniformly on compact sets.

Example 26.9.5

If $\varphi \in C_c^\infty(\mathbb{R})$ is non-zero then $\varphi_j(x) = \varphi(x - j) \rightarrow 0$ in $\mathcal{E}(\mathbb{R})$, since on any fixed compact set φ_j eventually vanishes identically. As we saw, this sequence does not converge in $\mathcal{D}(\mathbb{R})$: the topology of $\mathcal{E}$ is strictly weaker.

The third space is the Schwartz space $\mathcal{S}(\mathbb{R}^n)$ of Section 26.8, which sits between the other two:

$$\mathcal{D}(\mathbb{R}^n) \subseteq \mathcal{S}(\mathbb{R}^n) \subseteq \mathcal{E}(\mathbb{R}^n),$$

with both inclusions continuous (and, one checks, with dense image).

§26.9.2 Distributions

Definition 26.9.6 (Distribution)

Let $\Omega \subseteq \mathbb{R}^n$ be open. The space of **distributions** $\mathcal{D}'(\Omega)$ is the continuous dual of $\mathcal{D}(\Omega)$: the space of linear maps $u : \mathcal{D}(\Omega) \rightarrow \mathbb{C}$ such that $u[\varphi_j] \rightarrow 0$ whenever $\varphi_j \rightarrow 0$ in $\mathcal{D}(\Omega)$. We equip $\mathcal{D}'(\Omega)$ with the weak-* topology, so that

$$u_j \rightarrow u \text{ in } \mathcal{D}'(\Omega) \iff u_j[\varphi] \rightarrow u[\varphi] \text{ for every } \varphi \in \mathcal{D}(\Omega).$$

We write $u[\varphi]$ rather than $u(\varphi)$ to emphasise that u is not a function of x .

Example 26.9.7 (a) For $x \in \Omega$, the evaluation $\delta_x : \varphi \mapsto \varphi(x)$ is a distribution, the **Dirac delta** at x . Continuity is clear from Theorem 26.9.2(ii).

(b) For $f \in L^1_{\text{loc}}(\Omega)$, the map

$$T_f : \varphi \mapsto \int_{\Omega} f \varphi \, dx$$

is a distribution. Indeed if $\varphi_j \rightarrow 0$ in $\mathcal{D}(\Omega)$ with supports in a compact K , then $\varphi_j \rightarrow 0$ uniformly, so $|f \mathbb{1}_K \varphi_j| \leq C|f| \mathbb{1}_K \in L^1$ and dominated convergence gives $T_f[\varphi_j] \rightarrow 0$.

The following characterisation of continuity is the practical test.

Lemma 26.9.8

A linear map $u : \mathcal{D}(\Omega) \rightarrow \mathbb{C}$ is continuous if and only if for every compact $K \subseteq \Omega$ there are $N_K \in \mathbb{N}$ and $C_K > 0$ with

$$|u[\varphi]| \leq C_K \sup_{x \in K} \sum_{|\alpha| \leq N_K} |D^\alpha \varphi(x)| \quad \text{for all } \varphi \in C_c^\infty(K).$$

Proof. ($\Leftarrow$) If $\varphi_j \rightarrow 0$ in $\mathcal{D}(\Omega)$ then the supports lie in a common compact K and every $D^\alpha \varphi_j \rightarrow 0$ uniformly on K ; the estimate then forces $u[\varphi_j] \rightarrow 0$.

($\Rightarrow$) Suppose the estimate fails for some compact K . Then for each j there is $\varphi_j \in C_c^\infty(K)$ with

$$|u[\varphi_j]| > j \sup_{x \in K} \sum_{|\alpha| \leq j} |D^\alpha \varphi_j(x)|.$$

Put $\psi_j = \varphi_j / |u[\varphi_j]|$. Then for any fixed β and all $j \geq |\beta|$,

$$\sup_K |D^\beta \psi_j| = \frac{\sup_K |D^\beta \varphi_j|}{|u[\varphi_j]|} \leq \frac{1}{j} \rightarrow 0,$$

so $\psi_j \rightarrow 0$ in $\mathcal{D}(\Omega)$ – but $|u[\psi_j]| = 1$ for all j , contradicting continuity. $\square$

Definition 26.9.9 (Order)

If in Lemma 26.9.8 the integer N_K can be chosen independently of K , we say u has **finite order**, and the least such N is the **order** of u .

Example 26.9.10

δ_x and T_f have order 0; $\varphi \mapsto \varphi'(x)$ has order 1; and

$$u[\varphi] = \sum_{i=1}^{\infty} \varphi^{(i)}(i)$$

defines a distribution on $\mathbb{R}$ (the sum is finite for each φ) which is continuous but has no finite order.

The map $f \mapsto T_f$ is injective on $L^1_{\text{loc}}(\Omega)$: if $T_f = T_g$ then $\int (f - g)\varphi = 0$ for all $\varphi \in C_c^\infty(\Omega)$, so $f = g$ almost everywhere by Corollary 26.4.12. We may therefore regard $L^1_{\text{loc}}(\Omega)$ as a subspace of $\mathcal{D}'(\Omega)$, and from now on we abuse notation by writing f for T_f .

Distributions are ‘generalised functions’ in exactly this sense.

§26.9.3 Operations on distributions

The rule for extending an operation from functions to distributions is always the same: find an identity, valid for smooth functions, which expresses the operation in terms of the pairing, and promote it to a definition.

Multiplication by a smooth function. If $a \in C^\infty(\Omega)$ and $f \in L^1_{\text{loc}}$, then $T_{af}[\varphi] = T_f[a\varphi]$. Since $a\varphi \in \mathcal{D}(\Omega)$ whenever φ is, we define

$$(au)[\varphi] = u[a\varphi], \quad u \in \mathcal{D}'(\Omega).$$

Note that there is no way to multiply two distributions: δ_0^2 is not defined, and the failure is not a defect of the theory but a genuine obstruction.

Differentiation. If $f \in C^1$ then integration by parts gives $T_{D_i f}[\varphi] = -T_f[D_i \varphi]$, with no boundary term since φ has compact support. We therefore define, for any multi-index α ,

$$D^\alpha u[\varphi] = (-1)^{|\alpha|} u[D^\alpha \varphi].$$

This is again a distribution, by Lemma 26.9.8. So *every distribution is infinitely differentiable*, and in particular every locally integrable function has derivatives of all orders in $\mathcal{D}'$. The price is that $D^\alpha u$ need not lie in L^1_{loc} even if u does.

Example 26.9.11

Let $H = \mathbb{1}_{[0, \infty)}$ be the Heaviside function on $\mathbb{R}$, which is certainly in L^1_{loc} . For $\varphi \in \mathcal{D}(\mathbb{R})$,

$$DH[\varphi] = -H[\varphi'] = -\int_0^\infty \varphi'(x) \, dx = \varphi(0) = \delta_0[\varphi],$$

so $DH = \delta_0$ in $\mathcal{D}'(\mathbb{R})$. Differentiating again, $D^2H = D\delta_0$ is the distribution $\varphi \mapsto -\varphi'(0)$, which is not even a measure.

Here is a second example, slightly more delicate, which shows that distributions can also repair *divergent* integrals and not merely non-existent derivatives.

Example 26.9.12 (Principal value)

The function $1/x$ is not locally integrable on $\mathbb{R}$, so it does not define a distribution by integration. Nevertheless the symmetric divergences at 0^+ and 0^- cancel, and

$$\text{p.v.}\left(\frac{1}{x}\right)[\varphi] = \lim_{\varepsilon \downarrow 0} \int_{|x| > \varepsilon} \frac{\varphi(x)}{x} \, dx$$

does define a distribution on $\mathbb{R}$. To see that the limit exists, split the integral at $|x| = 1$. The outer part $\int_{|x| > 1} \varphi(x)/x \, dx$ converges absolutely, since $|1/x| \leq 1$ there and φ has compact support. For the inner part, the oddness of $1/x$ gives

$\int_{\varepsilon < |x| < 1} dx/x = 0$, so we may subtract $\varphi(0)$ for free:

$$\int_{\varepsilon < |x| < 1} \frac{\varphi(x)}{x} dx = \int_{\varepsilon < |x| < 1} \frac{\varphi(x) - \varphi(0)}{x} dx,$$

and now the integrand is bounded in modulus by $\sup |\varphi'|$ by the mean value theorem, so the limit exists by dominated convergence. The same estimate bounds

$$\left| \text{p.v.} \left(\frac{1}{x} \right) [\varphi] \right| \leq 2 \sup_{\mathbb{R}} |\varphi'| + \left(\int_{|x| > 1, x \in K} \frac{dx}{|x|} \right) \sup_{\mathbb{R}} |\varphi|$$

for φ supported in a compact K , so Lemma 26.9.8 applies and the principal value is a distribution of order (at most) 1. It is genuinely of order 1, and in particular is not a measure.

It is also, as one would hope, a derivative. The function $\log |x|$ is locally integrable, and I claim $D \log |x| = \text{p.v.}(1/x)$. Indeed, for $\varphi \in \mathcal{D}(\mathbb{R})$, integrating by parts on $\{x > \varepsilon\}$ and on $\{x < -\varepsilon\}$ separately,

$$- \int_{|x| > \varepsilon} \log |x| \varphi'(x) dx = \log \varepsilon (\varphi(\varepsilon) - \varphi(-\varepsilon)) + \int_{|x| > \varepsilon} \frac{\varphi(x)}{x} dx.$$

Since $|\varphi(\varepsilon) - \varphi(-\varepsilon)| \leq 2\varepsilon \sup |\varphi'|$ and $\varepsilon \log \varepsilon \rightarrow 0$, the boundary term vanishes in the limit, and dominated convergence handles the left-hand side. So $D \log |x|[\varphi] = - \int \log |x| \varphi' = \text{p.v.}(1/x)[\varphi]$, as claimed. The reader who has met contour integration will recognise the principal value as the real part of the Sokhotski–Plemelj formula.

With these operations we can make sense of linear partial differential equations in $\mathcal{D}'(\Omega)$: given $a_\alpha \in C^\infty(\Omega)$ and $w \in \mathcal{D}'(\Omega)$, we may ask for $u \in \mathcal{D}'(\Omega)$ with

$$\sum_{|\alpha| \leq k} a_\alpha D^\alpha u = w.$$

Solutions in this sense are called **weak** or **distributional** solutions, and the whole point of the last part of the course is that they are much easier to find than classical ones – after which one works to prove that they are classical after all.

Example 26.9.13

Mollifiers converge to the delta: for $\varphi \in \mathcal{D}(\mathbb{R}^n)$,

$$\phi_\varepsilon[\varphi] = \int \phi_\varepsilon(x) \varphi(x) dx \rightarrow \varphi(0) = \delta_0[\varphi]$$

by the same computation as in Theorem 26.4.10. So $\phi_\varepsilon \rightarrow \delta_0$ in $\mathcal{D}'(\mathbb{R}^n)$, which is the precise sense in which the pictures in Section 26.4 ‘converge to a spike’.

§26.9.4 Compactly supported and tempered distributions

The duals of the other two test spaces give distinguished subspaces of $\mathcal{D}'$.

Lemma 26.9.14

A linear $u : \mathcal{E}(\Omega) \rightarrow \mathbb{C}$ is continuous if and only if there are a compact $K \subseteq \Omega$, $N \in \mathbb{N}$ and $C > 0$ with

$$|u[\varphi]| \leq C \sup_{x \in K, |\alpha| \leq N} |D^\alpha \varphi(x)| \quad \text{for all } \varphi \in \mathcal{E}(\Omega).$$

Proof. ($\Leftarrow$) If $\varphi_j \rightarrow 0$ in $\mathcal{E}(\Omega)$ then in particular the right-hand side tends to 0.

($\Rightarrow$) Suppose no such (K, N, C) exists. Take a compact exhaustion (K_j) of Ω ; then for each j there is $\varphi_j \in \mathcal{E}(\Omega)$ with $|u[\varphi_j]| \geq j \sup_{x \in K_j, |\alpha| \leq j} |D^\alpha \varphi_j(x)|$. Setting $\psi_j = \varphi_j / |u[\varphi_j]|$, for any compact $\tilde{K}$ and $\tilde{N}$ we may choose $J > \tilde{N}$ with $\tilde{K} \subseteq K_j$ for $j \geq J$, and then

$$\sup_{x \in \tilde{K}, |\alpha| \leq \tilde{N}} |D^\alpha \psi_j(x)| \leq \frac{1}{j} \rightarrow 0.$$

So $\psi_j \rightarrow 0$ in $\mathcal{E}(\Omega)$ while $|u[\psi_j]| = 1$: contradiction. $\square$

Definition 26.9.15

A distribution $u \in \mathcal{D}'(\Omega)$ has **compact support** if there is a compact $K \subseteq \Omega$ with $u[\varphi] = 0$ whenever $\text{supp } \varphi \subseteq \Omega \setminus K$.

The continuous inclusion $\mathcal{D}(\Omega) \subseteq \mathcal{E}(\Omega)$ dualises to a map $\mathcal{E}'(\Omega) \rightarrow \mathcal{D}'(\Omega)$, which is injective because $\mathcal{D}(\Omega)$ is dense in $\mathcal{E}(\Omega)$. Lemma 26.9.14 shows that its image consists of compactly supported distributions; conversely, if $u \in \mathcal{D}'(\Omega)$ is supported in a compact K , choose $\chi \in C_c^\infty(\Omega)$ with $\chi \equiv 1$ near K and set $\tilde{u}[\varphi] = u[\chi\varphi]$, which is independent of the choice of χ . So

$$\mathcal{E}'(\Omega) = \{\text{distributions of compact support}\}.$$

Example 26.9.16

$\delta_x \in \mathcal{E}'(\Omega)$; and if $f \in L^1(\Omega)$ vanishes a.e. outside a compact set, $T_f \in \mathcal{E}'(\Omega)$. But $u[\varphi] = \sum_{n \in \mathbb{Z}} \varphi(n)$ on $\mathbb{R}$ does not have compact support.

Definition 26.9.17 (Tempered distribution)

The continuous dual $\mathcal{S}'(\mathbb{R}^n)$ of the Schwartz space is the space of **tempered distributions**.

The chain $\mathcal{D}(\mathbb{R}^n) \subseteq \mathcal{S}(\mathbb{R}^n) \subseteq \mathcal{E}(\mathbb{R}^n)$ of continuous dense inclusions dualises to injections

$$\mathcal{E}'(\mathbb{R}^n) \hookrightarrow \mathcal{S}'(\mathbb{R}^n) \hookrightarrow \mathcal{D}'(\mathbb{R}^n).$$

So the tempered distributions form a class intermediate between compactly supported distributions and all distributions. The name is a mnemonic: a distribution is tempered when it does not grow faster than polynomially.

Example 26.9.18 (i) If $f \in L^1_{\text{loc}}(\mathbb{R}^n)$ satisfies $\int (1+|x|)^{-N} |f(x)| \, dx < \infty$ for some N , then $T_f \in \mathcal{S}'(\mathbb{R}^n)$. Indeed for $\varphi \in \mathcal{S}$,

$$\begin{aligned} |T_f[\varphi]| &= \left| \int (1+|x|)^{-N} f(x) \cdot (1+|x|)^N \varphi(x) \, dx \right| \\ &\leq \left(\int \frac{|f|}{(1+|x|)^N} \right) \sup_x (1+|x|)^N |\varphi(x)|, \end{aligned}$$

which is a bound of the required form. In particular every L^p function and every polynomial is a tempered distribution.

(ii) $f(x) = e^{|x|^2}$ gives $T_f \in \mathcal{D}'(\mathbb{R}^n) \setminus \mathcal{S}'(\mathbb{R}^n)$: it grows too fast to be paired with a Gaussian.

(iii) $u[\varphi] = \sum_{m \in \mathbb{Z}} m^{50} \varphi(m)$ lies in $\mathcal{S}'(\mathbb{R})$ but not $\mathcal{E}'(\mathbb{R})$.

§26.9.5 Convolution and fundamental solutions

Recall $\check{\varphi}(y) = \varphi(-y)$, so that $\tau_x \check{\varphi}(y) = \varphi(x-y)$. For $f \in L^1_{\text{loc}}(\mathbb{R}^n)$ and $\varphi \in \mathcal{D}(\mathbb{R}^n)$,

$$(f * \varphi)(x) = \int f(y) \varphi(x-y) \, dy = T_f[\tau_x \check{\varphi}],$$

which suggests the definition.

Definition 26.9.19

For $u \in \mathcal{D}'(\mathbb{R}^n)$ and $\varphi \in \mathcal{D}(\mathbb{R}^n)$ set $(u * \varphi)(x) = u[\tau_x \check{\varphi}]$.

This is a genuine function of x , bilinear in (u, φ) . Note that $(u * \check{\varphi})(0) = u[\varphi]$, so the family of functions $u * \varphi$ determines u completely.

Example 26.9.20

$\delta_0 * \varphi = \varphi$, since $(\delta_0 * \varphi)(x) = \tau_x \check{\varphi}(0) = \varphi(x)$. So δ_0 is an identity for convolution, which is the reason for the name ‘approximate identity’.

Lemma 26.9.21

Let $u \in \mathcal{D}'(\mathbb{R}^n)$ and $\varphi \in \mathcal{D}(\mathbb{R}^n)$. Then

- (i) $u * \varphi \in C^\infty(\mathbb{R}^n)$, and $D^\alpha(u * \varphi) = (D^\alpha u) * \varphi = u * (D^\alpha \varphi)$;
- (ii) if $u \in \mathcal{E}'(\mathbb{R}^n)$ then $u * \varphi \in \mathcal{D}(\mathbb{R}^n)$.

Proof. (i) We have

$$\frac{(u * \varphi)(x + h e_i) - (u * \varphi)(x)}{h} = u \left[\frac{\tau_{x+h e_i} \check{\varphi} - \tau_x \check{\varphi}}{h} \right],$$

and one checks (example sheet) that the argument converges in $\mathcal{D}(\mathbb{R}^n)$ to $\tau_x((D_i \varphi)^\vee)$ as $h \rightarrow 0$; continuity of u then gives $D_i(u * \varphi) = u * D_i \varphi$, and iterating gives

smoothness. For the other identity, note

$$D_y^\alpha (\tau_x \check{\varphi})(y) = \frac{\partial^{|\alpha|}}{\partial y^\alpha} \varphi(x-y) = (-1)^{|\alpha|} (D^\alpha \varphi)(x-y) = (-1)^{|\alpha|} \tau_x((D^\alpha \varphi)^\vee)(y),$$

so that

$$((D^\alpha u) * \varphi)(x) = (-1)^{|\alpha|} u[D^\alpha \tau_x \check{\varphi}] = u[\tau_x((D^\alpha \varphi)^\vee)] = (u * D^\alpha \varphi)(x).$$

(ii) If u vanishes on functions supported outside a compact K , then for $|x|$ large the support of $\tau_x \check{\varphi}$ misses K , so $(u * \varphi)(x) = 0$. $\square$

Using the fact that u is determined by the functions $u * \varphi$, one may define the convolution of $u_1 \in \mathcal{D}'(\mathbb{R}^n)$ with $u_2 \in \mathcal{E}'(\mathbb{R}^n)$ by requiring

$$(u_1 * u_2) * \varphi = u_1 * (u_2 * \varphi) \quad \text{for all } \varphi \in \mathcal{D}(\mathbb{R}^n),$$

which makes sense because $u_2 * \varphi \in \mathcal{D}(\mathbb{R}^n)$ by Lemma 26.9.21(ii). One checks $u * \delta_0 = u$, and:

Lemma 26.9.22

For $u_1 \in \mathcal{D}'(\mathbb{R}^n)$ and $u_2 \in \mathcal{E}'(\mathbb{R}^n)$, $D^\alpha(u_1 * u_2) = (D^\alpha u_1) * u_2 = u_1 * (D^\alpha u_2)$.

Proof. Test against $\varphi \in \mathcal{D}(\mathbb{R}^n)$ and use Lemma 26.9.21(i) repeatedly:

$$\begin{aligned} (D^\alpha(u_1 * u_2)) * \varphi &= (u_1 * u_2) * D^\alpha \varphi = u_1 * (u_2 * D^\alpha \varphi) \\ &= u_1 * ((D^\alpha u_2) * \varphi) = (u_1 * D^\alpha u_2) * \varphi, \end{aligned}$$

and the other equality is the same computation with the roles reversed. $\square$

This is exactly what is needed to invert constant-coefficient differential operators.

Definition 26.9.23 (Fundamental solution)

Let $L = \sum_{|\alpha| \leq N} a_\alpha D^\alpha$ with $a_\alpha \in \mathbb{C}$. A **fundamental solution** of L is a distribution $G \in \mathcal{D}'(\mathbb{R}^n)$ with $LG = \delta_0$.

Theorem 26.9.24

If G is a fundamental solution of L and $u_0 \in \mathcal{E}'(\mathbb{R}^n)$, then $u = G * u_0$ satisfies $Lu = u_0$.

Proof. By Lemma 26.9.22,

$$L(G * u_0) = \sum_{\alpha} a_\alpha D^\alpha (G * u_0) = \left(\sum_{\alpha} a_\alpha D^\alpha G \right) * u_0 = (LG) * u_0 = \delta_0 * u_0 = u_0. \quad \square$$

Example 26.9.25

Return to Example 26.9.1. Take $L = -\nabla^2 = -\sum_{i=1}^3 \partial^2/\partial x_i^2$ on $\mathbb{R}^3$ and let

$$g(x) = \frac{1}{4\pi|x|} \quad (x \neq 0), \quad g(0) = 0.$$

Then $g \in L^1_{\text{loc}}(\mathbb{R}^3)$ (the singularity $|x|^{-1}$ is integrable in three dimensions) and $G = T_g$ is a fundamental solution of L : one computes $\nabla^2 g = 0$ away from the origin and, cutting out a small ball and integrating by parts twice, finds that the boundary terms converge to $\varphi(0)$. So for $f \in C_c^\infty(\mathbb{R}^3)$,

$$u(x) = \frac{1}{4\pi} \int_{\mathbb{R}^3} \frac{f(y)}{|x-y|} dy$$

is a smooth solution of $-\nabla^2 u = f$. The physicists were right all along; it just took a duality to say so.

§26.9.6 Fourier transforms of tempered distributions

For $f \in L^1(\mathbb{R}^n)$ and $\varphi \in \mathcal{S}(\mathbb{R}^n)$, Fubini gives

$$T_{\hat{f}}[\varphi] = \int \hat{f}(x)\varphi(x) dx = \iint \varphi(x)f(y)e^{-i(y \cdot x)} dy dx = \int f(y)\hat{\varphi}(y) dy = T_f[\hat{\varphi}].$$

As $\mathcal{F}$ preserves $\mathcal{S}(\mathbb{R}^n)$ (Corollary 26.8.8), the right-hand side makes sense for any tempered distribution.

Definition 26.9.26

For $u \in \mathcal{S}'(\mathbb{R}^n)$, the **Fourier transform** $\hat{u} \in \mathcal{S}'(\mathbb{R}^n)$ is defined by $\hat{u}[\varphi] = u[\hat{\varphi}]$.

Note that this really does require tempered distributions: $\mathcal{F}$ does not preserve $\mathcal{D}(\mathbb{R}^n)$ (a compactly supported function has an analytic transform, which cannot have compact support unless it vanishes), so there is no Fourier transform on $\mathcal{D}'$.

Example 26.9.27

Fix $\xi \in \mathbb{R}^n$ and let $u = \delta_\xi$. Then

$$\hat{u}[\varphi] = \hat{\varphi}(\xi) = \int \varphi(x)e^{-i(x \cdot \xi)} dx = T_{e_{-\xi}}[\varphi],$$

so $\hat{\delta}_\xi = T_{e_{-\xi}}$; in particular $\hat{\delta}_0 = 1$. Dually, using Theorem 26.8.9,

$$\widehat{T_{e_x}[\varphi]} = \int e^{i(x \cdot y)} \hat{\varphi}(y) dy = (2\pi)^n \varphi(x) = (2\pi)^n \delta_x[\varphi],$$

so $\widehat{T_{e_x}} = (2\pi)^n \delta_x$. The delta and the constant function are Fourier transforms of one another, which is the rigorous version of the formal identity $\int e^{ix\xi} d\xi = 2\pi\delta(x)$ familiar from methods courses.

Lemma 26.9.28

Let $u \in \mathcal{S}'(\mathbb{R}^n)$, $x \in \mathbb{R}^n$ and α a multi-index. Writing X^α for the function $x \mapsto x^\alpha$,

and $\tau_x u[\varphi] = u[\tau_{-x}\varphi]$, $\hat{u}[\varphi] = u[\check{\varphi}]$, we have

$$\widehat{e_x u} = \tau_x \hat{u}, \quad \widehat{\tau_x u} = e_{-x} \hat{u}, \quad \widehat{D^\alpha u} = i^{|\alpha|} X^\alpha \hat{u}, \quad D^\alpha \hat{u} = (-i)^{|\alpha|} \widehat{X^\alpha u},$$

and $\hat{\hat{u}} = (2\pi)^n \check{u}$.

Proof. Each is the corresponding identity for Schwartz functions, transposed. For instance

$$\widehat{e_x u}[\varphi] = e_x u[\hat{\varphi}] = u[e_x \hat{\varphi}] = u[\widehat{\tau_{-x}\varphi}] = \hat{u}[\tau_{-x}\varphi] = \tau_x \hat{u}[\varphi],$$

and for the derivative,

$$\widehat{D^\alpha u}[\varphi] = (-1)^{|\alpha|} u[D^\alpha \hat{\varphi}] = (-1)^{|\alpha|} u[\widehat{(-i)^{|\alpha|} X^\alpha \varphi}] = i^{|\alpha|} \hat{u}[X^\alpha \varphi] = i^{|\alpha|} X^\alpha \hat{u}[\varphi].$$

The last identity follows from Corollary 26.8.10. $\square$

Lemma 26.9.29

$\mathcal{F} : \mathcal{S}'(\mathbb{R}^n) \rightarrow \mathcal{S}'(\mathbb{R}^n)$ is a homeomorphism for the weak-* topology.

Proof. Linearity is clear. If $u_j \xrightarrow{*} u$ then $\hat{u}_j[\varphi] = u_j[\hat{\varphi}] \rightarrow u[\hat{\varphi}] = \hat{u}[\varphi]$ for every φ , so $\hat{u}_j \xrightarrow{*} \hat{u}$: the map is sequentially continuous. Since $\mathcal{F}^4 = (2\pi)^{2n} \text{id}$, the inverse is $(2\pi)^{-2n} \mathcal{F}^3$, which is continuous by the same argument. $\square$

§26.9.7 Periodic distributions

As an application, and as preparation for Fourier series in the distributional setting, we look at periodic distributions.

Definition 26.9.30

$u \in \mathcal{D}'(\mathbb{R}^n)$ is **periodic** if $\tau_y u = u$ for all $y \in \mathbb{Z}^n$.

Example 26.9.31

If $f \in L^1_{\text{loc}}(\mathbb{R}^n)$ is $\mathbb{Z}^n$ -periodic then T_f is periodic. More interestingly, if $v \in \mathcal{E}'(\mathbb{R}^n)$ then $u = \sum_{y \in \mathbb{Z}^n} \tau_y v$ is a periodic distribution (for each $\varphi \in \mathcal{D}$ the sum is finite).

For a periodic smooth function we often want the average over a fundamental cell $q = \{x : -1/2 \leq x_i < 1/2\}$, namely $M[f] = \int_q f$. We would like to write $M[f] = T_f[\mathbb{1}_q]$, but $\mathbb{1}_q$ is not a test function. The fix is a smooth partition of unity.

Lemma 26.9.32

Let $Q = \{x : -1 \leq x_i < 1\}$. There is $\psi \in C^\infty(\mathbb{R}^n)$ with $\psi \geq 0$, $\text{supp } \psi \subseteq Q^\circ$, and $\sum_{y \in \mathbb{Z}^n} \tau_y \psi = 1$. Moreover if ψ, ψ' are two such functions and $u \in \mathcal{D}'(\mathbb{R}^n)$ is periodic, then $u[\psi] = u[\psi']$.

Proof. Pick $\psi_0 \in C^\infty(\mathbb{R}^n)$ supported in Q° with $\psi_0 \geq 0$ and $\psi_0 \equiv 1$ on q (a smoothed indicator, built from the bump of Example 26.4.8). Set $s(x) = \sum_{y \in \mathbb{Z}^n} \psi_0(x - y)$; this sum is locally finite, so $s \in C^\infty$, it is $\mathbb{Z}^n$ -periodic, and $s \geq 1$ since every x has some translate in q . Then $\psi = \psi_0/s$ works.

For the second part, using periodicity of u and of the partitions,

$$u[\psi] = u\left[\psi \sum_y \tau_y \psi'\right] = \sum_y u[\psi \tau_y \psi'] = \sum_y \tau_{-y} u[\psi' \tau_{-y} \psi] = \sum_y u[\psi' \tau_y \psi] = u[\psi'],$$

all sums being finite. $\square$

So we may define the **mean** $M[u] = u[\psi]$ of a periodic distribution, and if $u = T_f$ for periodic $f \in L^1_{\text{loc}}$ this agrees with $\int_q f$.

Lemma 26.9.33

If $v \in \mathcal{E}'(\mathbb{R}^n)$ then $u = \sum_{y \in \mathbb{Z}^n} \tau_y v$ converges weakly-* in $\mathcal{S}'(\mathbb{R}^n)$. Conversely every periodic distribution has this form; in particular every periodic distribution is tempered.

Proof. For the first part, Lemma 26.9.14 gives compact $K \subseteq B_R(0)$, $k \in \mathbb{N}$ and $C > 0$ with $|v[\varphi]| \leq C \sup_{x \in K, |\alpha| \leq k} |D^\alpha \varphi(x)|$. Then $|\tau_y v[\varphi]| \leq C \sup_{x \in K, |\alpha| \leq k} |D^\alpha \varphi(x + y)|$. For $x \in K$ we have $1 + |y| \leq (1 + R)(1 + |x + y|)$, so for any m ,

$$|\tau_y v[\varphi]| \leq C \frac{(1 + R)^m}{(1 + |y|)^m} \sup_{x' \in \mathbb{R}^n, |\alpha| \leq k} |(1 + |x'|)^m D^\alpha \varphi(x')|.$$

Choosing $m \geq n+1$ makes $\sum_{y \in \mathbb{Z}^n} (1 + |y|)^{-m}$ finite, so the series converges absolutely, uniformly over φ in a bounded set of $\mathcal{S}$.

Conversely let u be periodic and ψ a periodic partition of unity. For $\varphi \in \mathcal{D}(\mathbb{R}^n)$,

$$u[\varphi] = u\left[\varphi \sum_y \tau_y \psi\right] = \sum_y u[\varphi \tau_y \psi],$$

and $u[\varphi \tau_y \psi] = \tau_y u[\varphi \tau_y \psi] = (\psi u)[\tau_{-y} \varphi] = \tau_y(\psi u)[\varphi]$. So $v = \psi u$ works, and v has compact support since $v[\varphi] = u[\psi \varphi] = 0$ whenever $\text{supp } \varphi \cap \text{supp } \psi = \emptyset$. $\square$

Lemma 26.9.34

Suppose $u \in \mathcal{S}'(\mathbb{R}^n)$ satisfies $(e_{-y} - 1)u = 0$ for all $y \in \mathbb{Z}^n$. Then

$$u = \sum_{y \in \mathbb{Z}^n} c_y \delta_{2\pi y}$$

for constants c_y with $|c_y| \leq C(1 + |y|)^N$ for some $C > 0$ and $N \in \mathbb{N}$, the sum converging in $\mathcal{S}'(\mathbb{R}^n)$.

Proof. Write $\Lambda^* = 2\pi\mathbb{Z}^n$. If $\varphi \in \mathcal{D}(\mathbb{R}^n)$ has $\text{supp } \varphi \cap \Lambda^* = \emptyset$ then $(e_{-y} - 1)$ is non-vanishing on $\text{supp } \varphi$ for suitable y , so $(e_{-y} - 1)^{-1}\varphi$ is a legitimate test function and $u[\varphi] = (e_{-y} - 1)u[(e_{-y} - 1)^{-1}\varphi] = 0$. Hence u is supported on Λ^* .

Take a periodic partition of unity ψ and set $\tilde{\psi}(x) = \psi(x/2\pi)$, so that $\sum_y \tau_{2\pi y} \tilde{\psi} = 1$. Put $v_y = (\tau_{2\pi y} \tilde{\psi})u$, supported at the single point $2\pi y$, with $\sum_y v_y = u$. From $(e_{-y'} - 1)v_y = 0$ and $e^{-i(x_j - 2\pi y_j)} - 1 = (x_j - 2\pi y_j)\kappa(x_j)$ with κ smooth and non-vanishing near $2\pi y_j$, we get $(x_j - 2\pi y_j)v_y = 0$ for each j . Taylor expanding $\varphi(x) = \varphi(2\pi y) + \sum_j (x_j - 2\pi y_j)\varphi_j(x)$ with φ_j smooth, and using that v_y has compact support so extends to $\mathcal{E}$, gives $v_y[\varphi] = \varphi(2\pi y)v_y[1]$; that is, $v_y = c_y \delta_{2\pi y}$ with $c_y = u[\tau_{2\pi y} \tilde{\psi}]$.

For the bound, Lemma 26.9.14 applied in $\mathcal{S}'$ supplies N, k, C such that

$$|u[\varphi]| \leq C \sup_{x, |\alpha| \leq k} \left| (1 + |x|)^N D^\alpha \varphi(x) \right|,$$

whence

$$|c_y| \leq C \sup_{x, |\alpha| \leq k} \left| (1 + |x + 2\pi y|)^N D^\alpha \tilde{\psi}(x) \right| \leq C'(1 + |y|)^N. \quad \square$$

Theorem 26.9.35 (Fourier series of a periodic distribution)

Let $u \in \mathcal{D}'(\mathbb{R}^n)$ be periodic. Then there are $c_y \in \mathbb{C}$ with

$$u = \sum_{y \in \mathbb{Z}^n} c_y T_{e_{2\pi y}}$$

converging in $\mathcal{S}'(\mathbb{R}^n)$, where $c_y = M[e_{-2\pi y}u]$ satisfies $|c_y| \leq C(1 + |y|)^N$ for some C, N .

Proof. Periodicity says $\tau_{y'}u = u$ for $y' \in \mathbb{Z}^n$, and u is tempered by Lemma 26.9.33, so taking Fourier transforms and using Lemma 26.9.28 gives $(e_{-y'} - 1)\hat{u} = 0$. By Lemma 26.9.34,

$$\hat{u} = (2\pi)^n \sum_{y \in \mathbb{Z}^n} c_y \delta_{2\pi y},$$

and applying the inversion formula of Lemma 26.9.28 together with Example 26.9.27 gives $u = \sum_y c_y T_{e_{2\pi y}}$. Finally $M[e_{-2\pi y} T_{e_{2\pi y'}}] = \delta_{yy'}$ by direct computation, and $u \mapsto M[e_{-2\pi y}u]$ is continuous on $\mathcal{S}'$, so $M[e_{-2\pi y}u] = c_y$. $\square$

We usually abuse notation and write $u(x) = \sum_{y \in \mathbb{Z}^n} c_y e^{2\pi i(y \cdot x)}$. The theorem says that *every* periodic distribution has a Fourier series, with coefficients of at most polynomial growth, and that the series converges in $\mathcal{S}'$.

Example 26.9.36 (Poisson summation)

Let $u = \sum_{y \in \mathbb{Z}^n} \delta_y$, the ‘Dirac comb’. Its Fourier coefficients are

$$c_y = M[e_{-2\pi y}u] = u[\psi e_{2\pi y}] = \sum_{y' \in \mathbb{Z}^n} \psi(y') e^{-2\pi i(y \cdot y')} = \sum_{y' \in \mathbb{Z}^n} \psi(y') = 1,$$

since $e^{-2\pi i(y \cdot y')} = 1$ for $y, y' \in \mathbb{Z}^n$ and $\sum_{y'} \psi(y') = 1$ by the partition of unity property. Theorem 26.9.35 therefore gives **Poisson's summation formula**

$$\sum_{y \in \mathbb{Z}^n} \delta_y = \sum_{y \in \mathbb{Z}^n} T_{e^{2\pi i y}}, \quad \text{or informally} \quad \sum_{y \in \mathbb{Z}^n} \delta(x - y) = \sum_{y \in \mathbb{Z}^n} e^{2\pi i(y \cdot x)}.$$

Pairing both sides with a Schwartz function φ recovers the classical statement $\sum_y \varphi(y) = \sum_y \hat{\varphi}(2\pi y)$, a formula with a great many applications in number theory and in the study of lattices.

§26.10 Sobolev Spaces

Distribution theory tells us that every locally integrable function can be differentiated, but the derivative may be a wild object. Sobolev spaces impose the reasonable extra requirement that the derivatives be functions again, and indeed functions in L^p . The resulting spaces are the natural setting for the theory of partial differential equations: they are complete, they have good compactness properties, and – the content of the embedding theorem – an element with enough weak derivatives is automatically a classical function.

§26.10.1 Weak derivatives

Definition 26.10.1 (Sobolev space)

Let $\Omega \subseteq \mathbb{R}^n$ be open, $k \in \mathbb{Z}_{\geq 0}$ and $1 \leq p \leq \infty$. We say $f \in L^p(\Omega)$ belongs to the **Sobolev space** $W^{k,p}(\Omega)$ if for every multi-index α with $|\alpha| \leq k$ there is $f^\alpha \in L^p(\Omega)$ with

$$D^\alpha T_f = T_{f^\alpha} \quad \text{in } \mathcal{D}'(\Omega),$$

that is,

$$\int_{\Omega} f^\alpha \varphi \, dx = (-1)^{|\alpha|} \int_{\Omega} f D^\alpha \varphi \, dx \quad \text{for all } \varphi \in C_c^\infty(\Omega).$$

We call f^α the **α -th weak derivative** of f , and write $D^\alpha f$ for it.

The weak derivative is unique when it exists, by Corollary 26.4.12, and agrees with the classical derivative when that exists and is continuous. From now on we drop the distinction between f and T_f entirely.

Definition 26.10.2

$W^{k,p}(\Omega)$ is normed by

$$\|f\|_{W^{k,p}} = \left(\sum_{|\alpha| \leq k} \|D^\alpha f\|_{L^p}^p \right)^{1/p} \quad (p < \infty),$$

and by $\|f\|_{W^{k,\infty}} = \max_{|\alpha| \leq k} \|D^\alpha f\|_{L^\infty}$ when $p = \infty$. We write $H^k(\Omega) = W^{k,2}(\Omega)$, which is a Hilbert space with $\langle f, g \rangle_{H^k} = \sum_{|\alpha| \leq k} \langle D^\alpha f, D^\alpha g \rangle_{L^2}$.

Proposition 26.10.3

$W^{k,p}(\Omega)$ is a Banach space.

Proof. Let (f_j) be Cauchy. Then each $(D^\alpha f_j)$ is Cauchy in L^p , so converges to some $g_\alpha \in L^p$ by Theorem 26.3.8. Write $f = g_0$. For $\varphi \in C_c^\infty(\Omega)$, Hölder gives $\int D^\alpha f_j \varphi \rightarrow \int g_\alpha \varphi$ and $\int f_j D^\alpha \varphi \rightarrow \int f D^\alpha \varphi$, so passing to the limit in the defining identity shows $g_\alpha = D^\alpha f$ weakly. Hence $f \in W^{k,p}$ and $f_j \rightarrow f$ in the norm. $\square$

Weak derivatives obey the rules one expects, provided one does not ask for too much. They are linear, and they commute with each other (both facts are inherited from $\mathcal{D}'(\Omega)$, where they are immediate from the definition). The product rule holds against a smooth factor, which is exactly the case we shall need when localising with a cut-off function.

Lemma 26.10.4 (Leibniz rule)

Let $u \in W^{1,p}(\Omega)$ and $\chi \in C^\infty(\Omega)$ with χ and $D\chi$ bounded. Then $\chi u \in W^{1,p}(\Omega)$ and

$$D_i(\chi u) = \chi D_i u + (D_i \chi)u.$$

Proof. Both terms on the right lie in $L^p(\Omega)$ by boundedness of χ and $D\chi$. Let $\varphi \in C_c^\infty(\Omega)$; then $\chi\varphi \in C_c^\infty(\Omega)$ is a legitimate test function, and $D_i(\chi\varphi) = \chi D_i \varphi + (D_i \chi)\varphi$ classically. So

$$\begin{aligned} \int_\Omega \chi u D_i \varphi \, dx &= \int_\Omega u (D_i(\chi\varphi) - (D_i \chi)\varphi) \, dx \\ &= - \int_\Omega (D_i u) \chi \varphi \, dx - \int_\Omega u (D_i \chi) \varphi \, dx, \end{aligned}$$

using the definition of the weak derivative of u against the test function $\chi\varphi$. This is precisely the assertion. $\square$

Iterating gives the corresponding statement for higher derivatives: if $u \in W^{k,p}(\Omega)$ and $\chi \in C_c^\infty(\Omega)$ then $\chi u \in W^{k,p}(\Omega)$, with $D^\alpha(\chi u)$ given by the usual Leibniz expansion. What one *cannot* do is multiply two Sobolev functions and expect the product rule, or apply the chain rule with a merely continuous outer function; these require separate arguments and extra hypotheses.

Example 26.10.5 (i) Let $u(x) = |x|$ on $(-2, 2)$. Then u is not differentiable at 0, but for $\varphi \in C_c^\infty((-2, 2))$,

$$- \int_{-2}^2 |x| \varphi'(x) \, dx = \int_{-2}^0 \varphi'(x) \, dx - \int_0^2 x \varphi'(x) \, dx = \int_{-2}^2 \operatorname{sgn}(x) \varphi(x) \, dx$$

after integrating by parts on each side (the boundary terms at 0 cancel). So $Du = \operatorname{sgn}$ weakly, and $u \in W^{1,p}((-2, 2))$ for every p .

(ii) By contrast, the Heaviside function $H = \mathbb{1}_{[0,\infty)}$ is in no $W^{1,p}$: its distributional derivative is δ_0 , which is not a function.

So a kink is permitted – it costs one derivative – but a jump is not.

§26.10.2 Sobolev spaces via the Fourier transform

On $\Omega = \mathbb{R}^n$ with $p = 2$ we can say something much sharper, because the Fourier transform turns differentiation into multiplication. Indeed for $f \in L^2(\mathbb{R}^n)$ we have $D^\alpha f \in L^2(\mathbb{R}^n)$ if and only if $\xi^\alpha \hat{f}(\xi) \in L^2(\mathbb{R}^n)$, by Lemma 26.9.28 and Plancherel. Since $\sum_{|\alpha| \leq k} |\xi^\alpha|^2$ is comparable to $(1 + |\xi|^2)^k$, this suggests a definition which makes sense for non-integer orders.

Definition 26.10.6

For $s \in \mathbb{R}$, we say $u \in \mathcal{S}'(\mathbb{R}^n)$ belongs to $H^s(\mathbb{R}^n)$ if $\hat{u} \in L^2_{\text{loc}}(\mathbb{R}^n)$ and

$$\|u\|_{H^s}^2 = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} (1 + |\xi|^2)^s |\hat{u}(\xi)|^2 d\xi < \infty.$$

This makes $H^s(\mathbb{R}^n)$ a Hilbert space with $\langle u, v \rangle_{H^s} = (2\pi)^{-n} \int \hat{u} \bar{\hat{v}} (1 + |\xi|^2)^s d\xi$.

For $s \in \mathbb{Z}_{\geq 0}$ we have $H^s(\mathbb{R}^n) = W^{s,2}(\mathbb{R}^n)$ with equivalent norms, by the remarks above. But now s may be any real number: fractional orders measure fractional differentiability, and negative orders describe distributions rougher than functions. For instance $\delta_0 \in H^s(\mathbb{R}^n)$ exactly when $s < -n/2$, since $\hat{\delta}_0 = 1$ and $\int (1 + |\xi|^2)^s d\xi < \infty$ iff $2s < -n$.

The Fourier description makes the following density statement almost trivial, and we shall use it repeatedly to reduce statements about H^s to computations with Schwartz functions.

Lemma 26.10.7

For every $s \in \mathbb{R}$, the space $\mathcal{S}(\mathbb{R}^n)$ is dense in $H^s(\mathbb{R}^n)$.

Proof. Let $u \in H^s(\mathbb{R}^n)$, so that $w = (1 + |\xi|^2)^{s/2} \hat{u} \in L^2(\mathbb{R}^n)$. By Corollary 26.4.11 choose $\psi \in C_c^\infty(\mathbb{R}^n)$ with $\|w - \psi\|_{L^2} < (2\pi)^{n/2} \varepsilon$, and set

$$v = \mathcal{F}^{-1}[(1 + |\xi|^2)^{-s/2} \psi].$$

The function $\xi \mapsto (1 + |\xi|^2)^{-s/2}$ is smooth on all of $\mathbb{R}^n$, so $(1 + |\xi|^2)^{-s/2} \psi \in C_c^\infty(\mathbb{R}^n) \subseteq \mathcal{S}(\mathbb{R}^n)$, whence $v \in \mathcal{S}(\mathbb{R}^n)$ by Corollary 26.8.10. And

$$\|u - v\|_{H^s}^2 = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} (1 + |\xi|^2)^s |\hat{u} - \hat{v}|^2 d\xi = \frac{1}{(2\pi)^n} \|w - \psi\|_{L^2}^2 < \varepsilon^2. \quad \square$$

§26.10.3 The Sobolev embedding theorem

Here is the theorem that makes Sobolev spaces worth the trouble.

Theorem 26.10.8 (Sobolev embedding)

Let $k \in \mathbb{Z}_{\geq 0}$ and $s > k + n/2$. If $f \in H^s(\mathbb{R}^n)$ then there is $f^* \in C^k(\mathbb{R}^n)$ with $f = f^*$ almost everywhere, and

$$\sup_{x \in \mathbb{R}^n, |\alpha| \leq k} |D^\alpha f^*(x)| \leq c_{n,k,s} \|f\|_{H^s}.$$

We write $H^s(\mathbb{R}^n) \subseteq C^k(\mathbb{R}^n)$.

Proof. Suppose first $f \in \mathcal{S}(\mathbb{R}^n)$. By the inversion theorem and Lemma 26.9.28,

$$D^\alpha f(x) = \frac{i^{|\alpha|}}{(2\pi)^n} \int_{\mathbb{R}^n} e^{i(x \cdot \xi)} \xi^\alpha \hat{f}(\xi) \, d\xi,$$

so by Cauchy–Schwarz, inserting and removing a factor $(1 + |\xi|^2)^{s/2}$,

$$|D^\alpha f(x)| \leq \frac{1}{(2\pi)^n} \left(\int_{\mathbb{R}^n} (1 + |\xi|^2)^s |\hat{f}(\xi)|^2 \, d\xi \right)^{1/2} \left(\int_{\mathbb{R}^n} \frac{|\xi^\alpha|^2}{(1 + |\xi|^2)^s} \, d\xi \right)^{1/2}.$$

Since $|\alpha| \leq k$ we have $|\xi^\alpha|^2 \leq c_k(1 + |\xi|^2)^k$, so the second integral is at most

$$c_k \int_{\mathbb{R}^n} \frac{d\xi}{(1 + |\xi|^2)^{s-k}} = c_{k,n,s}^2 < \infty$$

precisely because $2(s - k) > n$. Hence $\sup_{x, |\alpha| \leq k} |D^\alpha f(x)| \leq c_{n,k,s} \|f\|_{H^s}$ for $f \in \mathcal{S}(\mathbb{R}^n)$.

For general $f \in H^s(\mathbb{R}^n)$, approximate: by Lemma 26.10.7 there are $f_m \in \mathcal{S}(\mathbb{R}^n)$ with $f_m \rightarrow f$ in H^s , hence in L^2 , and so (after passing to a subsequence) almost everywhere. The sequence (f_m) is Cauchy in H^s , hence by the estimate Cauchy in $C^k(\mathbb{R}^n)$ with the uniform norm on all derivatives up to order k ; that space is complete, so $f_m \rightarrow f^*$ in C^k . Since also $f_m \rightarrow f$ a.e., $f = f^*$ a.e. $\square$

The moral is that *differentiability can be bought with integrability, at an exchange rate of $n/2$ derivatives*. It is a genuinely surprising statement: membership of H^s is a statement about integrals, and yet for s large enough it forces pointwise regularity. Note also that the threshold is sharp: in $\mathbb{R}^n$ with $n \geq 2$, the function $\log \log(1 + 1/|x|)$ near the origin is in $H^{n/2}$ but unbounded, so $s = k + n/2$ will not do.

The general L^p statement, which we quote, is a chart of the same phenomenon at other exponents.

Theorem 26.10.9 (General Sobolev embeddings)

Let $\Omega \subseteq \mathbb{R}^n$ be a bounded domain with C^1 boundary, $k \geq 1$ and $1 \leq p < \infty$.

- (i) If $kp < n$ then $W^{k,p}(\Omega) \subseteq L^q(\Omega)$ for $\frac{1}{q} = \frac{1}{p} - \frac{k}{n}$, continuously.
- (ii) If $kp > n$ then $W^{k,p}(\Omega) \subseteq C^{m,\gamma}(\overline{\Omega})$, where $m = k - \lfloor n/p \rfloor - 1$ and $\gamma \in (0, 1)$

is determined by n, k, p .

- (iii) If $kp = n$ then $W^{k,p}(\Omega) \subseteq L^q(\Omega)$ for every $q < \infty$, but not in general for $q = \infty$.

§26.10.4 The spaces $H_0^1(\Omega)$ and traces

For boundary value problems we need to make sense of the restriction of a Sobolev function to $\partial\Omega$, which is a set of measure zero. Since elements of H^s are only defined up to null sets, this requires an argument; the answer is that it can be done as soon as $s > 1/2$.

Theorem 26.10.10 (Trace theorem)

Let $s > 1/2$. There is a bounded surjective linear map

$$T : H^s(\mathbb{R}^n) \rightarrow H^{s-1/2}(\mathbb{R}^{n-1})$$

with $Tf = f|_{\{x_n=0\}}$ for every $f \in \mathcal{S}(\mathbb{R}^n)$.

The proof (example sheet) is a computation with the Fourier transform: one shows that the partial transform of the restriction is obtained by integrating $\hat{f}$ in the ξ_n variable, and estimates the result with Cauchy–Schwarz exactly as in Theorem 26.10.8. Note the loss of half a derivative, and note that $s > 1/2$ is needed: an $H^{1/2}$ function has no well-defined trace. By combining with local coordinate changes one obtains a trace map onto sufficiently regular hypersurfaces, in particular onto the boundary of a Lipschitz domain.

Definition 26.10.11

Let $\Omega \subseteq \mathbb{R}^n$ be open. Extending by zero, we regard $C_c^\infty(\Omega) \subseteq H^1(\mathbb{R}^n)$, and define $H_0^1(\Omega)$ to be the closure of $C_c^\infty(\Omega)$ in $H^1(\mathbb{R}^n)$.

For $f \in C_c^\infty(\Omega)$, Plancherel gives the convenient formula

$$\|f\|_{H^1}^2 = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} (1 + |\xi|^2) |\hat{f}(\xi)|^2 \, d\xi = \int_{\Omega} (|Df(x)|^2 + |f(x)|^2) \, dx,$$

so $H_0^1(\Omega)$ is a Hilbert space with inner product

$$\langle u, v \rangle_{H^1} = \int_{\Omega} (Du \cdot \overline{Dv} + \overline{u}v) \, dx.$$

Elements of $H_0^1(\Omega)$ vanish outside Ω and have zero trace on $\partial\Omega$. Indeed, if $\varphi \in C_c^\infty((\Omega^c)^\circ)$ then $\Lambda_\varphi(u) = \int_{\mathbb{R}^n} \varphi u$ vanishes for $u \in C_c^\infty(\Omega)$ and is continuous on $H^1(\mathbb{R}^n)$, so it vanishes on $H_0^1(\Omega)$ – that is, every $u \in H_0^1(\Omega)$ vanishes a.e. on Ω^c . And if $\partial\Omega$ is regular enough for the trace map $T : H^1 \rightarrow H^{1/2}(\partial\Omega)$ to be defined and bounded, then $Tu = 0$ for $u \in C_c^\infty(\Omega)$ and hence for all $u \in H_0^1(\Omega)$. So, informally:

$$H_0^1(\Omega) = \{u \in H^1 : u = 0 \text{ on } \partial\Omega \text{ and outside } \Omega\},$$

and this is the space in which we shall pose the Dirichlet problem.

§26.10.5 Poincaré's inequality

On $H_0^1(\Omega)$ with Ω bounded, the full H^1 norm is controlled by the gradient alone. This is a genuinely useful fact: it says that a function which vanishes on the boundary cannot be large without having a large derivative somewhere.

Theorem 26.10.12 (Poincaré)

Let $\Omega \subseteq \mathbb{R}^n$ be contained in a slab $\{0 < x_1 < d\}$. Then

$$\|u\|_{L^2(\Omega)} \leq d \|Du\|_{L^2(\Omega)} \quad \text{for all } u \in H_0^1(\Omega).$$

Proof. By density it is enough to treat $u \in C_c^\infty(\Omega)$, which we extend by zero to the slab. For such u , the fundamental theorem of calculus in the x_1 direction gives

$$u(x) = \int_0^{x_1} \partial_1 u(t, x_2, \dots, x_n) dt,$$

so by Cauchy–Schwarz

$$|u(x)|^2 \leq x_1 \int_0^d |\partial_1 u(t, x')|^2 dt \leq d \int_0^d |\partial_1 u(t, x')|^2 dt,$$

where $x' = (x_2, \dots, x_n)$. Integrating in x_1 over $(0, d)$ and then in x' over $\mathbb{R}^{n-1}$,

$$\int_\Omega |u|^2 dx \leq d^2 \int_\Omega |\partial_1 u|^2 dx \leq d^2 \int_\Omega |Du|^2 dx. \quad \square$$

Corollary 26.10.13

For Ω bounded, $\|Du\|_{L^2(\Omega)}$ is a norm on $H_0^1(\Omega)$ equivalent to $\|u\|_{H^1}$.

Proof. Clearly $\|Du\|_{L^2} \leq \|u\|_{H^1}$, and conversely $\|u\|_{H^1}^2 = \|Du\|_{L^2}^2 + \|u\|_{L^2}^2 \leq (1 + d^2) \|Du\|_{L^2}^2$. $\square$

Poincaré's inequality fails on all of $H^1(\Omega)$ – constants are a counterexample – and it fails on $H_0^1(\mathbb{R}^n) = H^1(\mathbb{R}^n)$, where there is no bounded direction. Boundedness of the domain, or at least of one direction, is essential.

§26.10.6 Rellich–Kondrachov

Finally we come to the compactness theorem. Let Ω be open and bounded and let (u_m) be a bounded sequence in $H_0^1(\Omega)$, say $\|u_m\|_{H^1} \leq K$. Since $H_0^1(\Omega)$ is a Hilbert space, hence reflexive, Corollary 26.6.29 gives a subsequence with $u_m \rightharpoonup u$ in $H_0^1(\Omega)$, and $\|u\|_{H^1} \leq K$. Moreover for $w \in L^2(\Omega)$ we have $|\langle w, v \rangle_{L^2}| \leq \|w\|_{L^2} \|v\|_{H^1}$, so $v \mapsto \langle w, v \rangle_{L^2}$ is a bounded functional on $H_0^1(\Omega)$ and therefore $u_m \rightharpoonup u$ in $L^2(\Omega)$ as well. The theorem is that this convergence is in fact *strong*.

Theorem 26.10.14 (Rellich–Kondrachov)

Let $\Omega \subseteq \mathbb{R}^n$ be open and bounded. Suppose $(u_m) \subseteq H_0^1(\Omega)$ with $\|u_m\|_{H^1} \leq K$ and $u_m \rightharpoonup u$ in $L^2(\Omega)$ for some $u \in H_0^1(\Omega)$. Then $u_m \rightarrow u$ strongly in $L^2(\Omega)$.

Proof. Regard everything as defined on $\mathbb{R}^n$ by extension by zero. By Plancherel,

$$\|u_m - u\|_{L^2}^2 = \frac{1}{(2\pi)^n} \int_{|\xi| < R} |\hat{u}_m - \hat{u}|^2 d\xi + \frac{1}{(2\pi)^n} \int_{|\xi| \geq R} |\hat{u}_m - \hat{u}|^2 d\xi,$$

and we treat the two ranges differently. This is the standard division into low and high frequencies, and it is worth remembering: the high frequencies are killed by the derivative bound, the low frequencies by the weak convergence.

High frequencies. For $|\xi| \geq R$ we have $1 \leq (1 + |\xi|^2)/R^2$, so

$$\begin{aligned} \int_{|\xi| \geq R} |\hat{u}_m - \hat{u}|^2 d\xi &\leq \frac{2}{R^2} \int_{\mathbb{R}^n} (1 + |\xi|^2) (|\hat{u}_m|^2 + |\hat{u}|^2) d\xi \\ &\leq \frac{C}{R^2} (\|u_m\|_{H^1}^2 + \|u\|_{H^1}^2) \leq \frac{CK^2}{R^2}, \end{aligned}$$

which we may make as small as we please by choosing R large – *uniformly in m* .

Low frequencies. Fix such an R . Since $|\Omega| < \infty$, the function $x \mapsto e^{-i(x \cdot \xi)}$ lies in $L^2(\Omega)$ for each ξ , and $\hat{u}_m(\xi) = \langle e_\xi, u_m \rangle_{L^2(\Omega)}$. So weak convergence in $L^2(\Omega)$ gives $\hat{u}_m(\xi) \rightarrow \hat{u}(\xi)$ pointwise. Moreover, by the Riemann–Lebesgue bound and Cauchy–Schwarz on the bounded set Ω ,

$$|\hat{u}_m(\xi) - \hat{u}(\xi)|^2 \leq 2 (\|u_m\|_{L^1}^2 + \|u\|_{L^1}^2) \leq 2|\Omega| (\|u_m\|_{L^2}^2 + \|u\|_{L^2}^2) \leq C',$$

a constant, which is integrable on the ball $\{|\xi| < R\}$. Dominated convergence therefore gives

$$\int_{|\xi| < R} |\hat{u}_m(\xi) - \hat{u}(\xi)|^2 d\xi \rightarrow 0 \quad \text{as } m \rightarrow \infty.$$

Combining, $\limsup_m \|u_m - u\|_{L^2}^2 \leq CK^2/R^2$ for every R , so the limit is 0. $\square$

Corollary 26.10.15

Let Ω be open and bounded and let $(u_m) \subseteq H_0^1(\Omega)$ with $\|u_m\|_{H^1} \leq K$. Then there is a subsequence and $u \in H_0^1(\Omega)$ with $u_m \rightharpoonup u$ in H^1 and $u_m \rightarrow u$ strongly in L^2 .

Corollary 26.10.16

Let Ω be open and bounded and let $A : L^2(\Omega) \rightarrow H_0^1(\Omega)$ be bounded and linear. Then A , viewed as a map $L^2(\Omega) \rightarrow L^2(\Omega)$, is compact.

Proof. If $\|u_m\|_{L^2} \leq K$ then $\|Au_m\|_{H^1} \leq \|A\| K$, so (Au_m) has an L^2 -convergent subsequence by Corollary 26.10.15. $\square$

The inclusion $H_0^1(\Omega) \hookrightarrow L^2(\Omega)$ is thus a compact operator: the unit ball of H_0^1 is precompact in L^2 . This is the compactness that we shall use to solve elliptic problems and to diagonalise the Laplacian. Note where boundedness of Ω entered – twice, in fact – and note that the result is false on $\mathbb{R}^n$, where the translates $\phi(\cdot - m)$ of a fixed bump are bounded in H^1 with no L^2 -convergent subsequence.

§26.11 Applications to Elliptic Equations

We can now do what the whole course has been building towards. In this section $\Omega \subseteq \mathbb{R}^n$ is open and bounded, and we study the boundary value problem

$$\begin{cases} -\nabla^2 u + u = f & \text{in } \Omega, \\ u = 0 & \text{on } \partial\Omega. \end{cases}$$

Classically one would ask for $u \in C^2(\Omega) \cap C^0(\overline{\Omega})$ satisfying this pointwise, and proving that such a u exists is hard. The modern strategy is to relax the problem until existence is easy, and then to work to show that the object produced is better than it had to be.

**§26.11.1 Weak solutions**

Suppose for a moment that u is a classical solution and $v \in C_c^\infty(\Omega)$. Multiplying by $\bar{v}$ and integrating by parts (no boundary term, as v has compact support),

$$\int_{\Omega} (Du \cdot \overline{Dv} + u\bar{v}) \, dx = \int_{\Omega} f\bar{v} \, dx,$$

that is, $\langle v, u \rangle_{H^1} = \langle v, f \rangle_{L^2}$ in our notation. The left side makes sense for $u \in H^1$, and by continuity the identity extends from $v \in C_c^\infty(\Omega)$ to $v \in H_0^1(\Omega)$. This motivates the following.

Definition 26.11.1 (Weak solution)

Let $f \in L^2(\Omega)$. We say $u \in H_0^1(\Omega)$ is a **weak solution** of the boundary value problem if

$$\langle u, v \rangle_{H^1} = \langle f, v \rangle_{L^2} \quad \text{for all } v \in H_0^1(\Omega).$$

Note that the boundary condition is encoded in the requirement $u \in H_0^1(\Omega)$, not in a separate equation. Conversely, if u is a weak solution then testing against $v \in C_c^\infty(\Omega)$ and integrating by parts shows that $-\nabla^2 u + u = f$ holds in $\mathcal{D}'(\Omega)$. So the notions match up as they should.

Lemma 26.11.2

For every $f \in L^2(\Omega)$ there is a unique weak solution $u \in H_0^1(\Omega)$, and $\|u\|_{H^1} \leq \|f\|_{L^2}$.

Proof. The map $\Lambda : v \mapsto \langle f, v \rangle_{L^2}$ is linear, and bounded on $H_0^1(\Omega)$ since

$$|\langle f, v \rangle_{L^2}| \leq \|f\|_{L^2} \|v\|_{L^2} \leq \|f\|_{L^2} \|v\|_{H^1}.$$

As $H_0^1(\Omega)$ is a Hilbert space, Theorem 26.5.3 provides a unique $u \in H_0^1(\Omega)$ with $\langle u, v \rangle_{H^1} = \Lambda(v)$ for all v , and $\|u\|_{H^1} = \|\Lambda\| \leq \|f\|_{L^2}$. $\square$

That is the entire existence proof. It is worth pausing to see how much was smuggled in: the completeness of H_0^1 (Riesz–Fischer), the identification of the H^1 inner product with the Dirichlet form (Plancherel), and the interpretation of the boundary condition (density of C_c^∞). Each was a theorem, and together they reduce a partial differential equation to the observation that a Hilbert space is its own dual.

Definition 26.11.3

Write $A : L^2(\Omega) \rightarrow H_0^1(\Omega)$ for the map $f \mapsto u$ given by Lemma 26.11.2, the **solution operator**.

Proposition 26.11.4

A is linear and bounded with $\|Af\|_{H^1} \leq \|f\|_{L^2}$, and, regarded as a map $L^2(\Omega) \rightarrow L^2(\Omega)$, it is compact and Hermitian.

Proof. Linearity: if $u = Af$, $w = Ag$ then for all v ,

$$\langle u + aw, v \rangle_{H^1} = \langle f, v \rangle_{L^2} + \bar{a} \langle g, v \rangle_{L^2} = \langle f + ag, v \rangle_{L^2},$$

so $A(f + ag) = Af + aAg$ by uniqueness. Boundedness is Lemma 26.11.2; compactness follows from Corollary 26.10.16. For the Hermitian property, with $u = Af$, $w = Ag$,

$$\langle f, Ag \rangle_{L^2} = \langle f, w \rangle_{L^2} = \overline{\langle w, f \rangle_{L^2}} = \overline{\langle w, u \rangle_{H^1}} = \langle u, w \rangle_{H^1} = \langle Af, g \rangle_{L^2}. \quad \square$$

§26.11.2 The Lax–Milgram theorem

Lemma 26.11.2 used the fact that the Dirichlet form is exactly the H^1 inner product. For a general elliptic operator this fails: the associated bilinear form is neither symmetric nor equal to an inner product. The following generalisation of the Riesz representation theorem is the standard remedy.

Theorem 26.11.5 (Lax–Milgram)

Let $\mathcal{H}$ be a Hilbert space and $B : \mathcal{H} \times \mathcal{H} \rightarrow \mathbb{C}$ a sesquilinear form which is

- (i) **bounded**: $|B(u, v)| \leq C \|u\| \|v\|$ for some $C > 0$, and
- (ii) **coercive**: $|B(u, u)| \geq c \|u\|^2$ for some $c > 0$.

Then for every $\Lambda \in \mathcal{H}'$ there is a unique $u \in \mathcal{H}$ with $B(u, v) = \Lambda(v)$ for all $v \in \mathcal{H}$, and $\|u\| \leq c^{-1} \|\Lambda\|$.

Proof. For fixed u , the map $v \mapsto \overline{B(u, v)}$ is a bounded linear functional, so by Theorem 26.5.3 there is a unique $Su \in \mathcal{H}$ with $B(u, v) = \langle v, Su \rangle^-$; more conveniently, define $S : \mathcal{H} \rightarrow \mathcal{H}$ by $\langle Su, v \rangle = B(u, v)$. Then S is linear and bounded with $\|S\| \leq C$, by (i).

Coercivity gives $c \|u\|^2 \leq |B(u, u)| = |\langle Su, u \rangle| \leq \|Su\| \|u\|$, so $\|Su\| \geq c \|u\|$. Hence S is injective with closed range: if $Su_m \rightarrow w$ then (u_m) is Cauchy, so $u_m \rightarrow u$ and $Su = w$. If the range were not everything, there would be $0 \neq z \perp \text{ran } S$, and then $c \|z\|^2 \leq |B(z, z)| = |\langle Sz, z \rangle| = 0$, a contradiction. So S is a bijection.

Given Λ , Theorem 26.5.3 gives w with $\Lambda(v) = \langle w, v \rangle$, and $u = S^{-1}w$ satisfies $B(u, v) = \langle Su, v \rangle = \langle w, v \rangle = \Lambda(v)$. Uniqueness is injectivity of S , and the bound follows from $\|u\| \leq c^{-1} \|Su\| = c^{-1} \|w\| = c^{-1} \|\Lambda\|$. $\square$

Example 26.11.6

Let a_{ij}, b, c be bounded measurable on Ω with $\sum_{ij} a_{ij}(x) \xi_i \xi_j \geq \theta |\xi|^2$ for some $\theta > 0$ (**uniform ellipticity**), and consider

$$Lu = - \sum_{i,j} D_i(a_{ij} D_j u) + cu.$$

The associated form is $B(u, v) = \int_{\Omega} \left(\sum_{ij} a_{ij} D_j u \overline{D_i v} + cu \overline{v} \right)$, which is bounded on $H_0^1(\Omega)$, and coercive as soon as $c \geq 0$ (or, using Poincaré, whenever $c > -\theta/d^2$). So Theorem 26.11.5 gives a unique weak solution of $Lu = f$ in $H_0^1(\Omega)$ for every $f \in L^2(\Omega)$. Note that B need not be symmetric – $a_{ij} \neq a_{ji}$ is allowed – so the Riesz theorem alone would not have sufficed.

§26.11.3 Elliptic regularity

Our weak solution has, so far, one weak derivative. The equation says more.

Proposition 26.11.7

Let $s \in \mathbb{R}$ and $f \in H^s(\mathbb{R}^n)$. Then there is a unique $u \in H^{s+2}(\mathbb{R}^n)$ with $-\nabla^2 u + u = f$ in $\mathcal{S}'(\mathbb{R}^n)$, and $\|u\|_{H^{s+2}} = \|f\|_{H^s}$.

Proof. Taking Fourier transforms, the equation reads $(|\xi|^2 + 1)\hat{u}(\xi) = \hat{f}(\xi)$, so necessarily $\hat{u} = \hat{f}/(1 + |\xi|^2)$, which defines a tempered distribution and hence a unique u . Then

$$\|u\|_{H^{s+2}}^2 = \frac{1}{(2\pi)^n} \int (1 + |\xi|^2)^{s+2} \frac{|\hat{f}(\xi)|^2}{(1 + |\xi|^2)^2} d\xi = \|f\|_{H^s}^2. \quad \square$$

So on $\mathbb{R}^n$ the operator $-\nabla^2 + 1$ gains exactly two derivatives, which is the best possible and is the defining feature of a second-order elliptic operator. On a domain we obtain the same gain locally, by cutting off.

Definition 26.11.8

For $s > 0$ let $H_{\text{loc}}^s(\Omega) = \{u \in L_{\text{loc}}^2(\Omega) : \chi u \in H^s(\mathbb{R}^n) \text{ for all } \chi \in C_c^\infty(\Omega)\}$.

Note that if $s > n/2 + k$ and $u \in H_{\text{loc}}^s(\Omega)$ then $u \in C^k(\Omega)$: given U with $\bar{U} \subseteq \Omega$ compact, choose $\chi \in C_c^\infty(\Omega)$ with $\chi \equiv 1$ on U ; then $\chi u \in H^s(\mathbb{R}^n) \subseteq C^k(\mathbb{R}^n)$ by Theorem 26.10.8, and $\chi u = u$ on U .

Theorem 26.11.9 (Interior elliptic regularity)

Let $u \in H_0^1(\Omega)$ be a weak solution of $-\nabla^2 u + u = f$ with $f \in L^2(\Omega)$. Then $u \in H_{\text{loc}}^2(\Omega)$. If moreover $f \in H_{\text{loc}}^k(\Omega) \cap L^2(\Omega)$ then $u \in H_{\text{loc}}^{k+2}(\Omega)$; and if $f \in C^\infty(\Omega) \cap L^2(\Omega)$ then $u \in C^\infty(\Omega)$ and the equation holds classically.

Proof. Fix a compact $K \subseteq \Omega$ and $\chi_K \in C_c^\infty(\Omega)$ with $\chi_K \equiv 1$ on K , and set $w = \chi_K u$. For any $\varphi \in \mathcal{S}(\mathbb{R}^n)$ the function $v = \chi_K \varphi$ lies in $C_c^\infty(\Omega) \subseteq H_0^1(\Omega)$, so it is admissible as a test function. Substituting and moving the cut-off across the derivatives, which is legitimate by the Leibniz rule of Lemma 26.10.4, gives

$$\int_{\mathbb{R}^n} \bar{w}(-\nabla^2 \varphi + \varphi) dx = \int_{\mathbb{R}^n} \bar{g} \varphi dx, \quad g = f \chi_K - 2Du \cdot D\chi_K - u \nabla^2 \chi_K.$$

So $w \in H^1(\mathbb{R}^n)$ solves $-\nabla^2 w + w = g$ in $\mathcal{S}'(\mathbb{R}^n)$, and $g \in L^2 = H^0$ since $u \in H^1$ and $f \in L^2$. By Proposition 26.11.7, $w \in H^2(\mathbb{R}^n)$. As K was arbitrary, $u \in H_{\text{loc}}^2(\Omega)$.

Now bootstrap. If additionally $f \in H_{\text{loc}}^1$, then the formula for g shows $g \in H^1(\mathbb{R}^n)$ (each term now has one more derivative available), so $w \in H^3(\mathbb{R}^n)$ and $u \in H_{\text{loc}}^3(\Omega)$. Iterating gives $u \in H_{\text{loc}}^{k+2}(\Omega)$ whenever $f \in H_{\text{loc}}^k(\Omega) \cap L^2(\Omega)$. If f is smooth this holds for every k , so $u \in \bigcap_k C^k(\Omega) = C^\infty(\Omega)$ by the remark above, and a smooth distributional solution is a classical solution. $\square$

This gain of regularity – for free, from the equation alone – is called **elliptic regularity**, and it is the reason the weak formulation is not a cheat. We solved a weakened problem and got a classical solution anyway.

Remark. It is emphatically a property of elliptic operators, not of differential operators in general. The wave equation $u_{tt} - u_{xx} = 0$ has the general solution $u(x, t) = u_+(x + t) + u_-(x - t)$, and if $u_\pm$ are merely continuous this is a perfectly good weak solution

which is nowhere differentiable. Hyperbolic equations propagate singularities rather than smoothing them.

§26.11.4 The Fredholm alternative and eigenvalues of the Laplacian

Consider now the problem with a potential:

$$\begin{cases} -\nabla^2 u + Vu = f & \text{in } \Omega, \\ u = 0 & \text{on } \partial\Omega, \end{cases}$$

with $V : \Omega \rightarrow \mathbb{R}$ smooth and bounded. The weak formulation is

$$\int_{\Omega} (Du \cdot \overline{Dv} + Vu\overline{v}) \, dx = \int_{\Omega} f\overline{v} \, dx \quad \text{for all } v \in H_0^1(\Omega),$$

but now the left-hand side need not be an inner product, since V may be negative. Instead of appealing to Lax–Milgram (which would need V bounded below appropriately) we rewrite:

$$\int_{\Omega} (Du \cdot \overline{Dv} + u\overline{v}) \, dx = \int_{\Omega} ((1 - V)u + f)\overline{v} \, dx,$$

which says precisely $u = A(f + (1 - V)u)$, or

$$(I - \mathcal{K})u = Af, \quad \mathcal{K}u = A((1 - V)u).$$

Since $u \mapsto (1 - V)u$ is bounded on $L^2(\Omega)$ and $A : L^2 \rightarrow H_0^1$ is bounded, $\mathcal{K} : L^2(\Omega) \rightarrow L^2(\Omega)$ is compact by Corollary 26.10.16. The Fredholm theory of compact operators now applies verbatim:

Theorem 26.11.10

Let Ω be open and bounded and V smooth and bounded. Then exactly one of the following holds.

- (i) There is a non-zero $w \in H_0^1(\Omega) \cap C^\infty(\Omega)$ with $-\nabla^2 w + Vw = 0$.
- (ii) For every $f \in L^2(\Omega)$ there is a unique weak solution $u \in H_0^1(\Omega)$ of the boundary value problem.

Proof. By the Fredholm alternative for the compact operator $\mathcal{K}$, either $(I - \mathcal{K})w = 0$ for some $w \neq 0$, or $I - \mathcal{K}$ is a bijection of $L^2(\Omega)$. In the first case $w = A((1 - V)w)$, so $w \in H_0^1(\Omega)$, and w is a weak solution of the homogeneous problem; Theorem 26.11.9 (applied with the potential term absorbed into the right-hand side, and bootstrapped) gives $w \in C^\infty(\Omega)$. In the second case, given f set $u = (I - \mathcal{K})^{-1}Af$. $\square$

The same circle of ideas produces the spectral decomposition of the Laplacian, which is one of the most-used theorems in mathematical physics.

Theorem 26.11.11

Let $\Omega \subseteq \mathbb{R}^n$ be open and bounded. There is an orthonormal basis $(w_k)_{k \geq 1}$ of $L^2(\Omega)$ with $w_k \in H_0^1(\Omega) \cap C^\infty(\Omega)$ and

$$-\nabla^2 w_k = \lambda_k w_k \quad \text{in } \Omega,$$

where $0 \leq \lambda_1 \leq \lambda_2 \leq \dots$ and $\lambda_k \rightarrow \infty$.

Proof. By Proposition 26.11.4, $A : L^2(\Omega) \rightarrow L^2(\Omega)$ is compact and Hermitian. By the spectral theorem for such operators, $\sigma(A) = \{0, \mu_1, \mu_2, \dots\}$ with μ_k real, accumulating only at 0, and $L^2(\Omega)$ has an orthonormal basis of eigenvectors of A .

Suppose $Aw = \mu w$ with $w \neq 0$. Then $w = \mu^{-1}Aw \in H_0^1(\Omega)$ provided $\mu \neq 0$, and indeed $\mu \neq 0$: for any $v \in H_0^1(\Omega)$ we have $\langle w, v \rangle_{L^2} = \langle Aw, v \rangle_{H^1} = \mu \langle w, v \rangle_{H^1}$, and taking $v = w$ gives $\|w\|_{L^2}^2 = \mu \|w\|_{H^1}^2$, which forces $\mu > 0$. So $w \in H_0^1(\Omega)$ is a weak solution of $-\nabla^2 w + w = \mu^{-1}w$, and elliptic regularity (Theorem 26.11.9, bootstrapping through $H_{\text{loc}}^1, H_{\text{loc}}^3, H_{\text{loc}}^5, \dots$) gives $w \in C^\infty(\Omega)$. Rewriting with $\lambda = \mu^{-1} - 1$ gives $-\nabla^2 w = \lambda w$, and $\lambda \geq 0$ since $\mu \|w\|_{H^1}^2 = \|w\|_{L^2}^2 \leq \|w\|_{H^1}^2$. Finally $\mu_k \rightarrow 0$ translates into $\lambda_k \rightarrow \infty$. $\square$

Corollary 26.11.12

$(\sqrt{2} \sin(k\pi x))_{k=1}^\infty$ is an orthonormal basis of $L^2((0, 1))$.

Proof. Take $\Omega = (0, 1)$, where the eigenvalue problem $-w'' = \lambda w$, $w(0) = w(1) = 0$ has exactly the solutions $w_k = \sqrt{2} \sin(k\pi x)$ with $\lambda_k = k^2\pi^2$. $\square$

That the classical Fourier sine series is an orthonormal basis is thus a corollary of Rellich–Kondrachov and the spectral theorem. This is a pleasingly indirect route to a classical fact, and unlike the classical proof it generalises: on any bounded domain whatever, however irregular, the Dirichlet eigenfunctions form a basis.

§26.11.5 The direct method in action

Finally we return to the variational point of view of Section 26.7, and show that the solution of the Dirichlet problem is a minimiser of an energy.

Proposition 26.11.13

Let $f \in L^2(\Omega)$ and define $S : H_0^1(\Omega) \rightarrow \mathbb{R}$ by

$$S[u] = \int_{\Omega} (|Du|^2 + |u|^2 - \bar{f}u - f\bar{u}) \, dx = \|u\|_{H^1}^2 - 2 \operatorname{Re} \langle f, u \rangle_{L^2}.$$

Then S attains its infimum, at a unique w , and w is precisely the weak solution of the Dirichlet problem.

Proof. Bounded below and coercive. By Cauchy–Schwarz and $2ab \leq a^2 + b^2$,

$$S[u] \geq \|u\|_{H^1}^2 - 2 \|u\|_{L^2} \|f\|_{L^2} \geq \|u\|_{H^1}^2 - \frac{1}{2} \|u\|_{L^2}^2 - 2 \|f\|_{L^2}^2 \geq \frac{1}{2} \|u\|_{H^1}^2 - 2 \|f\|_{L^2}^2.$$

So $\sigma = \inf S > -\infty$, and any u with $S[u] \leq K$ has $\|u\|_{H^1}^2 \leq 2K + 4 \|f\|_{L^2}^2$.

Minimising sequence and weak limit. Take u_m with $S[u_m] \rightarrow \sigma$. By the above the sequence is bounded in $H_0^1(\Omega)$, so by Corollary 26.6.29 we may pass to a subsequence with $u_m \rightharpoonup w$ in $H_0^1(\Omega)$.

Lower semicontinuity. The norm is weakly lower semicontinuous, so $\|w\|_{H^1} \leq \liminf \|u_m\|_{H^1}$; and $\langle f, \cdot \rangle_{L^2}$ is a bounded functional on $H_0^1(\Omega)$, so $\operatorname{Re}\langle f, u_m \rangle \rightarrow \operatorname{Re}\langle f, w \rangle$. Hence

$$S[w] = \|w\|_{H^1}^2 - 2 \operatorname{Re}\langle f, w \rangle \leq \liminf_m \left(\|u_m\|_{H^1}^2 - 2 \operatorname{Re}\langle f, u_m \rangle \right) = \liminf_m S[u_m] = \sigma,$$

and as $S[w] \geq \sigma$ we get $S[w] = \sigma$.

Euler–Lagrange equation. For $v \in H_0^1(\Omega)$ and $t \in \mathbb{R}$, expanding,

$$S[w + tv] = S[w] + 2t (\operatorname{Re}\langle w, v \rangle_{H^1} - \operatorname{Re}\langle f, v \rangle_{L^2}) + t^2 \|v\|_{H^1}^2.$$

Since $t = 0$ is a minimum of this quadratic in t , the linear coefficient vanishes: $\operatorname{Re}\langle w, v \rangle_{H^1} = \operatorname{Re}\langle f, v \rangle_{L^2}$ for all v , and replacing v by iv gives the imaginary parts too. So w is a weak solution, and conversely reading the expansion backwards shows any weak solution is a minimiser. Uniqueness now follows from Lemma 26.11.2, or directly from strict convexity of S . $\square$

The last computation is the general phenomenon: *critical points of an energy are weak solutions of its Euler–Lagrange equation*. What makes this valuable is that the direct method applies to functionals far more general than quadratic ones, where no Riesz representation theorem is available.

Theorem 26.11.14

Let $\Omega \subseteq \mathbb{R}^n$ be open and bounded, and let $L : \mathbb{C}^n \rightarrow \mathbb{R}$ be convex with

$$L(z) \geq \gamma|z|^2 - C \quad \text{for all } z,$$

for some $\gamma, C > 0$. Then $S[u] = \int_{\Omega} L(Du) \, dx$ attains its infimum on $H_0^1(\Omega)$.

Proof. The growth condition gives $S[u] \geq \gamma \|Du\|_{L^2}^2 - C|\Omega|$, so sublevel sets of S are bounded in $H_0^1(\Omega)$ by Poincaré’s inequality (Corollary 26.10.13), and S is bounded below. Convexity of L makes $u \mapsto S[u]$ convex, and it is strongly lower semicontinuous by Fatou’s lemma applied along an L^2 -convergent subsequence of gradients. Corollary 26.7.6 applies. $\square$

Example 26.11.15

The functional

$$u \mapsto \int_{\Omega} (1 + |Du|^4)^{1/4} \, dx$$

is not covered by any of our linear theory: its Euler–Lagrange equation is a quasilinear second-order PDE with no explicit solution and no useful integral representation. But the integrand is convex with the required growth (after adjusting for the quartic power on a bounded domain), so a minimiser exists. This is the direct method’s *raison d’être*: it produces solutions to problems that cannot be solved.

Remark. Let us close by recalling the pattern of the argument, since it is the moral of the course. We wanted a solution to an equation. We could not find one directly, so we

- (i) reformulated the problem in a Banach space of functions, chosen so that the rele-

- vant estimate is an inequality between norms (Sobolev spaces);
- (ii) enlarged the notion of solution until existence became a compactness argument (weak solutions, weak topologies, Banach–Alaoglu);
 - (iii) used convexity to ensure the limit object was still a solution (lower semicontinuity, the direct method);
 - (iv) and then used the equation itself to prove that the object we had constructed was much better behaved than the construction guaranteed (elliptic regularity).

Every step required a theorem, and every theorem required the machinery of measure, integration and functional analysis assembled in the earlier sections. That is what analysis of functions is for.

27 Automata and Formal Languages

We all know an algorithm when we see one, and for most of mathematics that is enough. But some questions cannot be answered without saying exactly what an algorithm *is*: if we want to prove that no algorithm solves a certain problem, we have to quantify over all possible algorithms, and to do that we need a definition. This course provides one – in fact several, which turn out to agree – and then uses it to show that a great many natural problems have no algorithmic solution at all.

Running alongside this is the theory of *formal languages*. A language here is just a set of finite strings over a fixed alphabet, and this is a flexible enough notion to encode almost anything: sets of numbers, sets of graphs, sets of programs. Chomsky’s insight was that languages come in a hierarchy, graded by how complicated a machine is needed to recognise them, and much of what follows is an exploration of the bottom two levels of that hierarchy – the regular languages, recognised by finite automata, and the context-free languages, recognised by automata with a stack – before we climb to the top and meet the languages recognised by a genuinely general-purpose computer.

This article constitutes my notes for the ‘Automata and Formal Languages’ course, held in Michaelmas 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§27.1 Introduction

§27.1.1 Algorithms and the Entscheidungsproblem

There is a difference between knowing that something exists and being able to find it. Compare the two statements

‘every polynomial of degree $n \geq 1$ over $\mathbb{C}$ has a root’

and

‘there is a procedure which, given such a polynomial, produces a root’.

The first is the fundamental theorem of algebra. The second is a genuinely different assertion, and there are plenty of situations in mathematics where the existence proof is available but no procedure is.

Historically, the demand for procedures came from Hilbert. In his 1900 address in Paris he set out a list of problems for the coming century, the tenth of which asks for a procedure which, given a Diophantine equation (a polynomial with integer coefficients), decides whether it has an integer solution. In 1928, in the book *Grundzüge der theoretischen Logik* of Hilbert and Ackermann, the [Entscheidungsproblem](#) (‘decision problem’) was posed: give a procedure which, given a formula of predicate logic, decides whether it is a tautology.

In both cases Hilbert expected a positive answer, and here is the crucial asymmetry. To answer such a question positively one does not need a definition of ‘algorithm’ at all: one simply writes an algorithm down, and everyone agrees on seeing it that it is one. To answer it negatively, one must rule out every conceivable algorithm, and for

that a precise definition is unavoidable. Both of Hilbert's questions turned out to have negative answers – Church and Turing settled the Entscheidungsproblem in 1936, and Matiyasevich settled the tenth problem in 1970 – and neither answer could have been given before the work we do in this course.

§27.1.2 Alphabets, Words and Languages

What are the objects on which computation is performed? One's first guess is 'numbers', but neither of the two problems above has numbers as its input: one takes polynomials and the other takes formulae. What is common to them is that the inputs can be written down as finite strings of symbols drawn from a fixed finite stock. This is how all modern computation works, and it is the setting we adopt.

Definition 27.1.1 (Strings)

Let Ω be a set, whose elements we call **symbols**. For $n \in \mathbb{N}$ we write Ω^n for the set of functions $n \rightarrow \Omega$, thinking of the natural number n as the set $\{0, 1, \dots, n-1\}$ in the usual von Neumann way, so that an element of Ω^n is a sequence $(x_0, \dots, x_{n-1})$ of symbols. We write

$$\Omega^* = \bigcup_{n \in \mathbb{N}} \Omega^n$$

for the set of all finite sequences of symbols, which we call **Ω -strings**.

We will suppress the sequence notation entirely and write strings by juxtaposition, so that (x_0, x_1, x_2) is written $x_0x_1x_2$. The following conventions will be used without comment.

- The **length** of a string $\alpha \in \Omega^n$ is $|\alpha| = n$.
- Ω^0 has exactly one element, the **empty string** ε .
- Given $\alpha \in \Omega^n$ and $k \leq n$, the **truncation** $\alpha \upharpoonright_k$ is the unique element of Ω^k which is an initial segment of α .
- Given $\alpha \in \Omega^m$ and $\beta \in \Omega^n$, their **concatenation** $\alpha\beta \in \Omega^{m+n}$ is defined in the obvious way. Concatenation is associative with identity ε , so Ω^* is a monoid.
- We define $\alpha^0 = \varepsilon$ and $\alpha^{n+1} = \alpha\alpha^n$.
- We identify a symbol $x \in \Omega$ with the string of length one that it determines.
- If $Y, Z \subseteq \Omega^*$ then $YZ = \{\alpha\beta \mid \alpha \in Y, \beta \in Z\}$, and if $Y = \{\alpha\}$ we simply write αZ .
- A function $f: \Omega \rightarrow \Omega'$ lifts to a function $\Omega^* \rightarrow \Omega'^*$ acting symbolwise; we write this lift as f as well.

Now, not every string is a sensible object. If Ω is a stock of letters then Ω^* contains a great many strings which are not words of English; if Ω is a stock of words then Ω^* contains a great many strings which are not sentences. So we will want to designate a subset of Ω^* as the *well-formed* strings, and it is these subsets which are the objects of study.

Definition 27.1.2 (Alphabet, word, language)

An **alphabet** is a finite nonempty set Σ , whose elements we call **letters** and denote $a, b, c, \dots$. We write

$$\mathbb{W} = \Sigma^*$$

for the set of **words**, denoted $u, v, w, \dots$, and $\mathbb{W}^+ = \mathbb{W} \setminus \{\varepsilon\}$ for the set of nonempty words. A **language** over Σ is a subset $L \subseteq \mathbb{W}$.

Because a language is simply a set of words, and words can encode anything, this is a very general notion indeed. The set of prime numbers written in binary is a language over $\{0, 1\}$; so is the set of (codes of) computer programs that never terminate. The whole of this course can be read as the study of how complicated a language can be.

§27.1.3 Counting Languages

We record here some counting facts from Numbers and Sets which will be used repeatedly, usually to demonstrate that some class of languages cannot possibly contain all of them. Recall that X is **countable** if there is a surjection $\mathbb{N} \rightarrow X$ (or $X = \emptyset$), and that X is **infinite** if there is an injection $\mathbb{N} \rightarrow X$.

Proposition 27.1.3

If X is nonempty and countable then X^* is countably infinite.

Proof. Pick $x \in X$. The map $n \mapsto x^n$ is an injection $\mathbb{N} \rightarrow X^*$, so X^* is infinite.

For countability, let $\pi: \mathbb{N} \rightarrow X$ be a surjection. Every $k \in \mathbb{N}$ with $k > 0$ has a unique prime factorisation $k = \prod_i p_i^{k_i}$, where $p_0 = 2, p_1 = 3, p_2 = 5, \dots$ enumerates the primes. Read k_0 as a length and send k to the string

$$\pi(k_1) \pi(k_2) \cdots \pi(k_{k_0}) \in X^*,$$

sending 0 to ε as well. Given any string $\alpha = y_1 \cdots y_n \in X^*$, choose m_j with $\pi(m_j) = y_j$ and take $k = 2^n 3^{m_1} 5^{m_2} \cdots$; this maps onto α . So the map is a surjection $\mathbb{N} \rightarrow X^*$. $\square$

Proposition 27.1.4

If X is countable then the set $\text{Fin}(X)$ of finite subsets of X is countable.

Proof. The ‘forgetful’ map $X^* \rightarrow \text{Fin}(X)$ sending $y_1 \cdots y_n$ to $\{y_1, \dots, y_n\}$ is a surjection: given a finite $F \subseteq X$, list its elements in any order. Composing with the surjection of Proposition 27.1.3 gives a surjection $\mathbb{N} \rightarrow \text{Fin}(X)$. $\square$

On the other hand, by Cantor’s theorem $\mathcal{P}(X)$ is uncountable whenever X is infinite. Since $\mathbb{W}$ is countably infinite, we obtain the following, which is the first thing worth knowing about languages.

Corollary 27.1.5

There are uncountably many languages over any alphabet.

Every method we shall meet for *specifying* a language – a grammar, an automaton, a regular expression, a register machine – is a finite object over some finite alphabet, and so there are only countably many of them. Consequently *every* such method fails to describe almost every language. This is not a defect of any particular formalism; it is a fact about cardinality, and it is worth keeping in mind throughout.

§27.2 Rewrite Systems and Grammars

§27.2.1 Rewrite Systems

The most primitive way of generating strings is to start with one and repeatedly replace pieces of it. This is the notion of a rewrite system, and everything in the first half of the course is a special case of it.

Definition 27.2.1 (Rewrite system)

Let Ω be a finite set of symbols. An element (α, β) of $\Omega^* \times \Omega^*$ is called a **rewrite rule** or **production rule**, and is written $\alpha \rightarrow \beta$. A pair $R = (\Omega, P)$ is a **rewrite system** if P is a *finite* set of rewrite rules.

The intended reading of $\alpha \rightarrow \beta$ is ‘wherever you see α , you may replace it by β ’. Let us make that precise.

Definition 27.2.2 (Derivation)

Let $R = (\Omega, P)$ be a rewrite system and let $\sigma, \tau \in \Omega^*$. We write

$$\sigma \Rightarrow_R \tau$$

and say that **R produces τ from σ in one step**, if there are $\alpha, \beta, \gamma, \delta \in \Omega^*$ with $\sigma = \alpha\gamma\beta$, $\tau = \alpha\delta\beta$ and $\gamma \rightarrow \delta \in P$. We write $\Rightarrow_R^*$ for the reflexive transitive closure of $\Rightarrow_R$. A sequence

$$\sigma_0 \Rightarrow_R \sigma_1 \Rightarrow_R \cdots \Rightarrow_R \sigma_n$$

is an **R -derivation of σ_n from σ_0 of length n** , and we write

$$\mathcal{D}(R, \sigma) = \{\tau \in \Omega^* \mid \sigma \Rightarrow_R^* \tau\}$$

for the set of strings derivable from σ .

Note that α and β here are the *context* in which the rewriting takes place; the rule fires regardless of what surrounds the occurrence of γ . We will meet later a restricted notion in which the context is allowed to constrain the rule, and this is the origin of the word ‘context-free’.

Since a rewrite system is a finite object over a finite alphabet, Propositions 27.1.3 and 27.1.4 give the following immediately.

Proposition 27.2.3

For fixed finite Ω , there are only countably many rewrite systems on Ω .

Proof. Ω^* is countable, hence so is $\Omega^* \times \Omega^*$, hence so is $\text{Fin}(\Omega^* \times \Omega^*)$, and every P lies in the latter. $\square$

§27.2.2 Grammars

The application we care about is to languages. Chomsky's idea was that a natural language should be modelled not by a finite list of well-formed sentences, but by a finite list of *rules* which generate infinitely many sentences. The reason for insisting on infinitude is **linguistic recursion**: if X is a grammatical English sentence then so is 'Alice believes that X ', and if we impose a maximum sentence length we are obliged to cut this off at some arbitrary point.

Here is a toy example of the sort of thing Chomsky had in mind. Take the rules

$$\begin{array}{lll} S \rightarrow \text{NP VP}, & \text{NP} \rightarrow \text{Adj NP}, & \text{NP} \rightarrow \text{Noun}, \\ \text{VP} \rightarrow \text{Verb}, & \text{VP} \rightarrow \text{Verb Adv}, & \end{array}$$

together with rules turning Adj into an adjective, Noun into a noun and so on. Starting from S one can derive 'colourless green ideas sleep furiously', Chomsky's famous example of a sentence that is grammatical but meaningless; one cannot derive 'furiously sleep ideas green colourless', which is neither. The moral is that grammaticality is a formal, checkable property, whereas meaningfulness is not something a rewrite system can see.

The symbols in this example fall into two classes: those like S and NP which are scaffolding, and those like 'ideas' which are part of the final product. This distinction is built into the definition.

Definition 27.2.4 (Grammar)

Let Σ be an alphabet and let V be a nonempty finite set disjoint from Σ , whose elements we call **variables** or **nonterminal symbols**, denoted $A, B, C, \dots$. Write $\Omega = \Sigma \cup V$. A **grammar** is a tuple $G = (\Sigma, V, P, S)$ where (Ω, P) is a rewrite system and $S \in V$ is the **start symbol**.

We use the notation for rewrite systems for the associated rewrite system, writing $\Rightarrow_G$, $\Rightarrow_G^*$ and $\mathcal{D}(G, \sigma)$. The **language generated by G** is

$$\mathcal{L}(G) = \mathcal{D}(G, S) \cap \mathbb{W}.$$

So a word lies in $\mathcal{L}(G)$ exactly when it can be derived from the start symbol and contains no variables. Two easy ways for this to fail are worth noting straight away.

Example 27.2.5

If P contains no rule of the form $S \rightarrow \alpha$, then $\mathcal{D}(G, S) = \{S\}$, which contains no words, so $\mathcal{L}(G) = \emptyset$. Similarly, if no rule has a right-hand side lying in $\mathbb{W}$, then nothing in $\mathcal{D}(G, S)$ can be a word, and again $\mathcal{L}(G) = \emptyset$.

Example 27.2.6

Let $\Sigma = \{a\}$, $V = \{S\}$ and $P_0 = \{S \rightarrow aaS, S \rightarrow a\}$. We claim that

$$\mathcal{L}(G_0) = \{a^{2n+1} \mid n \in \mathbb{N}\}.$$

Each rule replaces a string by one of length two greater, or of the same length, so by induction on the length of a derivation every element of $\mathcal{D}(G_0, S)$ has odd length; in particular every word produced is a^{2n+1} for some n . Conversely, applying $S \rightarrow aaS$ exactly n times and then $S \rightarrow a$ produces a^{2n+1} .

Observe that the only feature of P_0 used in the argument was that every rule preserves the parity of the length. So the rule sets

$$\begin{aligned} P_1 &= \{S \rightarrow aSa, S \rightarrow a\}, & P_2 &= \{S \rightarrow Saa, S \rightarrow a\}, \\ P_3 &= \{S \rightarrow aaS, S \rightarrow aaSaa, S \rightarrow a\} \end{aligned}$$

all generate the same language. Different grammars can generate the same language, and this is the phenomenon we look at next.

§27.2.3 Equivalence of Grammars

Definition 27.2.7 (Equivalent grammars)

Grammars G and G' over the same alphabet are **equivalent** if $\mathcal{L}(G) = \mathcal{L}(G')$.

Our aim in this subsection is to show that, for a fixed alphabet Σ , there are only countably many languages of the form $\mathcal{L}(G)$. The point requiring care is that V is allowed to be an arbitrary finite set, so there is a proper class of grammars to begin with; we must cut this down to a set. The tool is the observation that the names of the variables do not matter.

Definition 27.2.8 (Isomorphism of grammars)

Let $G = (\Sigma, V, P, S)$ and $G' = (\Sigma, V', P', S')$ be grammars over the same alphabet. A function $f: \Omega \rightarrow \Omega'$ is an **isomorphism** if

- (i) $f \upharpoonright_{\Sigma} = \text{id}$;
- (ii) $f(S) = S'$;
- (iii) $f \upharpoonright_V$ is a bijection $V \rightarrow V'$;
- (iv) $\alpha \rightarrow \beta \in P$ if and only if $f(\alpha) \rightarrow f(\beta) \in P'$,

where in (iv) we use the lift of f to Ω^* .

Proposition 27.2.9

Isomorphic grammars are equivalent.

Proof. If f is an isomorphism $G \rightarrow G'$ then f^{-1} is an isomorphism $G' \rightarrow G$, so it suffices to prove $\mathcal{L}(G) \subseteq \mathcal{L}(G')$. Let $w \in \mathcal{L}(G)$, with derivation

$$S = \sigma_0 \Rightarrow_G \sigma_1 \Rightarrow_G \cdots \Rightarrow_G \sigma_n = w.$$

Apply f throughout. By (ii) the first term is S' ; by (i) the last term is still w , since w contains only letters; and by (iv) each single step remains a legal step, since the decomposition $\sigma_i = \alpha\gamma\beta$ maps to $f(\sigma_i) = f(\alpha)f(\gamma)f(\beta)$. So $S' \Rightarrow_{G'}^* w$ and $w \in \mathcal{L}(G')$. $\square$

Proposition 27.2.10

Let $G = (\Sigma, V, P, S)$ be a grammar and let V' be any set with $|V| = |V'|$ and $V' \cap \Sigma = \emptyset$. Then there are P' and S' with $G' = (\Sigma, V', P', S')$ equivalent to G .

Proof. Choose a bijection $f: V \rightarrow V'$ and extend it to Ω by the identity on Σ , so that (i) and (iii) hold. Set $S' = f(S)$ and $P' = \{f(\alpha) \rightarrow f(\beta) \mid \alpha \rightarrow \beta \in P\}$, so that (ii) and (iv) hold. Then $G \cong G'$, so the two are equivalent. $\square$

Proposition 27.2.11

For a fixed alphabet Σ , there are only countably many languages of the form $\mathcal{L}(G)$ for a grammar G .

Proof. Fix a finite set V disjoint from Σ . There are only countably many rewrite systems on $\Omega = \Sigma \cup V$, and only finitely many choices of start symbol, so the collection $\mathcal{G}_V$ of grammars with this variable set is countable, and hence so is $\mathcal{L}_V = \{\mathcal{L}(G) \mid G \in \mathcal{G}_V\}$.

By Proposition 27.2.10, $\mathcal{L}_V$ depends only on $|V|$, so we may write $\mathcal{L}_n$ for the value at any n -element V , and every language generated by a grammar lies in some $\mathcal{L}_n$. Then $\bigcup_{n>0} \mathcal{L}_n$ is a countable union of countable sets and is therefore countable. $\square$

Combining this with Corollary 27.1.5, almost every language is generated by no grammar at all. Grammars are nevertheless the right thing to study, because the languages they generate are exactly the ones we can hope to compute with; we shall see in Section 27.8 that they are precisely the *computably enumerable* languages.

§27.2.4 The Chomsky Hierarchy

Restricting the *shape* of the allowed production rules restricts the languages that can be generated, and Chomsky's classification is obtained by imposing four increasingly severe such restrictions.

Definition 27.2.12 (Types of production rule)

Let $\alpha \rightarrow \beta$ be a production rule. We call it

- (i) **noncontracting** if $|\alpha| \leq |\beta|$;
- (ii) **context-sensitive** if there are $A \in V$, $\gamma, \delta \in \Omega^*$ and $\eta \in \Omega^*$ with $|\eta| > 0$ such that $\alpha = \gamma A \delta$ and $\beta = \gamma \eta \delta$;
- (iii) **context-free** if $\alpha = A \in V$ and $|\beta| > 0$;
- (iv) **regular** if $\alpha = A \in V$ and β is either a or aB for some $a \in \Sigma$ and $B \in V$.

A grammar has one of these properties if all of its rules do, and a language has one of these properties if it is generated by some grammar which has it.

A context-sensitive rule may replace A by η , but only when A occurs in the context γ_δ ; the surrounding material is not allowed to change. A context-free rule may replace A by β wherever it occurs. A regular rule may only replace a variable by a letter, or by a letter followed by a single variable, so that a derivation grows strictly from left to right.

Immediately from the definitions, $\text{regular} \Rightarrow \text{context-free} \Rightarrow \text{context-sensitive} \Rightarrow \text{non-contracting}$. (For the middle implication, take $\gamma = \delta = \varepsilon$.) In Chomsky's numbering, a language L is

- **type 0** if $L = \mathcal{L}(G)$ for some grammar G ;
- **type 1** if $L = \mathcal{L}(G)$ for some context-sensitive G ;
- **type 2** if $L = \mathcal{L}(G)$ for some context-free G ;
- **type 3** if $L = \mathcal{L}(G)$ for some regular G .

The picture is the one to keep in mind, and proving that the inclusions are all strict – that the sample languages really do sit where they are drawn – occupies a large part of the course. We will show that $\{0^k 1^k \mid k > 0\}$ is context-free but not regular, and that $\{a^n b^n c^n \mid n > 0\}$ is context-sensitive but not context-free; the halting set $\mathbb{K}$ and its complement will be dealt with in Section 27.8.

The following theorem of Chomsky says that two of our four conditions define the same class of languages, even though they do not define the same class of grammars. We shall not prove it.

Theorem 27.2.13 (Chomsky)

A language is noncontracting if and only if it is context-sensitive.

§27.2.5 Decision Problems

Alongside the question ‘which languages arise?’ we ask ‘what can we work out about them?’. Three questions will accompany us throughout.

Definition 27.2.14 (The three decision problems) (i) The **word problem** takes as

input a grammar G and a word w , and asks whether $w \in \mathcal{L}(G)$.

- (ii) The **emptiness problem** takes as input a grammar G and asks whether $\mathcal{L}(G) = \emptyset$.
- (iii) The **equivalence problem** takes as input grammars G and G' and asks whether $\mathcal{L}(G) = \mathcal{L}(G')$.

A problem is **solvable** if there is an algorithm giving the correct answer for every input, and **unsolvable** otherwise.

For the moment ‘algorithm’ is informal; in Section 27.8.7 we will replace it by a precise definition and revisit all three problems. It will turn out that all three are unsolvable for grammars in general. Lower down the hierarchy things are better, and we can already deal with the word problem.

Lemma 27.2.15

Let G be a noncontracting grammar and let $w \in \mathbb{W}$. There is a bound N , depending only on $|w|$ and $|\Omega|$, such that $w \in \mathcal{L}(G)$ if and only if w has a G -derivation of length at most N .

Proof. Let $S = \sigma_0 \Rightarrow_G \cdots \Rightarrow_G \sigma_n = w$ be a derivation of minimal length. As G is noncontracting, the sequence of lengths $1 = |\sigma_0| \leq |\sigma_1| \leq \cdots \leq |\sigma_n| = |w|$ is nondecreasing. If $\sigma_r = \sigma_s$ for some $r < s$ then deleting $\sigma_{r+1}, \dots, \sigma_s$ leaves a shorter derivation, so by minimality all the σ_i are distinct. But every σ_i is a string over Ω of length at most $|w|$, and there are only

$$N = \sum_{\ell=1}^{|w|} |\Omega|^\ell$$

of these, so $n \leq N$ by pigeonhole. $\square$

Corollary 27.2.16

The word problem is solvable for noncontracting, context-sensitive, context-free and regular grammars.

Proof. Given G and w , compute N as above. There are only finitely many derivations of length at most N , since at each step only finitely many rules can be applied at finitely many positions, and they can be enumerated; check each one. $\square$

This is a good illustration of the difference between solvability and practicality. The bound N is astronomically large, and the algorithm above is of no practical use whatsoever; but solvability is a statement about existence, and existence is what we get.

§27.2.6 Closure Properties

The other standard question about a class of languages is which operations it is closed under. Given languages L and M over Σ , the operations of interest are

$$LM, \quad L \cup M, \quad L \cap M, \quad L \setminus M, \quad \mathbb{W}^+ \setminus L.$$

We use $\mathbb{W}^+ \setminus L$ rather than $\mathbb{W} \setminus L$ for the complement, because (as we check below) a noncontracting grammar can never produce ε , so no class below type 0 could possibly be closed under an operation that introduces the empty word.

Some closure properties come for free from others: for instance, closure under complement and union implies closure under intersection, by De Morgan.

Definition 27.2.17 (Union and concatenation grammars)

Let $G = (\Sigma, V, P, S)$ and $G' = (\Sigma, V', P', S')$ be grammars, and let T be a variable in neither V nor V' . The **concatenation grammar** is

$$H = (\Sigma, V \cup V' \cup \{T\}, P \cup P' \cup \{T \rightarrow SS'\}, T),$$

and the **union grammar** is

$$H' = (\Sigma, V \cup V' \cup \{T\}, P \cup P' \cup \{T \rightarrow S, T \rightarrow S'\}, T).$$

It is clear that $\mathcal{L}(G)\mathcal{L}(G') \subseteq \mathcal{L}(H)$ and $\mathcal{L}(G) \cup \mathcal{L}(G') \subseteq \mathcal{L}(H')$. The reverse inclusions, however, are *not* automatic. Even after relabelling so that $V \cap V' = \emptyset$, the two rule sets can interact: a rule of P whose left-hand side contains letters can fire on a string produced by P' . The way to rule this out is to arrange that no rule mentions a letter on its left.

Definition 27.2.18 (Variable-based)

A rule $\alpha \rightarrow \beta$ is **variable-based** if every symbol occurring in α is a variable, and a grammar is variable-based if all of its rules are.

Regular and context-free grammars are automatically variable-based, since their rules have $\alpha = A \in V$. Context-sensitive grammars need not be.

Lemma 27.2.19

Every grammar is equivalent to a variable-based grammar. Moreover, if the original grammar is context-free, context-sensitive or noncontracting, then so is the new one.

Proof. Let $G = (\Sigma, V, P, S)$. For each letter $a \in \Sigma$ introduce a fresh variable X_a , and let $X: \Omega \rightarrow \Omega$ send $a \mapsto X_a$ for $a \in \Sigma$ and fix V pointwise; lift X to Ω^* . Put

$$P' = \{X(\alpha) \rightarrow X(\beta) \mid \alpha \rightarrow \beta \in P\}, \quad P'' = \{X_a \rightarrow a \mid a \in \Sigma\},$$

and let $G' = (\Sigma, V \cup \{X_a \mid a \in \Sigma\}, P' \cup P'', S)$. Every rule of P' has only variables on the left by construction, and every rule of P'' has a single variable on the left, so G' is variable-based. The added rules $X_a \rightarrow a$ are regular, so they preserve context-freeness, context-sensitivity and noncontraction.

It remains to check $\mathcal{L}(G) = \mathcal{L}(G')$. Applying X to a G -derivation of w gives a G' -derivation of $X(w)$, and then applying the rules $X_a \rightarrow a$ once for each letter of w gives w ; so $\mathcal{L}(G) \subseteq \mathcal{L}(G')$.

Conversely let $S = \sigma_0 \Rightarrow_{G'} \cdots \Rightarrow_{G'} \sigma_m = w$ be a G' -derivation. Apply X to every term to get a sequence $\tau_0, \dots, \tau_m$ with $\tau_0 = S$ and $\tau_m = X(w)$. If the step

$\sigma_i \Rightarrow_{G'} \sigma_{i+1}$ used a rule $X(\alpha) \rightarrow X(\beta)$, then since X fixes such strings we still have $\tau_i \Rightarrow_{G'} \tau_{i+1}$ by the same rule, which is a rule of G after erasing X . If instead it used a rule $X_a \rightarrow a$, then $\tau_i = \tau_{i+1}$, and we delete the repetition. Deleting all such repetitions leaves a genuine G -derivation of w (after erasing X throughout, which is legitimate since no string in the resulting sequence contains any X_a). Hence $w \in \mathcal{L}(G)$. $\square$

Theorem 27.2.20

Let G and G' be variable-based grammars over Σ with $V \cap V' = \emptyset$. Then

$$\mathcal{L}(H) = \mathcal{L}(G)\mathcal{L}(G'), \quad \mathcal{L}(H') = \mathcal{L}(G) \cup \mathcal{L}(G').$$

Consequently the classes of context-free, context-sensitive and noncontracting languages are closed under union and concatenation, and the class of regular languages is closed under union.

Proof. One inclusion in each case has already been observed. For the other, consider a derivation in H . The first step must be $T \rightarrow SS'$, since T occurs in no other rule's right-hand side and appears nowhere else. Thereafter every rule applied has a variable-only left-hand side, so it lies entirely within the V -part or entirely within the V' -part of the string, these being disjoint. Thus the derivation splits into a G -derivation acting on the first component and a G' -derivation acting on the second, and any word produced is of the form vw with $v \in \mathcal{L}(G)$ and $w \in \mathcal{L}(G')$. The argument for H' is the same, the first step being $T \rightarrow S$ or $T \rightarrow S'$.

For the closure statements, given two grammars of the relevant type we first pass to equivalent variable-based grammars with disjoint variable sets, using Lemma 27.2.19 and Proposition 27.2.10, and then apply the above. The union grammar of two regular grammars is not regular, because of the rules $T \rightarrow S$; we shall prove closure of the regular languages under union and concatenation by other means in Section 27.3. $\square$

§27.2.7 The Empty Word

Remark. No noncontracting grammar produces ε : every string in a derivation from S has length at least $|S| = 1$. In particular no type 1, 2 or 3 language contains the empty word, which is why $\mathbb{W}^+$ rather than $\mathbb{W}$ is the correct ambient set for those classes.

One might hope simply to add the rule $S \rightarrow \varepsilon$ to put ε into a language, but this can have side effects: if S occurs on the right-hand side of some rule then the new rule can fire in the middle of a derivation and delete a symbol that was doing work.

Definition 27.2.21

A rule $\alpha \rightarrow \beta$ is **S -safe** if S does not occur in β . A grammar is **ε -adequate** if all of its rules are S -safe.

If G is ε -adequate then S can only ever appear as the very first string of a derivation, so adding $S \rightarrow \varepsilon$ produces a grammar for $\mathcal{L}(G) \cup \{\varepsilon\}$ and nothing else. Moreover every

grammar is equivalent to an ε -adequate one: replace $G = (\Sigma, V, P, S)$ by

$$G' = (\Sigma, V \cup \{T\}, P \cup \{T \rightarrow S\}, T)$$

for a fresh variable T . This will be used without comment whenever it is convenient.

§27.3 Regular Languages

The lowest level of the hierarchy is the most thoroughly understood, and it is where we start. We will see that regular languages admit four completely different descriptions – by grammars, by deterministic automata, by nondeterministic automata, and by regular expressions – and that all four are effectively interchangeable. We will also obtain a tool (the pumping lemma) for proving that a language is *not* regular, and a canonical minimal automaton for each regular language.

§27.3.1 Regular Derivations

Recall that a regular rule has the form $A \rightarrow a$ or $A \rightarrow aB$. We call the first kind **terminal** and the second kind **nonterminal**. The shape of regular derivations is extremely rigid, which is what makes the theory work.

Lemma 27.3.1

Let G be a regular grammar. If $S \Rightarrow_G^* \alpha$ then $\alpha \in \mathbb{W} \cup \mathbb{W}V$; that is, α is a word, possibly followed by a single variable.

Proof. Induction on the length of the derivation. The empty derivation gives $\alpha = S = \varepsilon S \in \mathbb{W}V$. Suppose $S \Rightarrow_G^* \beta \Rightarrow_G \alpha$ with $\beta \in \mathbb{W} \cup \mathbb{W}V$. If $\beta \in \mathbb{W}$ then β contains no variable, but every rule rewrites a variable, so no step is possible; so $\beta = wA$ with $w \in \mathbb{W}$, $A \in V$. The applicable rules are $A \rightarrow a$ and $A \rightarrow aB$, giving $\alpha = wa \in \mathbb{W}$ or $\alpha = waB \in \mathbb{W}V$ respectively. $\square$

Lemma 27.3.2

Let G be regular and $w \in \mathbb{W}$ with $S \Rightarrow_G^* w$. Then every derivation of w from S has length exactly $|w|$, and consists of $|w| - 1$ nonterminal rules followed by a single terminal rule.

Proof. A nonterminal rule increases the length of the string by one and leaves the number of variables at one; a terminal rule leaves the length unchanged and reduces the number of variables from one to zero. Starting from S , of length 1 with one variable, we therefore need exactly $|w| - 1$ nonterminal steps to reach length $|w|$. Once the variable count reaches zero no further rule applies, so the terminal rule must come last, and there is exactly one of them. $\square$

Note that the derivation is nonetheless not *unique*, since there may be several rules $A \rightarrow aB$ with the same A and a . This is precisely the nondeterminism that we will have to deal with below.

As a first application, we can now handle concatenation, which Theorem 27.2.20 did not give us for regular languages.

Lemma 27.3.3

Regular languages are closed under concatenation.

Proof. Let $G = (\Sigma, V, P, S)$ and $G' = (\Sigma, V', P', S')$ be regular, with $V \cap V' = \emptyset$ after relabelling. Let P^* be obtained from P by replacing every terminal rule $A \rightarrow a$ by the nonterminal rule $A \rightarrow aS'$, and set $H = (\Sigma, V \cup V', P^* \cup P', S)$. This is regular. We claim $\mathcal{L}(H) = \mathcal{L}(G)\mathcal{L}(G')$.

If $S \Rightarrow_G^* v$ and $S' \Rightarrow_{G'}^* w$, then running the G -derivation in H and using the modified last rule yields $S \Rightarrow_H^* vS'$, and then the G' -derivation gives $S \Rightarrow_H^* vw$.

Conversely suppose $S \Rightarrow_H^* u$ with $u \in \mathbb{W}$. By Lemma 27.3.1 every intermediate string is $w_i X_i$ with $X_i \in V \cup V'$. Initially $X_0 = S \in V$. The only rules taking a variable of V to a variable of V' are the modified rules $A \rightarrow aS'$, and no rule of P' mentions a variable of V ; so once the derivation enters V' it stays there. Splitting the derivation at the unique step where this happens gives $u = vw$ with $S \Rightarrow_G^* v$ (using the original terminal rule in place of the modified one) and $S' \Rightarrow_{G'}^* w$. $\square$

§27.3.2 Deterministic Automata

We now come to the machine model. A deterministic automaton reads a word one letter at a time, from left to right, keeping track of nothing except which of finitely many states it is in.

Definition 27.3.4 (Deterministic automaton)

Let Σ be an alphabet. A **deterministic automaton** is a tuple $D = (\Sigma, Q, \delta, q_0, F)$ where Q is a finite set of **states**, $q_0 \in Q$ is the **start state**, $F \subseteq Q \setminus \{q_0\}$ is the set of **accept states**, and $\delta: Q \times \Sigma \rightarrow Q$ is the **transition function**.

The requirement $q_0 \notin F$ is a convention forced on us by the fact that regular grammars cannot generate ε ; it will mean that ε never lies in the language of an automaton, matching the grammar side exactly. It is a harmless restriction, and we will return to it when we discuss the Kleene star.

We draw an automaton as a labelled directed graph: one node per state, drawn as a circle, or as a double circle if the state is accepting; an unlabelled incoming arrow marks the start state; and for each q and a there is an arrow from q to $\delta(q, a)$ labelled a . Every node therefore has exactly $|\Sigma|$ outgoing arrows, though several may be drawn as one arrow with several labels.

Example 27.3.5

Let $\Sigma = \{0, 1\}$ and consider the following automaton.

Reading 110 we pass $q_0 \rightarrow q_2 \rightarrow q_2 \rightarrow q_1$ and finish in an accept state; reading 111 we pass $q_0 \rightarrow q_2 \rightarrow q_2 \rightarrow q_2$ and do not. We shall verify below that this machine accepts exactly the words containing at least one 0.

To say precisely what a machine accepts we extend δ from letters to words.

Definition 27.3.6 (Language of an automaton)

Define $\hat{\delta}: Q \times \mathbb{W} \rightarrow Q$ by recursion on the length of the word:

$$\hat{\delta}(q, \varepsilon) = q, \quad \hat{\delta}(q, aw) = \hat{\delta}(\delta(q, a), w).$$

The **language accepted by D** is

$$\mathcal{L}(D) = \{w \in \mathbb{W} \mid \hat{\delta}(q_0, w) \in F\}.$$

The **state sequence** of D on input $w = a_0a_1 \cdots a_{n-1}$ is the sequence $q_0, q_1, \dots, q_n$ with $q_{i+1} = \delta(q_i, a_i)$; it is uniquely determined and has length $|w| + 1$.

Note that $\varepsilon \notin \mathcal{L}(D)$ for every D , since $\hat{\delta}(q_0, \varepsilon) = q_0 \notin F$.

Example 27.3.7

We verify the claim of Example 27.3.5: $\mathcal{L}(D)$ is the set of words containing at least one 0.

Every 0-labelled arrow in the diagram leads to q_1 , and both arrows out of q_1 return to q_1 . So if w contains a 0, then after reading the first 0 the machine is in q_1 and stays there, and w is accepted. If w contains no 0, then $w = 1^k$; by induction $\hat{\delta}(q_0, 1^k) = q_2$ for $k \geq 1$ and $= q_0$ for $k = 0$, and neither is accepting. So w is rejected.

Example 27.3.8

Let $\Sigma = \{a, b\}$. The following automaton accepts the nonempty words containing an even number of a 's.

The states E and O record the parity of the number of a 's read so far, and q_0 is a copy of E which exists only to keep ε out of the language. Thus b is accepted ($q_0 \rightarrow E$), aa is accepted ($q_0 \rightarrow O \rightarrow E$), and a is rejected ($q_0 \rightarrow O$), as is ε .

The last example is slightly unsatisfying: the states q_0 and E do the same job. We will make this observation precise in Section 27.3.8, where we show that every automaton has a canonical smallest equivalent form. To do that we need a notion of map between automata.

Definition 27.3.9 (Homomorphism)

Let $D = (\Sigma, Q, \delta, q_0, F)$ and $D' = (\Sigma, Q', \delta', q'_0, F')$. A function $f: Q \rightarrow Q'$ is a **homomorphism** if

- (i) $\delta'(f(q), a) = f(\delta(q, a))$ for all $q \in Q, a \in \Sigma$;
- (ii) $f(q_0) = q'_0$;
- (iii) $q \in F$ if and only if $f(q) \in F'$.

A bijective homomorphism is an **isomorphism**; its inverse is then a homomorphism too.

Condition (i) says that f commutes with a single step, and a trivial induction upgrades this to $\hat{\delta}'(f(q), w) = f(\hat{\delta}(q, w))$ for all words w .

Proposition 27.3.10

If there is a homomorphism $f: D \rightarrow D'$ then $\mathcal{L}(D) = \mathcal{L}(D')$.

Proof. For any word w we have

$$\hat{\delta}(q_0, w) \in F \iff f(\hat{\delta}(q_0, w)) \in F' \iff \hat{\delta}'(q'_0, w) \in F'$$

using (iii), then (i) and (ii). □

So a homomorphism, even a very non-injective and non-surjective one, preserves the language. This tells us what failures of bijectivity mean. If f is not surjective, the

missing states of D' are not reachable from q'_0 . If f is not injective, say $f(p) = f(q)$ with $p \neq q$, then for every word w

$$f(\hat{\delta}(p, w)) = \hat{\delta}'(f(p), w) = \hat{\delta}'(f(q), w) = f(\hat{\delta}(q, w)),$$

so $\hat{\delta}(p, w) \in F$ if and only if $\hat{\delta}(q, w) \in F$: the states p and q cannot be told apart by any word. Both phenomena are forms of redundancy, and eliminating them is exactly what minimisation does.

§27.3.3 From Automata to Grammars

Theorem 27.3.11

If D is a deterministic automaton then $\mathcal{L}(D)$ is regular.

Proof. Let $D = (\Sigma, Q, \delta, q_0, F)$ and define a grammar $G = (\Sigma, Q, P, q_0)$ with variable set Q and

$$P = \{p \rightarrow aq \mid \delta(p, a) = q\} \cup \{p \rightarrow a \mid \delta(p, a) \in F\}.$$

Every rule is regular. Now let $w = a_0a_1 \cdots a_n$ be a nonempty word, and let $q_0, q_1, \dots, q_{n+1}$ be the state sequence of D on w . Then

$$\begin{aligned} w \in \mathcal{L}(D) &\iff q_{n+1} \in F \\ &\iff q_i \rightarrow a_i q_{i+1} \in P \text{ for } i < n, \text{ and } q_n \rightarrow a_n \in P \\ &\iff q_0 \Rightarrow_G a_0 q_1 \Rightarrow_G \cdots \Rightarrow_G a_0 \cdots a_{n-1} q_n \Rightarrow_G w, \end{aligned}$$

where the middle equivalence holds because the state sequence is uniquely determined by w . By Lemma 27.3.2 every derivation of w in G has this shape, so the last line holds if and only if $w \in \mathcal{L}(G)$. Finally ε lies in neither language. $\square$

We would like the converse. The obvious attempt – take $Q = V$ and read off δ from the rules – fails immediately, because a regular grammar may contain both $A \rightarrow aB$ and $A \rightarrow aB'$, and then there is no single value for $\delta(A, a)$. The standard remedy is to allow the machine to be in a *set* of states at once.

§27.3.4 Nondeterministic Automata and the Subset Construction

Definition 27.3.12 (Nondeterministic automaton)

A **nondeterministic automaton** is a tuple $N = (\Sigma, Q, \delta, q_0, F)$ exactly as before, except that

$$\delta: Q \times \Sigma \rightarrow \mathcal{P}(Q).$$

We read $\delta(q, a)$ as the set of states the machine *may* move to on reading a in state q ; if $\delta(q, a) = \emptyset$ then the computation gets stuck. The graphical convention is unchanged, except that a node may now have several, or no, outgoing arrows for a given letter.

Definition 27.3.13

For a nondeterministic automaton define $\hat{\delta}: Q \times \mathbb{W} \rightarrow \mathcal{P}(Q)$ by

$$\hat{\delta}(q, \varepsilon) = \{q\}, \quad \hat{\delta}(q, wa) = \bigcup_{p \in \hat{\delta}(q, w)} \delta(p, a),$$

and set

$$\mathcal{L}(N) = \{w \in \mathbb{W} \mid \hat{\delta}(q_0, w) \cap F \neq \emptyset\}.$$

So N accepts w if *some* run on w ends in an accept state. A deterministic automaton is the special case in which every $\delta(q, a)$ is a singleton, and the two definitions of $\hat{\delta}$ then agree.

Example 27.3.14

Let $\Sigma = \{a, b\}$ and consider the nondeterministic automaton N with states s (start), t and u (accept), and

$$\delta(s, a) = \{s, t\}, \quad \delta(s, b) = \{s\}, \quad \delta(t, b) = \{u\},$$

all other values being $\emptyset$.

The machine guesses when it has reached the penultimate letter. It accepts exactly the words ending in ab : on input aab we get $\hat{\delta}(s, a) = \{s, t\}$, then $\hat{\delta}(s, aa) = \{s, t\}$, then $\hat{\delta}(s, aab) = \{s\} \cup \{u\} = \{s, u\}$, which meets F ; whereas on input aba we get $\{s, t\}$, then $\{s, u\}$, then $\{s, t\}$, which does not.

The nondeterminism is only apparent, and this is the fundamental theorem about finite automata.

Theorem 27.3.15 (Subset construction)

Let N be a nondeterministic automaton. Then there is a deterministic automaton D with $\mathcal{L}(N) = \mathcal{L}(D)$.

Proof. Let $N = (\Sigma, Q, \delta, q_0, F)$ and define

$$D = (\Sigma, \mathcal{P}(Q), \Delta, \{q_0\}, \mathcal{F}), \quad \Delta(X, a) = \bigcup_{q \in X} \delta(q, a),$$

$$\mathcal{F} = \{X \subseteq Q \mid X \cap F \neq \emptyset\}.$$

(If $\{q_0\} \in \mathcal{F}$, that is if $q_0 \in F$, then F was not a legal accept set for N in the first place; so the convention $\mathcal{F} \subseteq \mathcal{P}(Q) \setminus \{\{q_0\}\}$ holds automatically.)

Fix a word $w = a_0 \cdots a_{n-1}$. The state sequence of D on w is $X_0 = \{q_0\}$ and $X_{i+1} = \bigcup_{q \in X_i} \delta(q, a_i)$; the sequence of state-sets of N is $Y_0 = \{q_0\}$ and $Y_{i+1} = \bigcup_{q \in Y_i} \delta(q, a_i)$.

These recursions are identical, so $X_i = Y_i$ for all i , whence

$$w \in \mathcal{L}(D) \iff X_n \cap F \neq \emptyset \iff \hat{\delta}(q_0, w) \cap F \neq \emptyset \iff w \in \mathcal{L}(N). \quad \square$$

Remark. The construction turns an n -state machine into one with 2^n states, and this exponential blow-up cannot in general be avoided. In practice one only ever builds the subsets *reachable* from $\{q_0\}$, which is often far fewer.

Example 27.3.16

Let us carry out the subset construction on the automaton N of Example 27.3.14. Starting from $\{s\}$ and closing off under Δ :

$$\begin{aligned} \Delta(\{s\}, a) &= \{s, t\}, & \Delta(\{s\}, b) &= \{s\}, & \Delta(\{s, t\}, a) &= \{s, t\}, & \Delta(\{s, t\}, b) &= \{s, u\}, \\ \Delta(\{s, u\}, a) &= \{s, t\}, & \Delta(\{s, u\}, b) &= \{s\}. \end{aligned}$$

Only three of the eight subsets are reachable, and only $\{s, u\}$ meets $F = \{u\}$. Writing $X = \{s\}$, $Y = \{s, t\}$, $Z = \{s, u\}$ we obtain the deterministic automaton D drawn on the right below, beside the original N .

Tracing $abab$ through D : $X \rightarrow Y \rightarrow Z \rightarrow Y \rightarrow Z$, ending in the accept state, and indeed $abab$ ends in ab . Tracing abb : $X \rightarrow Y \rightarrow Z \rightarrow X$, rejected, and indeed abb does not end in ab .

Theorem 27.3.17

If G is a regular grammar then there is a nondeterministic automaton N with $\mathcal{L}(G) = \mathcal{L}(N)$.

Proof. Let $G = (\Sigma, V, P, S)$ and let H be a fresh symbol, the **halt state**. Put $Q = V \cup \{H\}$ and define $N = (\Sigma, Q, \delta, S, \{H\})$ where, for $A \in V$,

$$\delta(A, a) = \begin{cases} \{B \mid A \rightarrow aB \in P\} & \text{if } A \rightarrow a \notin P, \\ \{B \mid A \rightarrow aB \in P\} \cup \{H\} & \text{if } A \rightarrow a \in P, \end{cases}$$

and $\delta(H, a) = \emptyset$. Note $H \neq S$, so the convention $F \subseteq Q \setminus \{q_0\}$ holds.

Let $w = a_0 \cdots a_n$ be a nonempty word. By Lemma 27.3.2, $w \in \mathcal{L}(G)$ if and only if there are variables $S = A_0, A_1, \dots, A_n$ with $A_i \rightarrow a_i A_{i+1} \in P$ for $i < n$ and $A_n \rightarrow a_n \in P$. By the definition of δ , this holds if and only if there are states with $A_{i+1} \in \delta(A_i, a_i)$ for $i < n$ and $H \in \delta(A_n, a_n)$, which holds if and only if $H \in \hat{\delta}(S, w)$, i.e. $w \in \mathcal{L}(N)$. Neither language contains ε . $\square$

Assembling Theorems 27.3.11, 27.3.15 and 27.3.17, we have the following, which is the first genuinely satisfying theorem of the course.

Corollary 27.3.18

For a language L , the following are equivalent:

- (i) L is regular, i.e. $L = \mathcal{L}(G)$ for a regular grammar G ;
- (ii) $L = \mathcal{L}(N)$ for a nondeterministic automaton N ;
- (iii) $L = \mathcal{L}(D)$ for a deterministic automaton D .

Moreover, each translation is effective: given one of the three objects we can compute the other two.

§27.3.5 The Pumping Lemma for Regular Languages

We now have three ways to show a language *is* regular. To show that one is not, the standard tool is the following. It expresses in combinatorial terms the fact that a machine with finitely many states must, on a long enough word, revisit a state, and can then be made to go round the resulting loop as often as we please.

Definition 27.3.19 (Regular pumping lemma)

A language L **satisfies the regular pumping lemma with pumping number n** if every $w \in L$ with $|w| \geq n$ can be written as $w = xyz$ with

$$|y| > 0, \quad |xy| \leq n, \quad xy^kz \in L \text{ for all } k \in \mathbb{N}.$$

We call y a **pump** for w .

Theorem 27.3.20 (Pumping lemma)

Every regular language satisfies the regular pumping lemma, with pumping number the number of states of any deterministic automaton accepting it.

Proof. Let $L = \mathcal{L}(D)$ with $D = (\Sigma, Q, \delta, q_0, F)$, and put $n = |Q|$. Let $w \in L$ with $|w| \geq n$, say $w = a_0a_1 \cdots a_{n-1}v$.

Let $q_0, q_1, \dots, q_n$ be the states visited while reading $a_0 \cdots a_{n-1}$. This is a list of $n+1$ states drawn from a set of size n , so by pigeonhole there are $i < j \leq n$ with $q_i = q_j$. Put

$$x = a_0 \cdots a_{i-1}, \quad y = a_i \cdots a_{j-1}, \quad z = a_j \cdots a_{n-1}v,$$

so that $xyz = w$, $|y| = j - i > 0$ and $|xy| = j \leq n$.

Now $\hat{\delta}(q_0, x) = q_i$ and $\hat{\delta}(q_i, y) = q_j = q_i$, so by induction on k we get $\hat{\delta}(q_0, xy^k) = q_i$ for every $k \in \mathbb{N}$. Finally $\hat{\delta}(q_i, z) = \hat{\delta}(q_j, z) = \hat{\delta}(q_0, w) \in F$, so $\hat{\delta}(q_0, xy^kz) \in F$ and $xy^kz \in L$. $\square$

The picture behind the proof is worth drawing: the accepting path through the machine, of length at least n , must contain a loop within its first n steps, and the loop can be traversed any number of times.

**Example 27.3.21**

The language $L = \{0^k 1^k \mid k > 0\}$ is not regular.

Suppose it were, with pumping number N . The word $w = 0^N 1^N$ lies in L and has length $2N \geq N$, so it can be written $w = xyz$ with $|xy| \leq N$ and $|y| = \ell > 0$. Since $|xy| \leq N$, the pump y lies within the first N letters of w , all of which are 0s; so $y = 0^\ell$. Pumping down with $k = 0$ gives $xz = 0^{N-\ell} 1^N \in L$, which is false since $\ell > 0$. So L is not regular.

We will see in Section 27.4 that $L = \{0^k 1^k\}$ is context-free, so this example already shows that the inclusion of type 3 in type 2 is strict.

Example 27.3.22

Fix $n \geq 2$ and let $L = \{0^n w \mid w \in \mathbb{W}\}$, the words beginning with n zeroes. This is regular: take $V = \{S, X_0, \dots, X_{n-1}\}$ and

$$P = \{S \rightarrow 0X_0\} \cup \{X_i \rightarrow 0X_{i+1} \mid i \leq n-3\} \cup \{X_{n-2} \rightarrow 0X_{n-1}, X_{n-2} \rightarrow 0\} \\ \cup \{X_{n-1} \rightarrow 0, X_{n-1} \rightarrow 1, X_{n-1} \rightarrow 0X_{n-1}, X_{n-1} \rightarrow 1X_{n-1}\}.$$

But no deterministic automaton with at most n states accepts L . Indeed, such an automaton would give L pumping number n by Theorem 27.3.20, and then the word $0^n \in L$ of length n could be pumped down to a word with fewer than n zeroes, which is not in L .

It is essential to remember that the pumping lemma is a necessary but *not* a sufficient condition for regularity. The next example makes this vivid.

Example 27.3.23

Let $\Sigma = \{0, 1\}$. For a word w containing at least one 0, define the **tail** of w to be the number of 1s following the last 0. Given $X \subseteq \mathbb{N}$, let

$$L_X = \{w \in \mathbb{W}^+ \mid w \text{ contains no } 0\} \cup \{w \mid w \text{ has a tail lying in } X\}.$$

If $X \neq Y$ then $L_X \neq L_Y$: taking m in the symmetric difference, the word 01^m distinguishes them. So $X \mapsto L_X$ is injective, and since $\mathcal{P}(\mathbb{N})$ is uncountable while there are only countably many regular languages, some L_X is not regular.

Nevertheless *every* L_X satisfies the pumping lemma with pumping number 2. Let $w \in L_X$ with $|w| \geq 2$.

- If $w = 0z$, take $x = \varepsilon$, $y = 0$. Pumping up prepends more 0s, which changes neither the presence of a 0 nor the tail. Pumping down gives z : either z still contains a 0, in which case the tail is unchanged, or it does not, in which case

$z \in 1^*$ and again lies in L_X (note $z \neq \varepsilon$ as $|w| \geq 2$).

- If $w = 1z$, take $x = \varepsilon$, $y = 1$. If z contains no 0 then neither does $1^k z$, so all pumps lie in L_X . If z contains a 0 then the tail of $1^k z$ equals the tail of z for every k , so again all pumps lie in L_X .

Hence there are uncountably many languages satisfying the regular pumping lemma, and in particular the pumping lemma does not characterise the regular languages.

§27.3.6 Closure Properties

We have already proved closure under union (Theorem 27.2.20 together with the automaton translation, or directly) and concatenation (Lemma 27.3.3). Automata make the Boolean operations easy.

Proposition 27.3.24

The regular languages are closed under complement (relative to $\mathbb{W}^+$), intersection and difference.

Proof. Let $L = \mathcal{L}(D)$ with $D = (\Sigma, Q, \delta, q_0, F)$. We may assume that no transition enters the start state, that is, that $\delta(q, a) \neq q_0$ for all q and a . Indeed, if this fails, adjoin a fresh state q'_0 , put $\delta(q'_0, a) = \delta(q_0, a)$ for every letter a , and take q'_0 as the new start state, demoting q_0 to an ordinary state (which is not accepting, since $q_0 \notin F$). No transition enters q'_0 , and $\hat{\delta}(q'_0, w) = \hat{\delta}(q_0, w)$ for every nonempty w , so the language is unchanged. We rename q'_0 back to q_0 .

Now set $D' = (\Sigma, Q, \delta, q_0, Q \setminus (F \cup \{q_0\}))$. For a nonempty word w we have $\hat{\delta}(q_0, w) \neq q_0$, so $\hat{\delta}(q_0, w) \in Q \setminus (F \cup \{q_0\})$ if and only if $\hat{\delta}(q_0, w) \notin F$. Hence $\mathcal{L}(D') = \mathbb{W}^+ \setminus L$.

Intersection and difference now follow from De Morgan, since $L \cap M = \mathbb{W}^+ \setminus ((\mathbb{W}^+ \setminus L) \cup (\mathbb{W}^+ \setminus M))$ and $L \setminus M = L \cap (\mathbb{W}^+ \setminus M)$. $\square$

There is a more direct construction for intersection and union which is worth knowing, because it is the one that fails for the higher classes.

Definition 27.3.25 (Product automaton)

Given $D = (\Sigma, Q, \delta, q_0, F)$ and $D' = (\Sigma, Q', \delta', q'_0, F')$, the **product automaton** is

$$D \times D' = (\Sigma, Q \times Q', \delta \times \delta', (q_0, q'_0), F''), \quad (\delta \times \delta')((q, q'), a) = (\delta(q, a), \delta'(q', a)),$$

where F'' is either $\{(q, q') \mid q \in F \text{ and } q' \in F'\}$ or $\{(q, q') \mid q \in F \text{ or } q' \in F'\}$.

An immediate induction gives $(\widehat{\delta \times \delta'})((q_0, q'_0), w) = (\hat{\delta}(q_0, w), \hat{\delta}'(q'_0, w))$, so the first choice of F'' yields $\mathcal{L}(D) \cap \mathcal{L}(D')$ and the second yields $\mathcal{L}(D) \cup \mathcal{L}(D')$. In words: the product machine runs both automata side by side on the same input, which it can afford to do because each has only finitely many states. We will see in Section 27.4 that no such construction can exist for context-free languages.

§27.3.7 Regular Expressions and Kleene's Theorem

There is a fourth description of the regular languages, and it is the one familiar from programming.

Definition 27.3.26 (Kleene star)

For a language L , the **Kleene star** of L is

$$L^* = \{w_1 w_2 \cdots w_k \mid k \in \mathbb{N}, w_i \in L\},$$

the set of all concatenations of finitely many words of L ; in particular $\varepsilon \in L^*$, taking $k = 0$. The **Kleene plus** is $L^+ = \{w_1 \cdots w_k \mid k \geq 1, w_i \in L\}$, so that $L^* = L^+ \cup \{\varepsilon\}$.

Definition 27.3.27 (Regular expression)

The **regular expressions** over Σ are defined inductively:

- (i) $\emptyset$ is a regular expression;
- (ii) ε is a regular expression;
- (iii) a is a regular expression for each $a \in \Sigma$;
- (iv) if R, S are regular expressions then so is $(R + S)$;
- (v) if R, S are regular expressions then so is (RS) ;
- (vi) if R is a regular expression then so are R^* and R^+ ,

and nothing else is. To each regular expression E we assign a language $\mathcal{L}(E)$ by the matching recursion:

$$\begin{aligned} \mathcal{L}(\emptyset) &= \emptyset, & \mathcal{L}(\varepsilon) &= \{\varepsilon\}, & \mathcal{L}(a) &= \{a\}, \\ \mathcal{L}(R + S) &= \mathcal{L}(R) \cup \mathcal{L}(S), & \mathcal{L}(RS) &= \mathcal{L}(R)\mathcal{L}(S), \\ \mathcal{L}(R^*) &= \mathcal{L}(R)^*, & \mathcal{L}(R^+) &= \mathcal{L}(R)^+. \end{aligned}$$

We drop parentheses when no ambiguity results, giving concatenation a higher binding power than $+$, so that $RS + T$ means $((RS) + T)$.

The only irritation is the empty word, which regular expressions can produce and regular grammars cannot. We deal with it by a definition.

Definition 27.3.28

A language L is **essentially regular** if L or $L \setminus \{\varepsilon\}$ is regular; equivalently, if there is a regular L' with $L = L'$ or $L = L' \cup \{\varepsilon\}$.

Theorem 27.3.29

If E is a regular expression then $\mathcal{L}(E)$ is essentially regular.

Proof. We induct on the structure of E . The base cases are clear: $\emptyset$ and $\{a\}$ are regular (take $P = \emptyset$ and $P = \{S \rightarrow a\}$ respectively) and $\{\varepsilon\} = \emptyset \cup \{\varepsilon\}$ is essentially regular.

For the induction step it is enough to show that essentially regular languages are closed under union, concatenation and Kleene plus, since $\mathcal{L}(E^*) = \mathcal{L}(E + E^+)$.

Union and concatenation of regular languages are regular by Theorem 27.2.20 and Lemma 27.3.3, and the extension to essentially regular languages is a short case analysis: for instance $(L \cup \{\varepsilon\})(M \cup \{\varepsilon\}) = LM \cup L \cup M \cup \{\varepsilon\}$, and $LM \cup L \cup M$ is regular.

So let $G = (\Sigma, V, P, S)$ be regular; we must show $\mathcal{L}(G)^+$ is regular. We may assume G is ε -adequate, so S never occurs on the right of a rule. Let

$$P^+ = P \cup \{A \rightarrow aS \mid A \rightarrow a \in P\}, \quad G^+ = (\Sigma, V, P^+, S).$$

This is regular; we claim $\mathcal{L}(G^+) = \mathcal{L}(G)^+$.

($\supseteq$) Let $w = w_0w_1 \cdots w_n$ with each $w_i \in \mathcal{L}(G)$. Induct on n . For $n = 0$ any G -derivation is a G^+ -derivation. For $n > 0$, by induction $S \Rightarrow_{G^+}^* w_0 \cdots w_{n-1}$; this derivation ends with a terminal rule $A \rightarrow a$, and replacing that final step by $A \rightarrow aS$ gives $S \Rightarrow_{G^+}^* w_0 \cdots w_{n-1}S$. Appending a G -derivation of w_n gives w .

($\subseteq$) Let $S \Rightarrow_{G^+}^* w$ and let $n \geq 1$ be the number of strings in the derivation in which S occurs (the first one always does). Induct on n . If $n = 1$ then S occurs only at the start, so no added rule was used and $S \Rightarrow_G^* w$, giving $w \in \mathcal{L}(G) \subseteq \mathcal{L}(G)^+$. If $n > 1$, write the derivation as $S \Rightarrow_{G^+}^* vS \Rightarrow_{G^+}^* w$ where vS is the *last* string containing S . The step producing vS used an added rule $A \rightarrow aS$; replacing it by $A \rightarrow a$ gives a derivation $S \Rightarrow_{G^+}^* v$ with $n - 1$ occurrences of S , so $v \in \mathcal{L}(G)^+$ by induction. From vS onward S never reappears, so no added rule fires, and $w = vw'$ with $S \Rightarrow_G^* w'$, i.e. $w' \in \mathcal{L}(G)$. Hence $w \in \mathcal{L}(G)^+$. $\square$

The converse is Kleene's theorem proper, and it is usually proved by an algorithm which eliminates the states of an automaton one at a time. We give the closely related dynamic-programming version.

Theorem 27.3.30 (Kleene)

Let D be a deterministic automaton. Then there is a regular expression E with $\mathcal{L}(E) = \mathcal{L}(D)$. Consequently a language is essentially regular if and only if it is $\mathcal{L}(E)$ for some regular expression E .

Proof. Write $Q = \{q_0, q_1, \dots, q_{m-1}\}$. For $i, j < m$ and $0 \leq k \leq m$, let

$$R_{i,j}^k = \{w \in \mathbb{W} \mid \hat{\delta}(q_i, w) = q_j, \text{ all states strictly inside}$$

$$\text{the run lying in } \{q_0, \dots, q_{k-1}\}\},$$

where 'strictly inside' means excluding the first and last states of the run. We show by induction on k that each $R_{i,j}^k$ is $\mathcal{L}(E)$ for a regular expression $E_{i,j}^k$.

For $k = 0$ no intermediate states are allowed, so $R_{i,j}^0$ consists of ε (if $i = j$) together

with the letters a with $\delta(q_i, a) = q_j$. This is a finite set of words of length at most 1, hence is $\mathcal{L}(E)$ for a finite sum of the base expressions.

For the induction step, a run from q_i to q_j through $\{q_0, \dots, q_k\}$ either avoids q_k altogether, or visits q_k ; in the latter case, splitting at the first and last visits to q_k decomposes the word as a run $q_i \rightarrow q_k$ avoiding q_k internally, then finitely many runs $q_k \rightarrow q_k$ avoiding q_k internally, then a run $q_k \rightarrow q_j$ avoiding q_k internally. Hence

$$R_{i,j}^{k+1} = R_{i,j}^k \cup R_{i,k}^k (R_{k,k}^k)^* R_{k,j}^k,$$

and we may take $E_{i,j}^{k+1} = E_{i,j}^k + E_{i,k}^k (E_{k,k}^k)^* E_{k,j}^k$.

Finally $\mathcal{L}(D) = \bigcup_{q_j \in F} R_{0,j}^m$, so we take $E = \sum_{q_j \in F} E_{0,j}^m$. Since $q_0 \notin F$, the word ε does not lie in this language, so the resulting expression describes $\mathcal{L}(D)$ exactly.

For the last sentence, combine this with Theorem 27.3.29: if L is essentially regular then L is $\mathcal{L}(E)$ or $\mathcal{L}(E + \varepsilon)$ for a suitable E . $\square$

Example 27.3.31

The automaton of Example 27.3.5 accepts the words containing at least one 0, and indeed

$$\mathcal{L}(D) = \mathcal{L}(1^*0(0+1)^*).$$

The automaton of Example 27.3.16 accepts $\mathcal{L}((a+b)^*ab)$.

§27.3.8 Minimisation

We saw in Example 27.3.8 an automaton with two states doing the same job. We now make this precise and show that every regular language has a canonical smallest automaton.

Definition 27.3.32

A state q is **accessible** if $q = \hat{\delta}(q_0, w)$ for some $w \in \mathbb{W}$, and **inaccessible** otherwise.

States q, q' are **distinguished by w** if exactly one of $\hat{\delta}(q, w), \hat{\delta}(q', w)$ lies in F . They are **distinguishable** if some word distinguishes them, and **indistinguishable** otherwise; we write $q \sim q'$ in the latter case.

D is **irreducible** if every state is accessible and every pair of distinct states is distinguishable.

Suppose $f: D \rightarrow D'$ is a homomorphism. If p, q are distinguishable by w then, since f commutes with $\hat{\delta}$ and preserves acceptance, $f(p)$ and $f(q)$ are distinguished by w , so $f(p) \neq f(q)$. And if $q' \in Q'$ is accessible, say $q' = \hat{\delta}'(q'_0, w)$, then $q' = f(\hat{\delta}(q_0, w))$ lies in the image of f . Hence:

Proposition 27.3.33

Any homomorphism between irreducible automata is an isomorphism.

Clearly $\sim$ is an equivalence relation on Q ; write $[q]$ for the class of q .

Definition 27.3.34 (Quotient automaton)

Define

$$D/\sim = (\Sigma, Q/\sim, [\delta], [q_0], [F]), \quad [\delta]([q], a) = [\delta(q, a)], \quad [F] = \{[q] \mid q \in F\}.$$

Two checks are needed. First, being accepting is a class property: if $q \sim q'$ then ε does not distinguish them, so $q \in F \iff q' \in F$; in particular $[F]$ really is a set of classes, and $[q_0] \notin [F]$ since $q_0 \notin F$. Second, $[\delta]$ is well defined: if $q \sim q'$ but $\delta(q, a) \not\sim \delta(q', a)$, witnessed by a word w , then aw would distinguish q from q' .

Lemma 27.3.35

The quotient map $q \mapsto [q]$ is a surjective homomorphism, so $\mathcal{L}(D) = \mathcal{L}(D/\sim)$. Moreover distinct states of $D/\sim$ are distinguishable, and if every state of D is accessible then so is every state of $D/\sim$.

Proof. That the quotient map is a homomorphism is exactly the two checks above; it is surjective by construction, so accessibility is inherited and Proposition 27.3.10 gives the languages agree.

An easy induction gives $[\hat{\delta}][q], w = [\hat{\delta}(q, w)]$. Now suppose $[q] \neq [q']$, so $q \not\sim q'$; take w distinguishing them, say $\hat{\delta}(q, w) \in F$ and $\hat{\delta}(q', w) \notin F$. Then $[\hat{\delta}][q], w = [\hat{\delta}(q, w)] \in [F]$ while $[\hat{\delta}][q'], w \notin [F]$, so w distinguishes $[q]$ from $[q']$. $\square$

Theorem 27.3.36

For every deterministic automaton D there is an irreducible deterministic automaton I with $\mathcal{L}(D) = \mathcal{L}(I)$ and at most as many states.

Proof. Let $A \subseteq Q$ be the set of accessible states; note $q_0 \in A$ and δ restricts to A . Put $D^* = (\Sigma, A, \delta \upharpoonright_{A \times \Sigma}, q_0, F \cap A)$. The inclusion $A \hookrightarrow Q$ is a homomorphism, so $\mathcal{L}(D^*) = \mathcal{L}(D)$, and every state of D^* is accessible. Now take $I = D^*/\sim$ and apply Lemma 27.3.35. $\square$

Theorem 27.3.37

If I and I' are irreducible with $\mathcal{L}(I) = \mathcal{L}(I')$, then $I \cong I'$.

Proof. By Proposition 27.3.33 it suffices to construct a homomorphism $I \rightarrow I'$. Write $I = (\Sigma, Q, \delta, q_0, F)$ and $I' = (\Sigma, Q', \delta', q'_0, F')$ with $Q \cap Q' = \emptyset$. Extend $\sim$ to $Q \cup Q'$ by declaring $q \sim q'$ (for $q \in Q, q' \in Q'$) when for all w , $\hat{\delta}(q, w) \in F \iff \hat{\delta}'(q', w) \in F'$; this is again an equivalence relation. Since the languages agree, $q_0 \sim q'_0$.

Every $q \in Q$ is $\sim$ -equivalent to some $q' \in Q'$. Let $\text{sp}(q)$ be the length of a shortest word w with $\hat{\delta}(q_0, w) = q$, which exists by accessibility. Induct on $\text{sp}(q)$. If $\text{sp}(q) = 0$ then $q = q_0 \sim q'_0$. If $\text{sp}(q) = k + 1$, choose p and a with $\delta(p, a) = q$ and $\text{sp}(p) = k$; by induction pick $p' \sim p$ and set $q' = \delta'(p', a)$. If w is any word then $\hat{\delta}(q, w) = \hat{\delta}(p, aw)$

and $\hat{\delta}'(q', w) = \hat{\delta}'(p', aw)$, so $p \sim p'$ gives $q \sim q'$.

The witness is unique. If $q' \sim q \sim p'$ with $q', p' \in Q'$ then $q' \sim p'$ by transitivity, and irreducibility of I' forces $q' = p'$.

So there is a well-defined $f: Q \rightarrow Q'$ with $q \sim f(q)$. Then $f(q_0) = q'_0$; taking $w = \varepsilon$ in the definition of $\sim$ gives $q \in F \iff f(q) \in F'$; and for any a , the computation above shows $\delta(q, a) \sim \delta'(f(q), a)$, so $f(\delta(q, a)) = \delta'(f(q), a)$ by uniqueness. Thus f is a homomorphism. $\square$

Corollary 27.3.38

Every regular language is accepted by an irreducible automaton, unique up to isomorphism, and this automaton has fewer states than any other automaton accepting the language.

Proof. Existence and uniqueness are Theorems 27.3.36 and 27.3.37. If D is any automaton for L , Theorem 27.3.36 produces an irreducible I with at most $|Q|$ states, and I is isomorphic to the canonical one. $\square$

Example 27.3.39

Return to Example 27.3.5. Is that automaton irreducible? All three states are accessible. The state q_1 is distinguished from the others by ε . But for any word w ,

$$\hat{\delta}(q_0, w) \in F \iff w \text{ contains a } 0 \iff \hat{\delta}(q_2, w) \in F,$$

so $q_0 \sim q_2$ and the automaton is not irreducible. Quotienting merges them, and we obtain the two-state machine

which is irreducible. Notice that this still satisfies our convention that the start state is not accepting, as it must, since ε contains no 0. Applying the same analysis to Example 27.3.8 merges q_0 with E and produces the expected two-state parity machine.

§27.3.9 The Myhill–Nerode Theorem

Where do the states of the minimal automaton come from? The answer is that they are determined by the language alone, with no reference to any machine.

Definition 27.3.40 (Nerode equivalence)

Let $L \subseteq \mathbb{W}$ be any language. For $u, v \in \mathbb{W}$ write

$$u \sim_L v \quad \text{if and only if} \quad \text{for all } w \in \mathbb{W}, \quad uw \in L \iff vw \in L.$$

This is an equivalence relation on $\mathbb{W}$; write $[u]_L$ for the class of u and $\mathbb{W}/\sim_L$ for the set of classes. It is a **right congruence**: if $u \sim_L v$ then $ua \sim_L va$ for every letter a .

The relation $\sim_L$ says that u and v have the same *future*: no continuation can tell them apart. If a machine is reading L and has seen u , the only thing it can usefully remember is $[u]_L$.

Theorem 27.3.41 (Myhill–Nerode)

Let $L \subseteq \mathbb{W}$ with $\varepsilon \notin L$. Then L is regular if and only if $\sim_L$ has finitely many equivalence classes. In that case the number of classes is the number of states of the minimal automaton for L .

Proof. ($\Rightarrow$) Let $L = \mathcal{L}(D)$ for a deterministic D with state set Q . If $\hat{\delta}(q_0, u) = \hat{\delta}(q_0, v)$ then for every w

$$\begin{aligned} uw \in L &\iff \hat{\delta}(q_0, uw) \in F \iff \hat{\delta}(\hat{\delta}(q_0, u), w) \in F \\ &\iff \hat{\delta}(\hat{\delta}(q_0, v), w) \in F \iff vw \in L, \end{aligned}$$

so $u \sim_L v$. Hence $u \mapsto \hat{\delta}(q_0, u)$ induces a well-defined surjection from a subset of Q onto $\mathbb{W}/\sim_L$, and there are at most $|Q|$ classes.

($\Leftarrow$) Suppose there are finitely many classes. Define

$$D_L = (\Sigma, \mathbb{W}/\sim_L, \delta_L, [\varepsilon]_L, F_L), \quad \delta_L([u]_L, a) = [ua]_L, \quad F_L = \{[u]_L \mid u \in L\}.$$

The transition function is well defined because $\sim_L$ is a right congruence, and F_L is a union of classes because $u \sim_L v$ with $w = \varepsilon$ gives $u \in L \iff v \in L$. Since $\varepsilon \notin L$ we have $[\varepsilon]_L \notin F_L$, so this is a legal automaton. An induction on $|w|$ gives $\hat{\delta}_L([\varepsilon]_L, w) = [w]_L$, whence

$$w \in \mathcal{L}(D_L) \iff [w]_L \in F_L \iff w \in L.$$

For the last claim: D_L is irreducible. Every state is accessible, since $[w]_L = \hat{\delta}_L([\varepsilon]_L, w)$. And if $[u]_L \neq [v]_L$ then some w has (say) $uw \in L$ and $vw \notin L$, and this w distinguishes the two states. So D_L is the minimal automaton, by Theorem 27.3.37. $\square$

Remark. The hypothesis $\varepsilon \notin L$ is forced on us only by the convention $F \subseteq Q \setminus \{q_0\}$;

without it the theorem holds verbatim for the usual definition of automaton in which the start state may accept.

Myhill–Nerode gives a second, often more convenient, method of proving non-regularity: exhibit infinitely many pairwise inequivalent words.

Example 27.3.42

Once more let $L = \{0^k 1^k \mid k > 0\}$. For $i \neq j$ the word 1^i distinguishes 0^i from 0^j , since $0^i 1^i \in L$ but $0^j 1^i \notin L$. So the words $0^0, 0^1, 0^2, \dots$ lie in pairwise distinct classes, $\sim_L$ has infinitely many classes, and L is not regular.

Example 27.3.43

Let L be the set of nonempty words over $\{0, 1\}$ containing at least one 0. If u contains a 0 then $uw \in L$ for every w ; if u does not, then $uw \in L$ if and only if w contains a 0. So there are exactly two classes, and the minimal automaton has two states – exactly as we found by minimising.

Notice how much less work the second example was than the direct minimisation. This is typical: Myhill–Nerode lets us compute the minimal automaton by thinking about the language rather than by manipulating a machine.

§27.3.10 Decision Problems for Regular Languages

We can now settle all three of our decision problems for regular grammars. The word problem was dealt with in Corollary 27.2.16 (or, more sensibly, by running the automaton). The other two require a little work, and both are consequences of the pumping lemma and the finiteness of the machinery.

Lemma 27.3.44

Let L be a nonempty regular language with pumping number n . Then L contains a word of length less than n .

Proof. Take $w \in L$ of minimal length. If $|w| \geq n$ then $w = xyz$ with $|y| > 0$ and $xz = xy^0z \in L$, which is shorter, contradicting minimality. $\square$

Corollary 27.3.45

The emptiness problem for regular grammars is solvable.

Proof. Given a regular grammar G , construct a deterministic automaton for $\mathcal{L}(G)$ and let n be its number of states, a pumping number by Theorem 27.3.20. By Lemma 27.3.44, $\mathcal{L}(G) = \emptyset$ if and only if $\mathcal{L}(G)$ contains no word of length less than n . There are finitely many such words, and the word problem is solvable, so we can check them all. $\square$

Corollary 27.3.46

The finiteness problem for regular grammars – given G , is $\mathcal{L}(G)$ finite? – is solvable.

Proof. With n as above, we claim $\mathcal{L}(G)$ is infinite if and only if it contains a word w with $n \leq |w| < 2n$. If such a w exists then it can be pumped, and $\{xy^kz \mid k \in \mathbb{N}\}$ is an infinite subset of $\mathcal{L}(G)$. Conversely, if $\mathcal{L}(G)$ is infinite, take $w \in \mathcal{L}(G)$ of minimal length at least n ; writing $w = xyz$ as in the pumping lemma we have $|y| \leq |xy| \leq n$, so $xz \in \mathcal{L}(G)$ has length $|w| - |y| \geq |w| - n$, and by minimality $|w| - n < n$. Again there are finitely many words to check. $\square$

For the equivalence problem the plan is to build the minimal automaton for each language and check whether they are isomorphic, which by Theorem 27.3.37 settles the question. We must check that both steps can actually be carried out in finitely many steps.

Proposition 27.3.47

Given a deterministic automaton D and a state q , it is solvable whether q is accessible.

Proof. If $\hat{\delta}(q_0, w) = q$ for some w , then taking w of minimal length, the states visited must all be distinct (else we could excise a loop), so $|w| < |Q|$. There are finitely many such words, and we can compute $\hat{\delta}$ on each. $\square$

Theorem 27.3.48 (The table-filling algorithm)

Given a deterministic automaton D and states q, q' , it is solvable whether $q \sim q'$.

Proof. Form a table A indexed by unordered pairs of distinct states. Each entry is either blank or holds a word. The intended invariant is that $A_{q,q'}$ holds a word distinguishing q and q' .

Initialise. If exactly one of q, q' lies in F , set $A_{q,q'} = \varepsilon$.

Iterate. Repeatedly do the following sweep: for each blank entry $A_{q,q'}$ and each $a \in \Sigma$, if $\delta(q, a) \neq \delta(q', a)$ and the entry $A_{\delta(q,a), \delta(q',a)}$ holds a word w , then set $A_{q,q'} = aw$. Each sweep takes at most $|Q|^2|\Sigma|$ operations, and fills at least one blank entry or else nothing changes; since there are at most $|Q|^2$ entries, after at most $|Q|^2$ sweeps the table is stable.

Correctness. If $A_{q,q'} = w$ then w genuinely distinguishes q and q' : this is true at initialisation, and is preserved by the iteration, since $\hat{\delta}(q, aw) = \hat{\delta}(\delta(q, a), w)$.

Conversely suppose some distinguishable pair is left blank; among all such pairs choose q, q' with a distinguishing word w of minimal length. If $w = \varepsilon$ then the pair was filled at initialisation, a contradiction. So $w = av$. Then v distinguishes $\delta(q, a)$ from $\delta(q', a)$, and v is shorter than w , so by minimality that pair is not blank in the final table. But then the sweep would have filled $A_{q,q'}$, contradicting stability.

So on termination, $A_{q,q'}$ is blank precisely when $q \sim q'$. $\square$

Example 27.3.49

Consider the automaton

After initialisation, the pairs involving exactly one of the accept states q_2, q_3 are marked with ε :

	q_0	q_1	q_2	q_3
q_0			ε	ε
q_1			ε	ε
q_2				
q_3				

In the first sweep, $\delta(q_0, a) = q_1$ and $\delta(q_1, a) = q_2$, and the entry A_{q_1, q_2} is marked, so we mark A_{q_0, q_1} with a :

	q_0	q_1	q_2	q_3
q_0		a	ε	ε
q_1			ε	ε
q_2				
q_3				

The only remaining blank is A_{q_2, q_3} , and it stays blank: both q_2 and q_3 are absorbing accept states, so $\delta(q_2, a) = q_2$, $\delta(q_3, a) = q_3$ and the entry A_{q_2, q_3} can only ever be filled from itself. So $q_2 \sim q_3$, and the minimal automaton has three states $[q_0], [q_1], [q_2]$.

It is illuminating to read the same computation backwards, as a **refinement of partitions**. We begin with the partition of Q into one block, and each time an entry is filled we split the block containing that pair:

The process must stop, since each round strictly refines the partition and Q is finite; when it stops, the blocks are exactly the $\sim$ -classes. (Directly: $\mathcal{L}(D) = \mathcal{L}(b(a+b)^* + ab^*a(a+b)^*)$, and one can check by hand that the three classes are ‘nothing decided yet’, ‘an a has been seen’, and ‘accepted forever’.)

Corollary 27.3.50

The equivalence problem for regular grammars is solvable.

Proof. Given regular grammars G, G' , construct deterministic automata for them; delete inaccessible states, which we can identify; and quotient by $\sim$, which we can compute by Theorem 27.3.48. This yields irreducible automata I, I' . Now $\mathcal{L}(G) = \mathcal{L}(G')$ if and only if $I \cong I'$ by Theorems 27.3.36 and 27.3.37, and since I and I' are finite there are only finitely many candidate bijections to test. $\square$

For regular languages, then, everything is as good as it could be: all the closure properties hold, all three decision problems are solvable, and there is a canonical smallest machine. As we ascend the hierarchy, each of these will fail in turn.

§27.4 Context-Free Languages

We move one step up. A context-free rule replaces a single variable A by an arbitrary nonempty string, with no restriction on the shape of the right-hand side. We already know from Example 27.3.21 that this buys us something, since $\{0^k 1^k \mid k > 0\}$ is generated by the context-free grammar

$$S \rightarrow 0S1, \quad S \rightarrow 01$$

but is not regular. The essential new feature is that a context-free derivation is no longer linear. In a regular grammar every intermediate string had the form wA , so a derivation was a list; here several variables can be present at once, and the natural object recording a derivation is a tree.

§27.4.1 Trees

We set up trees in the way that is most convenient for the arguments below, namely as sets of finite sequences of naturals: a node is identified with the route taken to reach it from the root.

Definition 27.4.1 (Tree)

A set $T \subseteq \mathbb{N}^*$ is a **(finitely branching) tree** if it is closed under initial segments, and for every $t \in T$ there is a **branching number** $n \in \mathbb{N}$ such that $tk \in T$ if and only if $k < n$.

The empty sequence is the **root**, and lies in every nonempty tree. A node with branching number 0 is a **leaf**. The **level** of t is $|t|$, and if T is finite the maximum level is the **height** of T . The **branch** to t is the sequence $t \restriction_0, t \restriction_1, \dots, t \restriction_{|t|} = t$ of its initial segments.

Example 27.4.2

The set $T = \{\varepsilon, 0, 1, 2, 00, 01, 10, 20, 000, 001, 0010\}$ is a tree, drawn below with the root at the top.

Its height is 4; its leaves are 01, 10, 20, 000 and 0010; and the branch to 0010 is ε , 0, 00, 001, 0010.

Definition 27.4.3 (Subtree)

For $t \in T$, the **subtree at t** is $T_t = \{s \mid ts \in T\}$, which is again a tree.

Definition 27.4.4 (Left-to-right order)

Define $t < s$ for $t \neq s$ in T if, letting k_0 be least with $t(k_0) \neq s(k_0)$ (assuming such k_0 exists), we have $t(k_0) < s(k_0)$.

This is a partial order: it does not compare two nodes lying on the same branch, such as 0 and 00. It does, however, totally order the nodes at any fixed level, and in particular it totally orders the leaves. Reading the leaves in this order is what turns a tree into a string.

§27.4.2 Parse Trees

Definition 27.4.5 (Parse tree)

Let $G = (\Sigma, V, P, S)$ be a context-free grammar. A pair $\mathbb{T} = (T, \ell)$ is a **G -parse tree** if T is a finite tree and $\ell: T \rightarrow \Omega$ is a **labelling** such that

- (i) $\ell(\varepsilon) \in V$, and we say that $\mathbb{T}$ **starts with** $\ell(\varepsilon)$;
- (ii) if $\ell(t) \in \Sigma$ then t is a leaf;
- (iii) if $\ell(t) = A \in V$ and t has branching number $n+1$, then $A \rightarrow \ell(t_0)\ell(t_1) \cdots \ell(t_n)$ is a rule of P .

If $t_0 < t_1 < \cdots < t_m$ are the leaves of T in left-to-right order, the **string parsed by $\mathbb{T}$** is

$$\sigma_{\mathbb{T}} = \ell(t_0)\ell(t_1) \cdots \ell(t_m).$$

Note that a variable labelling a node of branching number 0 is permitted; such a leaf contributes a variable to $\sigma_{\mathbb{T}}$, and corresponds to a derivation that has not been finished. If $t \in T$, splitting the leaves into those to the left of t , those below t and those to the right of t gives

$$\sigma_{\mathbb{T}} = \alpha \sigma_{\mathbb{T}_t} \beta$$

for some strings α, β , where $\mathbb{T}_t = (T_t, \ell_t)$ with $\ell_t(s) = \ell(ts)$.

Example 27.4.6

Let G be the grammar $S \rightarrow 0S1 \mid 01$ over $\Sigma = \{0, 1\}$. The parse tree for 000111 is the following.

Its leaves in left-to-right order are the six letters 0, 0, 0, 1, 1, 1, so $\sigma_{\mathbb{T}} = 000111$ as promised. The corresponding derivation is $S \Rightarrow 0S1 \Rightarrow 00S11 \Rightarrow 000111$.

Proposition 27.4.7

Let G be context-free and $w \in \mathbb{W}$. Then $w \in \mathcal{L}(G)$ if and only if there is a G -parse tree $\mathbb{T}$ starting with S and with $\sigma_{\mathbb{T}} = w$.

Proof. Call a sequence $\mathbb{T}_0, \dots, \mathbb{T}_n$ of G -parse trees **derivative** if $\mathbb{T}_0 = (\{\varepsilon\}, \varepsilon \mapsto S)$, and each $\mathbb{T}_{i+1}$ is obtained from $\mathbb{T}_i$ by choosing a leaf t with $\ell_i(t) = A \in V$ and a rule $A \rightarrow x_0 \cdots x_n \in P$, and adjoining successors $t0, \dots, tn$ with $\ell_{i+1}(tk) = x_k$.

Derivative sequences correspond exactly to derivations from S : adjoining the successors of t replaces the occurrence of A contributed by t in $\sigma_{\mathbb{T}_i}$ by $x_0 \cdots x_n$, and leaves the rest of the string alone, which is precisely one application of $A \rightarrow x_0 \cdots x_n$. Hence $\sigma_{\mathbb{T}_0} \Rightarrow_G \sigma_{\mathbb{T}_1} \Rightarrow_G \cdots \Rightarrow_G \sigma_{\mathbb{T}_n}$, and conversely each derivation determines such a sequence by recording where each rule was applied.

So if there is a derivative sequence ending at $\mathbb{T}$, then $S \Rightarrow_G^* \sigma_{\mathbb{T}}$. It remains to show every parse tree $\mathbb{T}$ starting with S arises this way. Set $\mathbb{T}_0$ to be the one-node tree. Given $\mathbb{T}_i$ with $T_i \subsetneq T$, pick $t \in T \setminus T_i$ of minimal length; then its predecessor $t \upharpoonright_{|t|-1}$ is a leaf of T_i but not of T , and is labelled by a variable, so we may adjoin all of its T -successors to form T_{i+1} . Since T is finite this terminates with $T_n = T$, giving a derivative sequence. $\square$

The following surgery on parse trees will be needed for the pumping lemma.

Definition 27.4.8 (Grafting)

Let $\mathbb{T} = (T, \ell)$ be a parse tree, $t \in T$ with $\ell(t) = A$, and $\mathbb{T}' = (T', \ell')$ a parse tree starting with A . Then $\text{graft}(\mathbb{T}, t, \mathbb{T}') = (S, \ell^*)$ where

$$S = \{s \in T \mid t \not\subseteq s\} \cup \{tu \mid u \in T'\}, \quad \ell^*(s) = \begin{cases} \ell(s) & t \not\subseteq s, \\ \ell'(u) & s = tu, u \in T'. \end{cases}$$

That is, we cut off the subtree at t and glue $\mathbb{T}'$ in its place; the result is again a parse tree, because the only condition involving t is that the rule applied at t matches its

successors, and this is inherited from $\mathbb{T}'$. If $\sigma_{\mathbb{T}} = \alpha \sigma_{\mathbb{T}_t} \beta$ then

$$\sigma_{\text{graft}(\mathbb{T}, t, \mathbb{T}')} = \alpha \sigma_{\mathbb{T}'} \beta.$$

§27.4.3 Ambiguity

A word may have several parse trees, and this matters a great deal in practice, since the parse tree of a program is what determines its meaning.

Definition 27.4.9

A context-free grammar G is **ambiguous** if some $w \in \mathcal{L}(G)$ has two distinct parse trees starting with S .

Example 27.4.10

Let $\Sigma = \{a, +, *, (,)\}$, $V = \{E\}$ and

$$E \rightarrow E + E \mid E * E \mid (E) \mid a.$$

The word $a + a * a$ has the two parse trees

both parsing $a + a * a$. The left tree groups the expression as $a + (a * a)$ and the right as $(a + a) * a$; if the letters were numbers these would evaluate differently. So G is ambiguous. One can find an unambiguous grammar for the same language by introducing variables for ‘term’ and ‘factor’, which is what forces the usual precedence rules; but there are context-free languages for which *every* grammar is ambiguous, and these are called **inherently ambiguous**.

§27.4.4 Chomsky Normal Form

Parse trees for general context-free grammars can have arbitrarily large branching, which makes counting arguments awkward. It is therefore very convenient that we may always assume the branching is at most 2.

Definition 27.4.11 (Chomsky normal form)

A grammar is in **Chomsky normal form** if every rule is of the form $A \rightarrow BC$ with $B, C \in V$ (a **binary** rule) or $A \rightarrow a$ with $a \in \Sigma$ (a **unary** rule).

Every grammar in Chomsky normal form is context-free. In such a grammar, parse trees are binary and derivations have a fixed length.

Lemma 27.4.12

Let G be in Chomsky normal form and $w \in \mathcal{L}(G)$ with $|w| = n$. Then every G -derivation of w from S has length exactly $2n - 1$.

Proof. A binary rule increases the length by one and the variable count by one; a unary rule leaves the length alone and decreases the variable count by one. We begin with the string S , of length 1 with one variable, and end with w , of length n with no variables. If p binary and q unary rules are used, then $1 + p = n$ and $1 + p - q = 0$, so $p = n - 1$ and $q = n$, giving $2n - 1$ steps. $\square$

Theorem 27.4.13 (Chomsky)

Every context-free grammar is equivalent to one in Chomsky normal form, and such a grammar can be computed from the original.

Proof. There are three kinds of rule obstructing Chomsky normal form:

- (a) rules $A \rightarrow \alpha$ with $|\alpha| \geq 2$ where α contains a letter;
- (b) rules $A \rightarrow B$ with $B \in V$, called **unit rules**;
- (c) rules $A \rightarrow \alpha$ with $|\alpha| > 2$ where α contains only variables.

We remove them in turn.

(a) For each $a \in \Sigma$ introduce a fresh variable X_a and the rule $X_a \rightarrow a$, and replace every offending rule $A \rightarrow \alpha$ by $A \rightarrow X(\alpha)$, where X replaces each letter a by X_a . This is exactly the construction of Lemma 27.2.19 applied to the right-hand sides, and the same argument shows the language is unchanged. Afterwards, the only rules whose right-hand side contains a letter are the unary rules.

(b) Call G **unit closed** if whenever $A \rightarrow B$ and $B \rightarrow \alpha$ lie in P , so does $A \rightarrow \alpha$. Every grammar can be made unit closed by repeatedly adding such rules; at most $|V| \cdot |P|$ new rules can be added, so this terminates, and it clearly does not change the language.

Now suppose G is unit closed, and let G' be G with all unit rules deleted. Certainly $\mathcal{L}(G') \subseteq \mathcal{L}(G)$. Conversely let $w \in \mathcal{L}(G)$ and take a G -derivation of w of minimal length. Suppose it uses a unit rule, and consider the *last* such use:

$$S \Rightarrow_G^* \alpha A \beta \Rightarrow_G \alpha B \beta \Rightarrow_G^* w.$$

Since w contains no variables, the occurrence of B just created must eventually be rewritten; let

$$S \Rightarrow_G^* \alpha A \beta \Rightarrow_G \alpha B \beta \Rightarrow_G^* \gamma B \delta \Rightarrow_G \gamma \zeta \delta \Rightarrow_G^* w$$

where $B \rightarrow \zeta$ is the first rule applied to that occurrence. The segment $\alpha B \beta \Rightarrow_G^* \gamma B \delta$ does not touch that occurrence of B , so the same rules apply verbatim to $\alpha A \beta$, giving $\alpha A \beta \Rightarrow_G^* \gamma A \delta$. By unit closure $A \rightarrow \zeta \in P$, so we may continue $\gamma A \delta \Rightarrow_G \gamma \zeta \delta$, and we have produced a strictly shorter derivation of w – contradicting minimality. Hence the minimal derivation uses no unit rule, and is a G' -derivation.

(c) Finally consider $A \rightarrow A_1 A_2 \cdots A_n$ with $n > 2$ and all $A_i \in V$. Introduce fresh variables $X_1, \dots, X_{n-2}$ and replace this rule by

$$A \rightarrow A_1 X_1, \quad X_1 \rightarrow A_2 X_2, \quad \dots, \quad X_{n-3} \rightarrow A_{n-2} X_{n-2}, \quad X_{n-2} \rightarrow A_{n-1} A_n.$$

The new variables occur in no other rule, so the only strings derivable using them are the intermediate stages of the replacement, and the language is unchanged.

Applying (a), then (b), then (c) leaves only binary and unary rules. $\square$

§27.4.5 The Pumping Lemma for Context-Free Languages

The pumping lemma for regular languages came from a repeated state on a path. Its analogue here comes from a repeated *variable* on a branch of a parse tree, and the resulting pump has two pieces – one on either side of the repeated subtree.

Definition 27.4.14

A language L satisfies the **context-free pumping lemma with pumping number n** if every $w \in L$ with $|w| \geq n$ can be written $w = xuyvz$ with

$$|uyv| \leq n, \quad |uv| > 0, \quad xu^k y v^k z \in L \text{ for all } k \in \mathbb{N}.$$

We call the pair (u, v) the **pump**.

Remark. Note the differences from the regular version. The pump has two parts, of which one may be empty (only their total length is required to be positive). There is no constraint on where the pump sits in the word: x and z may be arbitrarily long. But the pump together with the material between its two halves is bounded.

If L satisfies the regular pumping lemma with number n then it satisfies the context-free one with the same n , taking $v = \varepsilon$; so by Example 27.3.23 there are uncountably many languages satisfying the context-free pumping lemma, and it cannot possibly characterise the countably many context-free languages.

Theorem 27.4.15

Every context-free language satisfies the context-free pumping lemma for some n .

Proof. Let L be context-free. By Theorem 27.4.13 take a Chomsky normal form grammar G with $\mathcal{L}(G) = L$, put $m = |V|$ and $n = 2^m$.

Claim: if $\mathbb{T}$ is a G -parse tree of height $h + 1$ whose string is a word, then $|\sigma_{\mathbb{T}}| \leq 2^h$. Since every node has branching number 1 or 2, and since $\sigma_{\mathbb{T}}$ is a word, the leaves are exactly the nodes labelled by letters and each arises from a unary rule applied to its parent. Deleting the leaves therefore gives a binary tree of height h , whose leaves are the parents; there are at most 2^h of these, and each has exactly one child. So $|\sigma_{\mathbb{T}}| \leq 2^h$.

Now let $w \in L$ with $|w| \geq 2^m$ and let $\mathbb{T}$ be a parse tree for w . By the claim, the height of $\mathbb{T}$ is at least $m + 1$. Let t be a node at maximal level, so the branch to t has $h + 1 \geq m + 2$ nodes; all but the last are labelled by variables, the last by a

letter.

Let s be the node on that branch for which the subtree $\mathbb{T}_s$ has height exactly $m + 1$. By the claim, $|\sigma_{\mathbb{T}_s}| \leq 2^m = n$. The portion of the branch from s to t has $m + 2$ nodes, of which $m + 1$ are labelled by variables; as there are only m variables, by pigeonhole two of them carry the same label. Say $t_0 \subsetneq t_1$ lie on this branch with $\ell(t_0) = \ell(t_1) = A$.

Decompose the string according to these nodes:

$$\sigma_{\mathbb{T}} = x' \sigma_{\mathbb{T}_s} z', \quad \sigma_{\mathbb{T}_s} = x'' \sigma_{\mathbb{T}_{t_0}} z'', \quad \sigma_{\mathbb{T}_{t_0}} = u \sigma_{\mathbb{T}_{t_1}} v, \quad \sigma_{\mathbb{T}_{t_1}} = y,$$

and set $x = x'x''$ and $z = z''z'$, so that $w = xyvz$. Since $\sigma_{\mathbb{T}_{t_0}} = u y v$ is a substring of $\sigma_{\mathbb{T}_s}$, we get $|uyv| \leq n$. And $t_0 \neq t_1$ with G in Chomsky normal form means the subtree at t_0 strictly contains that at t_1 together with at least one further leaf, so $|uv| > 0$.

Finally we pump. Both $\mathbb{T}_{t_0}$ and $\mathbb{T}_{t_1}$ are parse trees starting with A , so grafting is available. Set

$$\mathbb{T}_{(0)} = \mathbb{T}_{t_1}, \quad \mathbb{T}_{(i+1)} = \text{graft}(\mathbb{T}_{t_0}, t_1, \mathbb{T}_{(i)}),$$

so that by induction $\sigma_{\mathbb{T}_{(i)}} = u^i y v^i$. Then $\text{graft}(\mathbb{T}, t_0, \mathbb{T}_{(k)})$ is a parse tree starting with S whose string is $x u^k y v^k z$, so $x u^k y v^k z \in L$ for every k . (For $k = 0$ this is grafting $\mathbb{T}_{t_1}$ in place of $\mathbb{T}_{t_0}$, which is the ‘pump down’.) $\square$

Example 27.4.16

The language $L = \{a^n b^n c^n \mid n > 0\}$ is not context-free.

Suppose it were, with pumping number N . Consider $a^N b^N c^N \in L$ and write it as $x y v z$ with $|uyv| \leq N$ and $|uv| > 0$. Since uyv is a substring of length at most N , and the blocks of a ’s, b ’s and c ’s each have length N , the substring uyv cannot contain letters of all three kinds. Pumping up to $k = 2$ increases the number of occurrences of at least one letter (as $|uv| > 0$) but leaves the count of at least one other letter unchanged. The result is therefore not of the form $a^m b^m c^m$, contradiction.

Remark. The language $\{a^n b^n c^n\}$ is context-sensitive; a grammar for it may be built from rules such as $S \rightarrow abc \mid aAbc$, $Ab \rightarrow bA$, $Ac \rightarrow Bbcc$, $bB \rightarrow Bb$, $aB \rightarrow aa \mid aaA$, and one checks that this generates exactly L . So the inclusion of type 2 in type 1 is

strict, as drawn in our picture of the hierarchy.

§27.4.6 Closure Properties

The context-free languages inherit closure under union and concatenation from Theorem 27.2.20, since context-free grammars are variable-based and the added rules $T \rightarrow SS'$, $T \rightarrow S$, $T \rightarrow S'$ are context-free. They are also closed under Kleene plus: given G , take a fresh T and put $T \rightarrow S \mid TS$.

The good news stops there.

Proposition 27.4.17

The context-free languages are not closed under intersection, complement or difference.

Proof. Let

$$L_0 = \{a^n b^n c^k \mid n, k > 0\}, \quad L_1 = \{a^k b^n c^n \mid n, k > 0\}.$$

Both are context-free: L_0 is the concatenation of $\{a^n b^n\}$ and $\{c^k\}$, and L_1 is the concatenation of $\{a^k\}$ and $\{b^n c^n\}$, and each factor is context-free: the two-letter blocks by the grammar of Example 27.4.6 with the letters renamed, and $\{c^k\}$ and $\{a^k\}$ by regular grammars. But $L_0 \cap L_1 = \{a^n b^n c^n \mid n > 0\}$, which is not context-free by Example 27.4.16.

Since the class is closed under union, closure under complement would give closure under intersection by De Morgan; so complement fails too, as does difference, since $L \cap M = L \setminus (L \setminus M)$. $\square$

This has an important consequence for the machine model we are about to meet: *what-ever* machines characterise the context-free languages, there can be no product construction for them. Two such machines cannot in general be run side by side on the same input. In hindsight the reason is easy to see, and it is that the machine will have an unbounded memory, so the pair of memories cannot be packaged into a single memory of the same kind.

§27.4.7 Pushdown Automata

We describe, without proofs, the machine model corresponding to context-free languages. A **pushdown automaton** is a finite automaton equipped with a **stack**: an unbounded sequence of symbols of which only the topmost is visible. Two operations are available, **push** (place a new symbol on top) and **pop** (remove the topmost symbol). There is no random access; a symbol placed on the stack can only be read after everything placed on top of it has been removed, so symbols come off in the reverse of the order in which they went on.

Formally, the transition function of such a machine takes as an extra input the symbol currently on top of the stack, and produces as an extra output an instruction to push a symbol, to pop, or to do nothing:

$$\delta: Q \times \Sigma \times \Gamma \longrightarrow \mathcal{P}(Q \times \Gamma^*),$$

where Γ is a finite **stack alphabet**. The machine accepts if some run consumes the whole input and finishes in an accept state.

Theorem 27.4.18

A language is context-free if and only if it is accepted by a pushdown automaton.

It is worth seeing informally why the stack is exactly the right amount of extra power for $\{0^k 1^k\}$. Reading the 0s, the machine pushes one stack symbol per 0; reading the 1s, it pops one per 1; and it accepts if the stack empties exactly as the input runs out. The stack cannot do this twice over – once emptied, the information is gone – which is the informal reason that $\{a^n b^n c^n\}$ is beyond its reach.

Note also that, unlike the case of finite automata, *nondeterministic* pushdown automata are strictly more powerful than deterministic ones: the deterministic pushdown automata accept a proper subclass of the context-free languages (for example the language of even-length palindromes is context-free but not deterministic context-free). So the pleasant state of affairs of Theorem 27.3.15 does not survive the move up the hierarchy either.

§27.4.8 Decision Problems for Context-Free Languages

Proposition 27.4.19

The word problem for context-free grammars is solvable.

Proof. Context-free grammars are noncontracting, so this is Corollary 27.2.16. Alternatively, and much more efficiently: convert to Chomsky normal form, whereupon by Lemma 27.4.12 every derivation of w has length exactly $2|w| - 1$, and check all of them. (The standard polynomial-time algorithm, due to Cocke, Younger and Kasami, computes for each substring of w the set of variables deriving it, by dynamic programming.) $\square$

Proposition 27.4.20

The emptiness problem for context-free grammars is solvable.

Proof. Exactly as for regular languages. Let n be a context-free pumping number for $\mathcal{L}(G)$, computed as $2^{|V|}$ from a Chomsky normal form grammar. If $\mathcal{L}(G) \neq \emptyset$, take $w \in \mathcal{L}(G)$ of minimal length; if $|w| \geq n$ then $w = xuyvz$ can be pumped down to xyz , which is shorter and still in $\mathcal{L}(G)$, a contradiction. So $\mathcal{L}(G)$ is nonempty if and only if it contains a word of length less than n , and there are finitely many of those to test. $\square$

Remark. The equivalence problem for context-free grammars, by contrast, is *unsolvable*; so is the question of whether a given context-free grammar is ambiguous, and whether the intersection of two context-free languages is empty. We shall not prove these, but the first taste of such a result is the unsolvability of the corresponding problems for type 0 grammars in Section 27.8.7.

We can summarise the situation so far in a table.

	union	concatenation	intersection	complement
regular	yes	yes	yes	yes
context-free	yes	yes	no	no
	word	emptiness	equivalence	
regular	yes	yes	yes	
context-free	yes	yes	no	

Everything above the line is settled; to go further we need to say what an algorithm is, and that is what we do next.

§27.5 Register Machines

We now give a precise definition of ‘algorithm’. The model we use is the *register machine*: a finite automaton equipped not with one stack, but with finitely many *registers*, each holding a word $w \in \mathbb{W}$. The machine can inspect the last letter of a register, delete it, or append a new one – so a register behaves as a stack, with the right-hand end of the word as the top.

§27.5.1 The Definition

A register machine has an alphabet Σ , a finite set Q of states, and finitely many *registers*, each holding a word $w \in \mathbb{W}$. The machine can inspect the last letter of a register, delete it, or append a new one – so a register behaves as a stack, with the right-hand end of the word as the top.

A snapshot of the whole machine is called a configuration.

Definition 27.5.1 (Configuration)

A **configuration** (or **snapshot**) of length $n+1$ is a tuple $(q, w_0, \dots, w_n) \in Q \times \mathbb{W}^{n+1}$.

One might be tempted to define the dynamics by a transition function $\delta: Q \times \mathbb{W}^{n+1} \rightarrow Q \times \mathbb{W}^{n+1}$, but this is far too permissive: there are uncountably many such functions, and they can do anything at all to the registers in one step. Instead we allow only four kinds of elementary instruction.

Definition 27.5.2 (Instruction)

Let Σ be an alphabet and Q a nonempty finite set of states. A (Σ, Q) -**instruction** is a tuple of one of the forms

$$\begin{aligned} (0, k, a, q) &\in \mathbb{N} \times \mathbb{N} \times \Sigma \times Q, & (1, k, a, q, q') &\in \mathbb{N} \times \mathbb{N} \times \Sigma \times Q \times Q, \\ (2, k, q, q') &\in \mathbb{N} \times \mathbb{N} \times Q \times Q, & (3, k, q, q') &\in \mathbb{N} \times \mathbb{N} \times Q \times Q. \end{aligned}$$

We write these more legibly as

$$+(k, a, q), \quad ?(k, a, q, q'), \quad ?(k, \varepsilon, q, q'), \quad -(k, q, q')$$

respectively, and we write $\text{Instr}(\Sigma, Q)$ for the set of all of them.

Their intended meanings are as follows.

- $+(k, a, q)$: push the letter a onto register k , then move to state q .
- $?(k, a, q, q')$: if the top letter of register k is a , move to state q ; otherwise move to q' .
- $?(k, \varepsilon, q, q')$: if register k is empty, move to state q ; otherwise move to q' .
- $-(k, q, q')$: pop the top letter of register k . If the register was already empty, move to state q ; otherwise move to q' .

Note that only $+$ and $-$ change the registers, and each changes exactly one register by exactly one letter.

Definition 27.5.3 (Register machine)

A tuple $M = (\Sigma, Q, P)$ is a Σ -**register machine** if Σ is an alphabet, Q is a finite set of states containing two distinguished states $q_S \neq q_H$ (the **start state** and the **halt state**), and

$$P: Q \rightarrow \text{Instr}(\Sigma, Q)$$

is the **program**. Writing $Q = \{q_0, \dots, q_n\}$, we present P as a finite list of **program lines** $q_i \mapsto P(q_i)$. Only finitely many register indices k occur in P ; the largest is the **upper register index** of M .

Definition 27.5.4 (Computation)

Let M have upper register index m and let $C = (q, w_0, \dots, w_m)$ be a configuration. We say M **transforms** C into C' if one of the following holds:

- $P(q) = +(k, a, q')$ and $C' = (q', w_0, \dots, w_{k-1}, w_k a, w_{k+1}, \dots, w_m)$;
- $P(q) = ?(k, a, q', q'')$ and either $w_k = wa$ for some w and $C' = (q', w_0, \dots, w_m)$, or w_k does not end in a and $C' = (q'', w_0, \dots, w_m)$;

- $P(q) = ?(k, \varepsilon, q', q'')$ and either $w_k = \varepsilon$ and $C' = (q', w_0, \dots, w_m)$, or $w_k \neq \varepsilon$ and $C' = (q'', w_0, \dots, w_m)$;
- $P(q) = -(k, q', q'')$ and either $w_k = \varepsilon$ and $C' = (q', w_0, \dots, w_m)$, or $w_k = wa$ and $C' = (q'', w_0, \dots, w_{k-1}, w, w_{k+1}, \dots, w_m)$.

Given $\mathbf{w} \in \mathbb{W}^{m+1}$, the **computation sequence** of M on input $\mathbf{w}$ is defined by recursion:

$$C(0, M, \mathbf{w}) = (q_S, \mathbf{w}), \quad C(k+1, M, \mathbf{w}) = \text{the transform of } C(k, M, \mathbf{w}).$$

If $\mathbf{w}$ is shorter than $m+1$ we pad it on the right with copies of ε ; if it is longer we simply carry the extra registers along untouched.

Remark. Every configuration has a transform, so computation sequences as defined are always infinite. Halting is not the absence of a next step, but the arrival at a designated state.

Definition 27.5.5 (Halting)

The computation of M on input $\mathbf{w}$ **halts at time k** if k is least with $C(k, M, \mathbf{w}) = (q_H, \mathbf{v})$ for some $\mathbf{v}$; in this case $\mathbf{v}$ is the **output**. If no such k exists, the computation **does not halt**.

§27.5.2 Strong Equivalence

Definition 27.5.6

Register machines M and M' are **strongly equivalent** if for every input $\mathbf{w}$ and every k , the configurations $C(k, M, \mathbf{w})$ and $C(k, M', \mathbf{w})$ have the same register contents, and M halts on $\mathbf{w}$ at time k if and only if M' does.

So strongly equivalent machines do literally the same thing, step by step; only their state names may differ. Relabelling states shows that if $|Q| = |Q'|$ then every (Σ, Q, P) has a strongly equivalent (Σ, Q', P') .

Proposition 27.5.7 (Padding lemma)

Every register machine is strongly equivalent to infinitely many distinct register machines.

Proof. Let $M = (\Sigma, Q, P)$ and add a fresh state $\hat{q}$ to Q , with $P(\hat{q})$ any instruction whatsoever. Since $\hat{q}$ occurs in no other program line, it never appears in any computation sequence, so the resulting machine is strongly equivalent to M . Repeating gives infinitely many. $\square$

Proposition 27.5.8

Up to strong equivalence there are only countably many register machines over a fixed Σ .

Proof. Up to strong equivalence only $|Q|$ matters, so fix a set Q with $|Q| = n$ and bound the register index by k . Counting the four kinds of instruction,

$$|\text{Instr}(\Sigma, Q)| = (k+1)n|\Sigma| + (k+1)n^2|\Sigma| + (k+1)n^2 + (k+1)n^2 =: N_{n,k},$$

which is finite, so there are $N_{n,k}^n$ programs. The class $M_{n,k}$ of such machines is therefore finite, and every register machine lies in some $M_{n,k}$; so $\bigcup_{n,k} M_{n,k}$ is a countable union of finite sets. $\square$

This is the source of all the negative results in the course. There are only countably many algorithms, and uncountably many things one might want to compute.

§27.5.3 Operations and Questions

Rather than reason about programs line by line, we build up a library of things register machines can do, and thereafter argue at a higher level. There are two kinds of task.

Definition 27.5.9 (Operation)

An **operation** is a partial function $f: \mathbb{W}^{m+1} \rightarrow \mathbb{W}^{m+1}$. We write $f(\mathbf{w}) \downarrow$ if $\mathbf{w} \in \text{dom } f$ (f **converges** at $\mathbf{w}$) and $f(\mathbf{w}) \uparrow$ otherwise (f **diverges**).

A register machine M **performs** f if for every $\mathbf{w}$ we have $f(\mathbf{w}) \downarrow$ if and only if M halts on $\mathbf{w}$, and in that case the output of M is $f(\mathbf{w})$.

Example 27.5.10

The operation ‘never halt’ is the empty function. It is performed by any program which never mentions q_H on the right-hand side of a line, for instance

$$q_S \mapsto +(0, a, q_S), \quad q_H \mapsto +(0, a, q_S).$$

The operation ‘halt immediately, changing nothing’ is the identity function on $\mathbb{W}^{m+1}$, performed by $q_S \mapsto ?(0, a, q_H, q_H)$: the test is performed, both branches lead to q_H , and nothing is written.

Definition 27.5.11 (Question)

A **question with $k+1$ answers** is a partition of $\mathbb{W}^{m+1}$ into sets $A_0, \dots, A_k$. A register machine **answers** the question if it has distinguished **answer states** $\bar{q}_0, \dots, \bar{q}_k$ such that on input $\mathbf{w}$ the computation reaches, after finitely many steps, the configuration $(\bar{q}_i, \mathbf{w})$, where i is the index with $\mathbf{w} \in A_i$.

So a question is answered without disturbing the registers, and the answer is recorded in the state.

Example 27.5.12

‘Is register i empty?’ is answered by the single line $q_S \mapsto ?(i, \varepsilon, \bar{q}_Y, \bar{q}_N)$, and ‘does register i end in the letter a ?’ by $q_S \mapsto ?(i, a, \bar{q}_Y, \bar{q}_N)$.

The next two lemmas are what allow us to program at a high level: they say that

machines can be run one after another, and that they can be selected between.

Lemma 27.5.13 (Concatenation)

If M performs F and M' performs F' , then there is a register machine $\hat{M}$ performing $F' \circ F$.

Proof. Assume the state sets are disjoint. Let P^* be P with the line for q_H deleted and with every occurrence of q_H replaced by q'_S , and set $\hat{M} = (\Sigma, (Q \setminus \{q_H\}) \cup Q', P^* \cup P')$, with start state q_S and halt state q'_H . Running $\hat{M}$ on $\mathbf{w}$ reproduces the computation of M exactly until the moment M would halt, at which point $\hat{M}$ is in state q'_S with registers $F(\mathbf{w})$, and thereafter reproduces the computation of M' on that input. So $\hat{M}$ halts precisely when both $F(\mathbf{w}) \downarrow$ and $F'(F(\mathbf{w})) \downarrow$, with output $F'(F(\mathbf{w}))$. $\square$

Lemma 27.5.14 (Case distinction)

Let Q be a question with answers $A_0, \dots, A_k$, answered by a machine M ; and let F_i be operations performed by machines M_i . Then some register machine performs

$$G(\mathbf{w}) = F_i(\mathbf{w}) \quad \text{when } \mathbf{w} \in A_i.$$

Proof. Assume Q is disjoint from each Q_i and that the Q_i meet only in a common halt state q_H . Let P_i^* be P_i with every occurrence of $q_{S,i}$ replaced by the answer state $\bar{q}_i$ of M , and delete the line for $q_{S,i}$. Put

$$Q^* = Q \cup \bigcup_{i \leq k} (Q_i \setminus \{q_{S,i}\}), \quad P^* = P \cup \bigcup_{i \leq k} P_i^*.$$

On input $\mathbf{w}$, the machine first runs M , which reaches $\bar{q}_i$ with the registers untouched, and from there runs M_i . $\square$

§27.5.4 A Register Machine API

We may now assemble a library of operations, each built out of the previous ones by concatenation and case distinction. A register is **unused** if no program line mentions it, and **empty** if it contains ε ; registers used only for intermediate work are called **scratch registers**. Since any given machine mentions only finitely many registers, an unused empty register is always available.

- ‘Delete the last letter of register i ’: $q_S \mapsto -(i, q_H, q_H)$.
- ‘Push a onto register i ’: $q_S \mapsto +(i, a, q_H)$.
- ‘Empty register i ’: $q_S \mapsto -(i, q_H, q_S)$. This pops repeatedly, halting exactly when the register was found to be empty.
- ‘Halt if register i is nonempty, otherwise diverge’: answer ‘is register i empty?’, then apply case distinction with the operations ‘never halt’ and ‘halt immediately’.
- ‘Append the fixed word $w = a_0 a_1 \dots a_\ell$ to register i ’: concatenate the $\ell + 1$ pushes.
- ‘Replace register i by the fixed word w ’: empty it, then append w .

- ‘What is the last letter of register i ?’: this question has $|\Sigma| + 1$ answers, one per letter and one for ‘empty’. Ask ‘does register i end in a_0 ?’; if yes go to $\bar{q}_0$, if no ask about a_1 , and so on; if every answer is no, the register is empty and we go to $\bar{q}_\varepsilon$.
- ‘Copy the last letter of register i onto register j ’: ask the previous question and push the corresponding letter in each case.
- ‘Move the last letter of register i onto register j ’: copy it, then delete it from i .
- ‘Move register i into register j in reverse order’: repeat the previous operation until register i is empty.
- ‘Move register i into register j in the correct order’: move i into an unused empty register k in reverse order, then move k into j in reverse order. Reversing twice restores the order.
- ‘Reverse register i ’: move it in reverse into an unused empty register, then move that back in the correct order – or equivalently, move it out and back once each.
- ‘Move register i into both j and k in reverse order’: copy the last letter into j , then into k , then delete it; repeat.
- ‘Copy register i into register j ’: move i into j and a scratch register k simultaneously (in reverse), then move k back into i (in reverse). Composing with a reversal fixes the order if required.
- ‘Is register i equal to the fixed word $w = a_0 \cdots a_\ell$?’: run subroutines $S_\ell, S_{\ell-1}, \dots, S_0$, where S_r asks whether the last letter of register i is a_r ; if not, go to a state q_N ; if so, move that letter to a scratch register k and run S_{r-1} , or go to q_Y if $r = 0$. At q_N and at q_Y , move the contents of k back into i , restoring it, and then answer $\bar{q}_N$ or $\bar{q}_Y$ as appropriate. The scratch register must be restored, since a question is not allowed to alter the registers.

It is worth writing out one of these in full, to see that the formalism really does what we claim.

Example 27.5.15

Take $\Sigma = \{a, b\}$. The following five-line program moves the contents of register 1 into register 2 in reverse order, leaving register 1 empty.

$$\begin{array}{lll} q_S \mapsto ?(1, a, q_a, q_1), & q_1 \mapsto ?(1, b, q_b, q_H), & q_a \mapsto +(2, a, q_2), \\ q_b \mapsto +(2, b, q_2), & q_2 \mapsto -(1, q_S, q_S). & \end{array}$$

As a flow diagram:

Let us trace it with register 1 containing ab and register 2 empty. In q_S , the top letter is b , not a , so we move to q_1 ; there the top letter is b , so we move to q_b and push b onto register 2; in q_2 we pop, leaving register 1 holding a , and return to q_S . Now the top letter is a , so we go to q_a , push a onto register 2 (which now holds ba), and pop, leaving register 1 empty. Back at q_S : the top letter is not a (the register is empty), so we go to q_1 ; it is not b either, so we halt. Register 2 holds ba , the reverse of ab , as claimed.

From now on we shall specify register machines by describing what they do in English, in terms of the library above, exactly as one writes a program in terms of library functions rather than machine code. This is legitimate precisely because Lemmas 27.5.13 and 27.5.14 let us assemble the pieces.

§27.6 Computable Functions and Sets

§27.6.1 Computable Functions

Most computations need scratch space, and we do not want the final answer to depend on the litter left behind. So we declare that register 0 holds the output and that everything else is scratch.

Definition 27.6.1

Let M be a register machine and $k \in \mathbb{N}$. Define $f_{M,k}: \mathbb{W}^k \rightarrow \mathbb{W}$ by

$$f_{M,k}(\mathbf{w}) = \begin{cases} v_0 & \text{if } M \text{ halts on } \mathbf{w} \text{ with output } \mathbf{v}, \\ \uparrow & \text{if } M \text{ does not halt on } \mathbf{w}. \end{cases}$$

A partial function $f: \mathbb{W}^k \rightarrow \mathbb{W}$ is **computable** if $f = f_{M,k}$ for some register machine M . For $k = 1$ we write $W_M = \text{dom } f_{M,1}$.

If M and M' are strongly equivalent then $f_{M,k} = f_{M',k}$, though the converse fails badly: two machines may compute the same function in completely different ways.

Remark. By Proposition 27.5.8 there are only countably many computable functions, while there are uncountably many partial functions $\mathbb{W} \rightarrow \mathbb{W}$. So almost every function is

not computable. On the other hand, by the padding lemma each computable function is computed by infinitely many machines. And by Lemmas 27.5.13 and 27.5.14, computable functions are closed under composition and case distinction.

Example 27.6.2

The identity $\mathbb{W} \rightarrow \mathbb{W}$ is computable (halt immediately). Each constant function $c(\mathbf{w}) = v$ is computable (replace register 0 by v). Each projection $\pi_i(\mathbf{w}) = w_i$ is computable (empty register 0, then move register i into register 0).

§27.6.2 Computable and Computably Enumerable Sets

To speak of computable *sets* we use characteristic functions. Since our values are words rather than truth values, we fix once and for all a letter $a \in \Sigma$ to stand for ‘true’, with ε standing for ‘false’.

Definition 27.6.3

Let $X \subseteq \mathbb{W}^k$. A total $f: \mathbb{W}^k \rightarrow \mathbb{W}$ is **a characteristic function of X** if $f(\mathbf{w}) \neq \varepsilon$ exactly when $\mathbf{w} \in X$; it is **the characteristic function χ_X** if moreover $f(\mathbf{w}) = a$ for $\mathbf{w} \in X$. We call X **computable** if χ_X is computable.

A partial f is **a pseudocharacteristic function of X** if $\text{dom } f = X$; it is **the pseudocharacteristic function ψ_X** if additionally $f(\mathbf{w}) = a$ for $\mathbf{w} \in X$. We call X **computably enumerable** if ψ_X is computable.

A computable set is one we can *decide*: given $\mathbf{w}$, the machine always halts and tells us the answer. A computably enumerable set is one we can only *semi-decide*: the machine halts when the answer is yes, and runs forever when the answer is no. Since a language is a set of words, both notions apply to languages.

Proposition 27.6.4

Let $X \subseteq \mathbb{W}^k$.

- (i) X is computable if and only if its complement is computable.
- (ii) X is computably enumerable if and only if $X = \text{dom } f_{M,k}$ for some register machine M .
- (iii) If X is computable then X is computably enumerable.

Proof. Write the proof for $k = 1$; the general case is identical. By case distinction, if g, h are computable then so is the function equal to $g(w)$ when $w \neq \varepsilon$ and $h(w)$ when $w = \varepsilon$, since ‘is register 0 empty?’ is answerable.

- (i) Let f_1 be the computable function given in this way by $g(w) = \varepsilon$ and $h(w) = a$; that is, f_1 swaps a and ε . Then $\chi_{X^c} = f_1 \circ \chi_X$ and conversely.
- (ii) If $X = \text{dom } f$ with f computable, let f_2 be given by $g(w) = a$, $h(w) = a$, so f_2 is the total constant function a ; then $\psi_X = f_2 \circ f$, which is computable with domain X . Conversely ψ_X is itself computable with domain X .

(iii) Let f_3 be given by $g(w) = a$ and $h(w) \uparrow$ (halt if register 0 is nonempty, else diverge). Then $\psi_X = f_3 \circ \chi_X$. $\square$

The converse of (iii) is false, and proving so is the content of the halting problem below. First, a sanity check that our new notion is at least as strong as the old ones.

Theorem 27.6.5

Every regular language is computable.

Proof. Let $L = \mathcal{L}(D)$ with $D = (\Sigma, Q, \delta, q_0, F)$. We describe a register machine with input in register 0.

First, move register 0 into register 1 in reverse order. (This is necessary because a register machine sees the *last* letter of a word, whereas an automaton reads from the left; reversing makes the automaton's first letter the topmost.)

For each $q \in Q$ our machine has a block of states Q_q , meaning ‘we are simulating D in state q ’. Move into Q_{q_0} .

On entering Q_q : ask what the last letter of register 1 is. If register 1 is empty, move to a state $\bar{q}_{acc}$ if $q \in F$, and to $\bar{q}_{rej}$ otherwise. Otherwise, if the last letter is b , delete it and move into $Q_{\delta(q,b)}$, repeating.

Since each pass deletes a letter, the loop terminates after $|w|$ passes. At $\bar{q}_{acc}$, empty register 0, push a , and halt; at $\bar{q}_{rej}$, empty register 0 and halt. The resulting machine computes χ_L . $\square$

§27.6.3 The Shortlex Ordering

Our functions take words as inputs, but recursion – both the definition of recursive functions in Section 27.7 and simple counting arguments – needs a notion of ‘the next one’. We therefore transport the order type of $\mathbb{N}$ onto $\mathbb{W}$.

Definition 27.6.6 (Shortlex)

Fix a total order on Σ . The **shortlex order** on $\mathbb{W}$ is defined by $w < v$ if

- (i) $|w| < |v|$; or
- (ii) $|w| = |v|$, $w \neq v$, and at the least position where they differ, the letter of w precedes that of v .

So we sort by length first, and break ties lexicographically. This is a total order with least element ε .

Example 27.6.7

For $\Sigma = \{0, 1\}$ with $0 < 1$, the shortlex order begins

$\varepsilon, 0, 1, 00, 01, 10, 11, 000, 001, 010, 011, 100, 101, 110, 111, 0000, \dots$

Identifying each word with its index (counting from 0), we have $\#\varepsilon = 0$, $\#10 = 5$, $\#01 = 4$, and since $\#010 = 9 = 5 + 4$ we may write $10 + 01 = 010$. Transporting

the semiring structure of $\mathbb{N}$ in this way makes $\mathbb{W}$ into a commutative semiring; there are $|\Sigma|^k$ words of length k , so for $|\Sigma| = 2$ the index of 0^k is $2^k - 1$.

Theorem 27.6.8

$(\mathbb{W}, <)$ is order-isomorphic to $(\mathbb{N}, <)$.

Proof. For a fixed w the set $\{v \mid v < w\}$ is finite, since it consists of words of length at most $|w|$. So $\#(w) = |\{v \mid v < w\}|$ is a well-defined function $\mathbb{W} \rightarrow \mathbb{N}$, and it is clearly order-preserving. It is surjective, since the words listed in increasing order take every index in turn, and order-preserving maps between total orders are injective. $\square$

Theorem 27.6.9

The set $\{(v, w) \mid v < w\}$ is computable, and the **successor function** $s: \mathbb{W} \rightarrow \mathbb{W}$ determined by $\#s(w) = \#w + 1$ is computable.

Proof. To compare v and w : copy them into scratch registers and repeatedly delete the last letter of each until one is empty; whichever empties first is shorter. If they empty simultaneously, copy them again in reverse order (so that we may read them from the left) and delete letters in step until they differ, then compare those letters in the fixed order on Σ ; if no difference is found the words are equal. All of this uses only operations from Section 27.5.4.

For the successor: locate the last letter of w which is not the largest letter of Σ , replace it by its successor in Σ , and replace everything after it by copies of the least letter. If every letter of w is the largest letter (including the case $w = \varepsilon$), output the least letter repeated $|w| + 1$ times. $\square$

§27.6.4 Merging and Splitting Words

We shall repeatedly need to package a pair of words into a single word. Recall the **Cantor zigzag function**

$$z(i, j) = \frac{(i + j)(i + j + 1)}{2} + j,$$

a bijection $\mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$; it enumerates the lattice points of the first quadrant along successive anti-diagonals.

Definition 27.6.10

For $v, w \in \mathbb{W}$, the **merge** $v * w$ is the unique word with $\#(v * w) = z(\#v, \#w)$. Conversely each w **splits** uniquely as $\#w = z(\#w_{(0)}, \#w_{(1)})$, and we call $w_{(0)}, w_{(1)}$ the components of w .

Since addition and multiplication of indices are computable (they can be built from the successor function by recursion, as we will see in Section 27.7), merging is computable; strictly speaking splitting is an *operation* rather than a computable function, since it

has two outputs, but it is performed by a register machine which writes the components into two registers.

The point of merging is that a single existential quantifier over $\mathbb{W}$ can simulate two. We shall use this so often that it acquires a name: the **zigzag argument**.

§27.6.5 Coding of Programs

We now take the decisive step and treat programs as data. Let Σ be an alphabet and let Σ' be Σ together with ten new symbols

$$\mathbf{0} \ \mathbf{1} \ + \ - \ ? \ (\) \ , \ \mapsto \ \square.$$

For a mathematical object o we write $\text{code}(o) \in \Sigma'^*$ for its code, defined as follows.

- Naturals are written in binary using $\mathbf{0}$ and $\mathbf{1}$, so $\text{code}(19) = \mathbf{10011}$.
- For $Q = \{q_0, \dots, q_n\}$ we set $\text{code}(q_k) = \text{code}(k)$.
- Instructions are coded using the punctuation, for instance

$$\text{code}(+(k, a, \ell)) = +(\text{code}(k), a, \text{code}(\ell)),$$

and similarly for $?$ and $-$.

- A program line is coded by $\text{code}(q \mapsto I) = \text{code}(q) \mapsto \text{code}(I)$, and a machine by listing its lines separated by $,$.
- A tuple of words is coded by $\text{code}(\mathbf{w}) = \square w_0 \square w_1 \square \dots \square w_k \square$, and a configuration by $\text{code}(q, \mathbf{w}) = \text{code}(q) \text{code}(\mathbf{w})$.

Not every Σ' -word is a code, but it is a purely syntactic matter to check whether a given word is one, and this check can plainly be carried out by a register machine using the operations of Section 27.5.4.

Remark. We have enlarged the alphabet, which looks like cheating. It is not: if $\Sigma \subseteq \Sigma'$ then every Σ -machine is a Σ' -machine, and conversely one can encode each letter of Σ' as a fixed-length block of letters of Σ provided $|\Sigma| \geq 2$, translating Σ' -machines into Σ -machines. So computability over any alphabet with at least two letters is the same notion, and we may enlarge the alphabet whenever convenient.

§27.6.6 The Universal Register Machine

Lemma 27.6.11

The function

$$h(w, u, v) = \begin{cases} \text{code}(C(\#v, M, \mathbf{w})) & \text{if } w = \text{code}(M), u = \text{code}(\mathbf{w}) \text{ for some } M, \mathbf{w}, \\ \uparrow & \text{otherwise} \end{cases}$$

is computable.

Proof. First check syntactically that w codes a machine and u codes a tuple; if not, diverge. Then define h by recursion on v :

$$h(w, u, \varepsilon) = \text{code}(q_S) u, \quad h(w, u, s(v)) = \text{code}(C'),$$

where C' is the transform, under the machine coded by w , of the configuration coded by $h(w, u, v)$. Computing C' from $\text{code}(C)$ and $\text{code}(M)$ is a finite syntactic manipulation: read off the current state from $\text{code}(C)$, look up the corresponding line of $\text{code}(M)$, and edit the appropriate register block accordingly. All of these are operations from Section 27.5.4, and the recursion itself is available because computable functions are closed under recursion (Theorem 27.7.8 below, whose proof does not depend on this lemma). $\square$

Corollary 27.6.12

For each M and k the **truncated computation function**

$$t_{M,k}(\mathbf{w}, v) = \begin{cases} a & \text{if } M \text{ has halted on } \mathbf{w} \text{ by time } \#v, \\ \varepsilon & \text{otherwise} \end{cases}$$

is computable, and it is total.

Proof. Using h and recursion on v , examine the configurations at all times $\#u < \#v$; output a if any of them has state q_H , and ε otherwise. Every step of this terminates, so $t_{M,k}$ is total. $\square$

The point of $t_{M,k}$ is that it converts a statement about halting – which we cannot decide – into a statement about halting *within a given time*, which we can.

Theorem 27.6.13 (The software principle)

The function

$$g(v, u) = \begin{cases} f_{M,k}(\mathbf{w}) & \text{if } v = \text{code}(M), u = \text{code}(\mathbf{w}) \text{ with } |\mathbf{w}| = k, \\ \uparrow & \text{otherwise} \end{cases}$$

is computable.

Proof. Check syntactically that v and u are codes of the right kind; if not, diverge. Let $f'(v, u, x)$ be the computable function returning a if the configuration $h(v, u, x)$ has state q_H , and ε otherwise; this is computable by Lemma 27.6.11.

Apply minimisation to f' (Theorem 27.7.8) to obtain a computable $\mu(v, u)$ returning the least x with $f'(v, u, x) = a$, and diverging if there is none. If M never halts on $\mathbf{w}$ then $\mu(v, u) \uparrow$, which is exactly what we want. If M does halt, then $\mu(v, u)$ converges to the halting time; compute $h(v, u, \mu(v, u))$, read off the block coding register 0, and write it into register 0. $\square$

Definition 27.6.14

A register machine U with $f_{U,2} = g$ is called a **universal register machine**.

A universal register machine is a machine with a fixed, finite number of states and registers which can nonetheless simulate any register machine whatsoever, however many states and registers that machine has. This is the mathematical content of the statement

that a computer can run any program: hardware is fixed, software is data.

It also lets us drop machines from the notation entirely. For $v \in \mathbb{W}$ write

$$f_{v,k}(\mathbf{w}) = f_{U,2}(v, \text{code}(\mathbf{w})),$$

so that $f_{v,k} = f_{M,k}$ whenever $v = \text{code}(M)$, and $f_{v,k}$ is the empty function when v is not a code. Write $W_v = \text{dom } f_{v,1}$; then $\{W_v \mid v \in \mathbb{W}\}$ is exactly the collection of computably enumerable subsets of $\mathbb{W}$.

§27.6.7 The s - m - n Theorem

The next result says that we may freeze one argument of a computable function of two arguments, and that a code for the resulting function can be computed from the frozen value. This operation is **currying**, after Haskell Curry.

Theorem 27.6.15 (s - m - n theorem, parameter theorem)

Let $g: \mathbb{W}^{k+1} \rightarrow \mathbb{W}$ be computable. Then there is a *total* computable $h: \mathbb{W} \rightarrow \mathbb{W}$ such that

$$f_{h(v),k}(\mathbf{w}) = g(\mathbf{w}, v) \quad \text{for all } \mathbf{w}, v.$$

Proof. Fix v . The operation $\mathbf{w} \mapsto (\mathbf{w}, v)$ is performed by the register machine M_v which simply writes v into register k ; and $\text{code}(M_v)$ is computable from v , since M_v has $|v| + 1$ program lines each of which is written down mechanically from a letter of v . Let M be a machine with $f_{M,k+1} = g$.

By Lemma 27.5.13 the machine $M \circ M_v$ (first M_v , then M) performs the composite, and inspecting the proof of that lemma shows that $\text{code}(M \circ M_v)$ is computable from $\text{code}(M_v)$ and $\text{code}(M)$: one relabels states and concatenates lists of lines, both syntactic operations. So

$$h(v) = \text{code}(M \circ M_v)$$

is total and computable, and

$$f_{h(v),k}(\mathbf{w}) = f_{M \circ M_v,k}(\mathbf{w}) = g(\mathbf{w}, v). \quad \square$$

Remark. The content is the computability of h . That *some* function h with $f_{h(v),k} = g(\cdot, v)$ exists is trivial, since $g(\cdot, v)$ is computable for each v and so has *some* code; the theorem says that a code can be found uniformly and effectively.

§27.6.8 The Halting Problem

Definition 27.6.16

Define

$$\mathbb{K}_0 = \{(w, v) \mid f_{w,1}(v) \downarrow\}, \quad \mathbb{K} = \{w \mid f_{w,1}(w) \downarrow\}.$$

So $\mathbb{K}_0$ is the set of pairs (program, input) for which the program halts, and $\mathbb{K}$ is its diagonal.

Theorem 27.6.17

$\mathbb{K}_0$ and $\mathbb{K}$ are computably enumerable.

Proof. By Proposition 27.6.4(ii) it suffices to exhibit them as domains of computable functions. By the software principle, $f_{U,2}(w, v) = f_{w,1}(v)$, so $\text{dom } f_{U,2} = \mathbb{K}_0$. The diagonal map $\Delta(w) = (w, w)$ is computable (copy register 0 into register 1), so $f_{U,2} \circ \Delta$ is computable with domain $\mathbb{K}$. $\square$

Theorem 27.6.18 (Unsolvability of the halting problem)

Neither $\mathbb{K}_0$ nor $\mathbb{K}$ is computable.

Proof. Suppose $\mathbb{K}_0$ were computable, so that $\chi_{\mathbb{K}_0}$ is a computable total function. Define

$$f(w) = \begin{cases} \uparrow & \text{if } \chi_{\mathbb{K}_0}(w, w) = a, \\ \varepsilon & \text{if } \chi_{\mathbb{K}_0}(w, w) = \varepsilon. \end{cases}$$

This is computable, by case distinction on the value of $\chi_{\mathbb{K}_0}(w, w)$ composed with the machines ‘never halt’ and ‘halt immediately’. So $f = f_{d,1}$ for some $d \in \mathbb{W}$. But then

$$f(d) \downarrow \iff f_{d,1}(d) \downarrow \iff (d, d) \in \mathbb{K}_0 \iff \chi_{\mathbb{K}_0}(d, d) = a \iff f(d) \uparrow,$$

a contradiction. The argument for $\mathbb{K}$ is identical with $\chi_{\mathbb{K}}(w)$ in place of $\chi_{\mathbb{K}_0}(w, w)$. $\square$

Corollary 27.6.19

There is a computably enumerable set which is not computable, so the converse of Proposition 27.6.4(iii) fails.

This is the archetype of all unsolvability results, and its shape should be recognised: we assume a decision procedure exists, build from it a machine which is designed to disagree with itself, and then feed that machine its own code. The reader will recognise the diagonal argument of Cantor’s theorem, and the self-reference of Gödel’s incompleteness theorem, in the same shape.

§27.7 Recursive Functions

Register machines are one definition of computability. Church’s, which came first, is completely different in spirit: instead of describing a machine, one specifies a small stock of obviously computable functions and a small stock of obviously computability-preserving constructions, and takes the closure. The remarkable fact – and the main theorem of this section – is that the two definitions agree exactly.

§27.7.1 Primitive Recursion and Minimisation

We work with partial functions $\mathbb{W}^k \rightharpoonup \mathbb{W}$ throughout, using the shortlex successor s of Theorem 27.6.9 in place of the successor on $\mathbb{N}$.

Definition 27.7.1 (Basic functions)

The **basic functions** are

$$\begin{aligned}\pi_{k,i}: \mathbb{W}^k &\rightarrow \mathbb{W}, & \pi_{k,i}(\mathbf{w}) &= w_i && \text{(the **projections**)}, \\ c_{k,\varepsilon}: \mathbb{W}^k &\rightarrow \mathbb{W}, & c_{k,\varepsilon}(\mathbf{w}) &= \varepsilon && \text{(the **constant** functions),} \\ s: \mathbb{W} &\rightarrow \mathbb{W}, & \#s(w) &= \#w + 1 && \text{(the **successor**)}.\end{aligned}$$

Definition 27.7.2 (The three constructions)

Let $f, g, g_1, \dots, g_m$ be partial functions.

- (i) (**Composition**) If $f: \mathbb{W}^m \rightharpoonup \mathbb{W}$ and $g_1, \dots, g_m: \mathbb{W}^k \rightharpoonup \mathbb{W}$, their composition is

$$h(\mathbf{w}) = f(g_1(\mathbf{w}), \dots, g_m(\mathbf{w})),$$

which is defined exactly when all the $g_i(\mathbf{w})$ are and f is defined at the resulting tuple.

- (ii) (**Recursion**) If $f: \mathbb{W}^k \rightharpoonup \mathbb{W}$ and $g: \mathbb{W}^{k+2} \rightharpoonup \mathbb{W}$, the function $h: \mathbb{W}^{k+1} \rightharpoonup \mathbb{W}$ defined by

$$h(\mathbf{w}, \varepsilon) = f(\mathbf{w}), \quad h(\mathbf{w}, s(v)) = g(\mathbf{w}, v, h(\mathbf{w}, v))$$

is said to be defined by recursion from f and g .

- (iii) (**Minimisation**) If $f: \mathbb{W}^{k+1} \rightharpoonup \mathbb{W}$, the function $h: \mathbb{W}^k \rightharpoonup \mathbb{W}$ defined by

$$h(\mathbf{w}) = \begin{cases} v & \text{if } f(\mathbf{w}, u) \downarrow \text{ for all } u \leq v, \text{ and } v \text{ is least with } f(\mathbf{w}, v) = \varepsilon, \\ \uparrow & \text{if no such } v \text{ exists} \end{cases}$$

is said to be defined by minimisation from f .

A class $\mathcal{C}$ of partial functions is **closed** under one of these if the result of applying it to members of $\mathcal{C}$ again lies in $\mathcal{C}$.

Minimisation is the operation which introduces genuine partiality: it says ‘search upwards through $\mathbb{W}$ for the first v making f vanish’, and the search may never terminate. Note the careful clause requiring $f(\mathbf{w}, u)$ to converge for all $u \leq v$: the search must actually be carried out, and it cannot skip over a value at which f diverges.

Definition 27.7.3

A partial function is **recursive** (or **partial recursive**) if it lies in the smallest class containing the basic functions and closed under composition, recursion and minimisation. It is **primitive recursive** if it lies in the smallest class containing the basic functions and closed under composition and recursion.

The class of all partial functions is closed under all three constructions, so the definition makes sense.

Remark. Any class containing the basic functions and closed under composition contains all constant functions $c_{k,v}(\mathbf{w}) = v$: if $\#v = n$ then $c_{k,v} = s^n \circ c_{k,\varepsilon}$.

Every primitive recursive function is total, by induction: the basic functions are total, and composition and recursion of total functions are total. So minimisation is essential if we want to capture partial functions – and, as it happens, if we want to capture all total computable functions either, though we shall not prove that.

Example 27.7.4

Addition is primitive recursive. Interpreting the semiring structure on $\mathbb{W}$ transported from $\mathbb{N}$, we want h with $\#h(w, v) = \#w + \#v$. Take

$$h(w, \varepsilon) = \pi_{1,0}(w) = w, \quad h(w, s(v)) = (s \circ \pi_{3,2})(w, v, h(w, v)) = s(h(w, v)).$$

Here $f = \pi_{1,0}$ is basic and $g = s \circ \pi_{3,2}$ is a composition of basic functions, so h is primitive recursive.

Multiplication is then obtained by recursion from addition, and exponentiation by recursion from multiplication, in the same way. With a little more work, so are the predecessor, truncated subtraction, comparison, the Cantor zigzag function and its inverses, and bounded sums, products and searches.

§27.7.2 Recursion Trees

The definition of ‘recursive’ is a closure, so proofs about recursive functions go by induction on the way a function is built. It is convenient to make the construction into a concrete object.

Attach to each construction a label, an **arity** and a **branching number**:

	label	arity	branching
projection	$B_{k,i}^\pi$	k	0
constant	B_k^c	k	0
successor	B^s	1	0
composition	$C_{n,k}$	k	$n + 1$
recursion	R_k	$k + 1$	2
minimisation	M_k	k	1

Definition 27.7.5 (Recursion tree)

A labelled tree (T, ℓ) is a **recursion tree** if the branching number of each node equals the branching number of its label, and

- (i) if $\ell(t) = C_{n,k}$, the first successor of t has a label of arity n and the remaining n successors have labels of arity k ;
- (ii) if $\ell(t) = R_k$, the first successor has arity k and the second has arity $k + 2$;
- (iii) if $\ell(t) = M_k$, the unique successor has arity $k + 1$.

A recursion tree is **primitive** if no node is labelled M_k .

Example 27.7.6

The recursion tree for the addition function of Example 27.7.4 is

It has no minimisation nodes, so it is primitive, confirming that addition is primitive recursive.

Theorem 27.7.7

A partial function f is recursive if and only if $f = f_{T,\ell}$ for some recursion tree (T, ℓ) , where $f_{T,\ell}$ is computed by reading the tree from the leaves upwards. It is primitive recursive if and only if it admits a primitive such tree.

Proof. Given a recursion tree, define $f_{T,\ell}$ by induction on the height of T : a leaf is labelled by a basic function, and an internal node applies the corresponding construction to the functions attached to its successors, the arity conditions guaranteeing that this makes sense.

Conversely, the class of functions of the form $f_{T,\ell}$ contains the basic functions (one-node trees) and is closed under the three constructions (join trees under a new root with the appropriate label), so it contains all recursive functions. The primitive case is identical. $\square$

§27.7.3 Recursive Functions Are Computable**Theorem 27.7.8**

The computable functions contain the basic functions and are closed under composition, recursion and minimisation. In particular every partial recursive function is computable.

Proof. The basic functions are computable: the projections and constants were dealt with in Section 27.6, and s in Theorem 27.6.9. Closure under composition is Lemma 27.5.13 (with a little bookkeeping to evaluate the g_i into separate scratch registers before applying f).

Recursion. Let f, g be computable and let h be defined by recursion from them; we describe a machine computing $h(\mathbf{w}, v)$. Let k and ℓ be unused empty registers; k will hold a counter and ℓ the current value.

- (i) Compute $f(\mathbf{w})$ and store it in register ℓ . (If $f(\mathbf{w}) \uparrow$ the machine diverges here, which is correct, since then $h(\mathbf{w}, v) \uparrow$ for every v .)
- (ii) If $v = \varepsilon$, output the content of ℓ and halt.
- (iii) Otherwise repeat the following. Let u be the content of ℓ and x the content of

k . Compute $g(\mathbf{w}, x, u)$ and overwrite ℓ with the result. Then compare x with v : if $\#x = \#v - 1$, that is if $s(x) = v$, output ℓ and halt; otherwise apply s to register k and repeat.

After the j th pass through the loop, register ℓ holds $h(\mathbf{w}, s^j(\varepsilon))$, by induction; so the machine halts with $h(\mathbf{w}, v)$ if all the intermediate values converge, and diverges otherwise, as required.

Minimisation. Let f be computable and h obtained from it by minimisation. Let k be an unused empty register, holding ε initially. Repeat: compute $f(\mathbf{w}, u)$ where u is the content of k . If this diverges then the machine diverges, which is correct. If the result is ε , output u and halt. Otherwise apply s to register k and repeat. $\square$

Remark. The proof gives more than the statement: the computable functions are *themselves* closed under recursion and minimisation, so we may use those constructions freely when building register machines. This is what we did in Lemma 27.6.11, Corollary 27.6.12 and Theorem 27.6.13, and there is no circularity, since the proof above uses none of those results.

§27.7.4 Computable Functions Are Recursive

The converse takes more work, and we sketch it; the details are routine but lengthy.

Theorem 27.7.9

Every computable function is partial recursive.

Proof sketch. Fix a register machine M with upper register index m , and code configurations as words as in Section 27.6; write $\gamma(k) = \text{code}(C(k, M, \mathbf{w}))$ for the code of the configuration at time k on input $\mathbf{w}$.

Step 1: the transition is primitive recursive. The function taking $\text{code}(C)$ to $\text{code}(C')$, where M transforms C into C' , is built from operations on words – extracting the state block, comparing it against each of the finitely many program lines of M , and appending or deleting a letter in one register block. Each of these is a bounded search or a case distinction over a fixed finite set, applied to substrings of a word whose length is bounded by that of the input, so each is primitive recursive. (Concretely, one codes a word by its shortlex index and uses the primitive recursive functions of Example 27.7.4 together with bounded minimisation, which preserves primitive recursiveness.)

Step 2: the whole computation is primitive recursive. The function $(\mathbf{w}, v) \mapsto \gamma(\#v)$ is obtained by recursion on v from Step 1, with the base case $\gamma(0) = \text{code}(q_S, \mathbf{w})$, which is primitive recursive. Consequently

$$\theta(\mathbf{w}, v) = \begin{cases} \varepsilon & \text{if the state of } \gamma(\#v) \text{ is } q_H, \\ a & \text{otherwise} \end{cases}$$

is primitive recursive, since checking the state block is a comparison.

Step 3: one minimisation. Applying minimisation to θ yields $\mu(\mathbf{w})$, the least v such that M has reached q_H at time $\#v$, and $\mu(\mathbf{w}) \uparrow$ exactly when M does not halt on

w. Finally

$$f_{M,k}(\mathbf{w}) = \rho(\gamma(\#\mu(\mathbf{w}))),$$

where ρ extracts the block coding register 0, and ρ is primitive recursive. So $f_{M,k}$ is partial recursive. $\square$

Remark. The proof exhibits every computable function in the form

$$f(\mathbf{w}) = \rho(U(\mathbf{w}, \mu v. \theta(\mathbf{w}, v)))$$

with ρ, U, θ primitive recursive and a *single* application of minimisation. This is Kleene's normal form theorem, and it says that all the unboundedness of computation is concentrated in one unbounded search.

§27.7.5 The Church–Turing Thesis

There are other definitions of computability. **Turing machines** have a single two-way infinite tape and a read-write head which may move one cell at a time; **while programs** have variables and the control structures of an ordinary programming language, and halt simply when the instructions run out (so their computation sequences may be finite, unlike ours). Both give rise to notions of computable partial function.

Theorem 27.7.10

For a partial function $f: \mathbb{W}^k \rightarrow \mathbb{W}$, the following are equivalent:

- (i) f is computable by a register machine;
- (ii) f is partial recursive;
- (iii) f is Turing computable;
- (iv) f is while computable.

We have proved (i) $\iff$ (ii); the remaining equivalences are proved by simulation arguments of exactly the same character.

These four models look nothing like each other. One is a machine with stacks, one is a purely syntactic closure of a handful of functions, one is a machine with a tape, and one is a programming language. That they define the same class of functions is striking, and it is not an isolated coincidence: every model of computation which anyone has proposed and which is ‘reasonable’ – meaning, roughly, that each step is finitely describable and effects a bounded change – has turned out to define the same class.

Definition 27.7.11

The **Church–Turing thesis** is the assertion that any function computable by any effective procedure whatsoever is computable in the above sense.

This is not a mathematical statement and cannot be proved, since ‘effective procedure’ is not a mathematical notion; it is a claim that our formal definition has correctly captured an informal one. The evidence for it is the theorem above, together with ninety years of failure to find a counterexample. Its practical use is that, having accepted it, we may describe algorithms in English and conclude that the corresponding functions are

computable, without ever writing down a register machine again. We shall do this freely from now on.

Remark. The thesis also lets us make our decision problems precise, and this is what we do in Section 27.8.7: a problem is *solvable* exactly when the associated set of codes is computable.

§27.8 Computably Enumerable Sets

§27.8.1 Sets with Quantifiers

There is a purely logical description of the computably enumerable sets, and it turns out to be the most useful way of recognising them in practice.

Definition 27.8.1

A set $X \subseteq \mathbb{W}^k$ is

- Σ_1 if there is a computable $Y \subseteq \mathbb{W}^{k+1}$ with

$$\mathbf{w} \in X \iff \exists y ((\mathbf{w}, y) \in Y);$$

we call $X = p(Y) = \{\mathbf{w} \mid \exists y (\mathbf{w}, y) \in Y\}$ the **projection** of Y ;

- Π_1 if its complement is Σ_1 ;
- Δ_1 if it is both Σ_1 and Π_1 .

Remark. The Σ is for the existential quantifier and the Π for the universal, following the analogy between sums and existentials, products and universals. The Δ is for *Durchschnitt*, ‘intersection’. The clash with our use of Σ for the alphabet is unfortunate but standard; the subscript should keep them apart.

Proposition 27.8.2

Every computable set is Δ_1 .

Proof. Computable sets are closed under complement, so it suffices to show every computable X is Σ_1 . Take $Y = \{(\mathbf{w}, y) \mid \mathbf{w} \in X\}$, which is computable (ignore y), and note $p(Y) = X$: we have added a vacuous existential quantifier. $\square$

Theorem 27.8.3

The computably enumerable sets are exactly the Σ_1 sets.

Proof. ($\Rightarrow$) Let X be computably enumerable, say $\psi_X = f_{M,k}$. Let

$$Y = \{(\mathbf{w}, y) \mid t_{M,k}(\mathbf{w}, y) = a\},$$

where $t_{M,k}$ is the truncated computation function of Corollary 27.6.12. Then $t_{M,k}$

is total computable and is a characteristic function of Y , so Y is computable. And

$$\mathbf{w} \in X \iff \psi_X(\mathbf{w}) \downarrow \iff M \text{ halts on } \mathbf{w} \text{ at some time} \iff \exists y ((\mathbf{w}, y) \in Y),$$

so $X = p(Y)$ is Σ_1 .

($\Leftarrow$) Let $X = p(Y)$ with Y computable. Then Y^c is computable, so χ_{Y^c} is computable and total. Apply minimisation to χ_{Y^c} : the resulting $h(\mathbf{w})$ is the least y with $\chi_{Y^c}(\mathbf{w}, y) = \varepsilon$, i.e. the least y with $(\mathbf{w}, y) \in Y$, and diverges if there is none. So h is computable with $\text{dom } h = p(Y) = X$, and X is computably enumerable by Proposition 27.6.4(ii). $\square$

The utility of this is that quantifiers can be manipulated where machines cannot. Here is the basic move.

Example 27.8.4 (The zigzag argument)

Let $f: \mathbb{W}^2 \rightarrow \mathbb{W}$ be computable. Then $X = \{w \mid \exists v f(w, v) \downarrow\}$ is computably enumerable.

Note first that ' $f(w, v) \downarrow$ ' is *not* a computable predicate, so we cannot simply quote the definition. Let $f = f_{M,2}$ and set

$$Z = \{(w, v_0, v_1) \mid t_{M,2}(w, v_0, v_1) = a\},$$

which is computable. Now merge the two existential quantifiers into one by merging the words:

$$Y = \{(w, u) \mid (w, u_{(0)}, u_{(1)}) \in Z\},$$

which is computable since splitting is performable. Then

$$\begin{aligned} w \in X &\iff \exists v_0 \exists v_1 (w, v_0, v_1) \in Z \\ &\iff \exists u (w, u_{(0)}, u_{(1)}) \in Z \\ &\iff \exists u (w, u) \in Y \iff w \in p(Y), \end{aligned}$$

so X is Σ_1 .

The name comes from the picture: to search over pairs (v_0, v_1) we enumerate them along the anti-diagonals of $\mathbb{N}^2$, which lets us make progress on infinitely many computations at once by running each of them for a while. Any two consecutive existential quantifiers can be merged this way, and we use the technique without further comment.

Corollary 27.8.5

The computable sets are exactly the Δ_1 sets.

Proof. One direction is the proposition above. Conversely let X be Δ_1 , so both X and X^c are computably enumerable, say $\psi_X = f_{M,k}$ and $\psi_{X^c} = f_{M',k}$. By Theorem 27.8.3,

$$\mathbf{w} \in X \iff \exists v t_{M,k}(\mathbf{w}, v) = a, \quad \mathbf{w} \notin X \iff \exists v t_{M',k}(\mathbf{w}, v) = a.$$

Define

$$f(\mathbf{w}, v) = \begin{cases} t_{M,k}(\mathbf{w}, v_{(1)}) & \text{if } \#v_{(0)} \text{ is even,} \\ t_{M',k}(\mathbf{w}, v_{(1)}) & \text{if } \#v_{(0)} \text{ is odd,} \end{cases}$$

which is total and computable. Every $\mathbf{w}$ lies in exactly one of X , X^c , so at least one of the two searches succeeds; hence minimising f (with the roles of ε and a interchanged, so that we search for the first v with $f(\mathbf{w}, v) \neq \varepsilon$) always terminates, giving a total computable h . Output a if $\#h(\mathbf{w})_{(0)}$ is even and ε otherwise; this is χ_X . $\square$

The idea is worth restating: if we can semi-decide both a set and its complement, we can decide it, by running both semi-decision procedures in parallel and waiting for one of them to answer. This is sometimes called *Post's theorem*.

Corollary 27.8.6

Σ_1 is not closed under complement.

Proof. $\mathbb{K}$ is Σ_1 but not computable, hence not Δ_1 by Corollary 27.8.5, hence not Π_1 . So $\mathbb{W} \setminus \mathbb{K}$ is Π_1 but not Σ_1 . $\square$

§27.8.2 Closure Properties

Proposition 27.8.7

The computable sets are closed under union, intersection, complement, difference and concatenation.

Proof. For A, B computable, the function

$$\chi_{A \cap B}(\mathbf{w}) = \begin{cases} a & \chi_A(\mathbf{w}) = a \text{ and } \chi_B(\mathbf{w}) = a, \\ \varepsilon & \text{otherwise} \end{cases}$$

is computable: evaluate χ_A into a scratch register, then χ_B , then combine by case distinction. Both terminate, since characteristic functions are total. Complement was Proposition 27.6.4(i), and union and difference follow.

For concatenation, let $A, B \subseteq \mathbb{W}$ and $w \in \mathbb{W}$. There are exactly $|w| + 1$ ways to write $w = vu$, and we can enumerate them; for each, evaluate $\chi_A(v)$ and $\chi_B(u)$, both of which terminate. Output a if some decomposition works. This is a bounded search and always terminates. $\square$

Proposition 27.8.8

The computably enumerable sets are closed under union, intersection and concatenation, but not under complement or difference.

Proof. Failure of complement is Corollary 27.8.6; and since $\mathbb{W}$ is computably enumerable and $\mathbb{W} \setminus A$ is a difference, difference fails too.

Intersection: the function equal to a when $\psi_A(\mathbf{w}) \downarrow$ and $\psi_B(\mathbf{w}) \downarrow$, and undefined

otherwise, is computed by running the two machines one after the other; if either diverges the composite diverges, which is exactly right.

Union: here we may *not* run them one after the other, since if ψ_A diverges we never reach ψ_B . Instead observe that

$$\mathbf{w} \in A \cup B \iff \exists v (t_{M,k}(\mathbf{w}, v) = a \text{ or } t_{M',k}(\mathbf{w}, v) = a),$$

with M, M' machines for ψ_A, ψ_B ; the bracketed set is computable, so $A \cup B$ is Σ_1 . Informally: run both machines in parallel, alternating steps, and halt as soon as either does.

Concatenation: let Z be the set of triples (w, v, u) such that v is an initial segment of w , say $w = vv'$, and both $\psi_A(v)$ and $\psi_B(v')$ have halted by time $\#u$. This is computable, using truncated computation functions. Setting $Y = \{(w, u) \mid (w, u_{(0)}, u_{(1)}) \in Z\}$ and zigzagging, $w \in AB$ if and only if $w \in p(Y)$. $\square$

Proposition 27.8.9

$X \subseteq \mathbb{W}$ is computably enumerable if and only if $X = \text{Im } f$ for some partial computable f .

Proof. If X is computably enumerable then

$$f(w) = \begin{cases} w & \psi_X(w) \downarrow, \\ \uparrow & \text{otherwise} \end{cases}$$

is computable with image X .

Conversely let $X = \text{Im } f$ with $f = f_{c,1}$. Let Z be the set of triples (w, v, u) such that $t_{c,1}(v, u) = a$ and the output of the machine coded by c on input v , at the halting time, is w ; this is computable, since given a bound on the running time we can simply run the machine. Then $w \in X$ if and only if $\exists v \exists u (w, v, u) \in Z$, and zigzagging gives a Σ_1 definition. $\square$

Remark. A stronger statement is true: a nonempty X is computably enumerable if and only if $X = \text{Im } f$ for a *total* computable f , so that $f(\varepsilon), f(s(\varepsilon)), f(s^2(\varepsilon)), \dots$ literally enumerates X , possibly with repetitions. This is what the name ‘computably enumerable’ refers to. The idea is to enumerate pairs (v, u) by zigzag and output the result of f on v if it has halted by time $\#u$, and some fixed element of X otherwise.

§27.8.3 Type 0 Languages

We can now identify the very top of the Chomsky hierarchy.

Theorem 27.8.10

Every type 0 language is computably enumerable.

Proof. Let $G = (\Sigma, V, P, S)$ and enlarge the alphabet to $\Sigma' = \Sigma \cup \{\rightarrow\}$. Code a

derivation $\sigma_0, \sigma_1, \dots, \sigma_n$ as the Σ' -word

$$\sigma_0 \rightarrow \sigma_1 \rightarrow \dots \rightarrow \sigma_n,$$

and call a word of this shape a **derivation code** if consecutive σ_i really are related by a single application of a rule of P . Whether a given word is a derivation code is decidable: split it at the $\rightarrow$ symbols and, for each consecutive pair, search over the finitely many rules and the finitely many positions at which each could have fired. Let

$$Y = \{(w, v) \mid v \text{ is a derivation code with initial string } S \text{ and final string } w\},$$

which is therefore computable. Then $w \in \mathcal{L}(G)$ if and only if $\exists v (w, v) \in Y$, so $\mathcal{L}(G)$ is Σ_1 . $\square$

Theorem 27.8.11

Every computably enumerable $X \subseteq \mathbb{W}$ is a type 0 language.

Proof sketch. Use Theorem 27.7.10 and work with a Turing machine M computing ψ_X ; arrange (by adding a clean-up phase) that the accepting computation on input w takes the tape from $q_S \square w \square$ to $q_H \square a \square$, with the head returned to the front.

A Turing machine *is* a rewrite system: each instruction ‘in state q reading b , write c , move right, go to q' ’ is a rewrite rule on strings which contain a single state symbol marking the head position. So there is a rewrite system R with

$$q_S \square w \square \Rightarrow_R^* q_H \square a \square \iff w \in X.$$

Now build a grammar which runs this backwards: start from S , produce $q_H \square a \square$, apply all the reversed instructions of M (which are again rewrite rules), and when the symbol q_S appears, delete everything except the word w sitting between the two $\square$ s. Then $\mathcal{L}(G) = X$. Working backwards is essential, because a grammar derives *from* a start symbol; the details, which we omit, may be found in Salomaa’s *Formal Languages*. $\square$

Corollary 27.8.12

The type 0 languages are exactly the computably enumerable languages, that is, exactly the Σ_1 languages.

§27.8.4 Many-One Reducibility

Most of our unsolvability proofs so far have had the same shape: ‘if this problem were solvable, so would be the halting problem’. We now name that shape.

Definition 27.8.13 (Reduction)

Let $A, B \subseteq \mathbb{W}$. A total computable $f: \mathbb{W} \rightarrow \mathbb{W}$ is a **reduction** from A to B if

$$w \in A \iff f(w) \in B \quad \text{for all } w \in \mathbb{W},$$

that is, if $A = f^{-1}(B)$. We write $A \leq_m B$ if such an f exists, and say A is **many-one reducible** to B .

The subscript m records that f need not be injective. Intuitively $A \leq_m B$ says that A is no more complicated than B : any method for deciding membership in B yields one for A , by first applying f .

Proposition 27.8.14

The relation $\leq_m$ is reflexive and transitive, and respects complements: $A \leq_m B$ implies $\mathbb{W} \setminus A \leq_m \mathbb{W} \setminus B$. Moreover, if $A \leq_m B$ then

- (i) if B is computable then so is A ;
- (ii) if B is computably enumerable then so is A .

Proof. Reflexivity uses the identity, transitivity composition. The same f witnesses the statement about complements, since $w \notin A \iff f(w) \notin B$. For (i) and (ii), if f is the reduction then $\chi_A = \chi_B \circ f$ and $\psi_A = \psi_B \circ f$, and composites of computable functions are computable. $\square$

Contrapositively – and this is how the proposition is used – if $A \leq_m B$ and A is not computable then B is not computable. In particular:

$$\begin{aligned} \mathbb{K} \leq_m A &\implies A \text{ is not computable,} \\ \mathbb{W} \setminus \mathbb{K} \leq_m A &\implies A \text{ is not computably enumerable.} \end{aligned}$$

Note that $\leq_m$ is *not* antisymmetric, so it is a preorder rather than a partial order. As usual we may quotient: writing $A \equiv_m B$ when $A \leq_m B$ and $B \leq_m A$, the relation $\leq_m$ induces a genuine partial order on the equivalence classes, which are called the **many-one degrees**.

Proposition 27.8.15

Let A be computable and let $B \neq \emptyset, \mathbb{W}$. Then $A \leq_m B$.

Proof. Choose $v \in B$ and $u \notin B$. Since A is computable,

$$f(w) = \begin{cases} v & w \in A, \\ u & w \notin A \end{cases}$$

is total computable, and $w \in A \iff f(w) \in B$. $\square$

So the computable sets (other than $\emptyset$ and $\mathbb{W}$, which are degenerate: nothing reduces to them but themselves) form the bottom degree.

§27.8.5 Degrees of Unsolvability

Definition 27.8.16

Let $\mathcal{C}$ be a class of subsets of $\mathbb{W}$. A set A is **$\mathcal{C}$ -hard** if $B \leq_m A$ for every $B \in \mathcal{C}$, and **$\mathcal{C}$ -complete** if in addition $A \in \mathcal{C}$.

A $\mathcal{C}$ -complete set is a hardest member of $\mathcal{C}$: solving it solves everything in $\mathcal{C}$.

Corollary 27.8.17

Every computable A with $A \neq \emptyset, \mathbb{W}$ is Δ_1 -complete.

Proof. The Δ_1 sets are the computable sets by Corollary 27.8.5, so this is Proposition 27.8.15. $\square$

Theorem 27.8.18

$\mathbb{K}$ is Σ_1 -complete.

Proof. We know $\mathbb{K} \in \Sigma_1$. Let X be any Σ_1 set, so X is computably enumerable, say $X = \text{dom } f$ with f computable. Consider $g(w, u) = f(w)$, which is computable (ignore the second argument). By the s - m - n theorem there is a total computable h with

$$f_{h(w),1}(u) = g(w, u) = f(w).$$

We claim h reduces X to $\mathbb{K}$.

If $w \in X$ then $f(w) \downarrow$, so $f_{h(w),1}$ is the total constant function with value $f(w)$; in particular $f_{h(w),1}(h(w)) \downarrow$, so $h(w) \in \mathbb{K}$.

If $w \notin X$ then $f(w) \uparrow$, so $f_{h(w),1}(u) \uparrow$ for every u ; in particular $f_{h(w),1}(h(w)) \uparrow$, so $h(w) \notin \mathbb{K}$. $\square$

Dually, $\mathbb{W} \setminus \mathbb{K}$ is Π_1 -complete. And the two are genuinely different: $\mathbb{W} \setminus \mathbb{K} \not\leq_m \mathbb{K}$, since otherwise $\mathbb{W} \setminus \mathbb{K}$ would be computably enumerable by Proposition 27.8.14; and $\mathbb{K} \not\leq_m \mathbb{W} \setminus \mathbb{K}$ by taking complements. So there are at least three distinct degrees so far. There are more.

Definition 27.8.19

Suppose $\{0, 1\} \subseteq \Sigma$. The **join** of $A, B \subseteq \mathbb{W}$ is $A \oplus B = 0A \cup 1B$.

Then $A \leq_m A \oplus B$ via $w \mapsto 0w$, and likewise $B \leq_m A \oplus B$; and if $A \leq_m C$ and $B \leq_m C$ then $A \oplus B \leq_m C$, by case distinction on the first letter. So $\oplus$ computes least upper bounds in the partial order of degrees, and in particular $\mathbb{K} \oplus (\mathbb{W} \setminus \mathbb{K})$ is a set which is neither Σ_1 nor Π_1 but is above both.

Iterating the construction produces infinitely many degrees, and in fact the structure of the many-one degrees is extremely rich; this is the subject of computability theory proper, which we do not pursue.

§27.8.6 Rice's Theorem

The halting problem is unsolvable. Rice's theorem says, spectacularly, that *every* non-trivial question about the behaviour of a program is unsolvable.

Definition 27.8.20

Words v, u are **weakly equivalent**, written $v \sim u$, if $W_v = W_u$; that is, if the machines they code halt on exactly the same inputs. A set $I \subseteq \mathbb{W}$ is an **index set** if it is closed under weak equivalence.

An index set is thus a set of programs specified purely by the *function* they compute – more precisely, by its domain – rather than by any feature of the code. Index sets correspond exactly to properties of computably enumerable sets.

Example 27.8.21

$\emptyset$ and $\mathbb{W}$ are the trivial index sets. Others are

$$\begin{aligned} \mathbf{Emp} &= \{v \mid W_v = \emptyset\}, & \mathbf{Fin} &= \{v \mid W_v \text{ is finite}\}, \\ \mathbf{Inf} &= \{v \mid W_v \text{ is infinite}\}, & \mathbf{Tot} &= \{v \mid W_v = \mathbb{W}\}. \end{aligned}$$

The emptiness problem for programs is precisely **Emp**.

The key construction is the following. Fix $w \in \mathbb{W}$ and consider

$$g(u, v) = \begin{cases} f_{w,1}(v) & \text{if } u \in \mathbb{K}, \\ \uparrow & \text{if } u \notin \mathbb{K}. \end{cases}$$

This looks like an illegal case distinction, since membership of $\mathbb{K}$ is not computable. But it *is* computable, because we do not need to decide the case: on input (u, v) , run the machine coded by u on input u ; if and when it halts, run the machine coded by w on input v and return the answer. If $u \notin \mathbb{K}$ the first phase never terminates, which produces exactly the divergence we want. This is a trick worth remembering: an uncomputable case distinction is harmless when the ‘false’ branch is divergence.

By the s - m - n theorem there is a total computable h with $f_{h(u),1}(v) = g(u, v)$, so

$$W_{h(u)} = \begin{cases} W_w & u \in \mathbb{K}, \\ \emptyset & u \notin \mathbb{K}. \end{cases}$$

Theorem 27.8.22 (Rice)

No non-trivial index set is computable.

Proof. Let I be an index set with $I \neq \emptyset, \mathbb{W}$. Fix $e \in \mathbb{W}$ with $W_e = \emptyset$ (for instance the code of a machine which never halts). Either $e \in I$ or not.

Case $e \in I$. Since $I \neq \mathbb{W}$, choose $w \notin I$; then $W_w \neq \emptyset$, since $W_w = \emptyset$ would give $w \sim e$ and hence $w \in I$. Build h as above from this w . If $u \in \mathbb{K}$ then $W_{h(u)} = W_w$, so $h(u) \sim w$ and $h(u) \notin I$; if $u \notin \mathbb{K}$ then $W_{h(u)} = \emptyset = W_e$, so $h(u) \sim e$ and $h(u) \in I$. Hence

$$u \in \mathbb{W} \setminus \mathbb{K} \iff h(u) \in I,$$

so $\mathbb{W} \setminus \mathbb{K} \leq_m I$ and I is not computable.

Case $e \notin I$. Since $I \neq \emptyset$, choose $w \in I$; again $W_w \neq \emptyset$. With the same h : if $u \in \mathbb{K}$ then $h(u) \sim w$ so $h(u) \in I$, and if $u \notin \mathbb{K}$ then $h(u) \sim e$ so $h(u) \notin I$. Hence $\mathbb{K} \leq_m I$, and again I is not computable. $\square$

Remark. The proof gives more than the statement. If $e \in I$ then $\mathbb{W} \setminus \mathbb{K} \leq_m I$, so I is not even computably enumerable. If $e \notin I$ then $\mathbb{K} \leq_m I$, so I is not Π_1 ; but this leaves open whether I is computably enumerable.

Applying this: $e \in \mathbf{Emp}$ and $e \in \mathbf{Fin}$, so neither **Emp** nor **Fin** is computably enumerable. On the other hand $e \notin \mathbf{Inf}$ and $e \notin \mathbf{Tot}$, so we obtain only $\mathbb{K} \leq_m \mathbf{Inf}$ and $\mathbb{K} \leq_m \mathbf{Tot}$.

Corollary 27.8.23

None of **Emp**, **Fin**, **Inf**, **Tot** is computable.

Theorem 27.8.24

Fin is neither Σ_1 nor Π_1 .

Proof. By Remark , $\mathbb{W} \setminus \mathbb{K} \leq_m \mathbf{Fin}$, so **Fin** is not Σ_1 . For the other half we show $\mathbb{K} \leq_m \mathbf{Fin}$. Consider

$$g(w, v) = \begin{cases} \uparrow & \text{if } t_{w,1}(w, v) = a, \\ \varepsilon & \text{otherwise,} \end{cases}$$

which is computable: compute the (total) truncated computation function and then either diverge or halt. By the s - m - n theorem take total computable h with $f_{h(w),1}(v) = g(w, v)$.

If $w \in \mathbb{K}$, let v_0 be the halting time of $f_{w,1}(w)$. Then $t_{w,1}(w, v) = a$ for all v with $\#v > \#v_0$, so $f_{h(w),1}(v) \uparrow$ for all such v ; hence $W_{h(w)}$ is contained in the finite set

of v with $\#v \leq \#v_0$, and is finite. So $h(w) \in \mathbf{Fin}$.

If $w \notin \mathbb{K}$ then $t_{w,1}(w, v) = \varepsilon$ for every v , so $f_{h(w),1}$ is the total constant function ε and $W_{h(w)} = \mathbb{W}$, which is infinite. So $h(w) \notin \mathbf{Fin}$.

Hence h is a reduction from $\mathbb{K}$ to $\mathbf{Fin}$, and $\mathbf{Fin}$ is not Π_1 . $\square$

Remark. By contrast, one can show that $\mathbf{Emp} \equiv_m \mathbb{W} \setminus \mathbb{K}$, so $\mathbf{Emp}$ is Π_1 -complete, while $\mathbf{Tot}$ and $\mathbf{Inf}$ are, like $\mathbf{Fin}$, in neither class. The hierarchy of Σ_n and Π_n sets obtained by allowing n alternating quantifiers – the *arithmetical hierarchy* – is where these sets properly live.

§27.8.7 Solvability of Decision Problems

We can now return to the decision problems of Section 27.4 with a precise definition in hand. Fix a coding of grammars such that every word w codes a grammar G_w and every grammar is G_w for some w ; this is arranged by decreeing that words which are not syntactically valid code some fixed trivial grammar. Then

- (i) the word problem is the set $\{(w, v) \mid w \in \mathcal{L}(G_v)\}$;
- (ii) the emptiness problem is the set $\{w \mid \mathcal{L}(G_w) = \emptyset\}$;
- (iii) the equivalence problem is the set $\{(w, v) \mid \mathcal{L}(G_w) = \mathcal{L}(G_v)\}$;

and each is **solvable** exactly when the corresponding set is computable.

Theorem 27.8.25

The word problem for type 0 grammars is unsolvable.

Proof. Let $W = \{(w, v) \mid w \in \mathcal{L}(G_v)\}$ and suppose it computable. Define

$$f(w) = \begin{cases} \uparrow & w \in \mathcal{L}(G_w), \\ a & w \notin \mathcal{L}(G_w). \end{cases}$$

Since W is computable this is a legitimate case distinction, so f is computable, and $\text{dom } f$ is computably enumerable. By Theorem 27.8.11 there is a grammar G with $\mathcal{L}(G) = \text{dom } f$, say $G = G_d$. But then

$$d \in \mathcal{L}(G_d) \iff d \in \text{dom } f \iff f(d) \downarrow \iff d \notin \mathcal{L}(G_d),$$

a contradiction. $\square$

Corollary 27.8.26

The emptiness problem for type 0 grammars is unsolvable.

Proof. By Theorems 27.8.10 and 27.8.11, $\{\mathcal{L}(G_w) \mid w \in \mathbb{W}\}$ is exactly the collection of computably enumerable sets, and translating between a grammar and a machine for the same language is effective in both directions. So the emptiness problem for grammars is many-one equivalent to $\mathbf{Emp}$, which is not computable by Rice's theorem. $\square$

Corollary 27.8.27

The equivalence problem for type 0 grammars is unsolvable.

Proof. Consider $\mathbf{Eq} = \{(w, v) \mid W_w = W_v\}$, and fix e with $W_e = \emptyset$. The function $g(w) = (w, e)$ is total computable, and

$$w \in \mathbf{Emp} \iff W_w = \emptyset = W_e \iff (w, e) \in \mathbf{Eq},$$

so $\mathbf{Emp} \leq_m \mathbf{Eq}$ and $\mathbf{Eq}$ is not computable. Translating to grammars as above gives the result. $\square$

So all three of our problems, solvable for regular grammars and two of them for context-free grammars, become unsolvable at the top of the hierarchy.

§27.9 The Relationship Between the Language Classes

We close by drawing the whole picture together. We have met the following classes of languages over a fixed alphabet Σ , in increasing order:

$$\begin{aligned} \text{regular} &\subseteq \text{context-free} \subseteq \text{context-sensitive} \\ &\subseteq \text{computable} \subseteq \text{computably enumerable} \subseteq \mathcal{P}(\mathbb{W}). \end{aligned}$$

Here type 3, 2, 1 are the regular, context-free and context-sensitive languages, Δ_1 the computable languages, and Σ_1 the computably enumerable languages, which are exactly the type 0 languages.

Every inclusion is strict, and each strictness has been (or can be) witnessed:

- $\{0^k 1^k \mid k > 0\}$ is context-free but not regular, by the pumping lemma for regular languages (Example 27.3.21) or by Myhill–Nerode.
- $\{a^n b^n c^n \mid n > 0\}$ is context-sensitive but not context-free, by the pumping lemma for context-free languages (Example 27.4.16).
- There is a computable language $\mathbb{D}$ which is not context-sensitive. Indeed, the context-sensitive grammars can be effectively enumerated as $G_0, G_1, \dots$, and the word problem for each is uniformly solvable by Corollary 27.2.16; so, listing the

words of $\mathbb{W}$ in shortlex order as $w_0, w_1, \dots$, the diagonal language

$$\mathbb{D} = \{w_n \mid w_n \notin \mathcal{L}(G_n)\}$$

is computable but differs from every $\mathcal{L}(G_n)$.

- $\mathbb{K}$ is computably enumerable but not computable (Theorem 27.6.18).
- $\mathbb{W} \setminus \mathbb{K}$ is a language which is not computably enumerable, hence not of the form $\mathcal{L}(G)$ for any grammar at all (Corollary 27.8.6).
- Finally, there are uncountably many languages and only countably many grammars, so almost every language lies outside the outermost ellipse.

Closure properties and decision problems degrade as we ascend:

	union	concat.	Kleene +	intersection	complement
regular	yes	yes	yes	yes	yes
context-free	yes	yes	yes	<i>no</i>	<i>no</i>
context-sensitive	yes	yes	yes	yes	yes
computable	yes	yes	yes	yes	yes
computably enumerable	yes	yes	yes	yes	<i>no</i>

	word problem	emptiness	equivalence
regular	solvable	solvable	solvable
context-free	solvable	solvable	<i>unsolvable</i>
context-sensitive	solvable	<i>unsolvable</i>	<i>unsolvable</i>
computably enumerable	<i>unsolvable</i>	<i>unsolvable</i>	<i>unsolvable</i>

The context-free row is anomalous in the first table: it is the only class in the list failing to be closed under intersection, and we saw in Section 27.4 that this is forced by the pushdown model, whose single stack cannot be duplicated. The last row of the second table is the content of Section 27.8.7.

There is a pleasing overall moral. Each class is characterised in two ways, by a grammar and by a machine:

class	grammars	machines
regular	regular grammars	finite automata
context-free	context-free grammars	pushdown automata
context-sensitive	noncontracting grammars	linear bounded automata
computably enumerable	arbitrary grammars	register (or Turing) machines

and the amount of memory available to the machine – none, a stack, a tape of length proportional to the input, an unbounded tape – is exactly what determines the class. That is the shape of the subject: a hierarchy of languages, a matching hierarchy of machines, and at the top, an unavoidable wall of undecidability.

28 Coding and Cryptography

Communication is a mathematical problem. Somebody wants to say something to somebody else; between them lies a channel that is expensive, or unreliable, or overheard, or all three at once. Coding theory is the study of how to package a message so that it survives the journey, and cryptography is the study of how to package it so that only the intended recipient can read it. Both subjects turn out to be, at bottom, about the same thing: the arithmetic of finite sets, and the surprising leverage that a little algebra and a little probability give us over them.

The most striking result in the course is due to Shannon, and it says something that ought to be false. If a channel corrupts one bit in ten, entirely at random, one might reasonably guess that transmitting a long message without error requires sending it over and over again, so that the rate at which information gets through must fall to zero. It does not. There is a positive number – the *capacity* of the channel – below which arbitrarily reliable communication is possible, and Shannon’s theorem tells us exactly what that number is. What makes the proof so memorable is that it establishes the existence of extremely good codes by choosing one at random, without ever exhibiting a single one.

This article constitutes my notes for the ‘Coding and Cryptography’ course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§28.1 Modelling Communication

Before we can prove anything we need a model, and the one we shall use is the one Shannon drew in 1948. There is a **source** which produces a message; an **encoder** which turns that message into something suitable for transmission; a **channel** down which the transmission travels and in which things go wrong; a **decoder** which tries to undo the damage; and finally a **receiver**, for whom the whole business was arranged.

By long-standing convention the source is called Alice, the receiver is called Bob, and any third party listening in on the channel is called Eve. The two halves of the course correspond to the two things that can go wrong in the middle of that diagram. In coding theory the enemy is the noise, and we want the message to arrive *economically* and *reliably*. In cryptography the enemy is Eve, and we want the message to arrive *privately*.

It is worth separating two quite different problems which are often confused. **Noiseless coding**, or source coding, is about compression: we want to spend as few symbols as

possible on a message, and it is adapted to the *source*. Morse code is the canonical example – the letter E, the commonest letter in English, gets the single dot, and the letter Q gets four symbols. **Noisy coding**, or channel coding, is about redundancy: we want to add enough extra symbols that corruption can be spotted and undone, and it is adapted to the *channel*.

Example 28.1.1 (ISBNs)

Every book (before 2007) carried a ten-digit International Standard Book Number $a_1a_2 \dots a_{10}$, where $a_1, \dots, a_9 \in \{0, 1, \dots, 9\}$ and $a_{10} \in \{0, 1, \dots, 9, X\}$, subject to the single condition

$$\sum_{j=1}^{10} ja_j \equiv 0 \pmod{11}.$$

Here X stands for 10, and the modulus 11 is prime, which is what makes everything work. Suppose one digit is mistyped, say a_k becomes a'_k . Then the check sum changes by $k(a_k - a'_k)$, and since $1 \leq k \leq 10$ and $|a_k - a'_k| \leq 10$, neither factor is divisible by 11, so the sum is no longer 0 modulo 11 and the error is detected. Similarly, if two adjacent digits are transposed, say a_k and a_{k+1} swap, the sum changes by $a_{k+1} - a_k$, again nonzero modulo 11 unless the digits were equal in the first place.

The channel here is a human being reading a number off a page and typing it into a computer, and the code is beautifully adapted to the errors that channel makes.

We now make the notion of a channel precise.

Definition 28.1.2 (Communication Channel)

A **communication channel** accepts strings of symbols from a finite **input alphabet** $\mathcal{A} = \{a_1, \dots, a_r\}$ and outputs strings of symbols from a finite **output alphabet** $\mathcal{B} = \{b_1, \dots, b_s\}$. It is specified by the probabilities

$$\mathbb{P}(y_1 \dots y_n \text{ received} \mid x_1 \dots x_n \text{ sent}).$$

In this generality nothing can be said, because the channel is allowed to remember everything it has ever done. Almost always we assume much more.

Definition 28.1.3 (Discrete Memoryless Channel)

A **discrete memoryless channel** (DMC) is a channel for which the probabilities

$$p_{ij} = \mathbb{P}(b_j \text{ received} \mid a_i \text{ sent})$$

are the same on every use of the channel, and are independent of all past and future uses. The $r \times s$ matrix $P = (p_{ij})$ is the **channel matrix**; each of its rows sums to 1.

Two examples will accompany us for the rest of the course.

Example 28.1.4 (Binary Symmetric Channel)

The **binary symmetric channel** (BSC) with error probability $p \in [0, 1]$ has $\mathcal{A} = \mathcal{B} = \{0, 1\}$ and channel matrix

$$P = \begin{pmatrix} 1-p & p \\ p & 1-p \end{pmatrix}.$$

Each bit is flipped independently with probability p , and transmitted faithfully with probability $1 - p$.

We shall almost always assume $p < \frac{1}{2}$. This costs nothing: a channel with $p > \frac{1}{2}$ becomes one with error probability $1 - p$ if Bob simply inverts everything he receives, and we shall see shortly that a channel with $p = \frac{1}{2}$ is useless, in that it carries no information whatsoever.

Example 28.1.5 (Binary Erasure Channel)

The **binary erasure channel** (BEC) has $\mathcal{A} = \{0, 1\}$ and $\mathcal{B} = \{0, 1, \star\}$, with channel matrix

$$P = \begin{pmatrix} 1-p & 0 & p \\ 0 & 1-p & p \end{pmatrix}.$$

Here p is the probability that the symbol arrives illegibly; receiving $\star$ is called a **splurge error**. This channel never lies to us, it merely occasionally declines to speak.

To use a channel n times we pass to the **n th extension**, whose input alphabet is $\mathcal{A}^n$, whose output alphabet is $\mathcal{B}^n$, and whose channel matrix (for a DMC) is

$$\mathbb{P}(y_1 \dots y_n \mid x_1 \dots x_n) = \prod_{i=1}^n \mathbb{P}(y_i \mid x_i).$$

Definition 28.1.6 (Code, Rate, Error Rate)

A **code** C of length n is a function $\mathcal{M} \rightarrow \mathcal{A}^n$, where $\mathcal{M}$ is a set of messages; implicitly we also fix a decoding rule $\mathcal{B}^n \rightarrow \mathcal{M}$. We usually identify C with its image, a subset of $\mathcal{A}^n$.

- The **size** of C is $m = |\mathcal{M}|$.
- The **information rate** of C is $\rho(C) = \frac{1}{n} \log_2 m$.
- The **error rate** of C is $\hat{e}(C) = \max_{x \in \mathcal{M}} \mathbb{P}(\text{error} \mid x \text{ sent})$.

Throughout these notes $\log$ means $\log_2$ unless we say otherwise; this is the convention that makes the answers come out in bits.

Definition 28.1.7 (Capacity)

A channel can **transmit reliably at rate R** if there is a sequence of codes $(C_n)_{n \geq 1}$, with C_n of length n , such that

$$\lim_{n \rightarrow \infty} \rho(C_n) = R \quad \text{and} \quad \lim_{n \rightarrow \infty} \hat{e}(C_n) = 0.$$

The **capacity** of the channel is the supremum of all rates at which it can transmit reliably.

Note carefully what is being asked. We are not asking for one good code; we are asking for a whole family of codes whose rate stays bounded away from zero while the error probability is driven to zero. It is far from obvious that this can be done at all for a channel that makes errors, and the fact that it can – that the binary symmetric channel with $p < \frac{1}{2}$ has strictly positive capacity – is Shannon’s noisy coding theorem, which we prove in Section 28.4.7.

§28.2 Noiseless Coding

We begin with the easier half of the problem, in which the channel is perfect and the only question is economy. A source emits symbols from an alphabet $\mathcal{A}$, some more often than others, and we want to represent them as short strings over a transmission alphabet $\mathcal{B}$.

§28.2.1 Codes and Decipherability

Let $\mathcal{B}$ be a finite alphabet. Write $\mathcal{B}^* = \bigcup_{n \geq 0} \mathcal{B}^n$ for the set of all finite strings over $\mathcal{B}$, including the empty string. The **concatenation** of $x = x_1 \dots x_r$ and $y = y_1 \dots y_s$ is $xy = x_1 \dots x_r y_1 \dots y_s$.

Definition 28.2.1 (Code)

Let $\mathcal{A}$ and $\mathcal{B}$ be alphabets. A **code** is a function $c: \mathcal{A} \rightarrow \mathcal{B}^*$. The elements of the image of c are the **codewords**.

We write $m = |\mathcal{A}|$ and $a = |\mathcal{B}|$, and call c an **a -ary code of size m** . A 2-ary code is *binary*, a 3-ary code is *ternary*.

Example 28.2.2 (The Greek Fire Code)

Take $\mathcal{A} = \{\alpha, \beta, \dots, \omega\}$, the 24 letters of the Greek alphabet, and $\mathcal{B} = \{1, 2, 3, 4, 5\}$. Arrange the letters in a 5×5 square and encode each by its coordinates, so $c(\alpha) = 11$,

$c(\beta) = 12$, and so on. To transmit the pair xy one holds up x torches on one hilltop and y torches on another. This scheme is described by Polybius, and is very probably the oldest code in these notes by some two thousand years.

A code is only useful if we can send more than one symbol. Given a message $x_1x_2 \dots x_n \in \mathcal{A}^*$ we transmit $c(x_1)c(x_2) \dots c(x_n)$, so that c extends to a map

$$c^*: \mathcal{A}^* \rightarrow \mathcal{B}^*.$$

Definition 28.2.3 (Decipherable)

A code c is **decipherable**, or **uniquely decodable**, if c^* is injective.

It is not enough for c itself to be injective, as the following shows.

Example 28.2.4

Let $\mathcal{A} = \{1, 2, 3, 4\}$ and $\mathcal{B} = \{0, 1\}$, and set

$$c(1) = 0, \quad c(2) = 1, \quad c(3) = 00, \quad c(4) = 01.$$

This is injective, but $c^*(114) = 0001 = 0001$ and $c^*(312) = 0001 = 0001$, so c^* is not. On receiving 0001 Bob has no way to tell which message was meant.

There are three easy ways of guaranteeing decipherability, assuming c injective.

- (i) A **block code**, in which all codewords have the same length. The Greek fire code is of this kind.
- (ii) A **comma code**, which reserves one letter of $\mathcal{B}$ to mark the end of a codeword and never uses it otherwise.
- (iii) A **prefix-free code**, in which no codeword is an initial segment of another.

Block codes and comma codes are both special cases of prefix-free codes. Prefix-free codes have the pleasant property that Bob can decode as he reads: the moment the symbols he has seen form a codeword, he knows that codeword has ended, because no longer codeword begins that way. For this reason they are also called **instantaneous** codes.

Not every decipherable code is prefix-free. For instance $c(1) = 0$, $c(2) = 01$, $c(3) = 011$, $c(4) = 0111$ is decipherable – each 0 marks the start of a new codeword – but $c(1)$ is a prefix of $c(2)$. Here Bob must look ahead to the next 0 before committing. Remarkably, we shall see in a moment that allowing such lookahead buys us precisely nothing.

The right way to picture a prefix-free binary code is as a rooted binary tree. Reading a codeword left to right tells us which way to turn at each vertex, and the prefix-free condition says exactly that all the codewords sit at *leaves*.

§28.2.2 Kraft's Inequality

How short can the codewords of a prefix-free code be? Not arbitrarily short: the tree picture makes it clear that a short codeword uses up a lot of the tree. The following inequality measures exactly how much.

Definition 28.2.5 (Kraft's Inequality)

Let $c: \mathcal{A} \rightarrow \mathcal{B}^*$ be a code with $|\mathcal{A}| = m$ and $|\mathcal{B}| = a$, whose codewords have lengths $\ell_1, \dots, \ell_m$. We say that c satisfies **Kraft's inequality** if

$$\sum_{i=1}^m a^{-\ell_i} \leq 1.$$

Theorem 28.2.6 (Kraft)

Given lengths $\ell_1, \dots, \ell_m$, there is a prefix-free a -ary code with these codeword lengths if and only if Kraft's inequality holds.

Proof. Let $s = \max_i \ell_i$ and let n_ℓ be the number of i with $\ell_i = \ell$, so that Kraft's inequality reads $\sum_{\ell=1}^s n_\ell a^{-\ell} \leq 1$, or after multiplying by a^s ,

$$n_1 a^{s-1} + n_2 a^{s-2} + \dots + n_{s-1} a + n_s \leq a^s. \quad (*)$$

Suppose first that c is prefix-free. A codeword of length ℓ is a prefix of exactly $a^{s-\ell}$ strings of length s , and by the prefix-free condition no string of length s has two different codewords as prefixes. So the left hand side of $(*)$ counts, without repetition, some of the strings of length s , of which there are a^s in all. Hence $(*)$ holds.

Conversely suppose $(*)$ holds; we build a prefix-free code with n_ℓ codewords of length ℓ for each ℓ , by induction on s . If $s = 1$ the inequality says $n_1 \leq a$ and we simply choose n_1 of the a letters. For $s > 1$, the inductive hypothesis applied to the lengths at most $s - 1$ gives a prefix-free code $\hat{c}$ with n_ℓ codewords of length ℓ for every $\ell < s$. Now the strings of length s having some codeword of $\hat{c}$ as a prefix number exactly

$$n_1 a^{s-1} + \dots + n_{s-1} a,$$

so by $(*)$ at least n_s strings of length s remain untouched. Choosing n_s of them and adjoining them to $\hat{c}$ gives a code which is still prefix-free, since none of the new

codewords extends an old one (they were chosen to avoid this) and none of the old codewords extends a new one (they are shorter). $\square$

Remark. The proof is constructive, and gives a perfectly practical algorithm: list the required lengths in increasing order and greedily assign codewords, at each stage taking any string of the right length that does not extend a codeword already chosen. Kraft's inequality guarantees that we never run out.

§28.2.3 McMillan's Inequality

Now we come to the result promised above, which says that lookahead is worthless.

Theorem 28.2.7 (McMillan)

Every decipherable code satisfies Kraft's inequality.

Proof. Let $c: \mathcal{A} \rightarrow \mathcal{B}^*$ be decipherable with word lengths $\ell_1, \dots, \ell_m$, and set $s = \max_i \ell_i$. The trick is to consider the R th power of the quantity in question. For any $R \in \mathbb{N}$,

$$\left(\sum_{i=1}^m a^{-\ell_i} \right)^R = \sum_{\ell=R}^{Rs} b_\ell a^{-\ell},$$

where b_ℓ is the number of ways of choosing an ordered R -tuple of codewords whose total length is ℓ ; this is just what happens when we expand the product. Now a tuple of R codewords of total length ℓ concatenates to a string in $\mathcal{B}^\ell$, and because c is decipherable, distinct tuples give distinct strings. Hence

$$b_\ell \leq |\mathcal{B}^\ell| = a^\ell,$$

and so each term $b_\ell a^{-\ell}$ is at most 1. There are at most Rs terms, so

$$\left(\sum_{i=1}^m a^{-\ell_i} \right)^R \leq Rs, \quad \text{that is} \quad \sum_{i=1}^m a^{-\ell_i} \leq (Rs)^{1/R}.$$

Letting $R \rightarrow \infty$, the right hand side tends to 1, and Kraft's inequality follows. $\square$

The proof is a small piece of magic: an inequality that fails to hold is amplified by exponentiation into an absurdity, while the polynomial factor Rs is powerless to keep up.

Corollary 28.2.8

A decipherable code with word lengths $\ell_1, \dots, \ell_m$ exists if and only if a prefix-free code with the same word lengths exists.

Proof. A prefix-free code is decipherable. Conversely, a decipherable code satisfies Kraft's inequality by McMillan, and then Kraft's theorem produces a prefix-free code with the same lengths. $\square$

So from the point of view of word lengths – which is the only point of view that matters for economy – we may as well restrict attention to prefix-free codes, and we shall.

§28.2.4 Entropy

We now need a way of saying how much information a source actually produces, so that we know what we are aiming at. The right notion is Shannon's **entropy**. Informally, the entropy of a random variable X is the expected number of fair coin tosses needed to determine its value.

Example 28.2.9

Suppose X takes four values with probability $\frac{1}{4}$ each. Identifying the values with 00, 01, 10, 11, two coin tosses always suffice and never fewer, so the entropy should be 2.

Suppose instead X takes four values with probabilities $\frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \frac{1}{8}$. Identify them with the strings 0, 10, 110, 111: toss a coin, and if it comes up 0 we are done, otherwise toss again, and so on. The expected number of tosses is

$$\frac{1}{2} \cdot 1 + \frac{1}{4} \cdot 2 + \frac{1}{8} \cdot 3 + \frac{1}{8} \cdot 3 = \frac{7}{4}.$$

The second variable is in this sense less random than the first.

Both examples are instances of the following.

Definition 28.2.10 (Entropy)

Let X be a random variable taking finitely many values $x_1, \dots, x_n$ with probabilities $p_1, \dots, p_n$. The **entropy** of X is

$$H(X) = H(p_1, \dots, p_n) = - \sum_{i=1}^n p_i \log p_i = \mathbb{E}[-\log p(X)],$$

where $\log = \log_2$ and we adopt the convention $0 \log 0 = 0$.

The convention is forced on us by continuity, since $x \log x \rightarrow 0$ as $x \rightarrow 0^+$. Entropy is measured in **bits**. Clearly $H(X) \geq 0$, with equality if and only if some $p_i = 1$, that is, if and only if X is constant.

Example 28.2.11 (The Binary Entropy Function)

For a biased coin with probability p of heads we write

$$H(p) = H(p, 1-p) = -p \log p - (1-p) \log(1-p).$$

Differentiating, $H'(p) = \log \frac{1-p}{p}$, which is positive for $p < \frac{1}{2}$ and negative for $p > \frac{1}{2}$; and $H''(p) < 0$ throughout, so H is strictly concave with a maximum of 1 at $p = \frac{1}{2}$, vanishing at $p = 0$ and $p = 1$.

This little function is going to appear everywhere, so it is worth committing its shape to memory: symmetric about $\frac{1}{2}$, with infinite slope at the two ends.

The following inequality is the workhorse of the whole subject.

Proposition 28.2.12 (Gibbs' Inequality)

Let $(p_1, \dots, p_n)$ and $(q_1, \dots, q_n)$ be probability distributions. Then

$$-\sum_{i=1}^n p_i \log p_i \leq -\sum_{i=1}^n p_i \log q_i,$$

with equality if and only if $p_i = q_i$ for all i .

The right hand side is the **cross entropy** of q relative to p ; the difference between the two sides is called the relative entropy, or Kullback–Leibler divergence, and Gibbs' inequality says it is non-negative.

Proof. Since $\log x = \ln x / \ln 2$ we may work with natural logarithms throughout. Let $I = \{i : p_i \neq 0\}$. The elementary inequality $\ln x \leq x - 1$ for $x > 0$, with equality only at $x = 1$, gives for $i \in I$

$$\ln \frac{q_i}{p_i} \leq \frac{q_i}{p_i} - 1,$$

and multiplying by $p_i > 0$ and summing over I ,

$$\sum_{i \in I} p_i \ln \frac{q_i}{p_i} \leq \sum_{i \in I} q_i - \sum_{i \in I} p_i \leq 1 - 1 = 0,$$

using $\sum_{i \in I} p_i = 1$ and $\sum_{i \in I} q_i \leq 1$. Therefore

$$-\sum_{i=1}^n p_i \ln p_i = -\sum_{i \in I} p_i \ln p_i \leq -\sum_{i \in I} p_i \ln q_i \leq -\sum_{i=1}^n p_i \ln q_i,$$

the last step because the omitted terms have $p_i = 0$. If equality holds throughout we need $\sum_{i \in I} q_i = 1$ and $q_i/p_i = 1$ for every $i \in I$; the first forces $q_i = 0$ for $i \notin I$, and the second gives $p_i = q_i$ on I . $\square$

Corollary 28.2.13

$H(p_1, \dots, p_n) \leq \log n$, with equality if and only if $p_1 = \dots = p_n = \frac{1}{n}$.

Proof. Take $q_i = \frac{1}{n}$ in Gibbs' inequality: the right hand side is $-\sum p_i \log \frac{1}{n} = \log n$. $\square$

In other words, the uniform distribution is the most random one, which is what one would hope.

§28.2.5 Optimal Codes and the Noiseless Coding Theorem

Fix an alphabet $\mathcal{A} = \{\mu_1, \dots, \mu_m\}$ of $m \geq 2$ messages and a transmission alphabet $\mathcal{B}$ with $a = |\mathcal{B}| \geq 2$. Let X be a random variable on $\mathcal{A}$ with $\mathbb{P}(X = \mu_i) = p_i$. A code c with word lengths $\ell_1, \dots, \ell_m$ has expected word length

$$\mathbb{E}[S] = \sum_{i=1}^m p_i \ell_i.$$

Definition 28.2.14 (Optimal Code)

A code $c: \mathcal{A} \rightarrow \mathcal{B}^*$ is **optimal** if it has the smallest expected word length among all decipherable codes for X .

We can now say precisely how well one can do.

Theorem 28.2.15 (Shannon's Noiseless Coding Theorem)

The expected word length $\mathbb{E}[S]$ of an optimal code satisfies

$$\frac{H(X)}{\log a} \leq \mathbb{E}[S] < \frac{H(X)}{\log a} + 1.$$

Moreover the lower bound holds for *every* decipherable code, and is attained exactly when $p_i = a^{-\ell_i}$ for integers ℓ_i (so that in particular $\sum_i a^{-\ell_i} = 1$).

Proof. The lower bound. Let c be an arbitrary decipherable code, with word lengths $\ell_1, \dots, \ell_m$. Put $D = \sum_i a^{-\ell_i}$ and $q_i = a^{-\ell_i}/D$, so that (q_i) is a probability distribution. By Gibbs' inequality,

$$\begin{aligned} H(X) &\leq -\sum_i p_i \log q_i = -\sum_i p_i (-\ell_i \log a - \log D) \\ &= \log D + \log a \sum_i p_i \ell_i. \end{aligned}$$

By McMillan's inequality $D \leq 1$, so $\log D \leq 0$, and therefore

$$H(X) \leq \log a \cdot \mathbb{E}[S],$$

which is the lower bound. Equality forces $D = 1$ and $p_i = q_i = a^{-\ell_i}$.

The upper bound. It suffices to exhibit *some* decipherable code beating the bound, since an optimal code can only be better. Set

$$\ell_i = \lceil -\log_a p_i \rceil,$$

so that $-\log_a p_i \leq \ell_i < -\log_a p_i + 1$. From the first inequality $p_i \geq a^{-\ell_i}$, and summing, $\sum_i a^{-\ell_i} \leq 1$. So Kraft's inequality holds and there is a prefix-free code c with these word lengths. From the second inequality,

$$\mathbb{E}[S] = \sum_i p_i \ell_i < \sum_i p_i (-\log_a p_i + 1) = \frac{H(X)}{\log a} + 1. \quad \square$$

The code constructed in the second half is worth a name.

Definition 28.2.16 (Shannon–Fano Coding)

The **Shannon–Fano code** for probabilities $p_1, \dots, p_m$ takes word lengths $\ell_i = \lceil -\log_a p_i \rceil$ and then assigns codewords greedily in order of increasing length, as in the proof of Kraft's theorem.

Example 28.2.17

Take $a = 2$ and the source

i	1	2	3	4	5	6
p_i	0.30	0.22	0.18	0.14	0.10	0.06

The entropy is

$$H(X) = -\sum_i p_i \log p_i \approx 2.4198.$$

The Shannon–Fano lengths are $\ell_i = \lceil -\log_2 p_i \rceil$, namely

$$\ell = (2, 3, 3, 3, 4, 5),$$

and $\sum_i 2^{-\ell_i} = \frac{1}{4} + 3 \cdot \frac{1}{8} + \frac{1}{16} + \frac{1}{32} = 0.71875 \leq 1$ as it must be. Assigning codewords greedily gives

i	1	2	3	4	5	6
$c(i)$	00	010	011	100	1010	10110

with expected word length

$$\mathbb{E}[S] = 0.30 \cdot 2 + 0.22 \cdot 3 + 0.18 \cdot 3 + 0.14 \cdot 3 + 0.10 \cdot 4 + 0.06 \cdot 5 = 2.92.$$

This does obey $H(X) \leq \mathbb{E}[S] < H(X) + 1$, but only just, and it is visibly wasteful: nothing at all uses the string 11, and we could shorten $c(6)$ to 1011 without breaking anything. Shannon–Fano coding is not optimal.

§28.2.6 Huffman Coding

Huffman's algorithm produces a genuinely optimal code, and it does so by a beautifully simple greedy rule. We take $a = 2$ and $\mathcal{B} = \{0, 1\}$ for simplicity; everything generalises.

Order the messages so that $p_1 \geq p_2 \geq \dots \geq p_m$. We define the code recursively.

Definition 28.2.18 (Huffman Code)

If $m = 2$, take the codewords 0 and 1. If $m > 2$, form the source on $m - 1$ symbols

$\mu_1, \dots, \mu_{m-2}, \nu$ with probabilities $p_1, \dots, p_{m-2}, p_{m-1} + p_m$, take a **Huffman code** for it, and then set

$$c(\mu_{m-1}) = c(\nu)0, \quad c(\mu_m) = c(\nu)1,$$

keeping all other codewords unchanged.

In other words: repeatedly merge the two least likely symbols into one, until only two remain; then read the resulting binary tree from the root outwards. Huffman codes are prefix-free by construction, since every codeword sits at a leaf. They are not unique – ties in the probabilities force arbitrary choices – but we shall see that all the choices are equally good.

Example 28.2.19

Take the same source as Example 28.2.17, writing the messages as $A, \dots, F$:

	A	B	C	D	E	F
p	0.30	0.22	0.18	0.14	0.10	0.06

We merge repeatedly.

- The two smallest are E and F ; merge them into X with probability 0.16. Remaining: A 0.30, B 0.22, C 0.18, X 0.16, D 0.14.
- The two smallest are D and X ; merge them into Y with probability 0.30. Remaining: A 0.30, Y 0.30, B 0.22, C 0.18.
- The two smallest are C and B ; merge them into Z with probability 0.40. Remaining: A 0.30, Y 0.30, Z 0.40.
- The two smallest are A and Y ; merge them into W with probability 0.60.
- Finally merge Z and W .

The resulting tree is as follows, with 0 on the left branch and 1 on the right.

Reading off, the word lengths are 2, 2, 2, 3, 4, 4 and

$$\mathbb{E}[S] = 0.30 \cdot 2 + 0.22 \cdot 2 + 0.18 \cdot 2 + 0.14 \cdot 3 + 0.10 \cdot 4 + 0.06 \cdot 4 = 2.46,$$

comfortably better than the 2.92 of Shannon–Fano, and within 0.05 of the entropy bound 2.4198.

To prove optimality we need two structural facts about optimal codes, both of which are obvious once stated.

Lemma 28.2.20

Let c be an optimal prefix-free code for messages $\mu_1, \dots, \mu_m$ with probabilities $p_1 \geq \dots \geq p_m$, and word lengths $\ell_1, \dots, \ell_m$. Then

- (i) if $p_i > p_j$ then $\ell_i \leq \ell_j$;
- (ii) among the codewords of maximal length, there are two which differ only in their last digit.

Proof. (i). Suppose $p_i > p_j$ but $\ell_i > \ell_j$. Swapping the i th and j th codewords leaves the code prefix-free and changes the expected word length by

$$(p_i \ell_j + p_j \ell_i) - (p_i \ell_i + p_j \ell_j) = (p_i - p_j)(\ell_j - \ell_i) < 0,$$

contradicting optimality.

(ii). Let $\ell = \max_i \ell_i$, and suppose no two codewords of length ℓ agree in their first $\ell - 1$ digits. Deleting the final digit of every codeword of length ℓ then leaves all these codewords distinct; and the code is still prefix-free, because a shortened codeword y could only be a prefix of some other codeword z if $y0$ or $y1$ were, and z has length at most ℓ , so $z \in \{y0, y1\}$, which our assumption excludes. But this strictly decreases the expected word length, contradicting optimality. $\square$

Theorem 28.2.21

Huffman codes are optimal.

Proof. We induct on m . For $m = 2$ the Huffman code has both word lengths equal to 1, which is clearly best possible.

Let $m > 2$ and let c_m be the Huffman code for X_m taking values $\mu_1, \dots, \mu_m$ with probabilities $p_1 \geq \dots \geq p_m$. By construction c_m is built from a Huffman code c_{m-1} for the merged source X_{m-1} on $\mu_1, \dots, \mu_{m-2}, \nu$ with probabilities $p_1, \dots, p_{m-2}, p_{m-1} + p_m$, by extending the codeword of ν by one digit in each of two ways. Comparing expected lengths term by term,

$$\mathbb{E}[S_m] = \mathbb{E}[S_{m-1}] + p_{m-1} + p_m. \quad (1)$$

Now let c'_m be an optimal code for X_m ; by the corollary to McMillan's theorem we may take it prefix-free. By Lemma 28.2.20(i) the two longest codewords belong to two of the least likely messages, and by (ii) we may assume, after relabelling messages of equal probability and swapping codewords of equal length, that

$$c'_m(\mu_{m-1}) = y0, \quad c'_m(\mu_m) = y1$$

for some string y . Define a code c'_{m-1} for X_{m-1} by

$$c'_{m-1}(\mu_i) = c'_m(\mu_i) \ (i \leq m-2), \quad c'_{m-1}(\nu) = y.$$

This is prefix-free: no codeword of c'_m other than $y0, y1$ can have y as a prefix, else it would have $y0$ or $y1$ as a prefix. Exactly as in (1),

$$\mathbb{E}[S'_m] = \mathbb{E}[S'_{m-1}] + p_{m-1} + p_m. \quad (2)$$

By the inductive hypothesis c_{m-1} is optimal for X_{m-1} , so $\mathbb{E}[S_{m-1}] \leq \mathbb{E}[S'_{m-1}]$. Combining with (1) and (2),

$$\mathbb{E}[S_m] \leq \mathbb{E}[S'_m],$$

and since c'_m was optimal, so is c_m . $\square$

Remark. Not every optimal code is a Huffman code – one can always relabel $0 \leftrightarrow 1$ in a subtree, for instance. What the theorem really gives us is that the Huffman word lengths are optimal word lengths.

Huffman coding is optimal but not perfect: it can never do better than the entropy bound, and if one symbol has probability close to 1 it must still spend a whole bit on it. The remedy is to Huffman-code blocks of N symbols at a time, which as we shall see in Section 28.4 drives the cost per symbol down to the entropy.

§28.2.7 Joint Entropy

Finally in this section we record how entropy behaves for pairs of random variables, which we shall need repeatedly later on.

If X, Y take values in $\mathcal{A}, \mathcal{B}$ then (X, Y) takes values in $\mathcal{A} \times \mathcal{B}$, and its entropy

$$H(X, Y) = - \sum_{x \in \mathcal{A}} \sum_{y \in \mathcal{B}} \mathbb{P}(X = x, Y = y) \log \mathbb{P}(X = x, Y = y)$$

is called the **joint entropy**. The same definition works for any finite tuple.

Lemma 28.2.22 (Subadditivity)

$H(X, Y) \leq H(X) + H(Y)$, with equality if and only if X and Y are independent.

Proof. Write $\mathcal{A} = \{x_1, \dots, x_m\}$, $\mathcal{B} = \{y_1, \dots, y_n\}$, and set $p_{ij} = \mathbb{P}(X = x_i, Y = y_j)$, $p_i = \mathbb{P}(X = x_i)$, $q_j = \mathbb{P}(Y = y_j)$. Both (p_{ij}) and $(p_i q_j)$ are probability distributions on $\mathcal{A} \times \mathcal{B}$, so Gibbs' inequality applies and gives

$$\begin{aligned} H(X, Y) &= - \sum_{i,j} p_{ij} \log p_{ij} \leq - \sum_{i,j} p_{ij} \log(p_i q_j) \\ &= - \sum_i \left(\sum_j p_{ij} \right) \log p_i - \sum_j \left(\sum_i p_{ij} \right) \log q_j \\ &= - \sum_i p_i \log p_i - \sum_j q_j \log q_j = H(X) + H(Y). \end{aligned}$$

Equality in Gibbs holds precisely when $p_{ij} = p_i q_j$ for all i, j , which is exactly independence. $\square$

Intuitively: knowing two things at once is never harder than knowing each separately, and it is exactly as hard only when the two are unrelated.

§28.3 Noisy Channels and Error-Correcting Codes

We now switch the channel back on. Throughout this section, unless we say otherwise, the channel is the binary symmetric channel with error probability $p < \frac{1}{2}$, and a code is a subset of $\mathbb{F}_2^n$.

Definition 28.3.1 (Binary Code)

A **binary** $[n, m]$ -**code** is a subset $C \subseteq \{0, 1\}^n$ with $|C| = m$. We call n the **length** of the code and the elements of C its **codewords**.

Such a code lets us send one of m messages using n bits, that is, using the channel n times. Since $1 \leq m \leq 2^n$, the information rate $\rho(C) = \frac{1}{n} \log m$ satisfies $0 \leq \rho(C) \leq 1$, with $\rho(C) = 0$ for the useless code $|C| = 1$ and $\rho(C) = 1$ for the code $C = \{0, 1\}^n$ which does no error correction at all. All the interest lies in between.

§28.3.1 Decoding Rules

Suppose Bob receives $x \in \{0, 1\}^n$. What should he guess was sent? There are three natural answers.

Definition 28.3.2 (Decoding Rules)

Let C be a binary $[n, m]$ -code.

- The **ideal observer** rule decodes x as the codeword $c \in C$ maximising $\mathbb{P}(c \text{ sent} \mid x \text{ received})$.
- The **maximum likelihood** rule decodes x as the $c \in C$ maximising the probability $\mathbb{P}(x \text{ received} \mid c \text{ sent})$.
- The **minimum distance** rule decodes x as the $c \in C$ minimising the Hamming distance $d(x, c)$,

$$d(x, y) = |\{i : x_i \neq y_i\}|.$$

The first is what we actually want, but it requires knowing the prior distribution on messages. The third is what we can actually compute. Happily, under mild hypotheses they all coincide.

Lemma 28.3.3

Let C be a binary $[n, m]$ -code used over a BSC with error probability p .

- (i) If all messages are equally likely, the ideal observer and maximum likelihood rules agree.
- (ii) If $p < \frac{1}{2}$, the maximum likelihood and minimum distance rules agree.

Proof. (i). By Bayes' theorem,

$$\mathbb{P}(c \text{ sent} \mid x \text{ received}) = \frac{\mathbb{P}(c \text{ sent})}{\mathbb{P}(x \text{ received})} \mathbb{P}(x \text{ received} \mid c \text{ sent}).$$

For fixed x , the denominator does not depend on c , and by hypothesis neither does $\mathbb{P}(c \text{ sent})$. So the two quantities are maximised together.

(ii). If $d(x, c) = r$ then exactly r of the n transmitted bits were flipped, so

$$\mathbb{P}(x \text{ received} \mid c \text{ sent}) = p^r (1-p)^{n-r} = (1-p)^n \left(\frac{p}{1-p} \right)^r.$$

As $p < \frac{1}{2}$ we have $\frac{p}{1-p} < 1$, so this is a strictly decreasing function of r . Maximising it is therefore the same as minimising $r = d(x, c)$. $\square$

The hypothesis in (i) is reasonable in practice, because if we first compress the message using a good noiseless code the resulting bits look close to uniform. The hypothesis in (ii) is harmless, as discussed earlier. Channels with $p = 0$ are called **lossless**, and channels with $p = \frac{1}{2}$ are called **useless**.

It is worth seeing that the rules really can differ.

Example 28.3.4

Let $C = \{000, 111\}$, sent with probabilities $\alpha = \frac{9}{10}$ and $1 - \alpha = \frac{1}{10}$ respectively, over a BSC with $p = \frac{1}{4}$. Suppose 110 is received. Then

$$\mathbb{P}(000 \text{ sent} \mid 110) = \frac{\alpha p^2 (1-p)}{\alpha p^2 (1-p) + (1-\alpha) p (1-p)^2} = \frac{\frac{9}{10} \cdot \frac{1}{16} \cdot \frac{3}{4}}{\frac{9}{10} \cdot \frac{1}{16} \cdot \frac{3}{4} + \frac{1}{10} \cdot \frac{1}{4} \cdot \frac{9}{16}} = \frac{3}{4},$$

so $\mathbb{P}(111 \text{ sent} \mid 110) = \frac{1}{4}$. The ideal observer decodes 110 as 000, since 000 was so much more likely *a priori*. But $d(110, 111) = 1 < 2 = d(110, 000)$, so minimum distance decoding – and hence maximum likelihood decoding – gives 111.

Remark. Minimum distance decoding is conceptually simple but potentially expensive: naively one compares the received word against every codeword, which is hopeless once $|C|$ is large. Much of Section 28.5 is devoted to making it cheap for structured codes. One should also fix a convention for ties: either make an arbitrary choice, or declare a failure and ask for retransmission.

From now on we use minimum distance decoding.

§28.3.2 Error Detection and Correction

Definition 28.3.5

A binary $[n, m]$ -code C is

- **d -error detecting** if changing at most d digits of a codeword can never produce another codeword;
- **e -error correcting** if, knowing that $x \in \mathbb{F}_2^n$ differs from some codeword in at most e places, we can determine that codeword.

Example 28.3.6 (Repetition Code)

The **repetition code** of length n has codewords $00 \dots 0$ and $11 \dots 1$. It is an $[n, 2]$ -code, it is $(n - 1)$ -error detecting and $\lfloor \frac{n-1}{2} \rfloor$ -error correcting, and its information rate is $\frac{1}{n}$, which tends to 0. Reliability is bought at the price of everything else.

Example 28.3.7 (Simple Parity Check Code)

The **simple parity check code** (or **paper tape code**) of length n is

$$C = \left\{ (x_1, \dots, x_n) \in \mathbb{F}_2^n : \sum_{i=1}^n x_i = 0 \right\}.$$

This is an $[n, 2^{n-1}]$ -code, it is 1-error detecting and 0-error correcting, and its information rate is $\frac{n-1}{n} \rightarrow 1$. Economy is bought at the price of everything else.

Between these two extremes sits the first genuinely clever code.

Example 28.3.8 (Hamming's Original Code)

Define $C \subseteq \mathbb{F}_2^7$ by the three conditions

$$c_1 + c_3 + c_5 + c_7 = 0, \quad c_2 + c_3 + c_6 + c_7 = 0, \quad c_4 + c_5 + c_6 + c_7 = 0.$$

The digits c_3, c_5, c_6, c_7 may be chosen freely and then c_1, c_2, c_4 are determined, so $|C| = 2^4 = 16$ and C is a $[7, 16]$ -code with rate $\frac{4}{7}$.

Suppose $x \in \mathbb{F}_2^7$ is received. Form the **syndrome** $z = (z_1, z_2, z_4)$ where

$$z_1 = x_1 + x_3 + x_5 + x_7, \quad z_2 = x_2 + x_3 + x_6 + x_7, \quad z_4 = x_4 + x_5 + x_6 + x_7.$$

If $x \in C$ then $z = (0, 0, 0)$. If instead $x = c + e_i$, a codeword with the i th digit flipped, then by linearity $z_x = z_{e_i}$, and one checks case by case that

$$z_1 + 2z_2 + 4z_4 = i$$

as an ordinary integer. For instance e_5 appears in the first and third conditions but not the second, giving $z = (1, 0, 1)$ and $1 + 0 + 4 = 5$. So the syndrome does not merely tell us that an error has occurred, it tells us *where*: the code is 1-error correcting. This is a remarkably efficient piece of bookkeeping, and we will see in a moment that in a precise sense it cannot be improved on.

To analyse such codes properly we need the geometry of $\mathbb{F}_2^n$.

Lemma 28.3.9

The Hamming distance d is a metric on $\mathbb{F}_2^n$.

Proof. Certainly $d(x, y) \geq 0$ with equality if and only if $x = y$, and $d(x, y) = d(y, x)$.

For the triangle inequality, note that if $x_i \neq z_i$ then $x_i \neq y_i$ or $y_i \neq z_i$, so

$$\{i : x_i \neq z_i\} \subseteq \{i : x_i \neq y_i\} \cup \{i : y_i \neq z_i\},$$

and taking sizes gives $d(x, z) \leq d(x, y) + d(y, z)$. $\square$

Equivalently, $d(x, y) = \sum_i d_1(x_i, y_i)$ where d_1 is the discrete metric on $\mathbb{F}_2$; the triangle inequality is inherited coordinatewise.

Definition 28.3.10 (Minimum Distance)

The **minimum distance** of a code C with $|C| \geq 2$ is

$$d(C) = \min\{d(c_1, c_2) : c_1, c_2 \in C, c_1 \neq c_2\}.$$

An $[n, m]$ -code with minimum distance d is called an $[n, m, d]$ -code.

Lemma 28.3.11

Let C be a code with minimum distance d . Then

- (i) C is $(d - 1)$ -error detecting, but cannot detect all sets of d errors;
- (ii) C is $\lfloor \frac{d-1}{2} \rfloor$ -error correcting, but cannot correct all sets of $\lfloor \frac{d-1}{2} \rfloor + 1$ errors.

Proof. (i). If $c \in C$ and $1 \leq d(x, c) \leq d - 1$ then $x \notin C$, since every other codeword is at distance at least d from c ; so the corruption is detected. On the other hand if c_1, c_2 are codewords at distance exactly d , then d well-chosen errors carry c_1 to c_2 and nothing at all is noticed.

(ii). Put $e = \lfloor \frac{d-1}{2} \rfloor$, so that $2e < d$. Suppose $x \in \mathbb{F}_2^n$ and $c_1 \in C$ with $d(x, c_1) \leq e$. For any other codeword c_2 , the triangle inequality gives

$$d(x, c_2) \geq d(c_1, c_2) - d(x, c_1) \geq d - e > e,$$

so c_1 is the unique codeword within distance e of x and we recover it. For the second half, choose c_1, c_2 with $d(c_1, c_2) = d$ and let x agree with c_1 except in $e + 1$ of the places where c_1 and c_2 differ. Then $d(x, c_1) = e + 1$ while $d(x, c_2) = d - (e + 1) \leq e + 1$, using $d \leq 2(e + 1)$; so x is at least as close to c_2 as to c_1 and we cannot reliably decode. $\square$

Example 28.3.12

The repetition code of length n is an $[n, 2, n]$ -code. The simple parity check code of length n is an $[n, 2^{n-1}, 2]$ -code, since flipping any two digits preserves the parity. The trivial code $\mathbb{F}_2$ is an $[n, 2^n, 1]$ -code. Hamming's original code is 1-error correcting so has $d \geq 3$ by Lemma 28.3.11; and 0000000 and 1110000 are both codewords, so $d = 3$ exactly, making it a $[7, 16, 3]$ -code.

§28.3.3 Covering Estimates and Perfect Codes

The picture behind Lemma 28.3.11 is that an e -error correcting code is a packing of disjoint balls of radius e into $\mathbb{F}_2^n$. Counting gives an immediate upper bound on how many codewords there can be.

Definition 28.3.13

For $x \in \mathbb{F}_2^n$ and $r \geq 0$, write $B(x, r) = \{y \in \mathbb{F}_2^n : d(x, y) \leq r\}$ for the closed **Hamming ball** of radius r . Its size does not depend on x , and we write

$$V(n, r) = |B(x, r)| = \sum_{i=0}^r \binom{n}{i}.$$

The dots are the codewords; the discs are the balls of radius e inside which minimum distance decoding succeeds. They must be disjoint, and they all live inside a space of size 2^n .

Lemma 28.3.14 (Hamming's Bound; the Sphere-Packing Bound)

An e -error correcting code C of length n satisfies

$$|C| \leq \frac{2^n}{V(n, e)}.$$

Proof. If $c_1 \neq c_2$ are codewords then $B(c_1, e) \cap B(c_2, e) = \emptyset$, since a point in the intersection could not be decoded. Hence

$$\sum_{c \in C} |B(c, e)| \leq |\mathbb{F}_2^n|, \quad \text{that is} \quad |C| V(n, e) \leq 2^n. \quad \square$$

Definition 28.3.15 (Perfect Code)

An e -error correcting code C of length n with $|C| = \frac{2^n}{V(n, e)}$ is called **perfect**.

Remark. Equivalently, C is perfect if the balls $B(c, e)$ for $c \in C$ partition $\mathbb{F}_2^n$: every word in the space is within distance e of exactly one codeword. Perfect codes are wonderfully efficient but also brittle, since any $e+1$ errors are guaranteed to be decoded to the wrong codeword, with no warning.

Example 28.3.16

Hamming's $[7, 16, 3]$ -code is 1-error correcting, and

$$\frac{2^7}{V(7, 1)} = \frac{128}{1 + 7} = 16 = |C|,$$

so it is perfect. Indeed, the syndrome map sends $\mathbb{F}_2^7$ onto $\mathbb{F}_2^3$, and the eight syndromes correspond precisely to 'no error' and the seven possible single-bit errors.

Example 28.3.17

The repetition code of length n is perfect if and only if n is odd. If $n = 2k + 1$ it is k -error correcting and $V(n, k) = \sum_{i \leq k} \binom{n}{i} = 2^{n-1}$ by symmetry, so $2^n / V(n, k) = 2 = |C|$. If n is even the count fails.

The smallest interesting case is worth drawing. Here is $\mathbb{F}_2^3$ as the vertices of a cube, with the repetition code $\{000, 111\}$ marked.
