Every vertex is adjacent to exactly one of the two blue vertices, which is the statement that the $[3, 2, 3]$ repetition code is perfect.

Remark. If $\frac{2^n}{V(n, e)}$ is not an integer then certainly no perfect e -error correcting code of length n exists. The converse is false: with $n = 90$ and $e = 2$ the quotient is an integer, but no such code exists.

Definition 28.3.18

$A(n, d)$ denotes the largest m for which an $[n, m, d]$ -code exists.

Determining $A(n, d)$ in general is a hard open problem, and only small cases are known.

Example 28.3.19

$A(n, 1) = 2^n$, achieved by the trivial code. $A(n, 2) = 2^{n-1}$, achieved by the simple parity check code (the upper bound follows from the next theorem). $A(n, n) = 2$, achieved by the repetition code.

Lemma 28.3.20

$A(n, d + 1) \leq A(n, d)$.

Proof. Let $m = A(n, d + 1)$ and let C be an $[n, m, d + 1]$ -code. Choose distinct $c_1, c_2 \in C$ with $d(c_1, c_2) = d + 1$, and let c'_1 differ from c_1 in exactly one of the places where c_1 and c_2 differ, so $d(c'_1, c_2) = d$. For any other $c \in C$,

$$d + 1 \leq d(c, c_1) \leq d(c, c'_1) + d(c'_1, c_1) = d(c, c'_1) + 1,$$

so $d(c, c'_1) \geq d$. Hence $C' = (C \setminus \{c_1\}) \cup \{c'_1\}$ has m elements, length n , and minimum distance exactly d . $\square$

Corollary 28.3.21

$A(n, d) = \max\{m : \text{there is an } [n, m, d']\text{-code for some } d' \geq d\}.$

Now we can sandwich $A(n, d)$ between two natural bounds.

Theorem 28.3.22 (Hamming and GSV Bounds)

$$\frac{2^n}{V(n, d-1)} \leq A(n, d) \leq \frac{2^n}{V(n, \lfloor \frac{d-1}{2} \rfloor)}.$$

The upper bound is Hamming's bound, a *packing* estimate. The lower bound is the **Gilbert–Shannon–Varshamov** (GSV) bound, and is a *covering* estimate: it says that a maximal code cannot leave any large empty region.

Proof. The upper bound is Lemma 28.3.14 together with Lemma 28.3.11(ii).

For the lower bound, let $m = A(n, d)$ and let C be an $[n, m, d]$ -code. There can be no $x \in \mathbb{F}_2^n$ with $d(x, c) \geq d$ for all $c \in C$, for then $C \cup \{x\}$ would be an $[n, m + 1, d]$ -code, contradicting maximality. Hence every x lies within distance $d - 1$ of some codeword, that is,

$$\mathbb{F}_2^n = \bigcup_{c \in C} B(c, d - 1),$$

and counting gives $2^n \leq m V(n, d - 1)$. $\square$

There is a third bound, of a completely different flavour, which is often the sharpest of all for large d .

Theorem 28.3.23 (Singleton Bound)

For any $[n, m, d]$ -code, $m \leq 2^{n-d+1}$.

Proof. Let C be an $[n, m, d]$ -code and consider the map $\pi: C \rightarrow \mathbb{F}_2^{n-d+1}$ which deletes the last $d - 1$ coordinates. If $c_1 \neq c_2$ had the same image then they would agree in the first $n - d + 1$ places and so differ in at most $d - 1$ places, contradicting $d(C) = d$. So π is injective and $m = |C| \leq 2^{n-d+1}$. $\square$

A code attaining the Singleton bound is called **maximum distance separable**, or MDS. Over $\mathbb{F}_2$ these are rare, but we shall meet a large family of them over larger alphabets in Section 28.6.

Example 28.3.24

Take $n = 10$, $d = 3$. Then $V(10, 1) = 11$ and $V(10, 2) = 1 + 10 + 45 = 56$, so Theorem 28.3.22 gives

$$\frac{1024}{56} \leq A(10, 3) \leq \frac{1024}{11}, \quad \text{that is} \quad 19 \leq A(10, 3) \leq 93.$$

Singleton gives only $A(10, 3) \leq 2^8 = 256$, which is worse here. The true value, established by computer search, is $A(10, 3) = 72$; so the GSV bound in particular is far from sharp.

§28.3.4 Asymptotics

For applications we care about long codes, and about how the rate behaves when we insist that the minimum distance grows proportionally to the length. So fix $\delta \in (0, \frac{1}{2})$ and study

$$\frac{1}{n} \log A(n, \lfloor n\delta \rfloor)$$

as $n \rightarrow \infty$. The answer is governed, once again, by the binary entropy function.

Proposition 28.3.25

Let $0 < \delta < \frac{1}{2}$. Then

- (i) $\log V(n, \lfloor n\delta \rfloor) \leq nH(\delta)$;
- (ii) $\frac{1}{n} \log A(n, \lfloor n\delta \rfloor) \geq 1 - H(\delta)$.

Proof. (i) implies (ii). By the GSV bound and monotonicity of V in its second argument,

$$A(n, \lfloor n\delta \rfloor) \geq \frac{2^n}{V(n, \lfloor n\delta \rfloor - 1)} \geq \frac{2^n}{V(n, \lfloor n\delta \rfloor)},$$

so taking logarithms and using (i),

$$\frac{1}{n} \log A(n, \lfloor n\delta \rfloor) \geq 1 - \frac{\log V(n, \lfloor n\delta \rfloor)}{n} \geq 1 - H(\delta).$$

Proof of (i). Since H is increasing on $(0, \frac{1}{2})$ and $V(n, \lfloor n\delta \rfloor) = V(n, \lfloor n\delta' \rfloor)$ for $\delta' = \lfloor n\delta \rfloor / n \leq \delta$, we may assume $n\delta$ is an integer. Now expand $1 = (\delta + (1 - \delta))^n$ and throw away all but the first $n\delta + 1$ terms:

$$\begin{aligned} 1 &= \sum_{i=0}^n \binom{n}{i} \delta^i (1 - \delta)^{n-i} \geq \sum_{i=0}^{n\delta} \binom{n}{i} \delta^i (1 - \delta)^{n-i} \\ &= (1 - \delta)^n \sum_{i=0}^{n\delta} \binom{n}{i} \left(\frac{\delta}{1 - \delta} \right)^i \geq (1 - \delta)^n \left(\frac{\delta}{1 - \delta} \right)^{n\delta} \sum_{i=0}^{n\delta} \binom{n}{i} \\ &= \delta^{n\delta} (1 - \delta)^{n(1-\delta)} V(n, n\delta), \end{aligned}$$

where the second inequality uses $\frac{\delta}{1-\delta} < 1$ (as $\delta < \frac{1}{2}$), so that each of the terms

$\left(\frac{\delta}{1-\delta}\right)^i$ with $i \leq n\delta$ is at least $\left(\frac{\delta}{1-\delta}\right)^{n\delta}$. Taking logarithms,

$$0 \geq n\delta \log \delta + n(1-\delta) \log(1-\delta) + \log V(n, n\delta) = -nH(\delta) + \log V(n, n\delta),$$

which is (i). $\square$

Lemma 28.3.26

For $0 < \delta < \frac{1}{2}$, $\lim_{n \rightarrow \infty} \frac{\log V(n, \lfloor n\delta \rfloor)}{n} = H(\delta)$.

Proof. The upper bound is Proposition 28.3.25(i). For the lower bound it suffices to keep the single term $\binom{n}{\lfloor n\delta \rfloor}$ and apply Stirling's formula, which gives $\frac{1}{n} \log \binom{n}{\lfloor n\delta \rfloor} \rightarrow H(\delta)$. $\square$

So the constant $H(\delta)$ in the proposition cannot be improved. It is instructive to plot the three bounds we now have, expressed as constraints on the rate $R = \frac{1}{n} \log |C|$ in terms of the relative distance $\delta = d/n$. The Hamming bound becomes $R \leq 1 - H(\delta/2)$, the Singleton bound becomes $R \leq 1 - \delta$, and the GSV bound becomes $R \geq 1 - H(\delta)$.

Anything achievable lies below the blue and green curves and, by GSV, at least the region below the red curve *is* achievable. The gap between red and blue is enormous, and closing it – determining the true asymptotic trade-off between rate and distance – remains one of the central open problems of coding theory.

§28.3.5 Constructing New Codes from Old

We finish this section with three easy operations on codes; each is worth knowing because they let us move around the parameter space by hand. Let C be an $[n, m, d]$ -code.

Example 28.3.27 (Parity Check Extension)

The **parity check extension** of C is

$$C^+ = \left\{ \left(c_1, \dots, c_n, \sum_{i=1}^n c_i \right) : (c_1, \dots, c_n) \in C \right\},$$

an $[n+1, m, d']$ -code where $d' = d+1$ if d is odd and $d' = d$ if d is even. (All codewords of C^+ have even weight, so distances between them are even; hence an odd d must increase.)

Example 28.3.28 (Punctured Code)

Deleting the i th digit from every codeword gives the **punctured code** C^- . If $d \geq 2$ this is an $[n-1, m, d']$ -code with $d' \in \{d-1, d\}$; the codewords remain distinct because they differed in at least two places.

Example 28.3.29 (Shortened Code)

Fix i and $\alpha \in \mathbb{F}_2$, and let

$$C' = \{ (c_1, \dots, c_{i-1}, c_{i+1}, \dots, c_n) : (c_1, \dots, c_{i-1}, \alpha, c_{i+1}, \dots, c_n) \in C \}.$$

This is the **shortened code**. It has length $n-1$ and minimum distance $d' \geq d$, and for a suitable choice of α (namely, the more popular value of the i th digit) it has size $m' \geq \frac{m}{2}$.

§28.4 Information Theory

We now have two loose ends to tie up. In Section 2 we measured the cost of encoding a *single* symbol and found the entropy $H(X)$ standing in the way; but a real source emits a long stream of symbols, possibly with dependence between them, and we should ask what the cost per symbol is in the long run. In Section 3 we defined the capacity of a channel and did not compute it for a single example. Both questions are answered by the same circle of ideas, and the answers are Shannon's two coding theorems.

§28.4.1 Sources and Information Rate

Definition 28.4.1 (Source)

A **source** is a sequence of random variables $X_1, X_2, \dots$ taking values in an alphabet $\mathcal{A}$.

Example 28.4.2

A **Bernoulli** or **memoryless** source is one in which the X_i are independent and identically distributed. English text is emphatically not of this kind – the letter u is much more likely after a q – but it is the case in which everything can be computed.

Definition 28.4.3 (Reliable Encoding)

A source $X_1, X_2, \dots$ is **reliably encodable at rate r** if there are subsets $A_n \subseteq \mathcal{A}^n$ with

- (i) $\lim_{n \rightarrow \infty} \frac{\log |A_n|}{n} = r$, and
- (ii) $\lim_{n \rightarrow \infty} \mathbb{P}((X_1, \dots, X_n) \in A_n) = 1$.

The **information rate** H of the source is the infimum of all rates at which it is reliably encodable.

The idea is that we agree to encode faithfully only the messages in A_n , which takes $\log |A_n|$ bits, and accept a vanishing probability of complete failure otherwise. Since $A_n = \mathcal{A}^n$ always works, $H \leq \log |\mathcal{A}|$; and clearly $H \geq 0$. Both extremes occur.

Before going further, a piece of notation which is easy to misread. If X is a discrete random variable with probability mass function $p_X(x) = \mathbb{P}(X = x)$, then $p(X)$ denotes the composite $p_X \circ X$, that is, the random variable

$$\omega \mapsto \mathbb{P}(X = X(\omega)).$$

It is the ‘probability of what actually happened’. Similarly, given a tuple of random variables $X^{(n)} = (X_1, \dots, X_n)$, we write $p(X^{(n)})$ for

$$\omega \mapsto \mathbb{P}(X_1 = X_1(\omega), \dots, X_n = X_n(\omega)).$$

With this notation, $H(X) = \mathbb{E}[-\log p(X)]$.

Example 28.4.4

Let $\mathcal{A} = \{A, B, C\}$ and suppose that $X^{(2)} = (X_1, X_2)$ takes the six values

$$AB, \quad AC, \quad BC, \quad BA, \quad CA, \quad CB$$

with probabilities 0.3, 0.1, 0.1, 0.2, 0.25, 0.05 respectively. Then $p_{X^{(2)}}(AB) = 0.3$ and so on, so the random variable $p(X^{(2)})$ takes the value 0.3 with probability 0.3, the value 0.1 with probability 0.2 (there are two outcomes of probability 0.1), the value 0.2 with probability 0.2, and so on.

Recall from IA Probability that $X_n \rightarrow L$ **in probability**, written $X_n \xrightarrow{\mathbb{P}} L$, if $\mathbb{P}(|X_n - L| > \varepsilon) \rightarrow 0$ for every $\varepsilon > 0$, and that the weak law of large numbers says that if $Y_1, Y_2, \dots$ are i.i.d. real random variables with finite mean then $\frac{1}{n} \sum_{i \leq n} Y_i \xrightarrow{\mathbb{P}} \mathbb{E}[Y_1]$.

Example 28.4.5

Let $X_1, X_2, \dots$ be a Bernoulli source. Then $p(X_1), p(X_2), \dots$ are i.i.d., and by independence

$$p(X_1, \dots, X_n) = p(X_1)p(X_2) \cdots p(X_n).$$

Applying the weak law to the i.i.d. variables $-\log p(X_i)$,

$$-\frac{1}{n} \log p(X_1, \dots, X_n) = -\frac{1}{n} \sum_{i=1}^n \log p(X_i) \xrightarrow{\mathbb{P}} \mathbb{E}[-\log p(X_1)] = H(X_1).$$

This last observation is the key to everything in this section, and it deserves a name; but first let us see that it gives the right answer for Bernoulli sources by an elementary route.

Lemma 28.4.6

The information rate of a Bernoulli source $X_1, X_2, \dots$ is at most the expected word length of an optimal binary code c for X_1 .

Proof. Let L_i be the length of the codeword $c(X_i)$, so the L_i are i.i.d. with mean $\mathbb{E}[L_1]$. Fix $\varepsilon > 0$ and let

$$A_n = \{x \in \mathcal{A}^n : c^*(x) \text{ has length} < n(\mathbb{E}[L_1] + \varepsilon)\}.$$

Then

$$\mathbb{P}((X_1, \dots, X_n) \in A_n) = \mathbb{P}\left(\frac{1}{n} \sum_{i=1}^n L_i < \mathbb{E}[L_1] + \varepsilon\right) \rightarrow 1$$

by the weak law. Since c is decipherable, c^* is injective, and there are fewer than $2^{n(\mathbb{E}[L_1] + \varepsilon) + 1}$ binary strings of length less than $n(\mathbb{E}[L_1] + \varepsilon)$; so

$$|A_n| \leq 2^{n(\mathbb{E}[L_1] + \varepsilon) + 1}.$$

Enlarging A_n if necessary so that $|A_n| = \lfloor 2^{n(\mathbb{E}[L_1] + \varepsilon)} \rfloor$ (which only helps condition (ii)), we get $\frac{1}{n} \log |A_n| \rightarrow \mathbb{E}[L_1] + \varepsilon$. Hence the source is reliably encodable at rate $\mathbb{E}[L_1] + \varepsilon$ for every $\varepsilon > 0$, and the result follows. $\square$

Corollary 28.4.7

A Bernoulli source has information rate $H < H(X_1) + 1$.

Proof. Combine Lemma 28.4.6 with the upper bound in Shannon's noiseless coding theorem (Theorem 28.2.15). $\square$

The '+1' is the same waste we met before, and the same trick removes it. Suppose we encode in blocks of size N : set $Y_1 = (X_1, \dots, X_N)$, $Y_2 = (X_{N+1}, \dots, X_{2N})$ and so on, giving a source over the alphabet $\mathcal{A}^N$. One checks directly from the definition that if (X_i) has information rate H then (Y_j) has information rate NH .

Proposition 28.4.8

The information rate H of a Bernoulli source satisfies $H \leq H(X_1)$.

Proof. The blocked source (Y_j) is again Bernoulli, so Corollary 28.4.7 applies to it:

$$NH < H(Y_1) + 1 = H(X_1, \dots, X_N) + 1 = NH(X_1) + 1,$$

the last equality by independence and Lemma 28.2.22 (with equality since the X_i are independent). Dividing by N gives $H < H(X_1) + \frac{1}{N}$ for every N . $\square$

§28.4.2 The Asymptotic Equipartition Property

Example 28.4.5 isolates exactly the property we need, and it is worth abstracting.

Definition 28.4.9 (AEP)

A source $X_1, X_2, \dots$ satisfies the **asymptotic equipartition property** (AEP) with constant $H \geq 0$ if

$$-\frac{1}{n} \log p(X_1, \dots, X_n) \xrightarrow{\mathbb{P}} H.$$

Example 28.4.10

Toss a biased coin with $\mathbb{P}(\text{head}) = q$, and let $X_1, X_2, \dots$ record the results. After N tosses we expect about qN heads, and any *particular* sequence with exactly qN heads has probability

$$q^{qN} (1-q)^{(1-q)N} = 2^{N(q \log q + (1-q) \log(1-q))} = 2^{-NH(q)}.$$

Not every sequence looks like this; but the atypical ones carry vanishing total probability. So with high probability we see a ‘typical sequence’, and typical sequences are all roughly *equally likely*, each with probability about $2^{-NH(q)}$. This is what the name is describing: the probability mass is asymptotically spread evenly over about 2^{NH} sequences.

That reformulation is worth recording precisely.

Lemma 28.4.11

A source satisfies the AEP with constant H if and only if for every $\varepsilon > 0$ there is n_0 such that for all $n \geq n_0$ there is a **typical set** $T_n \subseteq \mathcal{A}^n$ with

- (i) $\mathbb{P}((X_1, \dots, X_n) \in T_n) > 1 - \varepsilon$;
- (ii) $2^{-n(H+\varepsilon)} \leq p(x_1, \dots, x_n) \leq 2^{-n(H-\varepsilon)}$ for all $(x_1, \dots, x_n) \in T_n$.

Proof. Suppose the AEP holds and let $\varepsilon > 0$. Define

$$T_n = \left\{ (x_1, \dots, x_n) : \left| -\frac{1}{n} \log p(x_1, \dots, x_n) - H \right| \leq \varepsilon \right\},$$

which is precisely the set on which (ii) holds. By convergence in probability, $\mathbb{P}((X_1, \dots, X_n) \in T_n) \rightarrow 1$, so (i) holds for n large.

Conversely, given such sets T_n , for any $\varepsilon > 0$ we have

$$\mathbb{P}\left(\left|-\frac{1}{n} \log p(X_1, \dots, X_n) - H\right| \leq \varepsilon\right) \geq \mathbb{P}((X_1, \dots, X_n) \in T_n) > 1 - \varepsilon$$

for $n \geq n_0(\varepsilon)$, which is convergence in probability. $\square$

§28.4.3 Shannon's First Coding Theorem

Theorem 28.4.12 (Shannon's First Coding Theorem)

A source satisfying the AEP with constant H has information rate exactly H .

Proof. Rate H is achievable. Let $\varepsilon > 0$ and take typical sets T_n as in Lemma 28.4.11. For $n \geq n_0(\varepsilon)$ and $(x_1, \dots, x_n) \in T_n$ we have $p(x_1, \dots, x_n) \geq 2^{-n(H+\varepsilon)}$, so

$$1 \geq \mathbb{P}(T_n) \geq |T_n| 2^{-n(H+\varepsilon)}, \quad \text{giving} \quad \frac{1}{n} \log |T_n| \leq H + \varepsilon.$$

Taking $A_n = T_n$ (padded if necessary so that the limit in (i) exists and equals $H + \varepsilon$) shows that the source is reliably encodable at rate $H + \varepsilon$. As $\varepsilon > 0$ was arbitrary, the information rate is at most H .

No smaller rate is achievable. If $H = 0$ there is nothing to prove, so assume $H > 0$ and let $0 < \varepsilon < \frac{H}{2}$. Suppose for contradiction that the source is reliably encodable at rate $H - 2\varepsilon$, witnessed by sets A_n . Let T_n be typical sets for this ε . For $(x_1, \dots, x_n) \in T_n$ we have $p(x_1, \dots, x_n) \leq 2^{-n(H-\varepsilon)}$, so

$$\mathbb{P}((X_1, \dots, X_n) \in A_n \cap T_n) \leq |A_n| 2^{-n(H-\varepsilon)},$$

and hence

$$\frac{1}{n} \log \mathbb{P}(A_n \cap T_n) \leq -(H - \varepsilon) + \frac{1}{n} \log |A_n| \rightarrow -(H - \varepsilon) + (H - 2\varepsilon) = -\varepsilon.$$

Therefore $\log \mathbb{P}(A_n \cap T_n) \rightarrow -\infty$, so $\mathbb{P}(A_n \cap T_n) \rightarrow 0$. But

$$\mathbb{P}(T_n) \leq \mathbb{P}(A_n \cap T_n) + \mathbb{P}(\mathcal{A}^n \setminus A_n) \rightarrow 0 + 0 = 0,$$

contradicting $\mathbb{P}(T_n) > 1 - \varepsilon$. So the information rate is at least H . $\square$

Corollary 28.4.13

A Bernoulli source has information rate exactly $H(X_1)$.

Proof. Example 28.4.5 verifies the AEP with constant $H(X_1)$. $\square$

Remark. The theorem is not merely an existence statement; it comes with a coding scheme. Encode the typical sequences with a block code of length $\lceil n(H + \varepsilon) \rceil$, and encode the atypical sequences however you like (say, by a reserved escape symbol followed by the raw string). The scheme fails with vanishing probability and costs $H + \varepsilon$ bits per symbol.

Many non-Bernoulli sources also satisfy the AEP. Under suitable hypotheses – for in-

stance for a stationary ergodic source – the sequence $\frac{1}{n}H(X_1, \dots, X_n)$ is decreasing, and the AEP holds with $H = \lim_n \frac{1}{n}H(X_1, \dots, X_n)$. This is what makes the theory applicable to real text.

§28.4.4 Capacity of the Binary Symmetric Channel

We now turn to the channel side. Recall the definitions from Section 1: a code of length n is $C \subseteq \mathcal{A}^n$, its rate is $\rho(C) = \frac{\log|C|}{n}$, its error rate is $\hat{e}(C) = \max_{c \in C} \mathbb{P}(\text{error} \mid c \text{ sent})$, and the capacity is the supremum of rates at which reliable transmission is possible.

As a warm-up – and because it shows exactly where the GSV bound earns its keep – let us prove directly that a reasonably good binary symmetric channel has positive capacity.

Lemma 28.4.14

Let $\varepsilon > 0$ and let a BSC with error probability p be used n times. Then

$$\lim_{n \rightarrow \infty} \mathbb{P}(\text{the channel makes at least } n(p + \varepsilon) \text{ errors}) = 0.$$

Proof. Let U_i be the indicator that the i th digit is mistransmitted. The U_i are i.i.d. with $\mathbb{E}[U_i] = p$, and

$$\mathbb{P}\left(\sum_{i=1}^n U_i \geq n(p + \varepsilon)\right) \leq \mathbb{P}\left(\left|\frac{1}{n} \sum_{i=1}^n U_i - p\right| \geq \varepsilon\right) \rightarrow 0$$

by the weak law of large numbers. □

Proposition 28.4.15

A binary symmetric channel with error probability $p < \frac{1}{4}$ has nonzero capacity.

Proof. Choose δ with $2p < \delta < \frac{1}{2}$; this is possible precisely because $p < \frac{1}{4}$. We claim we can transmit reliably at rate $R = 1 - H(\delta) > 0$.

Let C_n be an $[n, A(n, \lfloor n\delta \rfloor), \lfloor n\delta \rfloor]$ -code of maximal size. By the GSV bound and Proposition 28.3.25,

$$|C_n| = A(n, \lfloor n\delta \rfloor) \geq 2^{n(1-H(\delta))} = 2^{nR},$$

and passing to a subcode we may assume $|C_n| = \lfloor 2^{nR} \rfloor$, still with minimum distance at least $\lfloor n\delta \rfloor$. Using minimum distance decoding, an error occurs only if the channel makes more than $\lfloor \frac{\lfloor n\delta \rfloor - 1}{2} \rfloor$ errors, so

$$\hat{e}(C_n) \leq \mathbb{P}\left(\text{at least } \frac{n\delta - 1}{2} \text{ errors in } n \text{ uses}\right).$$

Now pick $\varepsilon > 0$ with $p + \varepsilon < \frac{\delta}{2}$, which is possible as $2p < \delta$. For large n ,

$$\frac{n\delta - 1}{2} = n\left(\frac{\delta}{2} - \frac{1}{2n}\right) > n(p + \varepsilon),$$

so $\hat{e}(C_n) \leq \mathbb{P}(\text{at least } n(p + \varepsilon) \text{ errors}) \rightarrow 0$ by Lemma 28.4.14. Since $\rho(C_n) \rightarrow R$, we are done. $\square$

This is already remarkable, but the constant is wrong: the answer is not $1 - H(\delta)$ for some $\delta > 2p$, and the restriction $p < \frac{1}{4}$ is an artefact. To get the truth we need a more delicate measure of how much a channel destroys.

§28.4.5 Conditional Entropy and Fano's Inequality

Definition 28.4.16 (Conditional Entropy)

Let X, Y take values in $\mathcal{A}, \mathcal{B}$. The **conditional entropy** of X given $Y = y$ is

$$H(X | Y = y) = - \sum_{x \in \mathcal{A}} \mathbb{P}(X = x | Y = y) \log \mathbb{P}(X = x | Y = y),$$

and the **conditional entropy** of X given Y is

$$H(X | Y) = \sum_{y \in \mathcal{B}} \mathbb{P}(Y = y) H(X | Y = y).$$

Clearly $H(X | Y) \geq 0$. It measures how much uncertainty about X remains once Y is known.

Lemma 28.4.17 (Chain Rule)

$$H(X, Y) = H(X | Y) + H(Y).$$

Proof. Expanding the definition and writing $\mathbb{P}(X = x | Y = y)\mathbb{P}(Y = y) = \mathbb{P}(X = x, Y = y)$,

$$\begin{aligned} H(X | Y) &= - \sum_y \sum_x \mathbb{P}(X = x, Y = y) \log \frac{\mathbb{P}(X = x, Y = y)}{\mathbb{P}(Y = y)} \\ &= - \sum_y \sum_x \mathbb{P}(X = x, Y = y) \log \mathbb{P}(X = x, Y = y) \\ &\quad + \sum_y \left(\sum_x \mathbb{P}(X = x, Y = y) \right) \log \mathbb{P}(Y = y) \\ &= H(X, Y) + \sum_y \mathbb{P}(Y = y) \log \mathbb{P}(Y = y) = H(X, Y) - H(Y). \square \end{aligned}$$

Example 28.4.18

Let X be uniform on $\{1, \dots, 6\}$, modelling a die, and let Y be 0 if X is even and 1 if X is odd. Then Y is a function of X , so $H(X, Y) = H(X) = \log 6$, and $H(Y) = \log 2 = 1$. The chain rule gives $H(X | Y) = \log 6 - \log 2 = \log 3$, which is right: knowing the parity leaves three equally likely values. Applying the chain rule the other way round, $H(Y | X) = H(X, Y) - H(X) = 0$, as it must be.

Corollary 28.4.19

$H(X | Y) \leq H(X)$, with equality if and only if X and Y are independent.

Proof. Combine the chain rule with subadditivity (Lemma 28.2.22): $H(X | Y) = H(X, Y) - H(Y) \leq H(X)$, with the same equality condition. $\square$

Everything extends to tuples: replacing X by $X^{(r)} = (X_1, \dots, X_r)$ and Y by $Y^{(s)}$, we may speak of $H(X_1, \dots, X_r | Y_1, \dots, Y_s)$. One must read such expressions carefully: $H(X, Y | Z)$ is the entropy of the *pair* (X, Y) given Z , not the entropy of X together with the entropy of Y given Z .

Lemma 28.4.20

$H(X | Y) \leq H(X | Y, Z) + H(Z)$.

Proof. Expand $H(X, Y, Z)$ in two ways using the chain rule:

$$H(Z | X, Y) + \underbrace{H(X | Y) + H(Y)}_{H(X, Y)} = H(X, Y, Z) = H(X | Y, Z) + \underbrace{H(Z | Y) + H(Y)}_{H(Y, Z)}.$$

Since $H(Z | X, Y) \geq 0$ we get $H(X | Y) \leq H(X | Y, Z) + H(Z | Y)$, and $H(Z | Y) \leq H(Z)$ by Corollary 28.4.19. $\square$

Now for the key estimate. Think of X as what was sent and Y as what was decoded; then $p = \mathbb{P}(X \neq Y)$ is the probability of error, and Fano's inequality bounds how much uncertainty can remain.

Proposition 28.4.21 (Fano's Inequality)

Let X, Y take values in an alphabet $\mathcal{A}$ with $|\mathcal{A}| = m \geq 2$, and let $p = \mathbb{P}(X \neq Y)$. Then

$$H(X | Y) \leq H(p) + p \log(m - 1).$$

Proof. Let Z be the indicator of the event $X \neq Y$, so $H(Z) = H(p)$. By Lemma 28.4.20 it suffices to show $H(X | Y, Z) \leq p \log(m - 1)$.

If $Z = 0$ then $X = Y$, so $H(X | Y = y, Z = 0) = 0$. If $Z = 1$ then X is one of the $m - 1$ values other than y , so $H(X | Y = y, Z = 1) \leq \log(m - 1)$. Hence

$$\begin{aligned} H(X | Y, Z) &= \sum_{y \in \mathcal{A}} \sum_{z \in \{0,1\}} \mathbb{P}(Y = y, Z = z) H(X | Y = y, Z = z) \\ &\leq \sum_{y \in \mathcal{A}} \mathbb{P}(Y = y, Z = 1) \log(m - 1) \\ &= \mathbb{P}(Z = 1) \log(m - 1) = p \log(m - 1). \square \end{aligned}$$

The two terms have a clean reading: $H(p)$ is the information needed to say *whether* an error occurred, and $p \log(m - 1)$ is the information needed to say *which* error it was, in the worst case.

§28.4.6 Mutual Information and Information Capacity

Definition 28.4.22 (Mutual Information)

The **mutual information** of X and Y is

$$I(X; Y) = H(X) - H(X | Y).$$

By the chain rule $I(X; Y) = H(X) + H(Y) - H(X, Y)$, from which it is visibly symmetric in X and Y , and non-negative by subadditivity, with $I(X; Y) = 0$ if and only if X and Y are independent. It measures how much knowing one variable tells us about the other – exactly the quantity a channel ought to be judged by.

Definition 28.4.23 (Information Capacity)

Let a discrete memoryless channel have input alphabet $\mathcal{A}$ and output alphabet $\mathcal{B}$. For a random variable X on $\mathcal{A}$, let Y be the resulting output. The **information capacity** of the channel is

$$C = \max_X I(X; Y),$$

the maximum being over all distributions of X on $\mathcal{A}$.

This maximum really is attained, since I is a continuous function of the input distribution $(p_1, \dots, p_m)$, which ranges over the compact simplex $\{p_i \geq 0, \sum p_i = 1\}$. Note that the information capacity depends only on the channel matrix, and is a finite computation; whereas the (operational) capacity of Section 1 is defined by a limiting process over all possible codes. The content of Shannon's second theorem is that they agree.

Theorem 28.4.24 (Shannon's Noisy Coding Theorem)

For a discrete memoryless channel, the operational capacity equals the information capacity.

We shall prove the inequality 'operational $\leq$ information' in general, and the reverse inequality for the binary symmetric channel. First, let us see what the theorem buys us.

Example 28.4.25 (i) *The binary symmetric channel with error probability p .* Let $\mathbb{P}(X = 0) = \alpha$. Given X , the output differs from the input with probability p regardless, so $H(Y | X = 0) = H(Y | X = 1) = H(p)$ and hence $H(Y | X) = H(p)$. Also $\mathbb{P}(Y = 0) = \alpha(1 - p) + (1 - \alpha)p$. Therefore

$$\begin{aligned} C &= \max_{\alpha} [H(Y) - H(Y | X)] \\ &= \max_{\alpha} [H(\alpha(1 - p) + (1 - \alpha)p) - H(p)] = 1 - H(p), \end{aligned}$$

the maximum being at $\alpha = \frac{1}{2}$, when the argument of the outer H is $\frac{1}{2}$. So

$$C = 1 + p \log p + (1 - p) \log(1 - p).$$

If $p = 0$ or $p = 1$ then $C = 1$; if $p = \frac{1}{2}$ then $C = 0$, confirming that such a channel is useless.

- (ii) *The binary erasure channel with erasure probability p .* Here it is easier to compute $I(Y; X) = H(X) - H(X | Y)$. With $\mathbb{P}(X = 0) = \alpha$, receiving 0 or 1 determines X , so $H(X | Y = 0) = H(X | Y = 1) = 0$, while $H(X | Y = \star) = H(\alpha)$. As $\mathbb{P}(Y = \star) = p$,

$$C = \max_{\alpha} [H(\alpha) - pH(\alpha)] = (1 - p) \max_{\alpha} H(\alpha) = 1 - p,$$

again at $\alpha = \frac{1}{2}$. This is exactly what one would guess: a fraction p of the transmissions is simply lost.

Note the strength of the first computation. A channel that flips one bit in ten has capacity $1 - H(0.1) = 0.531$, so we can push more than half a bit of genuine information through each use of it, with arbitrarily small error probability.

Lemma 28.4.26

If a discrete memoryless channel has information capacity C , its n th extension has information capacity nC .

Proof. Let $X_1, \dots, X_n$ be the input and $Y_1, \dots, Y_n$ the output. Because the channel is memoryless, Y_i depends only on X_i , so

$$H(Y_1, \dots, Y_n | X_1, \dots, X_n) = \sum_{i=1}^n H(Y_i | X_1, \dots, X_n) = \sum_{i=1}^n H(Y_i | X_i).$$

Hence, using subadditivity for the first term,

$$\begin{aligned} I(X_1, \dots, X_n; Y_1, \dots, Y_n) &= H(Y_1, \dots, Y_n) - H(Y_1, \dots, Y_n | X_1, \dots, X_n) \\ &\leq \sum_{i=1}^n H(Y_i) - \sum_{i=1}^n H(Y_i | X_i) = \sum_{i=1}^n I(X_i; Y_i) \leq nC. \end{aligned}$$

Conversely, take the X_i independent and each achieving $I(X_i; Y_i) = C$. Then the Y_i are independent too, so $H(Y_1, \dots, Y_n) = \sum_i H(Y_i)$ and the first inequality is an equality. Hence the maximum is exactly nC . $\square$

§28.4.7 Proof of the Noisy Coding Theorem

We begin with the converse, which holds for any discrete memoryless channel.

Proposition 28.4.27 (Converse to the Noisy Coding Theorem)

The operational capacity of a discrete memoryless channel is at most its information capacity C .

Proof. Suppose, for contradiction, that reliable transmission is possible at some rate $R > C$. Then there are codes C_n of length n and size $\lfloor 2^{nR} \rfloor$ with $\rho(C_n) \rightarrow R$ and $\hat{e}(C_n) \rightarrow 0$.

Introduce the **average error rate**

$$e(C_n) = \frac{1}{|C_n|} \sum_{c \in C_n} \mathbb{P}(\text{error} \mid c \text{ sent}) \leq \hat{e}(C_n),$$

so $e(C_n) \rightarrow 0$ as well. Let X be uniform on C_n , let Y be the channel output, and let $\hat{X}$ be the decoded codeword; write $p = e(C_n) = \mathbb{P}(X \neq \hat{X})$.

Since X is uniform, $H(X) = \log|C_n| = \log\lfloor 2^{nR} \rfloor \geq nR - 1$ for n large. By Fano's inequality applied to X and $\hat{X}$, and then the fact that $\hat{X}$ is a function of Y (so conditioning on Y can only be more informative),

$$H(X \mid Y) \leq H(X \mid \hat{X}) \leq H(p) + p \log(|C_n| - 1) \leq 1 + pnR.$$

Therefore, using Lemma 28.4.26 for the n th extension,

$$nC \geq I(X; Y) = H(X) - H(X \mid Y) \geq (nR - 1) - (1 + pnR),$$

so that

$$pnR \geq n(R - C) - 2, \quad \text{that is} \quad p \geq \frac{n(R - C) - 2}{nR} \rightarrow \frac{R - C}{R} > 0.$$

This contradicts $p = e(C_n) \rightarrow 0$. Hence no rate above C is achievable. $\square$

The direct half is the celebrated one, and Shannon's proof is a masterpiece of the probabilistic method: rather than constructing a good code, we pick one at random and show that the average is good enough.

Proposition 28.4.28

Let a BSC have error probability p , and let $R < 1 - H(p)$. Then there are codes C_n of length n and size $\lfloor 2^{nR} \rfloor$ with $\rho(C_n) \rightarrow R$ and $e(C_n) \rightarrow 0$.

Note that this concerns the *average* error rate e ; we shall upgrade to $\hat{e}$ afterwards.

Proof. Without loss of generality $p < \frac{1}{2}$. Choose $\varepsilon > 0$ small enough that $p + \varepsilon < \frac{1}{2}$ and $R < 1 - H(p + \varepsilon)$; this is possible by continuity of H . Put $m = \lfloor 2^{nR} \rfloor$ and $r = \lfloor n(p + \varepsilon) \rfloor$. We use minimum distance decoding, breaking ties arbitrarily.

Let $\mathcal{C}$ be the set of all $[n, m]$ -codes, so $|\mathcal{C}| = \binom{2^n}{m}$, and choose $C = \{c_1, \dots, c_m\}$ from $\mathcal{C}$ uniformly at random. Choose $i \in \{1, \dots, m\}$ uniformly at random too, send c_i , and let Y be the output. Then

$$\mathbb{P}(Y \text{ not decoded as } c_i) = \frac{1}{|\mathcal{C}|} \sum_{C \in \mathcal{C}} e(C),$$

so there exists some $C_n \in \mathcal{C}$ with $e(C_n)$ at most this average. It therefore suffices to show that the left hand side tends to 0.

If $B(Y, r) \cap C = \{c_i\}$ then Y is certainly decoded as c_i , so

$$\mathbb{P}(Y \text{ not decoded as } c_i) \leq \mathbb{P}(c_i \notin B(Y, r)) + \mathbb{P}(B(Y, r) \cap C \supsetneq \{c_i\}),$$

and we handle the two terms separately.

The first term is $\mathbb{P}(d(c_i, Y) > r)$, which is the probability that the channel makes more than $n(p + \varepsilon)$ errors; this tends to 0 by Lemma 28.4.14.

For the second term, condition on Y and on c_i . Given that $c_i \in B(Y, r)$, each of the other $m - 1$ codewords is uniform over the remaining $2^n - 1$ words, so

$$\mathbb{P}(c_j \in B(Y, r) \mid c_i \in B(Y, r)) = \frac{V(n, r) - 1}{2^n - 1} \leq \frac{V(n, r)}{2^n}$$

for $j \neq i$. Hence, by a union bound and Proposition 28.3.25(i),

$$\begin{aligned} \mathbb{P}(B(Y, r) \cap C \not\supseteq \{c_i\}) &\leq \sum_{j \neq i} \mathbb{P}(c_j \in B(Y, r) \mid c_i \in B(Y, r)) \\ &\leq (m - 1) \frac{V(n, r)}{2^n} \leq 2^{nR} 2^{nH(p+\varepsilon)} 2^{-n} \\ &= 2^{-n(1-H(p+\varepsilon)-R)} \longrightarrow 0, \end{aligned}$$

because $R < 1 - H(p + \varepsilon)$. This completes the proof. $\square$

Proposition 28.4.29

In Proposition 28.4.28 we may replace e by $\hat{e}$.

Proof. Choose R' with $R < R' < 1 - H(p)$ and apply the previous proposition to R' , obtaining codes C'_n of size $\lfloor 2^{nR'} \rfloor$ with $e(C'_n) \rightarrow 0$. Order the codewords of C'_n by their individual error probabilities and delete the worse half, giving a code C''_n . If more than half the codewords had error probability exceeding $2e(C'_n)$ the average would exceed $e(C'_n)$; so $\hat{e}(C''_n) \leq 2e(C'_n) \rightarrow 0$. Now C''_n has size $\frac{1}{2} \lfloor 2^{nR'} \rfloor \geq 2^{nR}$ for large n , since $2^{nR'-1} = 2^{n(R'-1/n)} \geq 2^{nR}$ eventually. Passing to a subcode of size exactly $\lfloor 2^{nR} \rfloor$ can only decrease $\hat{e}$, and gives $\rho \rightarrow R$. $\square$

Putting the two halves together: the binary symmetric channel with error probability p has operational capacity exactly $1 - H(p)$, which by Example 28.4.25 is also its information capacity. This is Theorem 28.4.24 for the BSC.

Remark. The proof is purely existential. It tells us that almost every code of the right size is good, but it gives no way of writing one down, and no way of decoding one efficiently even if we could – minimum distance decoding over 2^{nR} codewords is hopeless. Finding explicit families of codes approaching capacity, with practical decoding algorithms, took another fifty years. The rest of these notes on coding theory is about algebraic constructions which are far from optimal but eminently practical.

§28.4.8 An Aside: the Kelly Criterion

Entropy turns up in places that have nothing obviously to do with communication. Here is one, included because it is charming and because it was lectured.

Suppose a biased coin with $\mathbb{P}(\text{head}) = p$ is tossed repeatedly, and that before each toss we may stake money on heads at odds u : a stake of k returns ku if the coin comes up heads and nothing otherwise. Start with a bankroll $X_0 = 1$ and bet a fixed fraction

$w \in [0, 1)$ of the current bankroll each time, so

$$X_{n+1} = \begin{cases} X_n(wu + (1-w)) & \text{if toss } n+1 \text{ is a head,} \\ X_n(1-w) & \text{otherwise.} \end{cases}$$

Then $Y_{n+1} = X_{n+1}/X_n$ are i.i.d., and $\log X_n = \sum_{i=1}^n \log Y_i$ is a sum of i.i.d. terms.

Lemma 28.4.30

Let $\mu = \mathbb{E}[\log Y_1]$ and $\sigma^2 = \text{Var}(\log Y_1)$. Then for $a > 0$,

$$\mathbb{P}\left(\left|\frac{\log X_n}{n} - \mu\right| \geq a\right) = \mathbb{P}\left(\left|\frac{1}{n} \sum_{i=1}^n \log Y_i - \mu\right| \geq a\right) \leq \frac{\sigma^2}{na^2}.$$

In particular, for any $\varepsilon, \delta > 0$ there is N with $\mathbb{P}(|\frac{\log X_n}{n} - \mu| \geq \delta) \leq \varepsilon$ for all $n \geq N$.

Proof. Immediate from Chebyshev's inequality applied to the sample mean. $\square$

So the bankroll behaves like $2^{n\mu}$, and to do well in the long run we should maximise μ rather than the expected return. Now

$$\mu = \mathbb{E}[\log Y] = p \log(1 + (u-1)w) + (1-p) \log(1-w).$$

Differentiating with respect to w and setting the result to zero, one finds that μ is maximised at $w = 0$ if $up \leq 1$ (the bet is not worth taking) and at

$$w = \frac{up - 1}{u - 1}$$

if $up > 1$. This is **Kelly's criterion**. Writing $q = 1 - p$ and substituting the optimal w ,

$$\mathbb{E}[\log Y] = p \log p + q \log q + \log u - q \log(u-1) = -H(p) + \log u - q \log(u-1).$$

Entropy has appeared, and it is exactly the penalty paid for the randomness of the coin. Betting below the Kelly fraction still grows the bankroll, but more slowly; betting sufficiently far above it makes the bankroll tend to zero almost surely, however favourable the odds.

§28.5 Linear Codes

Shannon's theorem guarantees good codes but produces none, and even if it did we could not use them, because minimum distance decoding over an unstructured code of size 2^{nR} is computationally hopeless. The way out is to insist that our codes be *linear subspaces*, at which point all the machinery of IB Linear Algebra becomes available and both encoding and decoding become matrix arithmetic.

§28.5.1 Linear Codes, Generator and Parity Check Matrices

Definition 28.5.1 (Linear Code)

A binary code $C \subseteq \mathbb{F}_2^n$ is **linear** if $0 \in C$ and $x + y \in C$ whenever $x, y \in C$; equivalently, if C is a vector subspace of $\mathbb{F}_2^n$.

Definition 28.5.2 (Rank)

The **rank** of a linear code C is its dimension as an $\mathbb{F}_2$ -vector space. A linear code of length n and rank k is an **(n, k) -code**; if its minimum distance is d it is an **(n, k, d) -code**.

We use round brackets for linear codes and square brackets for general ones. If $v_1, \dots, v_k$ is a basis then every codeword is uniquely $\sum \lambda_i v_i$ with $\lambda_i \in \mathbb{F}_2$, so $|C| = 2^k$. Thus an (n, k) -code is an $[n, 2^k]$ -code, and its information rate is $\frac{k}{n}$ – a pleasantly simple formula.

Definition 28.5.3 (Weight)

The **weight** of $x \in \mathbb{F}_2^n$ is $w(x) = d(x, 0)$, the number of nonzero digits.

Lemma 28.5.4

The minimum distance of a linear code equals the minimum weight of a nonzero codeword.

Proof. For $x, y \in \mathbb{F}_2^n$ we have $d(x, y) = d(x + y, 0) = w(x + y)$, since over $\mathbb{F}_2$ subtraction is addition. If C is linear and $x, y \in C$ are distinct then $x + y$ is a nonzero codeword, and conversely every nonzero codeword z arises as $z = z + 0$. So the two minima are over the same set of numbers. $\square$

This is already a large saving: computing $d(C)$ naively requires $\binom{2^k}{2}$ comparisons, but for a linear code only $2^k - 1$ weights.

Definition 28.5.5 (Dot Product, Dual Code)

For $x, y \in \mathbb{F}_2^n$ set $x \cdot y = \sum_{i=1}^n x_i y_i \in \mathbb{F}_2$; this is symmetric and bilinear. Given $P \subseteq \mathbb{F}_2^n$, the **parity check code** defined by P is

$$C = \{x \in \mathbb{F}_2^n : p \cdot x = 0 \text{ for all } p \in P\}.$$

For a linear code C , the **dual code** is

$$C^\perp = \{x \in \mathbb{F}_2^n : x \cdot y = 0 \text{ for all } y \in C\}.$$

A warning: this bilinear form is not an inner product, since $x \cdot x = 0$ for any x of even weight. In particular $C \cap C^\perp$ need not be $\{0\}$, and a code can even be *self-dual*.

Example 28.5.6 (i) $P = \{11 \dots 1\}$ gives the simple parity check code.

(ii) $P = \{1010101, 0110011, 0001111\}$ gives Hamming's original $[7, 16, 3]$ -code of Example 28.3.8.

(iii) If C is linear then so are the parity check extension C^+ and any punctured code C^- .

Lemma 28.5.7

Every parity check code is linear.

Proof. $p \cdot 0 = 0$, and if $p \cdot x = p \cdot y = 0$ then $p \cdot (x + y) = 0$ by bilinearity. $\square$

In particular $C^\perp$ is always linear. We shall shortly see the converse: every linear code is a parity check code.

Definition 28.5.8 (Generator and Parity Check Matrices)

Let C be an (n, k) -code. A **generator matrix** for C is a $k \times n$ matrix G whose rows form a basis of C . A **parity check matrix** for C is a generator matrix H for $C^\perp$; we shall see it is an $(n - k) \times n$ matrix.

The two matrices give two descriptions of the same code: codewords are the linear combinations of rows of G , and also the linear dependence relations among the columns of H ,

$$C = \{x \in \mathbb{F}_2^n : Hx = 0\},$$

where we regard x as a column vector. Encoding uses G and decoding uses H .

Definition 28.5.9 (Syndrome)

Let C be a linear code with parity check matrix H . The **syndrome** of $x \in \mathbb{F}_2^n$ is $Hx \in \mathbb{F}_2^{n-k}$.

Here is the point. Suppose we receive $x = c + z$ where $c \in C$ and z is the error pattern. Since $Hc = 0$,

$$Hx = Hz,$$

so the syndrome depends only on the error, not on the codeword that was sent. If C is e -error correcting we may precompute Hx for every x with $w(x) \leq e$ – there are $V(n, e)$ of them, far fewer than 2^k codewords in general – and store the results in a table. On receiving x we compute Hx , look it up, and decode as $c = x - z$. The cost of decoding is one matrix multiplication and one table lookup.

More generally, two words have the same syndrome exactly when they differ by a codeword, so the syndromes are in bijection with the cosets of C in $\mathbb{F}_2^n$. Minimum distance decoding amounts to choosing, in each coset, a word of least weight – a **coset leader** – and subtracting it. Displaying the cosets as the rows of an array gives the classical picture.

z	coset $z + C$				$H z$
0	0	c_2	$\cdots$	c_m	0
z_2	z_2	$z_2 + c_2$	$\cdots$	$z_2 + c_m$	s_2
z_3	z_3	$z_3 + c_2$	$\cdots$	$z_3 + c_m$	s_3
$\vdots$	$\vdots$	$\vdots$		$\vdots$	$\vdots$
z_t	z_t	$z_t + c_2$	$\cdots$	$z_t + c_m$	s_t

The first row is the code itself; the leftmost column holds the coset leaders; the rightmost column holds the syndromes, and it is the only column we need to store. On receiving x we find the row with syndrome Hx and subtract its leader.

Definition 28.5.10 (Equivalence)

Codes $C_1, C_2 \subseteq \mathbb{F}_2^n$ are **equivalent** if some permutation of the n coordinates carries C_1 onto C_2 .

Equivalent codes have the same length, size and minimum distance, so we generally work up to equivalence.

Lemma 28.5.11

Every (n, k) -code is equivalent to one with generator matrix in the **standard form**

$$G = (I_k \mid B)$$

for some $k \times (n - k)$ matrix B .

Proof. Let G be any generator matrix. Row operations do not change the row space, so by Gaussian elimination we may put G in row echelon form, with leading 1s in columns $\ell(1) < \ell(2) < \cdots < \ell(k)$. Permuting columns replaces C by an equivalent code, so we may assume $\ell(i) = i$. Further row operations clear the entries above the leading 1s, leaving $G = (I_k \mid B)$. $\square$

With G in standard form, a message $y \in \mathbb{F}_2^k$ (a row vector) is encoded as

$$yG = (y \mid yB),$$

that is, the message itself followed by $n - k$ **check digits**. Such an encoding is called **systematic**, and is convenient because the message can be read straight off the code-word.

Lemma 28.5.12

For a linear code $C \leq \mathbb{F}_2^n$, $\text{rank } C + \text{rank } C^\perp = n$.

Proof. This is the annihilator statement from IB Linear Algebra, but here is a direct argument. Passing to an equivalent code we may assume C has generator matrix $G = (I_k \mid B)$. Consider the linear map $\gamma: \mathbb{F}_2^n \rightarrow \mathbb{F}_2^k$, $x \mapsto Gx$. Since G contains I_k , its rows are linearly independent, so γ is surjective. Its kernel is exactly the set of x orthogonal to every row of G , that is, $C^\perp$. By rank-nullity,

$$n = \dim \ker \gamma + \dim \operatorname{img} \gamma = \operatorname{rank} C^\perp + k. \quad \square$$

Corollary 28.5.13

$(C^\perp)^\perp = C$. In particular every linear code is a parity check code, namely the one defined by $C^\perp$.

Proof. If $x \in C$ then $x \cdot y = 0$ for all $y \in C^\perp$ by definition, so $C \subseteq (C^\perp)^\perp$. Applying Lemma 28.5.12 twice,

$$\operatorname{rank}(C^\perp)^\perp = n - \operatorname{rank} C^\perp = n - (n - \operatorname{rank} C) = \operatorname{rank} C,$$

so the inclusion is an equality. $\square$

Lemma 28.5.14

If C has generator matrix $G = (I_k \mid B)$ then $H = (B^\top \mid I_{n-k})$ is a parity check matrix for C .

Proof. We compute

$$GH^\top = (I_k \mid B) \begin{pmatrix} B \\ I_{n-k} \end{pmatrix} = B + B = 0$$

over $\mathbb{F}_2$. So every row of H is orthogonal to every row of G , giving $\operatorname{rank} H \leq \dim C^\perp$ as subspaces; but H contains I_{n-k} , so $\operatorname{rank} H = n - k = \operatorname{rank} C^\perp$ by Lemma 28.5.12. Hence the rows of H are a basis of $C^\perp$. $\square$

The minimum distance can also be read off from H , which is often the most convenient way to compute it.

Lemma 28.5.15

Let C be a linear code with parity check matrix H . Then $d(C) = d$ if and only if some d columns of H are linearly dependent, but no $d - 1$ columns are.

Proof. A word x lies in C if and only if $Hx = 0$, that is, if and only if the columns of H indexed by the support of x sum to zero. So there is a nonzero codeword of weight w exactly when some w columns of H are linearly dependent. Now apply Lemma 28.5.4. $\square$

Example 28.5.16

Let C be the $(5, 2)$ -code with generator matrix

$$G = \begin{pmatrix} 1 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 & 1 \end{pmatrix} = (I_2 \ B), \quad B = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \end{pmatrix}.$$

Its four codewords are 00000, 10110, 01011, 11101, of weights 0, 3, 3, 4, so $d(C) = 3$ by Lemma 28.5.4 and C is a $(5, 2, 3)$ -code, correcting one error. By Lemma 28.5.14,

$$H = (B^\top \ I_3) = \begin{pmatrix} 1 & 0 & 1 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 \end{pmatrix},$$

and indeed no two columns of H are equal (so no two are dependent), while columns 1, 3, 4 sum to zero – these being the positions of the codeword 10110 – confirming $d = 3$ via Lemma 28.5.15.

The syndromes of the five single-bit errors are just the columns of H :

z	00000	10000	01000	00100	00010	00001	00101	10001
Hx	000	110	011	100	010	001	101	111

There are 8 syndromes and only 6 patterns of weight at most 1, so two cosets need leaders of weight 2; the last two columns give such a choice. Note the choice is not unique – the syndrome 101 also arises from 11000, and 111 from 01100 – which is Lemma 28.3.11 telling us that a code with $d = 3$ cannot correct two errors.

Let us decode. Suppose we receive $x = 10111$. Since Hx is the sum of the columns of H in the positions where x is nonzero, namely 1, 3, 4, 5, we compute

$$Hx = (1, 1, 0) + (1, 0, 0) + (0, 1, 0) + (0, 0, 1) = (0, 0, 1).$$

Looking up 001 in the table gives $z = 00001$, so we decode x as $10111 + 00001 = 10110$, which is a codeword as required.

§28.5.2 Hamming Codes

Lemma 28.5.15 makes the construction of 1-error correcting codes almost automatic. We need $d = 3$, so we need a parity check matrix whose columns are pairwise linearly independent; over $\mathbb{F}_2$ that just means the columns are nonzero and distinct. To get as many columns as possible for a given number of rows, we should use *all* of them.

Definition 28.5.17 (Hamming Code)

Let $d \geq 2$ and $n = 2^d - 1$. Let H be the $d \times n$ matrix whose columns are the n nonzero elements of $\mathbb{F}_2^d$, in some order. The **Hamming $(n, n - d)$ -code** is the linear code with parity check matrix H .

Lemma 28.5.18

The Hamming $(n, n - d)$ -code has minimum distance 3 and is a perfect 1-error correcting code.

Proof. The columns of H are distinct and nonzero, so no two are dependent; and any three columns $u, v, u + v$ are dependent, and such a triple exists as soon as $d \geq 2$. By Lemma 28.5.15, $d(C) = 3$, so C corrects $\lfloor \frac{3-1}{2} \rfloor = 1$ error. Finally

$$\frac{2^n}{V(n, 1)} = \frac{2^n}{1 + n} = \frac{2^n}{2^d} = 2^{n-d} = |C|,$$

so C is perfect. $\square$

If the columns of H are listed in the order $1, 2, \dots, n$ read as binary numbers, then the syndrome of a single error in position i is the binary expansion of i , and decoding is instantaneous: compute the syndrome, read it as a number, and flip that bit. Taking $d = 3$ recovers Hamming's original $(7, 4, 3)$ -code of Example 28.3.8.

That code has a famous picture. Draw three overlapping circles, one for each parity check, and place the seven digits in the seven regions so that digit i lies in circle j exactly when the j th binary digit of i is 1.

Each circle must contain an even number of 1s: those are exactly the three parity conditions

$$c_1 + c_3 + c_5 + c_7 = 0, \quad c_2 + c_3 + c_6 + c_7 = 0, \quad c_4 + c_5 + c_6 + c_7 = 0.$$

Now the decoding rule becomes visual. A single error breaks precisely the parity of those circles containing it, and since every region is determined by the set of circles containing it, the broken circles identify the erroneous digit uniquely. If, for instance, only the blue and green circles fail, the culprit is c_5 , which lies in those two and no other.

§28.5.3 Weight Enumerators

The weights of the codewords of a linear code contain a great deal of information, and it is convenient to package them into a polynomial.

Definition 28.5.19 (Weight Enumerator)

The **weight enumerator** of a linear code $C \leq \mathbb{F}_2^n$ is the homogeneous polynomial

$$W_C(x, y) = \sum_{c \in C} x^{n-w(c)} y^{w(c)} = \sum_{i=0}^n A_i x^{n-i} y^i,$$

where A_i is the number of codewords of weight i .

Note $W_C(1, 1) = |C|$ and $W_C(1, 0) = 1$, and that $d(C)$ is the least $i > 0$ with $A_i \neq 0$. If C is used over a BSC with error probability p , then the probability that a transmitted codeword is received as another codeword – an undetected error – is $W_C(1-p, p) - (1-p)^n$, so the weight enumerator is exactly what one needs to analyse error detection.

Example 28.5.20

The repetition code of length n has $W(x, y) = x^n + y^n$. The simple parity check code of length n has $W(x, y) = \sum_{i \text{ even}} \binom{n}{i} x^{n-i} y^i = \frac{1}{2} [(x+y)^n + (x-y)^n]$. Hamming's $(7, 4, 3)$ -code has weight distribution $A_0 = 1$, $A_3 = A_4 = 7$, $A_7 = 1$, so

$$W(x, y) = x^7 + 7x^4y^3 + 7x^3y^4 + y^7.$$

(One checks $A_3 = 7$ directly: a weight-3 codeword corresponds to a triple of columns of H summing to zero, and each of the 7 nonzero syndromes u determines such a triple. The remaining counts follow since C contains 1111111, so $A_i = A_{7-i}$.)

There is a beautiful and useful relation between the weight enumerator of a code and that of its dual, which comes from Fourier analysis on $\mathbb{F}_2^n$.

Lemma 28.5.21 (Poisson Summation)

Let $C \leq \mathbb{F}_2^n$ be linear and let $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$ have Fourier transform

$$\hat{f}(v) = \sum_{u \in \mathbb{F}_2^n} (-1)^{u \cdot v} f(u).$$

Then

$$\sum_{v \in C} \hat{f}(v) = |C| \sum_{u \in C^\perp} f(u).$$

Proof. Exchanging the order of summation,

$$\sum_{v \in C} \hat{f}(v) = \sum_{v \in C} \sum_u (-1)^{u \cdot v} f(u) = \sum_u f(u) \sum_{v \in C} (-1)^{u \cdot v}.$$

The inner sum is $|C|$ if $u \in C^\perp$. Otherwise the map $v \mapsto u \cdot v$ is a surjective linear map $C \rightarrow \mathbb{F}_2$, so its kernel has index 2 in C and the sum is $\frac{1}{2}|C| - \frac{1}{2}|C| = 0$. $\square$

Theorem 28.5.22 (MacWilliams Identity)

For a linear code $C \leq \mathbb{F}_2^n$,

$$W_{C^\perp}(x, y) = \frac{1}{|C|} W_C(x+y, x-y).$$

Proof. Apply Lemma 28.5.21 to $f(u) = x^{n-w(u)} y^{w(u)}$, which factorises as $f(u) =$

$\prod_{i=1}^n g(u_i)$ with $g(0) = x$, $g(1) = y$. Then the Fourier transform factorises too:

$$\hat{f}(v) = \sum_{u \in \mathbb{F}_2^n} \prod_{i=1}^n (-1)^{u_i v_i} g(u_i) = \prod_{i=1}^n \left(\sum_{u_i \in \mathbb{F}_2} (-1)^{u_i v_i} g(u_i) \right) = \prod_{i=1}^n (x + (-1)^{v_i} y),$$

which is $(x + y)^{n-w(v)}(x - y)^{w(v)}$. Summing over $v \in C$ gives $W_C(x + y, x - y)$ on the left of Lemma 28.5.21, and $|C| W_{C^\perp}(x, y)$ on the right. $\square$

Example 28.5.23

Take C the simple parity check code of length n , with $W_C(x, y) = \frac{1}{2}[(x+y)^n + (x-y)^n]$ and $|C| = 2^{n-1}$. Then

$$W_{C^\perp}(x, y) = \frac{1}{2^{n-1}} \cdot \frac{1}{2} [(2x)^n + (2y)^n] = x^n + y^n,$$

which is the weight enumerator of the repetition code. And indeed the dual of the parity check code is the repetition code, as one sees directly.

§28.5.4 Reed–Muller Codes

Our final family of linear codes is built out of the geometry of $\mathbb{F}_2^d$, and includes several codes we have already met. It is the family used by NASA to transmit the Mariner photographs of Mars.

Let $X = \{p_1, \dots, p_n\}$ be a set of size n . There is a chain of bijections

$$\mathcal{P}(X) \xrightarrow{A \mapsto \mathbb{1}_A} \{f: X \rightarrow \mathbb{F}_2\} \xrightarrow{f \mapsto (f(p_1), \dots, f(p_n))} \mathbb{F}_2^n,$$

under which the symmetric difference $A \triangle B$ corresponds to vector addition, and the intersection $A \cap B$ corresponds to the **wedge product**

$$x \wedge y = (x_1 y_1, \dots, x_n y_n).$$

So we may think of vectors in $\mathbb{F}_2^n$ as subsets of X , and we shall pass between the two pictures freely.

Now take $X = \mathbb{F}_2^d$, so that $n = |X| = 2^d$. Let $v_0 = (1, 1, \dots, 1) = \mathbb{1}_X$, and for $1 \leq i \leq d$ let

$$v_i = \mathbb{1}_{H_i}, \quad H_i = \{p \in X : p_i = 0\},$$

the indicator of the i th coordinate hyperplane.

Definition 28.5.24 (Reed–Muller Code)

For $0 \leq r \leq d$, the **Reed–Muller code** $RM(d, r)$ of **order** r and length 2^d is the linear code spanned by v_0 together with all wedge products of at most r of the v_i , $1 \leq i \leq d$. (By convention the empty wedge product is v_0 .)

Example 28.5.25

Let $d = 3$ and list $X = \mathbb{F}_2^3$ in binary order. Then the spanning vectors are

X	000	001	010	011	100	101	110	111
v_0	1	1	1	1	1	1	1	1
v_1	1	1	1	1	0	0	0	0
v_2	1	1	0	0	1	1	0	0
v_3	1	0	1	0	1	0	1	0
$v_1 \wedge v_2$	1	1	0	0	0	0	0	0
$v_1 \wedge v_3$	1	0	1	0	0	0	0	0
$v_2 \wedge v_3$	1	0	0	0	1	0	0	0
$v_1 \wedge v_2 \wedge v_3$	1	0	0	0	0	0	0	0

Notice that deleting the first column and keeping only the rows v_0, v_1, v_2, v_3 leaves a 4×7 matrix, and the code it generates has weight distribution $A_0 = 1$, $A_3 = A_4 = 7$, $A_7 = 1$. So it is a $(7, 4, 3)$ -code – indeed it is Hamming’s original code, punctured out of $RM(3, 1)$.

We can identify the small cases directly. $RM(3, 0)$ is spanned by v_0 alone, so it is the repetition code of length 8. $RM(3, 1)$ is spanned by v_0, v_1, v_2, v_3 , and is equivalent to the parity check extension of Hamming’s $(7, 4)$ -code. $RM(3, 2)$ is an $(8, 7)$ -code, equivalent to the simple parity check code of length 8. And $RM(3, 3)$ is the whole of $\mathbb{F}_2^8$.

Theorem 28.5.26 (i) The 2^d vectors $v_{i_1} \wedge \cdots \wedge v_{i_s}$ with $i_1 < \cdots < i_s$ and $0 \leq s \leq d$ form a basis of $\mathbb{F}_2^n$, where $n = 2^d$.

(ii) $\text{rank } RM(d, r) = \sum_{s=0}^r \binom{d}{s}$.

Proof. (i). There are $\sum_{s=0}^d \binom{d}{s} = 2^d = n$ vectors in the list, so it suffices to show they span, that is, that $RM(d, d) = \mathbb{F}_2^n$. Fix $p \in X$ and set

$$y_i = \begin{cases} v_i & \text{if } p_i = 0, \\ v_0 + v_i & \text{if } p_i = 1. \end{cases}$$

In the set picture y_i is the indicator of $\{q : q_i = p_i\}$, so

$$y_1 \wedge \cdots \wedge y_d = \mathbb{1}_{\{p\}}.$$

Expanding the left hand side by distributivity of $\wedge$ over $+$ writes $\mathbb{1}_{\{p\}}$ as a sum of wedge products of the v_i , hence $\mathbb{1}_{\{p\}} \in RM(d, d)$. As p was arbitrary and the $\mathbb{1}_{\{p\}}$ span $\mathbb{F}_2^n$, we are done.

(ii). $RM(d, r)$ is spanned by those basis vectors with $s \leq r$, of which there are $\sum_{s \leq r} \binom{d}{s}$, and these are linearly independent by (i). $\square$

To compute the minimum distance we use a construction which is of independent interest.

Definition 28.5.27 (Bar Product)

Let $C_2 \subseteq C_1$ be linear codes of length n . Their **bar product** is

$$C_1 \mid C_2 = \{(x \mid x + y) : x \in C_1, y \in C_2\},$$

a linear code of length $2n$.

Lemma 28.5.28 (i) $\text{rank}(C_1 \mid C_2) = \text{rank } C_1 + \text{rank } C_2$;

(ii) $d(C_1 \mid C_2) = \min\{2d(C_1), d(C_2)\}$.

Proof. (i). If $x_1, \dots, x_k$ is a basis of C_1 and $y_1, \dots, y_\ell$ a basis of C_2 , then

$$\{(x_i \mid x_i) : i \leq k\} \cup \{(0 \mid y_j) : j \leq \ell\}$$

spans $C_1 \mid C_2$, and is independent: a vanishing combination must have zero first half, forcing all x -coefficients to vanish, and then the y -coefficients too.

(ii). Let $(x \mid x + y)$ be a nonzero element. If $y \neq 0$ then, since weight is subadditive and $w(u) + w(u + v) \geq w(v)$,

$$w(x \mid x + y) = w(x) + w(x + y) \geq w(y) \geq d(C_2).$$

If $y = 0$ then $x \neq 0$ and $w(x \mid x) = 2w(x) \geq 2d(C_1)$. Hence $d(C_1 \mid C_2) \geq \min\{2d(C_1), d(C_2)\}$. For the reverse, choose $x \in C_1$ of weight $d(C_1)$ to get a codeword $(x \mid x)$ of weight $2d(C_1)$, and choose $y \in C_2$ of weight $d(C_2)$ to get $(0 \mid y)$ of weight $d(C_2)$. $\square$

Theorem 28.5.29 (i) $RM(d, r) = RM(d - 1, r) \mid RM(d - 1, r - 1)$ for $0 < r < d$;

(ii) $RM(d, r)$ has minimum distance 2^{d-r} .

Proof. (i). Order $X = \mathbb{F}_2^d$ so that the points with last coordinate 0 come first, identifying the two halves with $\mathbb{F}_2^{d-1}$. Under this splitting, the vectors $v_0, v_1, \dots, v_{d-1}$ for $\mathbb{F}_2^d$ become $(w \mid w)$ where w is the corresponding vector for $\mathbb{F}_2^{d-1}$, while $v_d = (\mathbf{1} \mid \mathbf{0})$. A wedge product of at most r of the v_i with $i < d$ therefore has the form $(w \mid w)$ with $w \in RM(d - 1, r)$; and a wedge product involving v_d has the form $(w \mid 0)$ with $w \in RM(d - 1, r - 1)$, since one of its r factors has been used up. As $(w \mid 0) = (w \mid w + w)$, every generator lies in $RM(d - 1, r) \mid RM(d - 1, r - 1)$; and comparing ranks using Theorem 28.5.26(ii), Lemma 28.5.28(i) and Pascal's rule

$$\sum_{s \leq r} \binom{d}{s} = \sum_{s \leq r} \binom{d-1}{s} + \sum_{s \leq r-1} \binom{d-1}{s}$$

shows the two codes have the same dimension, hence are equal.

(ii). If $r = 0$ then $RM(d, 0)$ is the repetition code of length 2^d , of minimum distance 2^d . If $r = d$ then $RM(d, d) = \mathbb{F}_2^{2^d}$, of minimum distance $1 = 2^{d-d}$. For $0 < r < d$ we induct on d , using (i) and Lemma 28.5.28(ii):

$$d(RM(d, r)) = \min\{2 \cdot 2^{(d-1)-r}, 2^{(d-1)-(r-1)}\} = \min\{2^{d-r}, 2^{d-r}\} = 2^{d-r}. \quad \square$$

Example 28.5.30

$RM(5, 1)$ is a $(32, 6)$ -code with minimum distance $2^4 = 16$, so it corrects 7 errors at rate $\frac{6}{32}$. This is the code used by Mariner 9 in 1971 to send back pictures of Mars: each pixel was one of 64 grey levels, encoded in 32 bits, and the channel was extremely noisy.

§28.6 Cyclic Codes

Linear codes made decoding into linear algebra. Imposing one further symmetry – invariance under cyclic shifts – turns them into ideals in a polynomial ring, and then all of the theory of finite fields from IB Groups, Rings and Modules comes into play. The reward is a family of codes with prescribed minimum distance and an efficient decoding algorithm.

§28.6.1 Cyclic Codes and Generator Polynomials**Definition 28.6.1 (Cyclic Code)**

A linear code $C \subseteq \mathbb{F}_2^n$ is **cyclic** if

$$(a_0, a_1, \dots, a_{n-1}) \in C \implies (a_{n-1}, a_0, \dots, a_{n-2}) \in C.$$

Identify $\mathbb{F}_2^n$ with the quotient ring

$$R = \mathbb{F}_2[X]/(X^n - 1)$$

via $\pi(a_0 + a_1X + \dots + a_{n-1}X^{n-1}) = (a_0, \dots, a_{n-1})$; this is a bijection because every class modulo $X^n - 1$ has a unique representative of degree less than n . Under this identification, cyclic shift becomes multiplication by X :

$$X \cdot (a_0 + a_1X + \dots + a_{n-1}X^{n-1}) = a_{n-1} + a_0X + \dots + a_{n-2}X^{n-1} \pmod{X^n - 1}.$$

Lemma 28.6.2

A code $C \subseteq \mathbb{F}_2^n$ is cyclic if and only if the corresponding subset $\mathcal{C} \subseteq R$ is an ideal of R .

Proof. Linearity of C says exactly that $\mathcal{C}$ is an additive subgroup, and the computation above says that closure under cyclic shift is closure under multiplication by X . Since $\mathcal{C}$ is closed under addition and multiplication by X , it is closed under multiplication by every polynomial, that is, it is an ideal; and conversely. $\square$

From now on we identify C with $\mathcal{C}$. Ideals of $R = \mathbb{F}_2[X]/(X^n - 1)$ correspond to ideals of $\mathbb{F}_2[X]$ containing $X^n - 1$; and $\mathbb{F}_2[X]$ is a principal ideal domain, so these correspond to the divisors of $X^n - 1$. This gives a complete classification.

Theorem 28.6.3 (Generator Polynomial)

Let C be a cyclic code of length n . Then there is a unique polynomial $g(X) \in \mathbb{F}_2[X]$ with

- (i) $C = (g)$, the ideal generated by g ;
- (ii) $g(X) \mid X^n - 1$.

In particular, $p(X)$ represents a codeword if and only if $g \mid p$. We call g the **generator polynomial** of C .

Proof. Assume $C \neq \{0\}$ and let g be a nonzero polynomial of least degree representing a codeword, so $\deg g < n$. Certainly $(g) \subseteq C$ since C is an ideal. Conversely let p represent a codeword; by the division algorithm in $\mathbb{F}_2[X]$, $p = qg + r$ with $\deg r < \deg g$. Then $r = p - qg \in C$, and minimality of $\deg g$ forces $r = 0$. So $C = (g)$. Taking $p = X^n - 1$, which represents $0 \in C$, gives $g \mid X^n - 1$, which is (ii).

For uniqueness, if $(g_1) = (g_2)$ then $g_1 \mid g_2$ and $g_2 \mid g_1$ in $\mathbb{F}_2[X]$ (using the divisibility of $X^n - 1$ to work in $\mathbb{F}_2[X]$ rather than the quotient), so $g_1 = cg_2$ with $c \in \mathbb{F}_2^\times = \{1\}$. $\square$

Lemma 28.6.4

Let C be cyclic of length n with generator polynomial $g(X) = a_0 + a_1X + \cdots + a_kX^k$, $a_k \neq 0$. Then

$$g, Xg, X^2g, \dots, X^{n-k-1}g$$

is a basis for C , so $\text{rank } C = n - k$.

Proof. These $n - k$ polynomials have degrees $k, k+1, \dots, n-1$, all less than n , so they are genuine representatives and are linearly independent (distinct leading terms). They span: any codeword is qg for some q , and reducing q modulo X^{n-k} we may assume $\deg q < n - k$, so qg is a combination of the listed elements. $\square$

Corollary 28.6.5

With g as above, a generator matrix for C is the $(n - k) \times n$ matrix

$$G = \begin{pmatrix} a_0 & a_1 & \cdots & a_k & 0 & \cdots & 0 \\ 0 & a_0 & \cdots & a_{k-1} & a_k & \cdots & 0 \\ \vdots & & \ddots & & & \ddots & \vdots \\ 0 & 0 & \cdots & a_0 & a_1 & \cdots & a_k \end{pmatrix}.$$

Definition 28.6.6 (Parity Check Polynomial)

Let g be the generator polynomial of a cyclic code C of length n . The **parity check polynomial** is the polynomial h with $g(X)h(X) = X^n - 1$.

Corollary 28.6.7

Writing $h(X) = b_0 + b_1X + \cdots + b_{n-k}X^{n-k}$, a parity check matrix for C is the $k \times n$

matrix

$$H = \begin{pmatrix} b_{n-k} & b_{n-k-1} & \cdots & b_0 & 0 & \cdots & 0 \\ 0 & b_{n-k} & \cdots & b_1 & b_0 & \cdots & 0 \\ \vdots & & \ddots & & & \ddots & \vdots \\ 0 & 0 & \cdots & b_{n-k} & b_{n-k-1} & \cdots & b_0 \end{pmatrix}.$$

Proof. The inner product of the i th row of G with the j th row of H is the coefficient of $X^{n-k-i+j}$ in $g(X)h(X) = X^n - 1$. Since $1 \leq i \leq n-k$ and $1 \leq j \leq k$, we have $0 < n-k-i+j < n$, and all such coefficients of $X^n - 1$ vanish. So the rows of H lie in $C^\perp$; and $b_{n-k} \neq 0$ gives $\text{rank } H = k = \text{rank } C^\perp$. $\square$

Remark. For $f(X) = \sum_{i=0}^m f_i X^i$ of degree m , the **reverse** polynomial is

$$\check{f}(X) = f_m + f_{m-1}X + \cdots + f_0 X^m = X^m f(1/X).$$

The matrix H above is exactly the generator matrix built from $\check{h}$, so the dual of a cyclic code is the cyclic code generated by $\check{h}$. In particular the dual of a cyclic code is cyclic.

Lemma 28.6.8

If n is odd then $X^n - 1 = f_1(X) \cdots f_t(X)$ with the f_i distinct irreducible polynomials in $\mathbb{F}_2[X]$. Consequently there are exactly 2^t cyclic codes of length n .

Proof sketch. $X^n - 1$ and its formal derivative $nX^{n-1} = X^{n-1}$ (as n is odd) are coprime, so $X^n - 1$ is separable and hence has no repeated irreducible factors. The cyclic codes correspond to the divisors of $X^n - 1$, of which there are 2^t . $\square$

The hypothesis is needed: over $\mathbb{F}_2$ we have $X^2 - 1 = (X - 1)^2$. From now on n is odd.

§28.6.2 BCH Codes

We now recall what we need about finite fields, all of which is from IB Groups, Rings and Modules. If $f \in \mathbb{F}_p[X]$ is irreducible then $\mathbb{F}_p[X]/(f)$ is a field with $p^{\deg f}$ elements, and every finite field arises this way; for each prime power $q = p^\alpha$ there is a unique field $\mathbb{F}_q$ of order q up to isomorphism (note $\mathbb{F}_q \not\cong \mathbb{Z}/q\mathbb{Z}$ when $\alpha > 1$). The multiplicative group $\mathbb{F}_q^\times$ is cyclic of order $q - 1$, and a generator is called a **primitive element**.

Fix an odd n , and choose $r \geq 1$ with $2^r \equiv 1 \pmod{n}$; such r exists since 2 is a unit modulo n . Let $K = \mathbb{F}_{2^r}$ and set

$$\mu_n(K) = \{x \in K : x^n = 1\} \leq K^\times.$$

As $n \mid 2^r - 1 = |K^\times|$ and $K^\times$ is cyclic, $\mu_n(K)$ is cyclic of order exactly n , say

$$\mu_n(K) = \{1, \alpha, \alpha^2, \dots, \alpha^{n-1}\}$$

for a primitive n th root of unity $\alpha \in K$. Since n is odd, $X^n - 1$ has n distinct roots in K , namely these, so K contains a splitting field for $X^n - 1$.

Definition 28.6.9 (Defining Set)

Let $A \subseteq \mu_n(K)$. The cyclic code of length n with **defining set** A is

$$C = \{f(X) \in \mathbb{F}_2[X]/(X^n - 1) : f(a) = 0 \text{ for all } a \in A\}.$$

This really is cyclic: the conditions $f(a) = 0$ are $\mathbb{F}_2$ -linear and are preserved under multiplication by X . Its generator polynomial is the nonzero polynomial in $\mathbb{F}_2[X]$ of least degree vanishing on A , that is, the least common multiple of the minimal polynomials over $\mathbb{F}_2$ of the elements of A .

Definition 28.6.10 (BCH Code)

The cyclic code of length n with defining set $\{\alpha, \alpha^2, \dots, \alpha^{\delta-1}\}$ is the **BCH code** with **design distance** δ . (The name is for Bose, Ray-Chaudhuri and Hocquenghem.)

The point of the definition is the following bound, which lets us specify the minimum distance in advance – something no construction so far has allowed.

Lemma 28.6.11 (Vandermonde)

$$\det \begin{pmatrix} 1 & 1 & \cdots & 1 \\ x_1 & x_2 & \cdots & x_n \\ \vdots & \vdots & \ddots & \vdots \\ x_1^{n-1} & x_2^{n-1} & \cdots & x_n^{n-1} \end{pmatrix} = \prod_{1 \leq j < i \leq n} (x_i - x_j).$$

In particular the determinant is nonzero whenever the x_i are distinct.

Theorem 28.6.12 (BCH Bound)

A BCH code C with design distance δ has $d(C) \geq \delta$.

Proof. Consider the $(\delta - 1) \times n$ matrix over K

$$H = \begin{pmatrix} 1 & \alpha & \alpha^2 & \cdots & \alpha^{n-1} \\ 1 & \alpha^2 & \alpha^4 & \cdots & \alpha^{2(n-1)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & \alpha^{\delta-1} & \alpha^{2(\delta-1)} & \cdots & \alpha^{(\delta-1)(n-1)} \end{pmatrix}.$$

A word $c \in \mathbb{F}_2^n$ lies in C precisely when $Hc = 0$, since the j th row of Hc is $c(\alpha^j)$. Take any $\delta - 1$ columns of H , say those indexed by $i_1 < \cdots < i_{\delta-1}$. Dividing the j th row by nothing and factoring α^{i_s} out of the s th column, the resulting $(\delta - 1) \times (\delta - 1)$ matrix is a Vandermonde matrix in the distinct elements $\alpha^{i_1}, \dots, \alpha^{i_{\delta-1}}$, hence invertible by Lemma 28.6.11. So no $\delta - 1$ columns of H are linearly dependent, and by the argument of Lemma 28.5.15 every nonzero codeword has weight at least δ . $\square$

Remark. The matrix H is not a parity check matrix in our earlier sense, since its entries lie in K rather than $\mathbb{F}_2$. Nevertheless the dependence argument goes through verbatim, because a codeword is a vector over $\mathbb{F}_2 \subseteq K$ and linear dependence over K is what we tested.

Example 28.6.13

Take $n = 7$. Over $\mathbb{F}_2$,

$$X^7 - 1 = (X + 1)(X^3 + X + 1)(X^3 + X^2 + 1),$$

so by Lemma 28.6.8 there are $2^3 = 8$ cyclic codes of length 7. Take $g(X) = X^3 + X + 1$, so

$$h(X) = (X + 1)(X^3 + X^2 + 1) = X^4 + X^2 + X + 1,$$

and $\text{rank } C = 7 - 3 = 4$. The parity check matrix built from $\check{h}(X) = X^4 + X^3 + X^2 + 1$ is

$$H = \begin{pmatrix} 1 & 0 & 1 & 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{pmatrix},$$

whose columns are precisely the seven nonzero elements of $\mathbb{F}_2^3$. So C is (equivalent to) the Hamming (7, 4)-code.

Let us see this again from the BCH point of view. Take $K = \mathbb{F}_8 = \mathbb{F}_2[\beta]/(\beta^3 + \beta + 1)$, so β is a root of g and a primitive 7th root of unity. The powers of β are

i	0	1	2	3	4	5	6
β^i	1	β	β^2	$\beta + 1$	$\beta^2 + \beta$	$\beta^2 + \beta + 1$	$\beta^2 + 1$

Squaring is a field automorphism of K fixing $\mathbb{F}_2$, so $g(\beta) = 0$ gives $g(\beta^2) = g(\beta)^2 = 0$ and likewise $g(\beta^4) = 0$. Hence the BCH code with defining set $\{\beta, \beta^2\}$ has generator polynomial exactly g , and its design distance is $\delta = 3$. So $d(C) \geq 3$; and we know Hamming's code has $d = 3$ exactly.

§28.6.3 Decoding BCH Codes

Let C be a BCH code of length n with defining set $\{\alpha, \dots, \alpha^{\delta-1}\}$, so $d(C) \geq \delta$ and C should correct

$$t = \lfloor \frac{\delta - 1}{2} \rfloor$$

errors. Suppose $c \in C$ is sent and $r = c + e$ is received, where the error pattern e has at most t nonzero digits. Writing $r(X), c(X), e(X)$ for the corresponding polynomials, $c(\alpha^j) = 0$ for $1 \leq j \leq \delta - 1$ and so

$$r(\alpha^j) = e(\alpha^j), \quad 1 \leq j \leq \delta - 1.$$

These $\delta - 1$ elements of K are the **syndromes**, and everything must be recovered from them.

Definition 28.6.14 (Error Locator Polynomial)

Let $\mathcal{E} = \{i : e_i = 1\}$ be the set of error positions. The **error locator polynomial** is

$$\sigma(X) = \prod_{i \in \mathcal{E}} (1 - \alpha^i X) \in K[X].$$

The roots of σ are exactly the α^{-i} for $i \in \mathcal{E}$, so knowing σ is the same as knowing where the errors are. Note $\sigma(0) = 1$ and $\deg \sigma = |\mathcal{E}| \leq t$.

Theorem 28.6.15

Suppose $|\mathcal{E}| \leq t$ where $2t + 1 \leq \delta$. Then $\sigma(X)$ is the unique polynomial of least degree in $K[X]$ such that

(i) $\sigma(0) = 1$;

(ii) $\sigma(X) \sum_{j=1}^{2t} r(\alpha^j) X^j \equiv \omega(X) \pmod{X^{2t+1}}$ for some $\omega \in K[X]$ with $\deg \omega \leq t$.

Proof. Existence. Define the **error co-locator** $\omega(X) = -X\sigma'(X)$, so by the product rule

$$\omega(X) = \sum_{i \in \mathcal{E}} \alpha^i X \prod_{j \in \mathcal{E}, j \neq i} (1 - \alpha^j X),$$

which has degree $\deg \sigma = |\mathcal{E}| \leq t$. Work in the ring $K[[X]]$ of formal power series, in which $1 - \alpha^i X$ is invertible. A partial fractions computation gives

$$\frac{\omega(X)}{\sigma(X)} = \sum_{i \in \mathcal{E}} \frac{\alpha^i X}{1 - \alpha^i X} = \sum_{i \in \mathcal{E}} \sum_{j \geq 1} (\alpha^i X)^j = \sum_{j \geq 1} X^j \sum_{i \in \mathcal{E}} (\alpha^j)^i = \sum_{j \geq 1} e(\alpha^j) X^j,$$

the last step because $e(X) = \sum_{i \in \mathcal{E}} X^i$. Hence

$$\sigma(X) \sum_{j \geq 1} e(\alpha^j) X^j = \omega(X)$$

exactly, in $K[[X]]$. Since $2t \leq \delta - 1$ we have $r(\alpha^j) = e(\alpha^j)$ for $1 \leq j \leq 2t$, and truncating modulo X^{2t+1} gives (ii).

Uniqueness. Suppose $\tilde{\sigma}, \tilde{\omega}$ also satisfy (i) and (ii) with $\deg \tilde{\sigma} \leq \deg \sigma$. The roots of σ are distinct and nonzero, and $\omega(X) = -X\sigma'(X)$ does not vanish at them (differentiate σ at a simple root); so σ and ω are coprime. From (ii) for both pairs,

$$\tilde{\sigma}(X)\omega(X) \equiv \sigma(X)\tilde{\omega}(X) \pmod{X^{2t+1}},$$

and both sides have degree at most $2t$, so this is an equality of polynomials. Since σ and ω are coprime, $\sigma \mid \tilde{\omega}$; combined with $\deg \tilde{\sigma} \leq \deg \sigma$ this gives $\tilde{\sigma} = \lambda\sigma$, and (i) forces $\lambda = 1$. $\square$

This yields an algorithm. On receiving $r(X)$:

- (1) Compute the syndromes $r(\alpha^j)$ for $1 \leq j \leq 2t$ and form $S(X) = \sum_{j=1}^{2t} r(\alpha^j) X^j$.
- (2) Write $\sigma(X) = 1 + \sigma_1 X + \cdots + \sigma_t X^t$ with unknown coefficients. Condition (ii) says the coefficients of X^i in $\sigma(X)S(X)$ vanish for $t+1 \leq i \leq 2t$, giving t linear equations

$$\sum_{j=0}^t \sigma_j r(\alpha^{i-j}) = 0, \quad \sigma_0 = 1.$$

- (3) Solve these over K , keeping a solution of least degree.
- (4) Compute $\mathcal{E} = \{i : \sigma(\alpha^{-i}) = 0\}$ and check $|\mathcal{E}| = \deg \sigma$.
- (5) Set $e(X) = \sum_{i \in \mathcal{E}} X^i$, put $c(X) = r(X) + e(X)$, and check that c is a codeword.

Example 28.6.16

Continue Example 28.6.13: $n = 7$, $g(X) = X^3 + X + 1$, defining set $\{\beta, \beta^2\}$, $\delta = 3$, $t = 1$. Take the codeword $c(X) = g(X) = 1 + X + X^3$, that is $c = 1101000$, and suppose an error occurs in position 5, so

$$r(X) = 1 + X + X^3 + X^5.$$

We compute the syndromes, using the table of powers of β above:

$$r(\beta) = 1 + \beta + (\beta + 1) + (\beta^2 + \beta + 1) = 1 + \beta + \beta^2 = \beta^5,$$

and $r(\beta^2) = r(\beta)^2 = \beta^{10} = \beta^3$. So $S(X) = \beta^5 X + \beta^3 X^2$.

With $t = 1$ we set $\sigma(X) = 1 + \sigma_1 X$; the coefficient of X^2 in $\sigma(X)S(X)$ is $\beta^3 + \sigma_1 \beta^5$, which must vanish, so

$$\sigma_1 = \beta^{3-5} = \beta^{-2} = \beta^5.$$

Thus $\sigma(X) = 1 + \beta^5 X$, whose root is $X = \beta^{-5} = \beta^2$. Solving $\beta^{-i} = \beta^2$ gives $i \equiv -2 \equiv 5 \pmod{7}$, so $\mathcal{E} = \{5\}$ and $|\mathcal{E}| = 1 = \deg \sigma$ as required. Correcting, $c(X) = r(X) + X^5 = 1 + X + X^3$, which is indeed a codeword. Everything is consistent.

Example 28.6.17

For a code that genuinely corrects two errors, take $n = 15$ and $K = \mathbb{F}_{16} = \mathbb{F}_2[\alpha]/(\alpha^4 + \alpha + 1)$, so α is a primitive 15th root of unity. The minimal polynomial of α is $X^4 + X + 1$ (with roots $\alpha, \alpha^2, \alpha^4, \alpha^8$) and that of α^3 is $X^4 + X^3 + X^2 + X + 1$ (with roots $\alpha^3, \alpha^6, \alpha^{12}, \alpha^9$). The BCH code with defining set $\{\alpha, \alpha^2, \alpha^3, \alpha^4\}$ therefore has

$$g(X) = (X^4 + X + 1)(X^4 + X^3 + X^2 + X + 1)$$

of degree 8, giving a $(15, 7)$ -code with design distance 5; in fact $d = 5$ exactly, so it is a $(15, 7, 5)$ -code correcting two errors.

§28.6.4 Reed–Solomon Codes

Everything above works over any finite field, and one particularly clean case deserves its own name. Let q be a prime power, let α be a primitive element of $\mathbb{F}_q$, and take $n = q - 1$, so that α is a primitive n th root of unity *in the field $\mathbb{F}_q$ itself*. Codes are now subsets of $\mathbb{F}_q^n$; Hamming distance, weight and linearity all make sense verbatim.

Definition 28.6.18 (Reed–Solomon Code)

Let $1 \leq k \leq n = q - 1$. The **Reed–Solomon code** $RS(n, k)$ is the cyclic code over $\mathbb{F}_q$ of length n with generator polynomial

$$g(X) = (X - \alpha)(X - \alpha^2) \cdots (X - \alpha^{n-k}).$$

Equivalently it is the BCH code with defining set $\{\alpha, \dots, \alpha^{n-k}\}$ and design distance $\delta = n - k + 1$; the difference from the binary case is that the defining set already consists of elements of the ground field, so no extension is needed and the degree of g is exactly

$n - k$.

Proposition 28.6.19

$RS(n, k)$ has rank k and minimum distance exactly $n - k + 1$. In particular it is MDS: it attains the Singleton bound.

Proof. Since $\deg g = n - k$, Lemma 28.6.4 gives $\text{rank} = n - (n - k) = k$. The BCH bound gives $d \geq \delta = n - k + 1$, and the Singleton bound (Theorem 28.3.23, whose proof works over any alphabet, giving $|C| \leq q^{n-d+1}$) gives $q^k \leq q^{n-d+1}$, that is, $d \leq n - k + 1$. $\square$

Example 28.6.20

Take $q = 5$ and $\alpha = 2$, a primitive root modulo 5 since 2, 4, 3, 1 are its successive powers. With $n = 4$ and $k = 2$,

$$g(X) = (X - 2)(X - 4) = X^2 - 6X + 8 = X^2 + 4X + 3 \in \mathbb{F}_5[X],$$

and indeed $g \mid X^4 - 1 = (X - 1)(X - 2)(X - 3)(X - 4)$. The code is

$$RS(4, 2) = \{(a + bX)g(X) : a, b \in \mathbb{F}_5\},$$

of size 25. For instance g itself is the codeword $(3, 4, 1, 0)$, of weight 3, and one checks that every nonzero codeword has weight at least $3 = n - k + 1$. So this is a $(4, 2, 3)$ MDS code over $\mathbb{F}_5$.

Remark. Reed–Solomon codes are ubiquitous in practice – they are what protects the data on a compact disc, in a QR code, and on the Voyager spacecraft. Their great virtue is that a symbol of $\mathbb{F}_{2^m}$ is a block of m bits, so a single symbol error absorbs a whole *burst* of up to m consecutive bit errors. Real channels tend to produce errors in bursts rather than independently, which is exactly the situation the binary symmetric channel fails to model.

§28.6.5 Linear Feedback Shift Registers

We now change tack, apparently completely, and consider a piece of hardware. The connection to what we have just done will emerge shortly, and it will also be the basis of the stream ciphers of Section 28.7.

Definition 28.6.21 (Feedback Shift Register)

A **(general) feedback shift register** of length d is a map $f: \mathbb{F}_2^d \rightarrow \mathbb{F}_2^d$ of the form

$$f(x_0, \dots, x_{d-1}) = (x_1, \dots, x_{d-1}, C(x_0, \dots, x_{d-1}))$$

for some function $C: \mathbb{F}_2^d \rightarrow \mathbb{F}_2$. Given an **initial fill** $(y_0, \dots, y_{d-1})$, the associated **stream** is the sequence $y_0, y_1, \dots$ defined by

$$y_n = C(y_{n-d}, \dots, y_{n-1}), \quad n \geq d.$$

Definition 28.6.22 (LFSR)

A feedback shift register is a **linear feedback shift register** (LFSR) if C is linear, say

$$C(x_0, \dots, x_{d-1}) = \sum_{i=0}^{d-1} a_i x_i.$$

We always take $a_0 = 1$, since otherwise the register really has length less than d .

Physically it is a row of d memory cells; at each tick every cell passes its contents to its left neighbour, the leftmost cell is output, and the rightmost cell receives the sum of the tapped cells.

For an LFSR the stream satisfies the linear recurrence

$$y_n = \sum_{i=0}^{d-1} a_i y_{n-d+i}, \quad n \geq d,$$

and it is natural to encode the coefficients in a polynomial.

Definition 28.6.23 (Auxiliary and Feedback Polynomials)

The **auxiliary polynomial** of the LFSR is

$$P(X) = X^d + a_{d-1}X^{d-1} + \dots + a_1X + a_0 = \sum_{i=0}^d a_i X^i \quad (a_d := 1),$$

and the **feedback polynomial** is its reverse

$$\check{P}(X) = a_0X^d + a_1X^{d-1} + \dots + a_{d-1}X + 1 = \sum_{i=0}^d a_{d-i}X^i.$$

The **generating function** of a stream (y_n) is $G(X) = \sum_{j \geq 0} y_j X^j \in \mathbb{F}_2[[X]]$.

Theorem 28.6.24

A stream $(y_n)_{n \geq 0}$ arises from an LFSR with auxiliary polynomial P if and only if its generating function has the form

$$G(X) = \frac{A(X)}{\check{P}(X)}$$

for some $A \in \mathbb{F}_2[X]$ with $\deg A < \deg \check{P} = d$.

Proof. The condition is that

$$G(X)\check{P}(X) = \left(\sum_{j \geq 0} y_j X^j\right) \left(\sum_{i=0}^d a_{d-i} X^i\right)$$

is a polynomial of degree less than d , that is, that the coefficient of X^n vanishes for all $n \geq d$. That coefficient is

$$\sum_{i=0}^d a_{d-i} y_{n-i} = y_n + \sum_{i=1}^d a_{d-i} y_{n-i},$$

using $a_d = 1$. Setting this to zero and reindexing gives exactly $y_n = \sum_{i=0}^{d-1} a_i y_{n-d+i}$. $\square$

So streams from LFSRs of length d are precisely the sequences whose generating function is a rational function with denominator of degree d – which is the same problem we solved when decoding BCH codes, where we had to recognise a power series as ω/σ . The two subjects are the same subject.

Example 28.6.25

Take $d = 4$ with $a_0 = a_1 = 1$ and $a_2 = a_3 = 0$, so

$$y_n = y_{n-4} + y_{n-3}, \quad P(X) = X^4 + X + 1, \quad \check{P}(X) = X^4 + X^3 + 1.$$

With initial fill 1000 the stream begins

$$1, 0, 0, 0, 1, 0, 0, 1, 1, 0, 1, 0, 1, 1, 1, 1, 0, 0, 0, 1, \dots$$

and one checks that $y_{15+r} = y_r$, so the period is $15 = 2^4 - 1$, the largest possible. (This happens exactly when P is a primitive polynomial, meaning that its roots are primitive elements of $\mathbb{F}_{16}$.)

§28.6.6 The Berlekamp–Massey Method

Suppose now that we are handed a stream (x_n) which we are told comes from *some* LFSR, but we know neither its length d nor its coefficients. Recovering them is the problem of **linear complexity**, and it has a clean linear-algebraic solution.

We seek d and $a_0, \dots, a_{d-1}$ (with $a_d = 1$) such that

$$x_n + \sum_{i=1}^d a_{d-i} x_{n-i} = 0 \quad \text{for all } n \geq d.$$

Writing out these equations for $n = d, d+1, \dots, 2d$ gives the matrix equation

$$\underbrace{\begin{pmatrix} x_d & x_{d-1} & \cdots & x_1 & x_0 \\ x_{d+1} & x_d & \cdots & x_2 & x_1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ x_{2d} & x_{2d-1} & \cdots & x_{d+1} & x_d \end{pmatrix}}_{A_d} \begin{pmatrix} a_d \\ a_{d-1} \\ \vdots \\ a_1 \\ a_0 \end{pmatrix} = 0.$$

This is a system of $d+1$ homogeneous equations in $d+1$ unknowns, and it has a nonzero solution – our sought-after coefficients, with $a_d = 1$ – so $\det A_d = 0$.

The **Berlekamp–Massey method** exploits this. Compute $\det A_0, \det A_1, \det A_2, \dots$ in turn (starting at A_r if we already know $d \geq r$).

- If $\det A_i \neq 0$ then $d \neq i$, and we move on.
- If $\det A_i = 0$ we tentatively assume $d = i$, solve the system for $a_0, \dots, a_{i-1}$, and test the resulting recurrence against as many further terms of the stream as we like. If it fails, we move on.

The first i that survives the test is the answer.

Example 28.6.26

Apply this to the stream of Example 28.6.25, pretending we do not know where it came from:

$$x = 1, 0, 0, 0, 1, 0, 0, 1, 1, 0, 1, 0, 1, 1, 1, \dots$$

- $A_0 = (x_0) = (1)$ has $\det = 1 \neq 0$, so $d \neq 0$.
- $A_1 = \begin{pmatrix} x_1 & x_0 \\ x_2 & x_1 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$ has $\det = 0$. Solving with $a_1 = 1$: the first row gives $0 \cdot 1 + a_0 = 0$, so $a_0 = 0$, and the recurrence $x_n = 0$ fails already at $x_4 = 1$. So $d \neq 1$.
- $A_2 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}$ has a zero row, so $\det = 0$. Solving with $a_2 = 1$: row 1 gives $a_0 = 0$, row 3 gives $x_4 + a_1x_3 + a_0x_2 = 1 \neq 0$. The system is inconsistent, so $d \neq 2$.
- $A_3 = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}$ is a permutation matrix, so $\det = 1 \neq 0$ and $d \neq 3$.
- $A_4 = \begin{pmatrix} 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 \\ 1 & 1 & 0 & 0 & 1 \end{pmatrix}$. Solving with $a_4 = 1$: the rows give in turn $a_0 = 1$, $a_3 = 0$, $a_2 = 0$, $a_1 = 1$, and the last row $1 + a_3 + a_0 = 1 + 0 + 1 = 0$ is consistent. (So $\det A_4 = 0$, as it must be.)

We conclude that $d = 4$ with $(a_0, a_1, a_2, a_3) = (1, 1, 0, 0)$, that is, $y_n = y_{n-4} + y_{n-3}$, which is exactly the register we started with. Checking against the later terms of the stream confirms it.

Remark. The moral for cryptography is discouraging. A stream produced by a linear feedback shift register of length d is completely determined by $2d$ of its terms, recoverable by solving a linear system. Any cipher whose key stream is generated linearly is therefore broken by a modest amount of known plaintext, as we shall see in Section 28.7.

§28.7 Cryptography

We now turn from noise to malice. Alice wants to send Bob a message, and Eve is listening. The techniques of the previous sections were designed against an opponent – the channel – who was random but not clever; now our opponent is clever, and we have to design against the worst case rather than the average one.

§28.7.1 Cryptosystems and Classical Ciphers

Alice and Bob share some secret information called the **key**, drawn from a set $\mathcal{K}$. The unencrypted message, the **plaintext**, lies in a set $\mathcal{M}$, and the encrypted message, the **ciphertext**, lies in a set $\mathcal{C}$.

Definition 28.7.1 (Cryptosystem)

A **cryptosystem** consists of sets $(\mathcal{M}, \mathcal{K}, \mathcal{C})$ together with an **encryption** function $e: \mathcal{M} \times \mathcal{K} \rightarrow \mathcal{C}$ and a **decryption** function $d: \mathcal{C} \times \mathcal{K} \rightarrow \mathcal{M}$ satisfying

$$d(e(m, k), k) = m \quad \text{for all } m \in \mathcal{M}, k \in \mathcal{K}.$$

Example 28.7.2 (Substitution and Vigenère Ciphers)

Let $\Sigma = \{A, B, \dots, Z\}$ and $\mathcal{M} = \mathcal{C} = \Sigma^*$.

- The **simple substitution cipher** takes $\mathcal{K}$ to be the set of permutations of Σ ; each plaintext letter is replaced by its image under the chosen $\pi \in \mathcal{K}$. There are $26! \approx 4 \times 10^{26}$ keys, which sounds like a lot.
- The **Vigenère cipher** takes $\mathcal{K} = \Sigma^d$ for some d . Identify Σ with $\mathbb{Z}/26\mathbb{Z}$, write the key repeatedly beneath the plaintext, and add. For instance, the plaintext ATTACKATDAWN with key LEMON gives

ATTACKATDAWN
LEMONLEMONLE
LXFOPVEFRNHR

The case $d = 1$ is the **Caesar cipher**.

Neither of these is secure, and it is worth being precise about what security would mean. We assume throughout **Kerckhoffs' principle**: Eve knows the functions e and d and the probability distributions on $\mathcal{K}$ and $\mathcal{M}$; the only thing she does not know is the key itself. There is then a hierarchy of attacks.

Level 1. *Ciphertext only.* Eve knows some ciphertext and nothing else.

Level 2. *Known plaintext.* Eve knows a substantial stretch of plaintext together with its ciphertext, but not the key.

Level 3. *Chosen plaintext.* Eve can obtain the ciphertext of any plaintext she likes.

Remark. Both examples above fail at Level 1 against English plaintext of any length, by frequency analysis: in the substitution cipher the letter frequencies are merely permuted, and in the Vigenère cipher the same is true within each residue class modulo d (and d

itself is found by looking for repeated ciphertext fragments). Even against random-looking plaintext, both fall immediately at Level 2, since a single plaintext–ciphertext pair reveals the key. Modern applications demand Level 3 security.

§28.7.2 Perfect Secrecy and the One-Time Pad

To do better we should say what perfect security means, and information theory gives us the language. Model the key and message as *independent* random variables K, M on $\mathcal{K}, \mathcal{M}$, and let $C = e(M, K)$ be the ciphertext.

Definition 28.7.3 (Perfect Secrecy)

A cryptosystem has **perfect secrecy** if $H(M | C) = H(M)$; equivalently $I(M; C) = 0$; equivalently M and C are independent.

In other words, seeing the ciphertext tells Eve nothing at all about the message that she did not already know. This is an extremely strong requirement, and it is expensive.

Proposition 28.7.4 (Shannon)

Suppose a cryptosystem has perfect secrecy, and that every message in $\mathcal{M}$ and every ciphertext in $\mathcal{C}$ occurs with positive probability. Then $|\mathcal{K}| \geq |\mathcal{C}| \geq |\mathcal{M}|$. In particular the key is at least as long as the message.

Proof. Fix a key k . The map $m \mapsto e(m, k)$ is injective, since $d(\cdot, k)$ inverts it; hence $|\mathcal{C}| \geq |\mathcal{M}|$.

Now fix a ciphertext $c \in \mathcal{C}$ and a message $m \in \mathcal{M}$. By perfect secrecy M and C are independent, so

$$\mathbb{P}(C = c | M = m) = \mathbb{P}(C = c) > 0,$$

and therefore there is at least one key k with $e(m, k) = c$. Fix c and let m range over $\mathcal{M}$: the keys so obtained are distinct, because a single key k can satisfy $e(m, k) = c$ for at most one m , again by injectivity. Hence $|\mathcal{K}| \geq |\mathcal{M}|$. Applying the same argument with m fixed and c ranging over $\mathcal{C}$ – for each c there is a key carrying m to c , and distinct c need distinct keys since $e(m, \cdot)$ is a function – gives $|\mathcal{K}| \geq |\mathcal{C}|$. $\square$

So perfect secrecy demands a key space at least as large as the message space: a fresh $\log|\mathcal{M}|$ bits of shared secret for every message sent. That is a heavy price, and we shall see at the end of this section that the one-time pad pays exactly it. Before that, it is worth quantifying how far short of perfection an imperfect system falls, and for that we need two more pieces of vocabulary.

Definition 28.7.5

The **message equivocation** is $H(M | C)$ and the **key equivocation** is $H(K | C)$.

Lemma 28.7.6

$$H(M | C) \leq H(K | C).$$

Proof. Since $M = d(C, K)$, knowing C and K determines M , so $H(M | C, K) = 0$ and hence $H(M, C, K) = H(C, K)$. Now expand by the chain rule in two ways:

$$\begin{aligned} H(K | C) &= H(K, C) - H(C) = H(M, C, K) - H(C) \\ &= H(K | M, C) + H(M, C) - H(C) = H(K | M, C) + H(M | C), \end{aligned}$$

and $H(K | M, C) \geq 0$. □

So determining the key is at least as hard as determining the message – which is reassuring, since it means we may safely study the key equivocation instead.

Suppose $\mathcal{M} = \mathcal{C} = \mathcal{A}$ and we send n messages $M^{(n)} = (M_1, \dots, M_n)$ using the *same* key, obtaining $C^{(n)}$.

Definition 28.7.7 (Unicity Distance)

The **unicity distance** is the least n for which $H(K | C^{(n)}) = 0$, that is, the least amount of ciphertext which determines the key uniquely.

Repeating the computation of the lemma with $M^{(n)}$ in place of M , and using independence of K and $M^{(n)}$,

$$H(K | C^{(n)}) = H(K) + H(M^{(n)}) - H(C^{(n)}).$$

Make three natural assumptions: all keys are equally likely, so $H(K) = \log|\mathcal{K}|$; the message source has information rate H , so $H(M^{(n)}) \approx nH$ for large n ; and all ciphertexts look equally likely, so $H(C^{(n)}) = n \log|\mathcal{A}|$. Then

$$H(K | C^{(n)}) \approx \log|\mathcal{K}| + nH - n \log|\mathcal{A}|,$$

which is non-negative precisely when

$$n \leq U = \frac{\log|\mathcal{K}|}{\log|\mathcal{A}| - H} = \frac{\log|\mathcal{K}|}{R \log|\mathcal{A}|}, \quad R = 1 - \frac{H}{\log|\mathcal{A}|},$$

where R is the **redundancy** of the source. So U is our estimate for the unicity distance. To make it large we may either enlarge the key space or, more cheaply, reduce the redundancy of the plaintext – which is to say, *compress before encrypting*. This is a genuinely practical moral, and it is pleasing that the two halves of the course meet here.

Definition 28.7.8 (One-Time Pad)

Let the plaintext, key and ciphertext be streams $p_0, p_1, \dots$, $k_0, k_1, \dots$ and $z_0, z_1, \dots$ in $\mathbb{F}_2$ with $z_n = p_n + k_n$. The **one-time pad** is the cryptosystem in which the k_i are independent and uniform on $\{0, 1\}$.

Then each $z_n = p_n + k_n$ is uniform on $\{0, 1\}$ and independent of everything else, so C is independent of M : the one-time pad has perfect secrecy, and its unicity distance is infinite. Eve, given the ciphertext, learns literally nothing.

The catch is in the name. The key must be as long as the message, must be truly random, and must never be reused (if $z = p + k$ and $z' = p' + k$ then $z + z' = p + p'$, and Eve is back to a classical cipher). Generating and distributing such a key is precisely the problem we were trying to solve. The one-time pad is therefore used only where the stakes justify the cost.

§28.7.3 Stream Ciphers

The practical compromise is to share a short key and use it to *generate* a long key stream deterministically, by means of a shift register. The security now rests on Eve being unable to predict the stream.

Lemma 28.7.9

Let $x_0, x_1, \dots$ be a stream produced by a feedback shift register of length d . Then there are $M, N \leq 2^d$ with $x_{N+r} = x_r$ for all $r \geq M$.

Proof. Let $f: \mathbb{F}_2^d \rightarrow \mathbb{F}_2^d$ be the register and $v_i = (x_i, \dots, x_{i+d-1})$, so $f(v_i) = v_{i+1}$. The $2^d + 1$ vectors $v_0, \dots, v_{2^d}$ cannot all be distinct, so $v_a = v_b$ for some $a < b \leq 2^d$. Put $M = a$ and $N = b - a$; then $v_M = v_{M+N}$ and applying f repeatedly gives $v_r = v_{r+N}$ for all $r \geq M$. $\square$

Remark. So the maximum period of a general feedback shift register of length d is 2^d . For a *linear* register the all-zero fill is a fixed point, so the maximum period is $2^d - 1$, attained exactly when the auxiliary polynomial is primitive – as in Example 28.6.25.

Stream ciphers built from LFSRs are cheap, fast, and error-tolerant: encryption and decryption happen bit by bit with no need to buffer the message, and a corrupted bit affects only itself. They are also, as we saw at the end of Section 28.6, completely broken at Level 2. Given $2d$ bits of known plaintext, Eve recovers $2d$ bits of key stream, runs Berlekamp–Massey, and obtains the register.

One might try to fix this by combining several registers. It does not help very much.

Lemma 28.7.10

Let (x_n) and (y_n) be streams from LFSRs of lengths M and N . Then

- (i) $(x_n + y_n)$ comes from an LFSR of length at most $M + N$;
- (ii) $(x_n y_n)$ comes from an LFSR of length at most MN .

Proof sketch, non-examinable. Assume for simplicity that the auxiliary polynomials P, Q have distinct roots $\alpha_1, \dots, \alpha_M$ and $\beta_1, \dots, \beta_N$ in some field $K \supseteq \mathbb{F}_2$. Solving the recurrences, $x_n = \sum_i \lambda_i \alpha_i^n$ and $y_n = \sum_j \mu_j \beta_j^n$ for constants in K . Then $x_n + y_n$ is a combination of the α_i^n and β_j^n , so satisfies the recurrence with auxiliary polynomial $P(X)Q(X)$, of degree $M + N$; and $x_n y_n = \sum_{i,j} \lambda_i \mu_j (\alpha_i \beta_j)^n$ satisfies the one with auxiliary polynomial $\prod_{i,j} (X - \alpha_i \beta_j)$, of degree MN . $\square$

Adding streams therefore buys nothing: the sum is no harder to analyse than a single register of length $M + N$ would have been. Multiplying does increase the effective length, but $x_n y_n = 0$ whenever either factor vanishes, so the output is heavily biased towards 0 and leaks information in other ways. Genuinely nonlinear feedback functions are used in practice, but they are hard to analyse – and the danger is that Eve may understand the register better than Alice and Bob do.

§28.7.4 Public Key Cryptography

Stream ciphers are **symmetric**: the decryption procedure is the encryption procedure, or is trivially deduced from it. Every symmetric system suffers the key exchange problem: before Alice and Bob can talk, they must somehow already have talked.

In an **asymmetric** or **public key** cryptosystem the key splits in two. There is a **public key**, used for encryption and broadcast freely, and a **private key**, used for decryption and known only to its owner. Knowing the algorithms and the public key, it should still be infeasible to find the private key or to decrypt messages. This automatically gives Level 3 security – Eve can encrypt whatever she likes, since so can anyone – and it removes the key exchange problem entirely.

Such systems are built on computational problems believed to be hard. Two dominate.

- (i) *Factoring*. Given $N = pq$ with p, q large primes, find p and q .
- (ii) *The discrete logarithm problem*. Given a large prime p , a primitive root g modulo p , and $x \in \mathbb{F}_p^\times$, find a with $x \equiv g^a \pmod{p}$.

Definition 28.7.11 (Polynomial Time)

An algorithm runs in **polynomial time** if the number of bit operations it performs on an input of size N bits is at most cN^d for constants c, d .

Note the input size for a problem about N is $\log_2 N$, the number of bits of N ; this is what makes trial division a bad algorithm.

Example 28.7.12

The following are polynomial time: addition, multiplication and division of integers; Euclid's algorithm and hence computation of greatest common divisors and modular inverses; modular exponentiation $x^a \bmod N$ by repeated squaring; and primality testing (see II Number Theory for the Miller–Rabin and Solovay–Strassen tests, which are fast and probabilistic, and note that a deterministic polynomial time test also exists).

No polynomial time algorithm is known for (i) or (ii). The naive methods take exponential time:

- For factoring, dividing N by successive primes up to $\sqrt{N}$ succeeds in $O(\sqrt{N}) = O(2^{B/2})$ steps where $B = \log_2 N$.
- For discrete logarithms there is the **baby-step giant-step** method. Set $m = \lceil \sqrt{p} \rceil$ and write $a = qm + r$ with $0 \leq q, r < m$. Then $x \equiv g^{qm+r}$ gives $g^{qm} \equiv g^{-r}x \pmod{p}$. Tabulate the m values g^{qm} and the m values $g^{-r}x$, sort, and look for a match; this takes $O(\sqrt{p} \log p)$ steps.

The best known general methods for both are factor base methods, culminating in the number field sieve, with running time

$$O\left(\exp\left(c(\log N)^{1/3}(\log \log N)^{2/3}\right)\right)$$

for a known constant c – subexponential, but still far from polynomial.

§28.7.5 The Rabin Cryptosystem

We recall from IA Numbers and Sets and II Number Theory that **Euler's totient function** $\varphi(n) = |(\mathbb{Z}/n\mathbb{Z})^\times|$ counts the integers below n coprime to it, that $\varphi(pq) = (p-1)(q-1)$ for distinct primes, and that by Lagrange's theorem

$$a^{\varphi(N)} \equiv 1 \pmod{N} \quad \text{whenever } (a, N) = 1,$$

the Fermat–Euler theorem; when $N = p$ is prime this is Fermat's little theorem.

Lemma 28.7.13

Let $p = 4k - 1$ be prime and $d \in \mathbb{Z}$. If $x^2 \equiv d \pmod{p}$ is soluble, then $x \equiv d^k$ is a solution.

Proof. Let x_0 be a solution; we may assume $p \nmid x_0$, else $d \equiv 0$ and the claim is trivial. Then

$$d^{2k-1} \equiv x_0^{2(2k-1)} = x_0^{4k-2} = x_0^{p-1} \equiv 1 \pmod{p},$$

$$\text{so } (d^k)^2 = d^{2k} \equiv d \cdot d^{2k-1} \equiv d.$$

□

So modulo a prime $p \equiv 3 \pmod{4}$ we can extract square roots in polynomial time. This is the basis of Rabin's scheme.

The private key is a pair of large distinct primes $p, q \equiv 3 \pmod{4}$; the public key is $N = pq$. We take $\mathcal{M} = \mathcal{C} = (\mathbb{Z}/N\mathbb{Z})^\times$ and encrypt m as

$$c \equiv m^2 \pmod{N}.$$

To decrypt, Bob uses Lemma 28.7.13 to find x_1 with $x_1^2 \equiv c \pmod{p}$ and x_2 with $x_2^2 \equiv c \pmod{q}$, then combines them with the Chinese Remainder Theorem: running Euclid's algorithm on p, q gives r, s with $rp + sq = 1$, and then

$$x = sqx_1 + rpx_2$$

satisfies $x \equiv x_1 \pmod{p}$ and $x \equiv x_2 \pmod{q}$, so $x^2 \equiv c \pmod{N}$.

Lemma 28.7.14 (i) Let p be an odd prime and $(d, p) = 1$. Then $x^2 \equiv d \pmod{p}$ has either no solutions or exactly two.

(ii) Let $N = pq$ with p, q distinct odd primes and $(d, N) = 1$. Then $x^2 \equiv d \pmod{N}$ has either no solutions or exactly four.

Proof. (i). $x^2 \equiv y^2$ if and only if $p \mid (x - y)(x + y)$, so $x \equiv \pm y$; and $y \not\equiv -y$ as p is odd.

(ii). If x_0 is a solution then by (i) and the Chinese Remainder Theorem the solutions are exactly those x with $x \equiv \pm x_0 \pmod{p}$ and $x \equiv \pm x_0 \pmod{q}$, and the four sign choices give four distinct residues modulo N . □

So Bob must sift four candidate plaintexts, and the message needs enough built-in redundancy (a checksum, say) to identify the right one. In exchange, we get a security guarantee of a kind that is unavailable for RSA.

Theorem 28.7.15

Breaking the Rabin cryptosystem is essentially as hard as factoring N .

Proof. If we can factor N then we can decrypt, as above. Conversely, suppose we have an algorithm which extracts square roots modulo N . Choose x modulo N at random and feed x^2 to the algorithm, obtaining some y with $y^2 \equiv x^2$. By the lemma there are four square roots, and the algorithm cannot know which one we started from, so with probability $\frac{1}{2}$ we get $y \not\equiv \pm x$. In that case $N \mid (x - y)(x + y)$ but N divides neither factor, so $\gcd(N, x - y)$ is a nontrivial factor of N . Repeating r times, we factor N with probability $1 - 2^{-r}$. $\square$

Example 28.7.16

Take $p = 7$, $q = 11$, so $N = 77$ (and indeed $7 \equiv 11 \equiv 3 \pmod{4}$). To encrypt $m = 13$: $c \equiv 13^2 = 169 \equiv 15 \pmod{77}$.

To decrypt, note $7 = 4 \cdot 2 - 1$ so $k = 2$ and $x_1 \equiv 15^2 = 225 \equiv 1 \pmod{7}$; and $11 = 4 \cdot 3 - 1$ so $k = 3$ and $x_2 \equiv 15^3 \equiv 4^3 = 64 \equiv 9 \pmod{11}$. Checking, $1^2 = 1 \equiv 15$ and $9^2 = 81 \equiv 4 \equiv 15$ modulo 7 and 11 respectively. Combining, $x \equiv 1 \pmod{7}$ and $x \equiv 9 \pmod{11}$ gives $x = 64$; and $64^2 = 4096 = 53 \cdot 77 + 15$, so indeed $64^2 \equiv 15$. The four square roots of 15 modulo 77 are $\{13, 20, 57, 64\}$, of which 13 was our message.

§28.7.6 The RSA Cryptosystem

RSA is the same idea with a general exponent in place of squaring. We begin with a factoring result which will do double duty.

Let $N = pq$ with p, q distinct odd primes, and suppose we know some multiple m of $\varphi(N)$. Write $m = 2^a b$ with $a \geq 1$ and b odd, write $o_p(x)$ for the multiplicative order of x modulo p , and set

$$X = \{x \in (\mathbb{Z}/N\mathbb{Z})^\times : o_p(x^b) \neq o_q(x^b)\}.$$

Theorem 28.7.17 (i) If $x \in X$ then there is $0 \leq t < a$ such that $\gcd(x^{2^t b} - 1, N)$ is a nontrivial factor of N .

(ii) $|X| \geq \frac{1}{2}\varphi(N) = \frac{1}{2}|(\mathbb{Z}/N\mathbb{Z})^\times|$.

Proof. (i). By Fermat–Euler, $x^{\varphi(N)} \equiv 1$, hence $x^m \equiv 1 \pmod{N}$. Put $y = x^b$, so $y^{2^a} \equiv 1$ and therefore $o_p(y)$ and $o_q(y)$ are both powers of 2. Since $x \in X$ they differ, so without loss of generality $o_p(y) < o_q(y)$; write $o_p(y) = 2^t$, so $0 \leq t < a$. Then $y^{2^t} \equiv 1 \pmod{p}$ but $y^{2^t} \not\equiv 1 \pmod{q}$, so

$$\gcd(y^{2^t} - 1, N) = p.$$

(ii). The Chinese Remainder Theorem gives a group isomorphism

$$(\mathbb{Z}/N\mathbb{Z})^\times \rightarrow (\mathbb{Z}/p\mathbb{Z})^\times \times (\mathbb{Z}/q\mathbb{Z})^\times, \quad x \mapsto (x \bmod p, x \bmod q).$$

We claim that if we partition $(\mathbb{Z}/p\mathbb{Z})^\times$ according to the value of $o_p(x^b)$, then one part has size exactly $\frac{1}{2}(p-1)$. Let g be a primitive root modulo p . As $g^{p-1} \equiv 1$ and $(p-1) \mid m = 2^a b$, we get $(g^b)^{2^a} \equiv 1$, so $o_p(g^b) = 2^t$ for some t . Writing $x = g^\kappa$ we have $x^b = (g^b)^\kappa$, so

$$o_p(x^b) = \frac{2^t}{\gcd(2^t, \kappa)} = \begin{cases} 2^t & \kappa \text{ odd,} \\ < 2^t & \kappa \text{ even,} \end{cases}$$

and exactly half of the $\kappa \in \{0, \dots, p-2\}$ are odd. This proves the claim, and the same holds modulo q .

Now fix $y \in (\mathbb{Z}/q\mathbb{Z})^\times$ and consider the possible $x \in (\mathbb{Z}/p\mathbb{Z})^\times$. At most half of them have $o_p(x^b)$ equal to the particular value $o_q(y^b)$, by the claim applied to whichever part that is. Hence at least $\frac{1}{2}(p-1)$ choices of x give $o_p(x^b) \neq o_q(y^b)$. Summing over the $q-1$ choices of y and using the isomorphism,

$$|X| \geq \frac{1}{2}(p-1)(q-1) = \frac{1}{2}\varphi(N). \quad \square$$

So knowing $\varphi(N)$, or any multiple of it, lets us factor N quickly: pick x at random, and with probability at least $\frac{1}{2}$ some $\gcd(x^{2^t b} - 1, N)$ splits N .

We can now describe the scheme. Alice chooses large distinct primes p, q at random and sets $N = pq$. She chooses an **encrypting exponent** e with $\gcd(e, \varphi(N)) = 1$ – for instance a prime larger than both p and q – and uses Euclid's algorithm to find d, k with

$$de - k\varphi(N) = 1;$$

d is the **decrypting exponent**. The public key is (N, e) and the private key is (N, d) . Encryption and decryption are

$$c \equiv m^e \pmod{N}, \quad m \equiv c^d \pmod{N}.$$

Proposition 28.7.18

Decryption inverts encryption: $c^d \equiv m \pmod{N}$.

Proof. We have $de = 1 + k\varphi(N)$, so if $\gcd(m, N) = 1$ then by Fermat–Euler

$$c^d \equiv m^{de} = m \cdot (m^{\varphi(N)})^k \equiv m \pmod{N}.$$

(The probability that a random m fails $\gcd(m, N) = 1$ is $\frac{p+q-1}{N}$, utterly negligible for large p, q ; in fact the congruence still holds in that case, by checking modulo p and q separately.) $\square$

Example 28.7.19

Take $p = 17$, $q = 23$, so $N = 391$ and $\varphi(N) = 16 \cdot 22 = 352$. Take $e = 3$, which is coprime to 352. Euclid gives $3 \cdot 235 = 705 = 2 \cdot 352 + 1$, so $d = 235$.

To encrypt $m = 100$: $100^2 = 10000 = 25 \cdot 391 + 225$, so $100^2 \equiv 225$, and $100^3 \equiv 225 \cdot 100 = 22500 = 57 \cdot 391 + 213$, so $c = 213$. Decrypting, one computes $213^{235} \equiv 100 \pmod{391}$ by repeated squaring, as promised.

Corollary 28.7.20

Finding the RSA private key (N, d) from the public key (N, e) is essentially as hard as factoring N .

Proof. If we can factor N we compute $\varphi(N)$ and then d . Conversely, suppose we have an algorithm producing d from (N, e) . Then $de \equiv 1 \pmod{\varphi(N)}$, so $m := de - 1$ is a multiple of $\varphi(N)$, and Theorem 28.7.17 factors N with probability at least $\frac{1}{2}$ per random trial, hence with probability $1 - 2^{-r}$ after r trials. $\square$

Remark. Note carefully what this does *not* say. It says that recovering the private key is as hard as factoring. Whether *decrypting a single message* is as hard as factoring is unknown, and for the Rabin scheme the corresponding statement is a theorem – which is one reason Rabin’s scheme is theoretically more satisfying, even though RSA is what the world uses.

RSA also has the drawback of being slow, since modular exponentiation with 2048-bit numbers is expensive. In practice one uses RSA once, to agree on a key for a fast symmetric cipher, and then switches.

§28.7.7 Attacks on RSA

Correct mathematics is not enough; the scheme must also be used correctly. Here are some ways it goes wrong.

Example 28.7.21 (Homomorphism Attack)

The map $m \mapsto m^e$ is multiplicative, and an attacker can exploit that. Suppose a bank sends instructions of the form (M_1, M_2) , where M_1 names a client and M_2 is an amount to be credited, encrypted as $(Z_1, Z_2) = (M_1^e, M_2^e)$. A client C deposits £100 and observes the resulting ciphertext (Z_1, Z_2) . Now C replays the message (Z_1, Z_2^3) , which decrypts to (M_1, M_2^3) – a credit of £10⁶ – without C having broken RSA at all. More crudely still, C could simply resend (Z_1, Z_2) repeatedly; that particular

attack is defeated by timestamping messages, but the first is not.

Example 28.7.22 (Authenticity via RSA)

The same algebra can be used constructively. If Alice encrypts m with her *private* key (N, d) , then anyone can decrypt it with her public key, since $(m^d)^e = (m^e)^d = m$; but nobody else could have produced it. So if Bob sends Alice a random message m and receives back something which, decrypted with her public key, ends in m , he can be confident that Alice is on the other end.

The lesson is that we should encrypt and authenticate deliberately rather than incidentally, which brings us to signatures.

§28.7.8 Signatures and Hash Functions

Consider a message m from Alice to Bob. There are four distinct goals one might have.

- (i) *Secrecy*: no third party can read m .
- (ii) *Integrity*: no third party can alter m undetectably.
- (iii) *Authenticity*: Bob is sure that Alice sent m .
- (iv) *Non-repudiation*: Bob can prove to a third party that Alice sent m .

Encryption addresses the first; signatures address the rest.

Definition 28.7.23 (Signature)

A message m is **signed** as a pair (m, s) , where the **signature** $s = s(m, k)$ depends on m and on the private key k . The signature function should be such that without the private key one cannot produce valid signatures, but anyone can check them using the public key.

Note that the signature depends on the message, not just on the sender; a signature that did not would simply be copied onto other messages.

Example 28.7.24 (RSA Signatures)

Alice has private key (N, d) and public key (N, e) . She signs m as (m, s) with $s \equiv m^d \pmod{N}$, and Bob verifies by checking $s^e \equiv m$.

For instance with $N = 391$, $e = 3$, $d = 235$ as above, Alice signs $m = 100$ with $s = 100^{235} \bmod 391 = 94$, and Bob checks $94^3 = 830584 = 2124 \cdot 391 + 100$, so $94^3 \equiv 100$ as required.

This naive scheme has two flaws. It inherits the homomorphism attack, since $s_1 s_2$ signs $m_1 m_2$. And it admits **existential forgery**: an attacker chooses s first and then computes $m = s^e \bmod N$, obtaining a validly signed pair (m, s) for a message she did not choose. One hopes that such an m is meaningless, but hope is not a security argument.

The standard fix is to sign a **digest** of the message rather than the message itself.

Definition 28.7.25 (Hash Function)

A **hash function** is a publicly known function $h: \mathcal{M} \rightarrow \{1, \dots, N-1\}$, from a large space of messages to a small space of digests, for which it is computationally infeasible to find a **collision**, that is, a pair $m \neq m'$ with $h(m) = h(m')$. One also asks that given y it should be infeasible to find m with $h(m) = y$.

Collisions certainly exist, by the pigeonhole principle; the requirement is that no one can find them. Signing $(m, h(m)^d)$ rather than (m, m^d) defeats both attacks above: the homomorphism attack fails because $h(m_1 m_2) \neq h(m_1)h(m_2)$, and existential forgery fails because the attacker would have to find a message with a prescribed digest. Widely used hash functions include the (now broken) MD5 and the SHA family.

§28.7.9 Diffie–Hellman Key Exchange

The discrete logarithm problem gives a completely different route to public key cryptography, beginning with an idea of striking simplicity: Alice and Bob can agree on a shared secret in public.

Example 28.7.26 (Diffie–Hellman Key Exchange)

Let p be a large prime and g a primitive root modulo p , both public. Alice chooses a secret exponent α and sends $g^\alpha \bmod p$; Bob chooses a secret β and sends $g^\beta \bmod p$. Each now raises what they received to their own secret exponent, and both obtain

$$k = g^{\alpha\beta} \bmod p,$$

which they use as a shared key. Eve has seen g , g^α and g^β and must produce $g^{\alpha\beta}$; Diffie and Hellman conjectured that this is as hard as the discrete logarithm problem.

**Example 28.7.27**

Take $p = 23$ and $g = 5$. Alice picks $\alpha = 6$ and sends $5^6 = 15625 \equiv 8$. Bob picks $\beta = 15$ and sends $5^{15} \equiv 19$. Alice computes $19^6 \equiv 2$ and Bob computes $8^{15} \equiv 2$, and the shared key is $k = 2$.

Remark. Diffie–Hellman is vulnerable to an active attacker who can intercept and replace messages – the *man in the middle* – who simply runs the protocol separately with each of Alice and Bob and relays traffic between the two sessions. Defeating this needs authentication, which is what signatures are for.

Example 28.7.28 (Shamir's Padlock Scheme)

Here is a related idea requiring no shared key at all. Work modulo a prime p . Alice picks a coprime to $p - 1$ and computes a' with $aa' \equiv 1 \pmod{p - 1}$; Bob does the same with b, b' . To send m , Alice sends m^a ; Bob returns $(m^a)^b$; Alice sends back $(m^{ab})^{a'}$; and Bob computes

$$(m^{aba'})^{b'} = m^{aa'bb'} \equiv m \pmod{p}$$

by Fermat's little theorem, since $aa'bb' \equiv 1 \pmod{p - 1}$. The picture is that Alice puts her padlock on a box and sends it; Bob adds his padlock and sends it back; Alice removes hers; Bob removes his.

$$m \xrightarrow{A} m^a \xrightarrow{B} m^{ab} \xrightarrow{A} m^{aba'} \xrightarrow{B} m$$

It costs three transmissions rather than one, which is why it is a curiosity rather than a standard.

§28.7.10 The ElGamal Scheme

Diffie–Hellman can be turned into a genuine public key cryptosystem.

Definition 28.7.29 (ElGamal Encryption)

Alice chooses a large prime p , a primitive root g modulo p , and a secret u with $1 < u < p - 1$. Her public key is (p, g, y) with $y \equiv g^u$, and her private key is u . To send Alice a message m , Bob chooses a random k and sends the pair

$$(c_1, c_2) = (g^k, my^k) \pmod{p}.$$

Alice recovers $m = c_2 c_1^{-u} \pmod{p}$, since $c_1^u = g^{ku} = y^k$.

Example 28.7.30

Take $p = 23$, $g = 5$, $u = 7$, so $y = 5^7 \equiv 17$. To send $m = 10$, Bob picks $k = 3$: then $c_1 = 5^3 = 125 \equiv 10$ and $c_2 = 10 \cdot 17^3 \equiv 10 \cdot 14 = 140 \equiv 2$. So the ciphertext is $(10, 2)$. Alice computes $c_1^u = 10^7 \equiv 14$, inverts it ($14 \cdot 5 = 70 \equiv 1$, so $14^{-1} = 5$), and finds $m = 2 \cdot 5 = 10$.

Note that a fresh k is used for every message, so the same plaintext encrypts differently each time – a genuine advantage over textbook RSA. The same construction gives a signature scheme.

Definition 28.7.31 (ElGamal Signature Scheme)

With p, g, u, y as above and a collision-resistant hash function $h: \mathcal{M} \rightarrow \{1, \dots, p - 1\}$, Alice signs m as follows. She chooses a random k with $1 \leq k \leq p - 2$ and $\gcd(k, p - 1) = 1$, and computes r, s with

$$r \equiv g^k \pmod{p}, \quad h(m) \equiv ur + ks \pmod{p - 1}.$$

The congruence for s is soluble because k is invertible modulo $p - 1$. The signature is (r, s) .

Verification is a one-line computation:

$$g^{h(m)} \equiv g^{ur+ks} \equiv (g^u)^r (g^k)^s \equiv y^r r^s \pmod{p},$$

so Bob accepts (r, s) if and only if $g^{h(m)} \equiv y^r r^s$. Forging a signature by the obvious routes requires solving a discrete logarithm.

Example 28.7.32

Take $p = 23$, $g = 5$, $u = 7$, $y = 17$, and suppose $h(m) = 9$. Alice picks $k = 5$, which is coprime to 22. Then $r = 5^5 = 3125 \equiv 20$. Solving $9 \equiv 7 \cdot 20 + 5s \pmod{22}$, that is $5s \equiv 9 - 140 \equiv 1 \pmod{22}$, gives $s = 9$ (as $5 \cdot 9 = 45 = 2 \cdot 22 + 1$). Checking: $g^{h(m)} = 5^9 \equiv 11$, and $y^r r^s = 17^{20} \cdot 20^9 \equiv 11$. The signature verifies.

It is vital that Alice choose a fresh k for each message. Suppose she signs m_1 and m_2 with the same k , giving signatures (r, s_1) and (r, s_2) – note r depends only on k , so it repeats, which is how Eve spots the mistake. Then

$$h(m_1) \equiv ur + ks_1, \quad h(m_2) \equiv ur + ks_2 \pmod{p-1},$$

so subtracting,

$$h(m_1) - h(m_2) \equiv k(s_1 - s_2) \pmod{p-1}.$$

We need one small fact to finish.

Lemma 28.7.33

The congruence $ax \equiv b \pmod{n}$ has either no solutions or exactly $\gcd(a, n)$ solutions modulo n .

Proof. Let $\delta = \gcd(a, n)$. If $\delta \nmid b$ there is no solution, since δ divides the left hand side for any x . If $\delta \mid b$, the congruence is equivalent to $\frac{a}{\delta}x \equiv \frac{b}{\delta} \pmod{\frac{n}{\delta}}$, and $\frac{a}{\delta}, \frac{n}{\delta}$ are coprime, so this has a unique solution modulo $\frac{n}{\delta}$ and hence δ solutions modulo n . $\square$

By Lemma 28.7.33 there are $\gcd(p-1, s_1 - s_2)$ candidate values of k ; Eve tests each against $r \equiv g^k$ and keeps the right one. Then from $ur \equiv h(m_1) - ks_1$ she gets $\gcd(p-1, r)$ candidates for u , and tests each against $y \equiv g^u$. So a single repeated k hands over Alice's private key.

§28.7.11 The Digital Signature Algorithm

The **Digital Signature Algorithm** (DSA), developed by the NSA, is a variant of the ElGamal signature scheme designed to keep signatures short by working in a small subgroup.

The public parameters are (p, q, g) constructed as follows.

- p is a prime of exactly N bits, where N is a multiple of 64 with $512 \leq N \leq 1024$.
- q is a prime of 160 bits with $q \mid p - 1$.

- $g \equiv h^{(p-1)/q} \pmod{p}$, where h is a primitive root modulo p ; thus g has order exactly q in $\mathbb{F}_p^\times$.
- Alice chooses a private key x with $1 < x < q$ and publishes $y \equiv g^x \pmod{p}$.

To sign a message m with $0 \leq m < q$, Alice chooses a random k with $1 < k < q$ and computes

$$s_1 \equiv (g^k \bmod p) \bmod q, \quad s_2 \equiv k^{-1}(m + xs_1) \bmod q.$$

The signature is (s_1, s_2) , a pair of 160-bit numbers however large p is. To verify, Bob computes

$$w \equiv s_2^{-1}, \quad u_1 \equiv mw, \quad u_2 \equiv s_1w \pmod{q}, \quad v = (g^{u_1}y^{u_2} \bmod p) \bmod q,$$

and accepts if $v = s_1$.

Proposition 28.7.34

A correctly signed and unaltered message is accepted.

Proof. From the definition of s_2 we get $(m + xs_1)w \equiv (m + xs_1)s_2^{-1} \equiv k \pmod{q}$. Since g has order q modulo p , exponents of g only matter modulo q , so

$$\begin{aligned} v &= (g^{mw}g^{xs_1w} \bmod p) \bmod q = (g^{(m+xs_1)w} \bmod p) \bmod q \\ &= (g^k \bmod p) \bmod q = s_1. \square \end{aligned}$$

As with ElGamal, reusing k is fatal: if Alice signs m_1 and m_2 with the same k then s_1 repeats and subtracting the two congruences for s_2 recovers k , hence x .

§28.7.12 Commitment Schemes

Suppose Alice wants to commit to a bit $m \in \{0, 1\}$ so that

- Bob cannot determine m without Alice's help, and
- Alice cannot change m after committing.

This is **bit commitment**, and it is what one needs to toss a coin over the telephone, or to run a poll whose results stay hidden until everyone has voted.

The first solution is immediate given any secure cipher. Alice commits by sending $c = e_A(m)$, using a key known only to her; Bob cannot read it. To reveal, she sends her key, and Bob decrypts. He can also check that e_A and d_A really are mutually inverse, so she cannot pass off a bogus key that decrypts c to the other bit.

The second is prettier and uses coding theory. Suppose Alice and Bob have two channels: a clear one and a binary symmetric channel with error probability $p \in (0, \frac{1}{2})$ which neither of them can influence. Bob publishes a binary linear code C of length N and minimum distance d , and Alice publishes a random nontrivial linear map $\theta: C \rightarrow \mathbb{F}_2$. To commit to m , Alice picks a random $c \in C$ with $\theta(c) = m$ and sends c down the *noisy* channel; Bob receives $r = c + e$.

Now $\mathbb{E}[d(r, c)] = Np$, and we choose N so that $Np \gg d$. Then the received word r is far further from c than codewords are from each other, so Bob has no idea which codeword was sent and hence no idea of $\theta(c) = m$. That is (i).

To reveal, Alice sends c down the clear channel, and Bob checks that $d(c, r) \approx Np$. She cannot cheat: she knows c but not e , so if she tries to reveal some $c' \neq c$ she must arrange $d(r, c') \approx Np$ without knowing r . The only way to be confident of that is to take c' very close to c ; but distinct codewords are at distance at least d , and the probability that a codeword at distance $\geq d$ from c happens to be at distance about Np from r is negligible for suitable N and d . That is (ii). (One should choose N and d so that the probability of an *honest* commitment being rejected, because the channel happened to make far too many or too few errors, is also negligible.)

§28.7.13 Secret Sharing

We finish with a scheme of a rather different flavour. Suppose entry to a bunker is controlled by a secret positive integer S , known only to the Leader. Each of the n members of the Faculty is to be given a **shadow** or **share**, in such a way that any k of them together can reconstruct S , but no $k - 1$ of them can learn anything about it at all.

Definition 28.7.35 (Threshold Scheme)

Let $k \leq n$. A **(k, n) -threshold scheme** is a method of distributing a secret S among n participants so that any k of them can reconstruct S , but no smaller subset can.

Shamir's construction is a one-line application of Lagrange interpolation: a polynomial of degree $k - 1$ is determined by its values at k points, and completely undetermined by its values at $k - 1$ points.

Let $0 \leq S \leq M$ be the secret. The Leader chooses and publishes a prime $p > n, M$, chooses independent uniform random coefficients $a_1, \dots, a_{k-1}$ in $\{0, \dots, p-1\}$, sets $a_0 = S$, and chooses distinct $x_1, \dots, x_n$ in $\{1, \dots, p-1\}$. Writing

$$P(x) = a_0 + a_1x + \dots + a_{k-1}x^{k-1} \pmod{p},$$

the r th participant receives the pair $(x_r, P(x_r))$, and the Leader destroys all working.

Now suppose k participants assemble, with pairs (y_j, z_j) , $1 \leq j \leq k$, where the y_j are distinct. They must solve

$$\begin{pmatrix} 1 & y_1 & \cdots & y_1^{k-1} \\ 1 & y_2 & \cdots & y_2^{k-1} \\ \vdots & & \ddots & \vdots \\ 1 & y_k & \cdots & y_k^{k-1} \end{pmatrix} \begin{pmatrix} c_0 \\ c_1 \\ \vdots \\ c_{k-1} \end{pmatrix} = \begin{pmatrix} z_1 \\ z_2 \\ \vdots \\ z_k \end{pmatrix}$$

for $(c_0, \dots, c_{k-1})$ over $\mathbb{F}_p$. By Lemma 28.6.11 the matrix is Vandermonde with distinct nodes, so it is invertible and the solution is unique; and $(a_0, \dots, a_{k-1})$ is a solution by construction. Hence $c_0 = a_0 = S$.

If instead only $k - 1$ participants assemble, the corresponding system has $k - 1$ equations in k unknowns. Moving the c_0 column to the right hand side, the remaining matrix

$$\begin{pmatrix} y_1 & y_1^2 & \cdots & y_1^{k-1} \\ \vdots & & \ddots & \vdots \\ y_{k-1} & y_{k-1}^2 & \cdots & y_{k-1}^{k-1} \end{pmatrix}$$

has determinant $y_1 \cdots y_{k-1} \prod_{j < i} (y_i - y_j) \neq 0$, so for *every* choice of c_0 there is exactly one consistent completion. The $k - 1$ participants therefore learn nothing whatsoever about S : all p values remain exactly equally likely.

Example 28.7.36

Take $k = 3$, $p = 17$ and secret $S = 5$, with random coefficients $a_1 = 3$, $a_2 = 2$, so $P(x) = 5 + 3x + 2x^2$. The shares at $x = 1, \dots, 5$ are

$$(1, 10), \quad (2, 2), \quad (3, 15), \quad (4, 15), \quad (5, 2)$$

working modulo 17. Suppose the first three participants meet. Lagrange interpolation at 0 gives

$$S = 10 \cdot \frac{(0-2)(0-3)}{(1-2)(1-3)} + 2 \cdot \frac{(0-1)(0-3)}{(2-1)(2-3)} + 15 \cdot \frac{(0-1)(0-2)}{(3-1)(3-2)} = 10 \cdot 3 + 2 \cdot (-3) + 15 \cdot 1,$$

which is $30 - 6 + 15 = 39 \equiv 5 \pmod{17}$, recovering the secret.

Remark. The scheme has several pleasant features. The shares can be refreshed at any time without changing S , by choosing a new random polynomial with the same constant term; an eavesdropper who has slowly accumulated shares from the old polynomial learns nothing about the new one. And the shares are no larger than the secret, which is optimal.

Example 28.7.37 (Hierarchical Schemes)

In a $(3, n)$ -threshold scheme, give ordinary employees one share each, vice-presidents two, and the Leader three. Then the secret can be recovered by any three employees, or by a vice-president together with any one employee, or by the Leader alone. The number of shares held encodes seniority.

Example 28.7.38 (Reliable Storage)

Alice wishes to store a private key both securely and reliably. She uses a $(k, 2k - 1)$ -threshold scheme and puts the $2k - 1$ shares in different places. She can recover the key as long as she does not lose more than half of them, so the scheme is reliable; and a thief must steal more than half of them, so it is secure. This is exactly the same trade-off between redundancy and information rate that occupied us in Section 3, in a new costume.

29 Differential Geometry

Differential geometry is what happens when you take the calculus you learned in first year and try to do it on something that isn't flat. The objects of study are *smooth manifolds* – spaces which, close up, look like a piece of Euclidean space, but which globally may be curved, knotted or twisted in interesting ways – and the tools of study are the derivative and the integral, suitably reinterpreted. The central discovery of the subject, and the one which gives it its character, is that curvature is not merely a feature of how a space sits inside a bigger space: a two-dimensional creature confined to a surface can measure the curvature of its world without ever leaving it. This is Gauss's *Theorema Egregium*, and everything in the second half of this course flows from it, culminating in the Gauss–Bonnet theorem, which ties the total curvature of a compact surface to a purely topological invariant.

This article constitutes my notes for the 'Differential Geometry' course, held in Michaelmas 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§29.1 Differential Topology

§29.1.1 Manifolds

The idea of a manifold is to generalize our typical boring and flat 'Euclidean space' with an object where everything isn't necessarily flat. For example, we can take some surfaces as drawn below.

We really care about surfaces where, in a sufficiently small region around each point, things look like we are in normal flat Euclidean space. This, along with a desire for things to be nice and smooth (as we shall define) will manifest into our basic notion of a *manifold*.

Definition 29.1.1 (Smooth)

For an open subset $U \subseteq \mathbb{R}^n$, we say a function $f : U \rightarrow \mathbb{R}^m$ is **smooth**^a if it has continuous partial derivatives of all orders.

^aFor a function $f : X \rightarrow \mathbb{R}^m$ with X not open, we say that f is smooth if the above definition holds for some open neighborhood V_x containing x for each $x \in X$.

Definition 29.1.2 (Diffeomorphism)

A smooth function $f : X \rightarrow Y$ is a **diffeomorphism** if it's a bijection with smooth inverse. If a diffeomorphism between X and Y exists we say they are **diffeomorphic**.

Definition 29.1.3 (Manifold)

We say that $X \subseteq \mathbb{R}^n$ is a **k -dimensional manifold** if each $x \in X$ has a neighborhood $V \subseteq X$ diffeomorphic to an open set of $\mathbb{R}^k$.

With neighborhoods around each point looking like $\mathbb{R}^k$, we can sensibly imagine that one could locally put a coordinate system on such neighborhoods, one coming from the diffeomorphism to $\mathbb{R}^k$. This motivates the definition of a *chart* on a manifold.

Definition 29.1.4 (Chart)

A diffeomorphism $\phi : U \rightarrow V$, where U is an open set of $\mathbb{R}^k$ is a **parameterisation** of the neighborhood V . The inverse diffeomorphism $\phi^{-1} : V \rightarrow U$ is called a **chart** on V .

Of course, if we have manifolds X and Z with $Z \subseteq X$ we say that Z is a **submanifold** of X . In this case, the **codimension** of Z in X is $\dim X - \dim Z$.

§29.1.2 Tangent Spaces and Derivatives

This is a course in differential geometry, and we've pinned down the 'geometry' part, now it's time to pin down the 'differential part'. We want to generalise the notion of a derivative for smooth functions on manifolds.

The idea you should have in your head of derivatives are that they are the best linear approximation to a given function. From this perspective, defining the derivative on manifolds requires us to answer two questions: what space should be our 'linear approximation' to a manifold that our derivative should act on, and then what is our linear approximation? Answering the first of these questions will lead us to the notion of **tangent spaces**.

Definition 29.1.5 (Tangent Space of a Manifold)

Let $X \subseteq \mathbb{R}^n$ be an arbitrary smooth manifold, and let $x \in X$. Choose a parameterisation $\phi : U \rightarrow X$ with $\phi(0) = x$ where U is an open set of $\mathbb{R}^k$. Then thinking of ϕ as a map from U to $\mathbb{R}^N$, we define the **tangent space** $T_x X$ to be the image of the derivative of ϕ at 0, $D_0\phi(\mathbb{R}^k)$.

In this definition we had to pick some parameterisation ϕ , but one would hope that our resulting space is independent of this choice. Indeed, this is the case.

Lemma 29.1.6 (Tangent Spaces are Parameterisation Independent)

$T_x X$ does not depend on the parameterisation ϕ chosen.

Proof. Suppose $\psi : V \rightarrow X$ is another choice of parameterisation, and suppose without loss of generality that $\phi(0) = \psi(0) = x$. By shrinking both U and V , we may assume that $\phi(U) = \psi(V)$. Then the map $h = \psi^{-1} \circ \phi : U \rightarrow V$ is a diffeomorphism. Now we write $\phi = \psi \circ h$ and we differentiate. Using the chain rule we have: $D_0\phi = D_0\psi \circ D_0h$. Since D_0h is an invertible linear map, it follows at once that $D_0\phi$ and $D_0\psi$ have the same image. $\square$

We are now ready to define the derivative of a smooth map $f : X \rightarrow Y$ between arbitrary manifolds, and we will see that it comes rather naturally. We would hope that for X and Y open subsets of euclidean space, our new definition should coincide with our previous definition of the derivative. Also, we would expect that the chain rule should still hold. This is going to force our definition.

Let $\phi : U \rightarrow X$ and $\psi : V \rightarrow Y$ be parameterisations, with $\phi(0) = x$, $\psi(0) = y$ and U, V being open subsets of $\mathbb{R}^k$ and $\mathbb{R}^l$ respectively. Then for small enough U , the following diagram commutes:

$$\begin{array}{ccc} X & \xrightarrow{f} & Y \\ \phi \uparrow & & \uparrow \psi \\ U & \xrightarrow{h=\psi^{-1} \circ f \circ \phi} & V \end{array}$$

Then $D_0\psi$, $D_0\phi$, D_0h are all well defined, and as we said previously we would hope the chain rule still holds, which implies that the following square of linear maps commutes:

$$\begin{array}{ccc} T_x X & \xrightarrow{df_x} & T_y Y \\ d\phi_0 \uparrow & & \uparrow d\psi_0 \\ \mathbb{R}^k & \xrightarrow{dh_0} & \mathbb{R}^l \end{array}$$

Then since $D_0\phi$ is an isomorphism, only one definition of $D_x f$ will meet our requirements, namely

$$D_x f = D_0\psi \circ D_0h \circ D_0\phi^{-1}.$$

Again, one would hope that this definition of $D_x f$ is independent of ϕ and ψ , and this is the case (and the same proof as before works). Also, we have forced the chain rule still to hold.

Theorem 29.1.7 (Chain Rule)

If $f : X \rightarrow Y$ and $g : Y \rightarrow Z$ are smooth maps between manifolds, then

$$D_x(g \circ f) = D_{f(x)}g \circ D_xf.$$

Proof. This is immediate from the ordinary chain rule. Choose smooth extensions F of f and G of g to open neighbourhoods of x and $f(x)$ in the ambient Euclidean spaces, arranged so that $G \circ F$ is defined; then $G \circ F$ is a smooth extension of $g \circ f$, and

$$D_x(g \circ f) = D(G \circ F)|_x|_{T_xX} = (DG|_{f(x)} \circ DF|_x)|_{T_xX} = D_{f(x)}g \circ D_xf,$$

where the middle equality is the chain rule in Euclidean space and the last uses that D_xf maps T_xX into $T_{f(x)}Y$. $\square$

The Inverse Function Theorem

Let $f : X \rightarrow Y$ be a smooth map between manifolds. We say that f is a **local diffeomorphism** at x if f maps a neighbourhood of x diffeomorphically onto a neighbourhood of $f(x)$.

Theorem 29.1.8 (Inverse Function Theorem)

Suppose that $f : X \rightarrow Y$ is a smooth map whose derivative df_x at the point x is an isomorphism. Then f is a local diffeomorphism at x .

Proof Sketch. This can be proven using the inverse function theorem for smooth functions between open sets of Euclidean space, as was shown in Analysis II. $\square$

§29.1.3 Regular Values and Sard's Theorem

Let $f : X \rightarrow Y$ be a smooth map between manifolds. Let C be the set of all points $x \in X$ such that $df_x : T_xX \rightarrow T_{f(x)}Y$ is not surjective.

Definition 29.1.9

A point in C will be called a **critical point**. A point in $f(C)$ will be called a **critical value**. A point in the complement of $f(C)$ will be called a **regular value**.

Remark. Note that if $\dim X < \dim Y$, then $C = X$ and the preimage of a regular value is the empty set.

Theorem 29.1.10 (Preimage Theorem)

Let y be a regular value of $f : X \rightarrow Y$ with $\dim X \geq \dim Y$. Then the set $f^{-1}(y)$ is a submanifold of X with $\dim f^{-1}(y) = \dim X - \dim Y$.

Proof. Let $x \in f^{-1}(y)$. Since y is a regular value, the derivative df_x maps T_xX onto T_yY . The kernel of df_x is a subspace K of T_xX of dimension $p := \dim X - \dim Y$.

Suppose $X \subset \mathbb{R}^N$ and let $T : \mathbb{R}^N \rightarrow \mathbb{R}^p$ be any linear map such that $\text{Ker}(T) \cap K = \{0\}$. Consider the map $F : X \rightarrow Y \times \mathbb{R}^p$ given by

$$F(z) = (f(z), T(z)).$$

The derivative of F is given by

$$dF_x(v) = (df_x(v), T(v))$$

which is clearly nonsingular by our choice of T . By the inverse function theorem, F is a local diffeomorphism at x , i.e. F maps some neighbourhood U of x diffeomorphically onto a neighbourhood V of $(y, T(x))$. Hence F maps $f^{-1}(y) \cap U$ diffeomorphically onto $(\{y\} \times \mathbb{R}^p) \cap V$ which proves that $f^{-1}(y)$ is a manifold with $\dim f^{-1}(y) = p$. $\square$

The case $\dim X = \dim Y$ is particularly important. The theorem says that if y is a regular value of f , then $f^{-1}(y)$ is a 0-dimensional manifold, i.e. collection of points. If X is compact, this collection must be finite (why?) so we obtain:

Corollary 29.1.11

Let $f : X \rightarrow Y$ be a smooth map between manifolds of the same dimension. If X is compact and y is a regular value, $f^{-1}(y)$ consists of a finite set of points.

We can actually say a bit more:

Theorem 29.1.12 (Stack of Records Theorem)

Let $f : X \rightarrow Y$ be a smooth map between manifolds of the same dimension with X compact. Let y be a regular value of f and write $f^{-1}(y) = \{x_1, \dots, x_k\}$. Then there exists a neighbourhood U of y in Y such that $f^{-1}(U)$ is a disjoint union $V_1 \cup \dots \cup V_k$, where V_i is an open neighbourhood of x_i and f maps each V_i diffeomorphically onto U .

Proof. By the inverse function theorem we can pick disjoint neighbourhoods W_i of x_i such that f maps W_i diffeomorphically onto a neighbourhood of y . Observe that $f(X - \cup_i W_i)$ is a compact set which does not contain y . Now take

$$U := \cap_i f(W_i) - f(X - \cup_i W_i).$$

$\square$

If we let $\#f^{-1}(y)$ be the cardinality of $f^{-1}(y)$, the theorem implies that the function $y \mapsto \#f^{-1}(y)$ is locally constant as y ranges over regular values of f .

The Preimage theorem gives a particularly nice way of producing manifolds. For example, if we consider the map $f : \mathbb{R}^{n+1} \rightarrow \mathbb{R}$ given by $f(x) = |x|^2$ we can check easily that 1 is a regular value of f (do it!). Hence $S^n = f^{-1}(1)$ is a smooth manifold of dimension n . By switching our mental wavelength a little we can produce quite interesting examples as follows:

Example 29.1.13 (Orthogonal Group)

Let $O(n)$ be the group of orthogonal matrices of size $n \times n$, i.e., a matrix $A \in O(n)$ if and only if $AA^t = I$, where I is the identity matrix. The space of all $n \times n$ matrices $M(n)$ is just $\mathbb{R}^{n^2}$, so we can think of $O(n)$ as living inside $\mathbb{R}^{n^2}$. We will show that $O(n)$ is a manifold of dimension $\frac{n(n-1)}{2}$.

Let $S(n) \subset M(n)$ be the space of all symmetric matrices. Since it is a vector space, is clearly a submanifold of $M(n)$ and it has dimension $\frac{n(n+1)}{2}$.

Let $f : M(n) \rightarrow S(n)$ be the smooth map $f(A) = AA^t$. Since $O(n) = f^{-1}(I)$ it suffices to show that I is a regular value of f . We compute:

$$\begin{aligned} df_A(H) &= \lim_{s \rightarrow 0} \frac{f(A + sH) - f(A)}{s} \\ &= \lim_{s \rightarrow 0} \frac{(A + sH)(A + sH)^t - AA^t}{s} \\ &= HA^t + AH^t. \end{aligned}$$

Fix A with $AA^t = I$. We must prove that given any $C \in S(n) = T_I S(n)$ there is $H \in M(n) = T_A M(n)$ such that

$$df_A(H) = HA^t + AH^t = C.$$

Since C is symmetric, we can write $C = \frac{1}{2}C + \frac{1}{2}C^t$ so if we can solve $HA^t = \frac{1}{2}C$ we are done. Multiplying by A on the right and using $AA^t = I$ we obtain $H = \frac{1}{2}CA$ which solves $df_A(H) = C$. Thus I is a regular value of f .

Note that $O(n)$ is both a group and a manifold. In fact, the group operations are smooth, that is, the maps $(A, B) \mapsto AB$ and $A \mapsto A^{-1} = A^t$ are smooth. (Why?) A group that is manifold, and whose group operations are smooth, is called a Lie group.

Sard's Theorem

The Preimage theorem raises the question: is it easy to find regular values? How are abundant are they?

Recall that an arbitrary set A in $\mathbb{R}^n$ has measure zero if it can be covered by a countable number of rectangular solids with arbitrary small total volume. In other words given $\varepsilon > 0$, there exists a countable collection $\{R_1, R_2, \dots\}$ of rectangular solids in $\mathbb{R}^n$, such that A is contained in $\cup_i R_i$ and

$$\sum_i \text{Vol}(R_i) < \varepsilon.$$

Let X be manifold. An arbitrary subset $A \subset X$ has **measure zero** if, for every local parametrization ϕ of X , $\phi^{-1}(A)$ has measure zero in Euclidean space.

The following deep theorem, tells us that there are plenty of regular values.

Theorem 29.1.14 (Sard's Theorem, 1942)

The set of critical values of a smooth map $f : X \rightarrow Y$ has measure zero.

Since a set of measure zero cannot contain a non-empty open set we obtain:

Corollary 29.1.15

The regular values of any smooth map $f : X \rightarrow Y$ are dense in Y .

Morse Functions

A particularly useful class of maps to a one-dimensional target are those whose critical points are as simple as possible.

Definition 29.1.16

Let X be a smooth manifold. A smooth function $f : X \rightarrow \mathbb{R}$ is a **Morse function** if at every critical point x of f the Hessian of f , computed in any chart, is non-singular. Equivalently, the critical points of f are non-degenerate, and in particular isolated.

Sard's theorem is exactly what one needs to show that Morse functions are abundant: for $X \subseteq \mathbb{R}^N$ and almost every $a \in \mathbb{R}^N$, the function $f_a(x) = f(x) + \langle a, x \rangle$ is Morse. This, and the Morse lemma (near a non-degenerate critical point one can choose coordinates in which f is a quadratic form), are developed on the first example sheet; they are the starting point of Morse theory, which reconstructs the topology of X from the critical points of a single function on it.

§29.1.4 Transversality

We know that the solutions of the equation $f(x) = y$ form a smooth manifold, provided that y is a regular value of $f : X \rightarrow Y$. Suppose now that we replace y by a submanifold $Z \subset Y$ and we ask, when is $f^{-1}(Z)$ a submanifold of X ?

Definition 29.1.17 (Transversal)

A smooth map $f : X \rightarrow Y$ is said to be **transversal** to a submanifold $Z \subset Y$ if for every $x \in f^{-1}(Z)$ we have

$$\text{Image}(df_x) + T_{f(x)}Z = T_{f(x)}Y.$$

We write $f \pitchfork Z$.

Note that if $Z = \{y\}$, the notion of transversality reduces to the notion of regular value.

With this definition, we can now state a more general version of the Preimage theorem.

Theorem 29.1.18

If the smooth map $f : X \rightarrow Y$ is transversal to a submanifold $Z \subset Y$, then $f^{-1}(Z)$ is submanifold of X . Moreover, $f^{-1}(Z)$ and Z have the same codimension.

Proof (Non-examinable, sketch only). It is not hard to see that Z can be written in a neighbourhood of a point $y = f(x)$ as the zero set of a collection of functions $h_1, \dots, h_r$, where r is the codimension of Z in Y . Let $H := (h_1, \dots, h_r)$. Then near x , $f^{-1}(Z)$ is the zero set of the function $H \circ f$. Thus if $0 \in \mathbb{R}^r$ is a regular value of

$H \circ f$ we are done. But $dH_y \circ df_x$ is surjective if and only if

$$\text{Image}(df_x) + T_{f(x)}Z = T_{f(x)}Y$$

since $dH_y : T_yY \rightarrow \mathbb{R}^r$ is onto with kernel T_yZ . $\square$

Example 29.1.19

Consider $f : \mathbb{R} \rightarrow \mathbb{R}^2$ given by $f(t) = (0, t)$ and let Z be the x axis in $\mathbb{R}^2$. Then f is transversal to Z , but for example the map $h(t) = (t, t^2)$ is not.

An important special case occurs when f is the inclusion of a submanifold X of Y and Z is another submanifold of Y . In this case the condition of transversality reduces to

$$T_xX + T_xZ = T_xY$$

for every $x \in X \cap Z$. This condition is quite easy to visualize and when it holds we say that X and Z are transversal (we write $X \pitchfork Z$). We now have:

Theorem 29.1.20

The intersection of two transversal submanifolds of Y is a submanifold of codimension given by

$$\text{codim}(X \cap Z) = \text{codim } X + \text{codim } Z.$$

One of the main virtues of the notion of transversality is its stability i.e. it survives after small perturbations of the map f . You can convince yourself of this property by looking at pictures of transversal submanifolds of Euclidean space. Another very important virtue is genericity: smooth maps may be deformed by arbitrary small amounts into a map that is transversal to Z . (This is non-obvious and we refer to Chapter 2 in the book by Guillemin and Pollack for details.)

§29.1.5 Manifolds with Boundary

Consider the closed half-space

$$\mathbb{H}^k := \{(x_1, \dots, x_k) \in \mathbb{R}^k : x_k \geq 0\}.$$

The boundary $\partial\mathbb{H}^n$ is defined to be the hyperplane $x_k = 0$ in $\mathbb{R}^k$.

Definition 29.1.21

A subset $X \subset \mathbb{R}^N$ is called a smooth k -manifold with boundary if each $x \in X$ has a neighbourhood diffeomorphic to an open set in $\mathbb{H}^k$. As before, such a diffeomorphism is called a chart on X . The boundary of X , denoted ∂X , is given by the set of points that belong to the image of $\partial\mathbb{H}^k$ under some local parametrization. Its complement is called the interior of X , $\text{Int}(X) = X - \partial X$.

Remark (Warning). Do not confuse the boundary or interior of X as defined above with the topological notions of interior and boundary as a subset of $\mathbb{R}^N$.

The tangent space is defined as before, so that $T_x X$ is a k -dimensional vector space even for points $x \in \partial X$. The interior of X is a k -manifold without boundary and ∂X is a manifold without boundary of dimension $k - 1$ (this requires a proof!).

Here is an easy way of generating examples.

Lemma 29.1.22

Let X be a manifold without boundary and let $f : X \rightarrow \mathbb{R}$ be a smooth function with 0 as a regular value. Then the subset $\{x \in X : f(x) \geq 0\}$ is a smooth manifold with boundary equal to $f^{-1}(0)$.

Proof. The set where $f > 0$ is open in X and is therefore a submanifold of the same dimension as X . For a point $x \in X$ with $f(x) = 0$, the same proof as in Theorem 29.1.10 shows that x has a neighbourhood diffeomorphic to a neighbourhood of a point in $\mathbb{H}^k$. $\square$

As an easy application of the lemma, consider the unit ball B^k given by all $x \in \mathbb{R}^k$ such that $|x| \leq 1$. By considering the function $f(x) = 1 - |x|^2$ it follows that B^k is a smooth manifold with boundary S^{k-1} .

Theorem 29.1.23

Let $f : X \rightarrow Y$ be a smooth map from an m -manifold with boundary to an n -manifold, where $m > n$. If y is a regular value, both for f and for the restriction of f to ∂X , then $f^{-1}(y)$ is a smooth $(m - n)$ -manifold with boundary equal to $f^{-1}(y) \cap \partial X$.

Proof. Recall that being a submanifold is a local property so without loss of generality we can suppose that $f : \mathbb{H}^m \rightarrow \mathbb{R}^n$ with $y \in \mathbb{R}^n$ a regular value. Consider $z \in f^{-1}(y)$. If z belongs to the interior of $\mathbb{H}^m$, then as in Theorem 29.1.10, $f^{-1}(y)$ is a smooth manifold near z .

Let z be now in $\partial \mathbb{H}^m$. Since f is smooth, there is a neighbourhood U of z in $\mathbb{R}^m$ and a smooth map $F : U \rightarrow \mathbb{R}^n$ such that F restricted to $U \cap \mathbb{H}^m$ is f . By shrinking U if necessary we can assume that F has no critical points in U (why?). Hence $F^{-1}(y)$ is a smooth manifold of dimension $m - n$.

Let $\pi : F^{-1}(y) \rightarrow \mathbb{R}$ be the projection $(x_1, \dots, x_m) \mapsto x_m$. Observe that the tangent space of $F^{-1}(y)$ at a point $x \in \pi^{-1}(0)$ is equal to the kernel of

$$dF_x = df_x : \mathbb{R}^m \rightarrow \mathbb{R}^n.$$

Hence 0 must be a regular value of π since we are assuming that y is a regular value of f restricted to $\partial \mathbb{H}^m$.

But $F^{-1}(y) \cap \mathbb{H}^m = f^{-1}(y) \cap U$ is the set of all $x \in F^{-1}(y)$ with $\pi(x) \geq 0$ and by Lemma 29.1.22, is a smooth manifold with boundary equal to $\pi^{-1}(0)$. $\square$

It is not hard to guess what is the appropriate version of this theorem for the more general case of a map $f : X \rightarrow Y$ and a submanifold Z of Y . Suppose X has boundary, but Y and Z are boundaryless. The next theorem is stated without proof.

Theorem 29.1.24

Suppose that both $f : X \rightarrow Y$ and $f|_{\partial X} : \partial X \rightarrow Y$ are transversal to Z . Then $f^{-1}(Z)$ is a manifold with boundary given by $f^{-1}(Z) \cap \partial X$ and codimension equal to the codimension of Z .

§29.1.6 Degree Modulo 2

Let X be a smooth boundaryless manifold. Then $X \times [0, 1]$ is a manifold with boundary $\partial X = X \times \{0\} \cup X \times \{1\}$.

Definition 29.1.25

Two maps $f, g : X \rightarrow Y$ are called **smoothly homotopic** if there exists a smooth map $F : X \times [0, 1] \rightarrow Y$ with $F(x, 0) = f(x)$ and $F(x, 1) = g(x)$ for all $x \in X$. The map F is called a **smooth homotopy** between f and g . The relation of smooth homotopy is an equivalence relation. (Why?) The equivalence class to which a map belongs is its **homotopy** class. Let $f_t : X \rightarrow Y$ be the 1-parameter family of maps given by $f_t(x) = F(x, t)$.

Definition 29.1.26

The diffeomorphism f is **smoothly isotopic** to g if there exists a smooth homotopy $F : X \times [0, 1] \rightarrow Y$ from f to g such that for each $t \in [0, 1]$, f_t maps X diffeomorphically onto Y .

Lemma 29.1.27 (Homotopy Lemma)

Let $f, g : X \rightarrow Y$ be smooth maps which are smoothly homotopic. Suppose X is compact, has the same dimension as Y and $\partial X = \emptyset$. If y is a regular value for both f and g , then

$$\#f^{-1}(y) = \#g^{-1}(y) \pmod{2}.$$

Proof. The proof relies on the following important fact, the ‘Classification of 1-manifolds’: Every compact connected 1-manifold is diffeomorphic to $[0, 1]$ or S^1 .

As every compact manifold is the disjoint union of finitely many compact connected manifolds we have that the boundary of any compact 1-manifold consists of an even number of points.

Let $F : X \times [0, 1] \rightarrow Y$ be a smooth homotopy between f and g . Assume for the time being that y is also a regular value for F . Then $F^{-1}(y)$ is a compact 1-manifold with boundary equal to

$$F^{-1}(y) \cap (X \times \{0\} \cup X \times \{1\}) = f^{-1}(y) \times \{0\} \cup g^{-1}(y) \times \{1\}.$$

Thus the cardinality of the boundary of $F^{-1}(y)$ is just $\#f^{-1}(y) + \#g^{-1}(y)$. By the corollary above

$$\#f^{-1}(y) = \#g^{-1}(y) \pmod{2}.$$

If y is not a regular value of F we proceed as follows. From Theorem 29.1.12 we

know that $w \mapsto \#f^{-1}(w), w \mapsto \#g^{-1}(w)$ are locally constant as w ranges over regular values. Thus there are neighbourhoods V and W of y , consisting of regular values of f and g respectively for which

$$\#f^{-1}(w) = \#f^{-1}(y)$$

for all $w \in V$, and

$$\#g^{-1}(w) = \#g^{-1}(y)$$

for all $w \in W$. By Sard's theorem we can choose a regular value z of F in $V \cap W$. Then

$$\#f^{-1}(y) = \#f^{-1}(z) = \#g^{-1}(z) = \#g^{-1}(y) \pmod{2}$$

as desired. $\square$

Lemma 29.1.28 (Homogeneity Lemma)

Let X be a smooth connected manifold, possibly with boundary. Let y and z be points in $\text{Int}(X)$. Then there exists a diffeomorphism $h : X \rightarrow X$ smoothly isotopic to the identity such that $h(y) = z$.

Proof. Let us call two points y and z “isotopic” if there exists a diffeomorphism h isotopic to the identity that maps y to z . It is evident that this is an equivalence relation. Since X is connected, it suffices to show that each equivalence class is a open set.

To prove that equivalence classes are open we will construct an isotopy h_t of $\mathbb{R}^k$ such that h_0 is the identity, each h_t is the identity outside the open unit ball around the origin, and $h_1(0)$ is any specified point in the open unit ball. This will suffice, since we can now parametrize a small neighbourhood of y in $\text{Int}(X)$ and use h_t to construct an isotopy that will move y to any point nearby.

Let $\varphi : \mathbb{R}^k \rightarrow \mathbb{R}$ be a smooth function such that $\varphi(x) > 0$ for $|x| < 1$ and $\varphi(x) = 0$ for $|x| \geq 1$ (why do they exist?). Given a unit vector $u \in \mathbb{R}^k$ consider the ordinary differential equation in $\mathbb{R}^k$ given by

$$\frac{dx}{dt} = u\varphi(x).$$

Let $F_t : \mathbb{R}^k \rightarrow \mathbb{R}^k$ be the flow of this differential equation, i.e., for each $x \in \mathbb{R}^k$, the curve $t \mapsto F_t(x)$ is the unique solution passing through x . Standard theorems on differential equations tell us that:

1. F_t is defined for all $x \in \mathbb{R}^k$ and $t \in \mathbb{R}$ and smooth;
2. F_0 is the identity;
3. $F_{t+s} = F_t \circ F_s$.

Clearly for each t , F_t leaves all points outside the unit ball fixed. For appropriate choices of u and t , F_t will map the origin to any point in the open unit ball. (I may replace this proof by the one given by Guillemin and Pollack on page 142 of their book which does not use flows.) $\square$

In what follows suppose that X is compact and without boundary and Y is connected

and with the same dimension as X . Let $f : X \rightarrow Y$ be a smooth map.

Theorem 29.1.29 (Degree mod 2)

If y and z are regular values of f then

$$\#f^{-1}(y) = \#f^{-1}(z) \pmod{2}.$$

This common residue class is called the **degree mod 2** of f (denoted $\deg_2(f)$) and only depends on the homotopy class of f .

Proof. Given y and z , let h be the diffeomorphism smoothly isotopic to the identity such that $h(y) = z$ given by the Homogeneity Lemma. Observe that z is also a regular value of $h \circ f$. Since $h \circ f$ is homotopic to f , the Homotopy Lemma tells us that

$$\#(h \circ f)^{-1}(z) = \#f^{-1}(z) \pmod{2}.$$

But $(h \circ f)^{-1}(z) = f^{-1}(h^{-1}(z)) = f^{-1}(y)$ and therefore

$$\#f^{-1}(y) = \#f^{-1}(z) \pmod{2}$$

as desired. Let g be smoothly homotopic to f . By Sard's theorem, there is a point $y \in Y$ which is a regular value for both f and g (why?). By the Homotopy Lemma

$$\deg_2(f) = \#f^{-1}(y) \pmod{2} = \#g^{-1}(y) \pmod{2} = \deg_2(g)$$

which completes the proof. $\square$

Example 29.1.30

The identity map of a compact boundaryless manifold X has $\deg_2 = 1$, since any point has exactly one preimage, while a constant map has $\deg_2 = 0$, since a point other than the image value has none. Since $\deg_2$ is a homotopy invariant, the identity is never homotopic to a constant map.

This innocuous observation has real force.

Corollary 29.1.31

There is no smooth map $f : B^{k+1} \rightarrow S^k$ restricting to the identity on $S^k = \partial B^{k+1}$; that is, the sphere is not a smooth retract of the ball.

Proof. If such an f existed, then $F : S^k \times [0, 1] \rightarrow S^k$ given by $F(x, t) = f(tx)$ would be a smooth homotopy between the constant map $x \mapsto f(0)$ and the identity, contradicting the example above. $\square$

The previous example yields the smooth version of a famous fixed point theorem.

Theorem 29.1.32 (Smooth Brouwer Fixed Point Theorem)

Any smooth map $f : B^k \rightarrow B^k$ has a fixed point.

Proof. Suppose f has no fixed point. We will construct a map $g : B^k \rightarrow S^{k-1}$ which restricts to the identity on S^{k-1} which contradicts Corollary 29.1.31. For $x \in B^k$, let $g(x) \in S^{k-1}$ be the point where the line segment starting at $f(x)$ and passing through x hits the boundary. One can write a formula for g to show smoothness. $\square$

In fact, any continuous map $f : B^k \rightarrow B^k$ has a fixed point (Brouwer fixed point theorem). One can prove this using the smooth version approximating f by polynomials. Indeed, by the Weierstrass approximation theorem, given $\varepsilon > 0$, there is a polynomial P such that $|f(x) - P(x)| < \varepsilon$ for all $x \in B^k$. Set $Q(x) = P(x)/(1 + \varepsilon)$. Now Q maps B^k into B^k and $|f(x) - Q(x)| < 2\varepsilon$ for all $x \in B^k$. Suppose $f(x) \neq x$ for all x . Then the continuous function $|f(x) - x|$ must take a positive minimum τ on B^k . If now let $\varepsilon = \tau/2$ the Q from above does not have a fixed point, which contradicts the smooth Brouwer fixed point theorem.

Intersection Numbers Modulo 2

What we said above about degree modulo 2 can be generalized to the case of a smooth map $f : X \rightarrow Y$ and Z a submanifold of Y . Suppose that:

1. X is compact without boundary;
2. Z is closed and without boundary;
3. $f \pitchfork Z$
4. $\dim X + \dim Z = \dim Y$.

Under these conditions $f^{-1}(Z)$ is a closed 0-dimensional submanifold of X and hence it consists of finitely many points. Define the **mod 2 intersection number** of the map f with Z , $I_2(f, Z)$, to be the cardinality of $f^{-1}(Z)$ modulo 2. An analogue of the Homotopy Lemma (for intersection numbers) also holds here: if f_0 and f_1 are maps transversal to Z and homotopic, then $I_2(f_0, Z) = I_2(f_1, Z)$. In fact, we can define $I_2(f, Z)$ for a map f which is not necessarily transversal to Z . Using that transversality is generic, we can find a map g homotopic to f such that $g \pitchfork Z$ and we now set $I_2(f, Z) := I_2(g, Z)$. It does not matter which g we choose as long as g is homotopic to f , thanks to the Homotopy Lemma for intersection numbers.

Let us have a closer look at the important special case in which X itself is a compact submanifold of Y and Z a closed submanifold of complementary dimension. In this case f is the inclusion map $X \hookrightarrow Y$, and if $X \pitchfork Z$, $I_2(X, Z) := I_2(f, Z)$ is just $\#(X \cap Z) \bmod 2$. If $I_2(X, Z) \neq 0$, it means that no matter how X is deformed, we cannot move it away completely from Z .

Example 29.1.33

Let Y be the 2-torus $S^1 \times S^1$. Let $X = S^1 \times \{1\}$ and $Z = \{1\} \times S^1$. Then $I_2(X, Z) = 1$ and we cannot smoothly pull the circles apart. When $\dim X = \frac{1}{2} \dim Y$, we can consider $I_2(X, X)$ the self-intersection number modulo 2. If X is the central curve in a Möbius band, then $I_2(X, X) = 1$.

§29.1.7 Abstract Manifolds and Whitney's Embedding Theorem

One can actually define manifolds without making any reference to the ambient space $\mathbb{R}^N$. You will study manifolds in this more abstract setting in Part III and in the Riemann Surfaces course. In any case, here is the definition:

Definition 29.1.34

An n -dimensional smooth manifold is a second countable Hausdorff space X together with a collection of maps called **charts** such that:

1. a chart is a homeomorphism $\phi : U \rightarrow \phi(U)$, where U is open in X and $\phi(U)$ is open in $\mathbb{R}^n$
2. each point $x \in X$ belongs to the domain of some chart;
3. for charts $\phi : U \rightarrow \phi(U) \subset \mathbb{R}^n$ and $\psi : V \rightarrow \phi(V) \subset \mathbb{R}^n$, the map $\phi \circ \psi^{-1} : \psi(U \cap V) \rightarrow \phi(U \cap V)$ is smooth;
4. the collection of charts is maximal with respect to the properties above.

A set of charts satisfying the first three properties is called an **atlas**. An atlas can always be enlarged uniquely to give a maximal atlas as in the definition. If in the definition we require the maps $\phi \circ \psi^{-1}$ just to be of class C^k ($k \geq 1$) then we say that we have a manifold of class C^k . (Recall that a map is of class C^k if it has continuous partial derivatives up to order k .)

The definition is set up so that it is plain how to define a smooth map between manifolds. An **immersion** is a smooth map $f : X \rightarrow Y$ such that df_x is injective for all $x \in X$. A **submersion** is a smooth map $f : X \rightarrow Y$ such that df_x is surjective for all $x \in X$. An **embedding** is a smooth map $f : X \rightarrow Y$ which is an immersion and a homeomorphism onto its image.

The next theorem tells us that we did not lose much by restricting our attention to manifolds as subsets of Euclidean space.

Theorem 29.1.35 (Whitney's embedding theorem)

A smooth n -manifold X can be embedded into $\mathbb{R}^{2n+1}$.

The proof of this theorem can be found in most books about manifolds. In fact, Whitney proved the much harder result that X can be embedded in $\mathbb{R}^{2n}$.

§29.2 Curves in $\mathbb{R}^3$

Before we look at surfaces it is worth spending some time on the simplest interesting manifolds of all: one-dimensional ones, that is, curves. Curves are simple enough that we can say everything about them, and the story we will tell – attach a moving frame to the object, differentiate it, and read off the geometry from the coefficients that appear – is exactly the story we will tell for surfaces later, but with all the technicalities stripped away.

The punchline is that a curve in $\mathbb{R}^3$ has precisely two local invariants, its *curvature* and its *torsion*, and that these determine the curve completely up to a rigid motion of space.

Curvature says how fast the curve is turning, and torsion says how fast it is failing to be planar.

§29.2.1 Regular Curves and Arc Length

We should first be careful about what we mean by a curve. There is a difference between a curve as a *map* and a curve as a *subset* of $\mathbb{R}^3$, and it is the map we want.

Definition 29.2.1 (Smooth Curve)

A **smooth curve** in $\mathbb{R}^n$ is a smooth map $\gamma : (a, b) \rightarrow \mathbb{R}^n$, where $-\infty \leq a < b \leq \infty$. Its image $\gamma((a, b))$ is called the **trace** of the curve. We say γ is **regular** if $\gamma'(t) \neq 0$ for all $t \in (a, b)$.

Regularity is exactly the condition that γ is an immersion, and it is what stops the trace from having corners. It really is needed: the map $\gamma(t) = (t^2, t^3)$ is a perfectly smooth map $\mathbb{R} \rightarrow \mathbb{R}^2$, but $\gamma'(0) = 0$ and the trace has a cusp at the origin.

For a regular curve there is a preferred way to parametrise: by the distance travelled along it.

Definition 29.2.2 (Arc Length)

Let $\gamma : (a, b) \rightarrow \mathbb{R}^n$ be a smooth curve and fix $t_0 \in (a, b)$. The **arc length** of γ starting at t_0 is

$$s(t) = \int_{t_0}^t \|\gamma'(u)\| \, du.$$

We say γ is parametrised by arc length, or has **unit speed**, if $\|\gamma'(t)\| = 1$ for all t .

Lemma 29.2.3 (Unit Speed Reparametrisation)

Every regular curve admits a unit speed reparametrisation. That is, if $\gamma : (a, b) \rightarrow \mathbb{R}^n$ is regular then there is a diffeomorphism φ from an interval (c, d) onto (a, b) such that $\tilde{\gamma} = \gamma \circ \varphi$ has unit speed.

Proof. With s as above we have $s'(t) = \|\gamma'(t)\| > 0$ by regularity, so s is strictly increasing and smooth, hence a diffeomorphism from (a, b) onto an interval (c, d) ; its inverse $\varphi = s^{-1}$ is smooth by the inverse function theorem. Setting $\tilde{\gamma} = \gamma \circ \varphi$, the chain rule gives

$$\tilde{\gamma}'(s) = \gamma'(\varphi(s))\varphi'(s) = \frac{\gamma'(\varphi(s))}{\|\gamma'(\varphi(s))\|},$$

which has unit norm. $\square$

From now on, when a curve is unit speed we will write s for the parameter and use a dot for d/ds ; for a general parameter we write t and use a prime. Everything we define will be checked to be independent of the parametrisation, so we may always compute in whichever one is convenient.

§29.2.2 Curvature and the Frenet–Serret Formulae

Let γ be a unit speed curve. Its velocity $T = \dot{\gamma}$ is a unit vector, the **unit tangent**. Differentiating $\langle T, T \rangle = 1$ gives

$$\langle \dot{T}, T \rangle = 0,$$

so the acceleration of a unit speed curve is always perpendicular to its velocity. All the acceleration goes into turning, none into speeding up, and the size of that turning is our first invariant.

Definition 29.2.4 (Curvature)

The **curvature** of a unit speed curve γ is

$$\kappa(s) = \|\ddot{\gamma}(s)\| = \|\dot{T}(s)\| \geq 0.$$

For a curve given in an arbitrary regular parametrisation it would be painful to have to find the arc length reparametrisation before computing anything, so it is worth recording a direct formula.

Proposition 29.2.5

If γ is a regular curve in $\mathbb{R}^3$ with arbitrary parameter t , then

$$\kappa = \frac{\|\gamma' \times \gamma''\|}{\|\gamma'\|^3}.$$

Proof. Write $v = \|\gamma'\|$ and let s be arc length, so $ds/dt = v$ and $\gamma' = vT$. Differentiating,

$$\gamma'' = v'T + v \frac{dT}{dt} = v'T + v^2 \dot{T}.$$

Since $T \times T = 0$ and $\dot{T} \perp T$ with $\|\dot{T}\| = \kappa$, we get

$$\gamma' \times \gamma'' = vT \times (v'T + v^2 \dot{T}) = v^3(T \times \dot{T}),$$

and $\|T \times \dot{T}\| = \|T\| \|\dot{T}\| = \kappa$ as the two are orthogonal. Rearranging gives the result. $\square$

Example 29.2.6 (Lines and Circles)

A straight line $\gamma(s) = p + sq$ with $\|q\| = 1$ has $\ddot{\gamma} = 0$, so $\kappa \equiv 0$. Conversely if $\kappa \equiv 0$ then $\ddot{\gamma} \equiv 0$, so $\gamma(s) = p + sq$ for constants p, q : a unit speed curve is a straight line if and only if its curvature vanishes identically.

The circle of radius a traversed at unit speed is $\gamma(s) = (a \cos(s/a), a \sin(s/a))$, and

$$\ddot{\gamma}(s) = -\frac{1}{a} (\cos(s/a), \sin(s/a)),$$

so $\kappa \equiv 1/a$. Small circles are very curved, large circles are nearly straight, which is as it should be.

The circle example gives the standard geometric interpretation of κ : at a point where $\kappa(s) > 0$ there is a unique circle which agrees with γ to second order at $\gamma(s)$, namely the circle of radius $1/a = 1/\kappa(s)$ lying in the plane spanned by $\dot{\gamma}$ and $\ddot{\gamma}$ and centred on the concave side. This is the **osculating circle**, and $1/\kappa(s)$ is the **radius of curvature**.

Now suppose $\kappa(s) > 0$ everywhere. Then $\dot{T}/\kappa$ is a unit vector orthogonal to T , and we can complete to an orthonormal basis of $\mathbb{R}^3$.

Definition 29.2.7 (Frenet Frame)

Let γ be a unit speed curve in $\mathbb{R}^3$ with $\kappa > 0$ everywhere. The **principal normal** and **binormal** are

$$N = \frac{\dot{T}}{\kappa}, \quad B = T \times N.$$

The triple (T, N, B) is a right-handed orthonormal basis of $\mathbb{R}^3$ at each point, called the **Frenet frame** of γ .

The plane spanned by T and N is the **osculating plane**; it is the plane the curve is doing its best to lie in. The whole of the local theory of curves comes from differentiating the frame and expressing the answer back in terms of the frame.

Theorem 29.2.8 (Frenet–Serret Formulae)

Let γ be a unit speed curve in $\mathbb{R}^3$ with $\kappa > 0$. Then there is a smooth function τ , the **torsion** of γ , such that

$$\begin{aligned} \dot{T} &= \kappa N, \\ \dot{N} &= -\kappa T + \tau B, \end{aligned}$$

$$\dot{B} = -\tau N.$$

Equivalently, writing the frame as the rows of a matrix,

$$\frac{d}{ds} \begin{pmatrix} T \\ N \\ B \end{pmatrix} = \begin{pmatrix} 0 & \kappa & 0 \\ -\kappa & 0 & \tau \\ 0 & -\tau & 0 \end{pmatrix} \begin{pmatrix} T \\ N \\ B \end{pmatrix}.$$

Proof. Since (T, N, B) is an orthonormal basis at each point we may expand each derivative in it, so we must simply identify the nine coefficients $\langle \dot{T}, T \rangle$, $\langle \dot{T}, N \rangle$ and so on. Differentiating the six relations $\langle X, Y \rangle = \delta_{XY}$ for $X, Y \in \{T, N, B\}$ gives

$$\langle \dot{X}, Y \rangle + \langle X, \dot{Y} \rangle = 0,$$

so the matrix of coefficients is antisymmetric and only three entries need to be found. By definition $\dot{T} = \kappa N$, which gives the first row and, by antisymmetry, the $\langle \dot{N}, T \rangle = -\kappa$ entry and $\langle \dot{B}, T \rangle = 0$. Defining $\tau := \langle \dot{N}, B \rangle$ fills in the rest, and τ is smooth since N and B are. $\square$

Remark. Note the sign convention: some books define τ with the opposite sign. Ours is the one for which the right-handed helix (below) has positive torsion.

Torsion measures the rate at which the osculating plane rotates, or equivalently the rate at which the curve pulls out of that plane. So it should vanish exactly for planar curves, and it does.

Proposition 29.2.9

A unit speed curve γ in $\mathbb{R}^3$ with $\kappa > 0$ has $\tau \equiv 0$ if and only if its trace is contained in a plane.

Proof. If $\tau \equiv 0$ then $\dot{B} = -\tau N = 0$, so B is a constant vector b . Fix s_0 and consider $f(s) = \langle \gamma(s) - \gamma(s_0), b \rangle$. Then $f(s_0) = 0$ and $\dot{f} = \langle T, b \rangle = 0$, so $f \equiv 0$ and γ lies in the plane through $\gamma(s_0)$ with normal b .

Conversely, suppose γ lies in a plane with unit normal b . Differentiating $\langle \gamma - \gamma(s_0), b \rangle = 0$ twice gives $\langle T, b \rangle = 0$ and $\langle \dot{T}, b \rangle = 0$, so b is orthogonal to both T and N and hence $B = \pm b$ is constant. Therefore $\dot{B} = 0$ and, since $N \neq 0$, $\tau \equiv 0$. $\square$

As with curvature, it is convenient to have a formula valid in an arbitrary parametrisation.

Proposition 29.2.10

If γ is a regular curve in $\mathbb{R}^3$ with $\gamma' \times \gamma'' \neq 0$, then

$$\tau = \frac{\langle \gamma' \times \gamma'', \gamma''' \rangle}{\|\gamma' \times \gamma''\|^2}.$$

Proof. Again put $v = \|\gamma'\|$. We computed $\gamma' = vT$ and $\gamma'' = v'T + v^2\kappa N$, so

differentiating once more and collecting only the terms we need,

$$\gamma''' = (\text{multiple of } T) + (\text{multiple of } N) + v^3 \kappa \tau B,$$

using $\dot{N} = -\kappa T + \tau B$. From the proof of the curvature formula, $\gamma' \times \gamma'' = v^3 \kappa B$. Hence

$$\langle \gamma' \times \gamma'', \gamma''' \rangle = v^3 \kappa \cdot v^3 \kappa \tau = v^6 \kappa^2 \tau = \|\gamma' \times \gamma''\|^2 \tau,$$

as claimed. $\square$

Example 29.2.11 (The Helix)

Let $a > 0$, $b \neq 0$ and consider the helix $\gamma(t) = (a \cos t, a \sin t, bt)$. We have

$$\gamma' = (-a \sin t, a \cos t, b), \quad \gamma'' = (-a \cos t, -a \sin t, 0), \quad \gamma''' = (a \sin t, -a \cos t, 0),$$

so $\|\gamma'\| = \sqrt{a^2 + b^2}$ and

$$\gamma' \times \gamma'' = (ab \sin t, -ab \cos t, a^2), \quad \|\gamma' \times \gamma''\| = a\sqrt{a^2 + b^2}.$$

Therefore

$$\kappa = \frac{a\sqrt{a^2 + b^2}}{(a^2 + b^2)^{3/2}} = \frac{a}{a^2 + b^2}, \quad \tau = \frac{\langle \gamma' \times \gamma'', \gamma''' \rangle}{a^2(a^2 + b^2)} = \frac{a^2 b}{a^2(a^2 + b^2)} = \frac{b}{a^2 + b^2}.$$

Both are constant. Letting $b \rightarrow 0$ we recover the circle of radius a , with $\kappa = 1/a$ and $\tau = 0$.

The helix is in fact the *only* curve with constant curvature and torsion, which is a consequence of the following, the fundamental theorem of the local theory of curves. It says that (κ, τ) is a complete set of local invariants.

Theorem 29.2.12 (Fundamental Theorem of Curve Theory)

Let $\kappa : (a, b) \rightarrow (0, \infty)$ and $\tau : (a, b) \rightarrow \mathbb{R}$ be smooth. Then there is a unit speed curve $\gamma : (a, b) \rightarrow \mathbb{R}^3$ with curvature κ and torsion τ , and any two such curves differ by a rigid motion of $\mathbb{R}^3$ (that is, by a map $x \mapsto Ax + c$ with $A \in \text{SO}(3)$).

Proof. Existence. The Frenet–Serret formulae are a linear system of ordinary differential equations for the nine components of (T, N, B) , with smooth coefficients. By Picard’s theorem there is a unique solution on all of (a, b) with any prescribed initial value at s_0 ; take the initial value to be the standard basis (e_1, e_2, e_3) .

We must check the solution stays orthonormal. Consider the six functions $\langle X, Y \rangle$ for $X, Y \in \{T, N, B\}$. Differentiating and substituting the equations shows these six functions themselves satisfy a linear system of ODEs, one solution of which is the constant δ_{XY} ; by uniqueness, and since they agree at s_0 , they are equal to it for all s . So (T, N, B) remains orthonormal, and by continuity it stays right-handed.

Now set $\gamma(s) = \int_{s_0}^s T(u) du$. Then $\dot{\gamma} = T$ has unit length, $\ddot{\gamma} = \dot{T} = \kappa N$ has norm κ since $\kappa > 0$, so the curvature of γ is κ and its principal normal is N ; the binormal is then $T \times N = B$ (right-handedness) and $\langle \dot{N}, B \rangle = \tau$, as required.

Uniqueness. Suppose γ_1, γ_2 both have curvature κ and torsion τ , with frames (T_i, N_i, B_i) . The two frames at s_0 are right-handed orthonormal bases, so there is a unique $A \in \text{SO}(3)$ carrying the first to the second; replacing γ_1 by $A\gamma_1 + (\gamma_2(s_0) - A\gamma_1(s_0))$ – a rigid motion, which changes neither κ nor τ – we may assume the two curves and their frames agree at s_0 . Consider

$$f(s) = \|T_1 - T_2\|^2 + \|N_1 - N_2\|^2 + \|B_1 - B_2\|^2.$$

Differentiating and using Frenet–Serret for both curves, every term cancels: for instance

$$\frac{1}{2} \frac{d}{ds} \|T_1 - T_2\|^2 = \langle \kappa N_1 - \kappa N_2, T_1 - T_2 \rangle,$$

and adding the analogous expressions for N and B the κ and τ terms cancel in pairs, giving $\dot{f} = 0$. Since $f(s_0) = 0$ and $f \geq 0$ we get $f \equiv 0$, so $T_1 = T_2$ everywhere and hence $\gamma_1 - \gamma_2$ is constant; as they agree at s_0 they are equal. $\square$

Corollary 29.2.13

A unit speed curve in $\mathbb{R}^3$ with constant curvature $\kappa_0 > 0$ and constant torsion τ_0 is a circular helix (a circle if $\tau_0 = 0$).

Proof. Solve $a/(a^2 + b^2) = \kappa_0$, $b/(a^2 + b^2) = \tau_0$ for $a > 0$ and b : taking $a = \kappa_0/(\kappa_0^2 + \tau_0^2)$ and $b = \tau_0/(\kappa_0^2 + \tau_0^2)$ works. The corresponding helix, reparametrised at unit speed, has the given curvature and torsion, so by uniqueness our curve is a rigid motion of it. $\square$

§29.2.3 Plane Curves

For curves in the plane the theory simplifies, but in one respect it improves: a plane curve has a preferred normal direction available whether or not κ vanishes, and so we can attach a *sign* to the curvature.

Definition 29.2.14 (Signed Curvature)

Let $\gamma : (a, b) \rightarrow \mathbb{R}^2$ be a unit speed plane curve with tangent $T = \dot{\gamma}$. Let N_s be T rotated anticlockwise by $\pi/2$, so that (T, N_s) is a positively oriented orthonormal basis of $\mathbb{R}^2$. The **signed curvature** κ_s is defined by

$$\dot{T} = \kappa_s N_s.$$

This makes sense because $\dot{T} \perp T$, so $\dot{T}$ is automatically a multiple of N_s . Differentiating $\langle N_s, N_s \rangle = 1$ and $\langle T, N_s \rangle = 0$ gives $\dot{N}_s = -\kappa_s T$, so we have a two-dimensional Frenet system

$$\dot{T} = \kappa_s N_s, \quad \dot{N}_s = -\kappa_s T,$$

and clearly $\kappa = |\kappa_s|$. The sign records which way the curve is turning: anticlockwise where $\kappa_s > 0$, clockwise where $\kappa_s < 0$. Reversing the orientation of the curve reverses the sign.

Since T is a unit vector in the plane, we can write it as an angle, and it is worth knowing that the angle can be chosen smoothly.

Lemma 29.2.15 (Turning Angle)

Let $\gamma : (a, b) \rightarrow \mathbb{R}^2$ be a unit speed curve. Then there is a smooth function $\theta : (a, b) \rightarrow \mathbb{R}$ with

$$T(s) = (\cos \theta(s), \sin \theta(s)),$$

unique up to adding a constant in $2\pi\mathbb{Z}$, and $\dot{\theta} = \kappa_s$.

Proof. Write $T = (T_1, T_2)$. Pick θ_0 with $T(s_0) = (\cos \theta_0, \sin \theta_0)$ and define

$$\theta(s) = \theta_0 + \int_{s_0}^s (T_1 \dot{T}_2 - T_2 \dot{T}_1) \, du,$$

which is smooth. Using $T_1^2 + T_2^2 = 1$ one checks that both

$$\frac{d}{ds} (T_1 \cos \theta + T_2 \sin \theta) \quad \text{and} \quad \frac{d}{ds} (T_2 \cos \theta - T_1 \sin \theta)$$

vanish identically; evaluating at s_0 then gives $T_1 \cos \theta + T_2 \sin \theta \equiv 1$ and $T_2 \cos \theta - T_1 \sin \theta \equiv 0$, which forces $T = (\cos \theta, \sin \theta)$. Finally

$$\dot{T} = \dot{\theta}(-\sin \theta, \cos \theta) = \dot{\theta}N_s,$$

so $\dot{\theta} = \kappa_s$. Uniqueness is clear since two such angle functions differ by a continuous $2\pi\mathbb{Z}$ -valued function. $\square$

Now let $\gamma : [0, L] \rightarrow \mathbb{R}^2$ be a **closed** unit speed curve, meaning that γ and all its derivatives agree at 0 and L (so that γ extends to an L -periodic smooth curve on $\mathbb{R}$). Then $T(0) = T(L)$, so $\theta(L) - \theta(0) \in 2\pi\mathbb{Z}$.

Definition 29.2.16 (Turning Number)

The **turning number** of a closed plane curve γ of length L is the integer

$$n(\gamma) = \frac{1}{2\pi} (\theta(L) - \theta(0)) = \frac{1}{2\pi} \int_0^L \kappa_s \, ds.$$

The circle traversed anticlockwise has turning number 1, and traversed k times has turning number k ; a figure eight has turning number 0. What is intuitively obvious but genuinely delicate to prove is that a curve which does not cross itself cannot do anything exotic.

Theorem 29.2.17 (Hopf's Umlaufsatz)

A simple closed plane curve has turning number ± 1 , with the sign $+$ if it is traversed anticlockwise.

Proof Sketch. Translate so that γ lies in the upper half plane with $\gamma(0)$ on the x -axis, so the tangent at $s = 0$ is horizontal. On the triangle $\Delta = \{(s_1, s_2) : 0 \leq s_1 \leq s_2 \leq L\}$ define the *secant map*

$$\Psi(s_1, s_2) = \frac{\gamma(s_2) - \gamma(s_1)}{\|\gamma(s_2) - \gamma(s_1)\|}$$

off the diagonal and the two corners, extended by $\Psi(s, s) = T(s)$ and $\Psi(0, L) = -T(0)$. Simplicity of γ is exactly what makes Ψ well defined and continuous on Δ . The turning number is the degree of Ψ restricted to the diagonal edge, and since Δ is convex we may deform that edge to the other two edges without changing the degree. Along those two edges the secant vector sweeps monotonically through a half turn each (the curve lies on one side of the x -axis), giving a total of one full turn. $\square$

§29.2.4 The Isoperimetric Inequality

We now turn to two global results about plane curves: statements which involve the curve as a whole rather than a neighbourhood of a point. The first is the oldest theorem in the subject, going back to the legend of Dido: among all closed curves of a given length, the circle encloses the most area.

The proof is a beautiful piece of Fourier analysis, resting on the following inequality, which says that a mean-zero periodic function cannot oscillate slower than the fundamental frequency of its period.

Lemma 29.2.18 (Wirtinger's Inequality)

Let $f : \mathbb{R} \rightarrow \mathbb{R}$ be a C^1 function of period L with $\int_0^L f \, dt = 0$. Then

$$\int_0^L |f'|^2 \, dt \geq \frac{4\pi^2}{L^2} \int_0^L |f|^2 \, dt,$$

with equality if and only if $f(t) = a \cos(2\pi t/L) + b \sin(2\pi t/L)$ for some constants a, b .

Proof. Write $f(t) = \sum_{n \in \mathbb{Z}} a_n e^{2\pi i n t/L}$ and $f'(t) = \sum_{n \in \mathbb{Z}} b_n e^{2\pi i n t/L}$ for the Fourier series of f and f' ; these converge absolutely and uniformly since f is C^1 . The hypothesis $\int_0^L f = 0$ says $a_0 = 0$, and periodicity of f gives $b_0 = \frac{1}{L} \int_0^L f' = 0$. Integrating by parts,

$$b_n = \frac{1}{L} \int_0^L f'(t) e^{-2\pi i n t/L} \, dt = \frac{2\pi i n}{L} \cdot \frac{1}{L} \int_0^L f(t) e^{-2\pi i n t/L} \, dt = \frac{2\pi i n}{L} a_n.$$

Now Parseval's identity gives

$$\int_0^L |f'|^2 \, dt = L \sum_{n \neq 0} |b_n|^2 = \frac{4\pi^2}{L} \sum_{n \neq 0} n^2 |a_n|^2 \geq \frac{4\pi^2}{L} \sum_{n \neq 0} |a_n|^2 = \frac{4\pi^2}{L^2} \int_0^L |f|^2 \, dt,$$

using $n^2 \geq 1$. Equality holds if and only if $a_n = 0$ for every $|n| \geq 2$, which is the stated form. $\square$

Theorem 29.2.19 (Isoperimetric Inequality)

Let $\Omega \subseteq \mathbb{R}^2$ be a bounded domain whose boundary $\partial\Omega$ is a simple closed C^1 curve, of length L and enclosing area A . Then

$$L^2 \geq 4\pi A,$$

with equality if and only if Ω is a disc.

Proof. Parametrise $\partial\Omega$ by arc length $s \in [0, L]$, writing the position vector as $X(s) = (x(s), y(s))$, and let ν be the outward unit normal along $\partial\Omega$. Translating Ω changes neither L nor A , so we may assume $\int_0^L X \, ds = 0$.

Applied to the position vector field $X(x, y) = (x, y)$, whose divergence is 2, the divergence theorem gives

$$2A = \int_{\Omega} \nabla \cdot X \, dA = \int_{\partial\Omega} \langle X, \nu \rangle \, ds \leq \int_0^L \|X\| \, ds \leq \left(\int_0^L \|X\|^2 \, ds \right)^{1/2} L^{1/2},$$

the last step by Cauchy–Schwarz. Now x and y are C^1 and L -periodic with vanishing mean, so Wirtinger’s inequality applies to each, and since $(x')^2 + (y')^2 = 1$,

$$\int_0^L \|X\|^2 \, ds \leq \frac{L^2}{4\pi^2} \int_0^L ((x')^2 + (y')^2) \, ds = \frac{L^3}{4\pi^2}.$$

Substituting, $2A \leq (L^{3/2}/2\pi) \cdot L^{1/2} = L^2/2\pi$, which is the inequality.

If equality holds then in particular equality holds in Cauchy–Schwarz, so $\|X\|$ is constant along $\partial\Omega$: every boundary point is the same distance from the origin, and $\partial\Omega$ is a circle. $\square$

Remark. The same argument in fact shows a little more. If we had used Green’s theorem in the form $A = \int_0^L xy' \, ds$ instead, adding and subtracting x^2 gives the identity

$$\frac{L^2}{2\pi} - 2A = \int_0^L \left((x')^2 - \frac{4\pi^2}{L^2} x^2 \right) \, ds + \int_0^L \left(\frac{2\pi}{L} x - y' \right)^2 \, ds$$

after rescaling the parameter to have period 2π , which exhibits the deficit $L^2 - 4\pi A$ as a sum of two explicitly non-negative quantities.

§29.2.5 The Four Vertex Theorem

Our second global result concerns the curvature function of a closed plane curve. On a circle κ_s is constant; on any other simple closed curve it must vary, and the theorem says it must do so in a reasonably complicated way.

Definition 29.2.20 (Vertex)

A **vertex** of a plane curve γ is a point where $\kappa'_s = 0$, that is, a stationary point of the signed curvature.

An ellipse which is not a circle has exactly four vertices, the ends of the two axes, so the following is sharp.

Theorem 29.2.21 (Four Vertex Theorem)

Every simple closed plane curve has at least four vertices.

We will prove this for *convex* curves, meaning that the curve bounds a convex region; equivalently (after choosing the anticlockwise orientation) $\kappa_s \geq 0$ everywhere. The general case is true but substantially harder, and was only settled in full by Osserman in 1985.

Proof for convex curves. Parametrise γ by arc length on $[0, L]$. Since κ_s is a smooth function on a circle it attains a maximum and a minimum, so there are at least two vertices. Vertices where κ_s changes from increasing to decreasing alternate with those where it changes from decreasing to increasing, so the number of vertices, if finite, is even; hence it suffices to rule out the case of exactly two.

So suppose the only vertices are $p = \gamma(s_1)$ and $q = \gamma(s_2)$, at which κ_s attains its maximum and minimum. Then κ_s is strictly increasing on one of the two arcs of γ between p and q and strictly decreasing on the other. Let ℓ be the line through p and q . As γ is convex, ℓ meets the curve only at p and q , and the two arcs lie strictly on opposite sides of ℓ . Choose coordinates so that ℓ is the x -axis, and write $\gamma = (x, y)$; then $\kappa'_s \cdot y$ has a constant sign along the curve, and is not identically zero, so

$$\int_0^L \kappa'_s(s)y(s) \, ds \neq 0.$$

On the other hand, the Frenet equations in the plane read $\dot{T} = \kappa_s N_s$, that is, with $T = (\dot{x}, \dot{y})$ and $N_s = (-\dot{y}, \dot{x})$,

$$\ddot{x} = -\kappa_s \dot{y}, \quad \ddot{y} = \kappa_s \dot{x}.$$

Integrating by parts around the closed curve (all boundary terms vanish by periodicity),

$$\int_0^L \kappa'_s y \, ds = - \int_0^L \kappa_s \dot{y} \, ds = \int_0^L \ddot{x} \, ds = [\dot{x}]_0^L = 0,$$

a contradiction. □

Remark. A converse also holds (Gluck): any strictly positive smooth periodic function with at least two maxima and two minima is the curvature function of a simple closed convex curve.

§29.3 Surfaces, Length and Area

We now specialise the general machinery of Section 1 to the case that interests us most: two-dimensional manifolds sitting inside $\mathbb{R}^3$. This is where differential geometry began, with Gauss's work on surveying, and it remains the setting in which every important

idea in the subject can be seen in its simplest non-trivial form.

Everything in Section 1 applies verbatim. But we are now going to do *geometry* rather than topology: we will measure lengths, angles and areas on our surfaces, and then measure how they curve. The extra structure needed to do this comes from the ambient Euclidean inner product, and it will be packaged into two quadratic forms, the first and second fundamental forms.

§29.3.1 Smooth Surfaces

Definition 29.3.1 (Smooth Surface)

A **smooth surface** is a 2-dimensional smooth manifold $\Sigma \subseteq \mathbb{R}^3$. As in Section 1, a diffeomorphism $\sigma : V \rightarrow U \subseteq \Sigma$ from an open set $V \subseteq \mathbb{R}^2$ onto an open subset U of Σ is called an **allowable parametrisation** (or *allowable parameterisation*) of U .

We will consistently write $\sigma : V \rightarrow U \subseteq \Sigma$ for an allowable parametrisation, with coordinates (u, v) on V , and abbreviate the partial derivatives of σ by

$$\sigma_u = \frac{\partial \sigma}{\partial u}, \quad \sigma_v = \frac{\partial \sigma}{\partial v}, \quad \sigma_{uu} = \frac{\partial^2 \sigma}{\partial u^2}, \quad \text{and so on.}$$

Regularity of σ – which is part of it being a parametrisation – says exactly that σ_u and σ_v are linearly independent at every point, so $\{\sigma_u, \sigma_v\}$ is a basis for the tangent plane.

It is worth recording the standard ways in which surfaces turn up, all of which we already have the tools to handle.

Example 29.3.2 (Ways to Build Surfaces) (i) *Graphs.* If $f : V \rightarrow \mathbb{R}$ is smooth on an open $V \subseteq \mathbb{R}^2$ then $\sigma(u, v) = (u, v, f(u, v))$ parametrises the graph of f , which is therefore a smooth surface. Every surface looks like this locally.

(ii) *Level sets.* If $f : W \rightarrow \mathbb{R}$ is smooth on an open $W \subseteq \mathbb{R}^3$ and c is a regular value, then $f^{-1}(c)$ is a smooth surface by the preimage theorem. For instance $f(x, y, z) = x^2 + y^2 + z^2$ gives the spheres, and $f(x, y, z) = x^2 + y^2 - z^2$ gives the hyperboloids.

(iii) *Surfaces of revolution.* Let $\eta(u) = (f(u), 0, g(u))$ be a regular injective curve in the xz -plane with $f > 0$. Rotating about the z -axis gives

$$\sigma(u, v) = (f(u) \cos v, f(u) \sin v, g(u)).$$

(iv) *Ruled surfaces.* Given a curve η and a nowhere-zero vector field w along it, $\sigma(u, v) = \eta(u) + v w(u)$ sweeps out a surface (where regular): a union of straight lines. Cylinders, cones and the helicoid all arise this way.

§29.3.2 Orientability and Tangent Planes

Let's now use the framework we have developed to discuss a geometric property of surfaces: *orientability*.

Definition 29.3.3 (Orientation-Preserving Maps)

Let V, V' be open sets in $\mathbb{R}^2$, and let $f : V \rightarrow V'$ be a diffeomorphism. We say that f is **orientation-preserving** if $Df|_x$ has positive determinant for all $x \in V$.

Definition 29.3.4 (Orientability)

An abstract smooth surface Σ is **orientable** if it admits an atlas $\{(U_i, \phi_i)\}$ where the transition maps are all orientation-preserving. Such an atlas is a **orientation** of Σ .

We will now show that orientability is a ‘topological’ property of surfaces, in that it is preserved by diffeomorphisms.

Theorem 29.3.5

If Σ_1 and Σ_2 are diffeomorphic abstract smooth surfaces, then Σ_1 is orientable if and only if Σ_2 is orientable.

Proof. Let $f : \Sigma_1 \rightarrow \Sigma_2$ be diffeomorphism. Suppose Σ_2 is orientable and equipped with an oriented smooth atlas. Consider the atlas on Σ_1 of charts of the form $(f^{-1}(U), \phi \circ f|_{f^{-1}(U)})$, where (U, ψ) is a chart at $f(p)$ in the oriented atlas for Σ_2 . Then the transition map between two such charts is exactly a transition map between charts in the Σ_2 atlas. $\square$

So what does orientability *feel like*, in a geometric sense? To discuss this, we are going to need the idea of *tangent planes*.

Definition 29.3.6 (Tangent Plane)

Let Σ be a smooth surface in $\mathbb{R}^3$, and $p \in \Sigma$. Let $\sigma : V \rightarrow U \subseteq \Sigma$ be an allowable parameterisation of Σ near p , so V is an open subset of $\mathbb{R}^2$ and U is open in Σ , such that $\sigma(0) = p$. The **tangent plane** $T_p\Sigma$ to p at Σ is the image of $D\sigma|_0 \subseteq \mathbb{R}^3$, which is a two-dimensional vector subspace of $\mathbb{R}^3$. The **affine tangent plane** is $p + T_p\Sigma$, which is an affine^a subspace of $\mathbb{R}^3$.

^aAn *affine* subspace of a vector space is a translate of a linear subspace.

We should check that this notion makes geometric sense, in that it's independent of the choice of parametrisation used.

Lemma 29.3.7

$T_p\Sigma$ is independent of the choice of allowable parametrisation.

Proof. Suppose $\sigma : V \rightarrow U$ and $\tilde{\sigma} : \tilde{V} \rightarrow \tilde{U}$ are allowable parametrisations with $\sigma(0) = \tilde{\sigma}(0) = p$. Then there exists a transition map $\sigma^{-1} \circ \tilde{\sigma}$ which is a diffeomorphism of open sets in $\mathbb{R}^2$. So $D(\sigma^{-1} \circ \tilde{\sigma})|_0$ is an isomorphism, and since $\tilde{\sigma} = \sigma \circ (\sigma^{-1} \circ \tilde{\sigma})$ the images of $D\tilde{\sigma}|_0$ and $D\sigma|_0$ agree. $\square$

We can then sensibly define the *normal* to a smooth surface.

Definition 29.3.8

If Σ is a smooth surface in $\mathbb{R}^3$ and $p \in \Sigma$, the **normal direction** to Σ at p is $(T_p\Sigma)^\perp$, the Euclidean orthogonal complement to the tangent plane at p .

We can see that for every $p \in \Sigma$, there exist exactly two normalized normal vectors, and from this, we finally get our interpretation of orientability.

Definition 29.3.9

A smooth surface in $\mathbb{R}^3$ is **two-sided** if it admits a continuous global choice of unit normal vector.

Lemma 29.3.10 (Interpretation of Orientability)

A smooth surface in $\mathbb{R}^3$ is orientable if and only if it is two-sided.

Proof. Suppose Σ is orientable, with an atlas $\{(U_i, \sigma_i)\}$ whose transition maps all

have positive Jacobian determinant. On each U_i define

$$n_i = \frac{(\sigma_i)_u \times (\sigma_i)_v}{\|(\sigma_i)_u \times (\sigma_i)_v\|},$$

which is smooth and unit. If $p \in U_i \cap U_j$ and φ is the transition map, then as in the proof that area is well defined we have $(\sigma_j)_u \times (\sigma_j)_v = \det(D\varphi) (\sigma_i)_u \times (\sigma_i)_v$, and $\det(D\varphi) > 0$, so $n_i = n_j$ on the overlap. Hence the n_i glue to a global continuous (indeed smooth) unit normal, and Σ is two-sided.

Conversely suppose n is a global continuous unit normal. Take any atlas, and for each chart discard it in favour of the chart with u and v swapped if necessary, so that

$$\frac{\sigma_u \times \sigma_v}{\|\sigma_u \times \sigma_v\|} = n$$

on that patch – possible since the left hand side is a continuous unit normal, hence equal to $\pm n$ on each connected component, and swapping the coordinates changes its sign. For two such charts the same identity as above gives $\det(D\varphi) > 0$, so this atlas is an orientation. $\square$

Some illustrations of an orientable and non-orientable surface are shown below.

§29.3.3 The First Fundamental Form

Having pinned down what our surfaces are, we can start doing geometry on them: measuring lengths, angles and areas.

Recall that for a curve $\gamma : (a, b) \rightarrow \mathbb{R}^3$, the length of γ is given by

$$L(\gamma) = \int_a^b \|\gamma'(t)\| \, dt,$$

and that this is independent of the parametrisation.¹ Now suppose the curve lies on a surface. We would like to compute its length without ever leaving the surface, that is, in terms of the coordinates (u, v) of a parametrisation.

So let Σ be a smooth surface in $\mathbb{R}^3$, let $\sigma : V \rightarrow U \subseteq \Sigma$ be an allowable parametrisation, and let $\gamma : (a, b) \rightarrow \mathbb{R}^3$ be a smooth curve whose image lies in U . Writing $\gamma(t) = \sigma(u(t), v(t))$, the chain rule gives $\gamma'(t) = \sigma_u u'(t) + \sigma_v v'(t)$, and so

$$\|\gamma'(t)\|^2 = Eu'(t)^2 + 2Fu'(t)v'(t) + Gv'(t)^2,$$

where

$$E = \langle \sigma_u, \sigma_u \rangle, \quad F = \langle \sigma_u, \sigma_v \rangle = \langle \sigma_v, \sigma_u \rangle, \quad G = \langle \sigma_v, \sigma_v \rangle,$$

¹Feel free to check this – it is just the substitution rule.

and $\langle \cdot, \cdot \rangle$ is the Euclidean inner product. So three functions on V are all we need.

Definition 29.3.11 (First Fundamental Form)

The **first fundamental form** of Σ in the parametrisation σ is the expression

$$I = E \, du^2 + 2F \, du \, dv + G \, dv^2,$$

equivalently the symmetric matrix $\begin{pmatrix} E & F \\ F & G \end{pmatrix} = (D\sigma)^\top (D\sigma)$ representing the restriction of the Euclidean inner product to $T_p\Sigma$ in the basis $\{\sigma_u, \sigma_v\}$.

Since the inner product is positive definite and $\{\sigma_u, \sigma_v\}$ is a basis, we always have $E > 0$, $G > 0$ and $EG - F^2 > 0$. In terms of the first fundamental form, if γ has image in the image of σ then

$$L(\gamma) = \int_a^b \sqrt{E(u')^2 + 2Fu'v' + G(v')^2} \, dt,$$

and the angle θ between two tangent vectors $a\sigma_u + b\sigma_v$ and $c\sigma_u + d\sigma_v$ is given by

$$\cos \theta = \frac{Eac + F(ad + bc) + Gbd}{\sqrt{Ea^2 + 2Fab + Gb^2} \sqrt{Ec^2 + 2Fcd + Gd^2}}.$$

So *all* of the metric geometry of the surface, as far as a curve-measuring inhabitant of it is concerned, is contained in E , F and G .

Example 29.3.12 (Some First Fundamental Forms) (i) The plane $\sigma(u, v) = (u, v, 0)$ has $\sigma_u = (1, 0, 0)$ and $\sigma_v = (0, 1, 0)$, so $I = du^2 + dv^2$, as it must.

(ii) The cylinder $\sigma(u, v) = (a \cos u, a \sin u, v)$ has $\sigma_u = a(-\sin u, \cos u, 0)$ and $\sigma_v = (0, 0, 1)$, so $I = a^2 du^2 + dv^2$.

(iii) A surface of revolution $\sigma(u, v) = (f(u) \cos v, f(u) \sin v, g(u))$ has

$$\sigma_u = (f' \cos v, f' \sin v, g'), \quad \sigma_v = (-f \sin v, f \cos v, 0),$$

so $E = (f')^2 + (g')^2$, $F = 0$ and $G = f^2$. If the profile curve $\eta = (f, 0, g)$ is unit speed then this is simply

$$I = du^2 + f(u)^2 dv^2.$$

(iv) The unit sphere, parametrised by latitude and longitude as

$$\sigma(u, v) = (\cos u \cos v, \cos u \sin v, \sin u),$$

is the surface of revolution with $f = \cos u$ and $g = \sin u$, so

$$I = du^2 + \cos^2 u \, dv^2.$$

(v) The torus $\sigma(u, v) = ((a + r \cos u) \cos v, (a + r \cos u) \sin v, r \sin u)$ (with $a > r > 0$) is the surface of revolution with $f = a + r \cos u$, $g = r \sin u$, so $E = r^2$, $F = 0$, $G = (a + r \cos u)^2$.

§29.3.4 Isometries and Conformal Maps

With length encapsulated by the first fundamental form, we get a nice way to capture when two surfaces have the same geometry in a *length* sense.

Definition 29.3.13 (Isometric)

Let Σ, Σ' be smooth surfaces in $\mathbb{R}^3$. A diffeomorphism $f : \Sigma \rightarrow \Sigma'$ is an **isometry** if $Df|_p : T_p\Sigma \rightarrow T_{f(p)}\Sigma'$ is a linear isometry for every p ; equivalently, if f preserves the length of all curves. If such an f exists we say Σ and Σ' are **isometric**.

Definition 29.3.14 (Locally Isometric)

We say that Σ, Σ' are **locally isometric** near points $p \in \Sigma$ and $q \in \Sigma'$ if there exist open neighbourhoods U of p and U' of q which are isometric.

The whole point of the first fundamental form is the following, which turns a geometric question into a computation.

Lemma 29.3.15

Smooth surfaces Σ, Σ' in $\mathbb{R}^3$ are locally isometric near $p \in \Sigma$ and $q \in \Sigma'$ if and only if there exist allowable parametrisations $\sigma : V \rightarrow U \subseteq \Sigma$ and $\sigma' : V \rightarrow U' \subseteq \Sigma'$, with the same domain V , whose first fundamental forms are equal.

Proof. Suppose such parametrisations exist and set $f = \sigma' \circ \sigma^{-1} : U \rightarrow U'$, a diffeomorphism. In the bases $\{\sigma_u, \sigma_v\}$ and $\{\sigma'_u, \sigma'_v\}$, $Df|_p$ is the identity matrix, and the two first fundamental forms are equal, so $Df|_p$ carries an inner product to the same inner product, and is therefore a linear isometry.

Conversely, suppose $f : U \rightarrow U'$ is an isometry and let $\sigma : V \rightarrow U$ be any allowable parametrisation. Then $\sigma' = f \circ \sigma$ is an allowable parametrisation of U' on the same domain, and $\sigma'_u = Df|(\sigma_u)$, $\sigma'_v = Df|(\sigma_v)$. Since $Df|$ preserves inner products, $E' = E$, $F' = F$ and $G' = G$. $\square$

Example 29.3.16 (The Plane and the Cylinder)

Parametrise the plane by $\sigma(u, v) = (au, v, 0)$, so that $I = a^2 du^2 + dv^2$, and compare with the cylinder $\tilde{\sigma}(u, v) = (a \cos u, a \sin u, v)$ computed above. On $V = (0, 2\pi) \times \mathbb{R}$ the two first fundamental forms agree, so a cylinder is locally isometric to a plane: you really can roll a sheet of paper into a tube without stretching it. They are not globally isometric, since one is simply connected and the other is not.

Example 29.3.17 (The Sphere Cannot be Flattened)

No open subset of S^2 is isometric to an open subset of the plane. This is not obvious from the definition – it follows immediately from the Theorema Egregium of Section 5 – but it is worth flagging now as the reason that every world map distorts distances.

A weaker but very useful notion asks only that angles, not lengths, be preserved.

Definition 29.3.18 (Conformal)

A diffeomorphism $f : \Sigma \rightarrow \Sigma'$ is **conformal** if for every p there is $\lambda(p) > 0$ with

$$\langle Df|_p(w_1), Df|_p(w_2) \rangle = \lambda(p) \langle w_1, w_2 \rangle$$

for all $w_1, w_2 \in T_p\Sigma$. Equivalently, in corresponding parametrisations $I' = \lambda I$.

Since the angle formula above is unchanged when E, F, G are all multiplied by the same positive function, a conformal map is precisely one that preserves angles (though not orientation of angles unless we also ask $\det Df > 0$). A parametrisation is called **isothermal** if in it

$$I = \lambda(u, v)^2 (du^2 + dv^2),$$

that is, if σ is a conformal map from a piece of the plane to the surface. Isothermal parametrisations always exist locally, though this is a genuinely hard theorem; they will be crucial when we come to minimal surfaces.

Example 29.3.19 (Stereographic Projection)

Stereographic projection $\pi : S^2 \setminus \{N\} \rightarrow \mathbb{R}^2$ from the north pole is conformal, with the inverse parametrisation

$$\sigma(u, v) = \frac{1}{1 + u^2 + v^2} (2u, 2v, u^2 + v^2 - 1)$$

having first fundamental form

$$I = \frac{4}{(1 + u^2 + v^2)^2} (du^2 + dv^2),$$

so it is isothermal. This is why nautical charts made by stereographic projection get the angles right, and it is the reason for the appearance of $\pi \circ \mathcal{N}$ later in the Weierstrass representation.

§29.3.5 Area

With length pinned down by the first fundamental form, it is not too hard to pin down area.

Recall that the parallelogram spanned by two vectors w_1, w_2 has area $\|w_1 \times w_2\|$, and that

$$\|w_1 \times w_2\|^2 = \langle w_1, w_1 \rangle \langle w_2, w_2 \rangle - \langle w_1, w_2 \rangle^2.$$

So if $\sigma : V \rightarrow U \subseteq \Sigma$ is an allowable parametrisation, the infinitesimal parallelogram spanned by $\sigma_u du$ and $\sigma_v dv$ has area

$$\|\sigma_u \times \sigma_v\| du dv = \sqrt{EG - F^2} du dv.$$

This gives us a sensible way to define area, but we had better check it does not depend on the parametrisation.

Lemma 29.3.20

Let $\Omega \subseteq \Sigma$ be a bounded domain contained in the images of two allowable parametrisations.

sations $\sigma : V \rightarrow U$ and $\tilde{\sigma} : \tilde{V} \rightarrow \tilde{U}$. Then

$$\int_{\sigma^{-1}(\Omega)} \sqrt{EG - F^2} \, du \, dv = \int_{\tilde{\sigma}^{-1}(\Omega)} \sqrt{\tilde{E}\tilde{G} - \tilde{F}^2} \, d\tilde{u} \, d\tilde{v}.$$

Proof. Let $\varphi = \sigma^{-1} \circ \tilde{\sigma}$ be the transition map, a diffeomorphism between open subsets of $\mathbb{R}^2$, and let $J = \det D\varphi$ be its Jacobian determinant. Since $\tilde{\sigma} = \sigma \circ \varphi$, the chain rule gives $D\tilde{\sigma} = D\sigma \circ D\varphi$, and hence

$$\tilde{\sigma}_{\tilde{u}} \times \tilde{\sigma}_{\tilde{v}} = J(\sigma_u \times \sigma_v),$$

since taking the cross product of the two columns of a 3×2 matrix and then post-composing with a 2×2 matrix scales by its determinant. Taking norms, $\sqrt{\tilde{E}\tilde{G} - \tilde{F}^2} = |J|\sqrt{EG - F^2} \circ \varphi$, and the claim is exactly the change of variables formula. $\square$

Definition 29.3.21 (Area)

Let Σ be a smooth surface in $\mathbb{R}^3$, let $\sigma : V \rightarrow U \subseteq \Sigma$ be an allowable parametrisation and let $\Omega \subseteq U$ be a bounded domain. Then

$$\text{area}(\Omega) = \int_{\sigma^{-1}(\Omega)} \sqrt{EG - F^2} \, du \, dv.$$

More generally, for continuous $h : \Sigma \rightarrow \mathbb{R}$ we write

$$\int_{\Omega} h \, dA = \int_{\sigma^{-1}(\Omega)} h(\sigma(u, v)) \sqrt{EG - F^2} \, du \, dv,$$

and call $dA = \sqrt{EG - F^2} \, du \, dv$ the **area element** of Σ .

Remark. For regions not contained in a single parametrised patch, one patches these integrals together using a partition of unity. In practice we can nearly always find a single parametrisation covering everything except a finite union of curves, which contribute no area, and so we will not fuss about this.

Example 29.3.22 (Area of the Torus)

For the torus with $E = r^2$, $F = 0$, $G = (a + r \cos u)^2$ we have $\sqrt{EG - F^2} = r(a + r \cos u)$, so

$$\text{area} = \int_0^{2\pi} \int_0^{2\pi} r(a + r \cos u) \, du \, dv = 4\pi^2 ra.$$

This is Pappus's theorem: the area is the circumference $2\pi r$ of the generating circle times the distance $2\pi a$ travelled by its centre.

Remark. Isometries preserve area, since they preserve E, F, G . The converse is false: an area-preserving map need not be an isometry. Archimedes' theorem gives a beautiful example – the projection of the unit sphere onto the circumscribed cylinder, radially away from the axis, preserves area but certainly not lengths.

§29.4 The Gauss Map and Curvature

§29.4.1 The Second Fundamental Form

Intuitively, the first fundamental form pins down how length works along our surface. We now, through the second fundamental form, will try to pin down how *curved* our surface is (as an embedding of $\mathbb{R}^3$).

We are (informally) going to look at curvature at a point as measuring how much we deviate from the tangent plane by moving a small amount away from our point.

Let Σ be a smooth surface in $\mathbb{R}^3$, and let $\sigma : V \rightarrow U \subseteq \Sigma$ be an allowable parameterisation. Consider a point $p = \sigma(u, v)$, and some nearby point $q = \sigma(u + h, v + \ell)$. Then by Taylor's theorem we have

$$\begin{aligned} \sigma(u + h, v + \ell) &= \sigma(u, v) + h\sigma_u(u, v) + \ell\sigma_v(u, v) \\ &\quad + \frac{1}{2} (h^2\sigma_{uu}(u, v) + 2h\ell\sigma_{uv}(u, v) + \ell^2\sigma_{vv}(u, v)) \\ &\quad + O(h^3, \ell^3). \end{aligned}$$

Recalling that the tangent plane is given by $T_p\Sigma = \text{span}\{\sigma_u, \sigma_v\}$, we get the perpendicular distance from $q = \sigma(u + h, v + \ell)$ to the affine tangent plane $T_p\Sigma + p$ is given by

$$\begin{aligned} \langle n, \sigma(u + h, v + \ell) - \sigma(u, v) \rangle &= \frac{1}{2} (\langle n, \sigma_{uu} \rangle h^2 + 2\langle n, \sigma_{uv} \rangle h\ell + \langle n, \sigma_{vv} \rangle \ell^2) \\ &\quad + O(h^3, \ell^3). \end{aligned}$$

and so we can see that these inner products give us this difference. This inspires our definition of the second fundamental form.

Definition 29.4.1 (Second Fundamental Form)

The **second fundamental form** of Σ in the allowable parameterisation σ is

$$L \, du^2 + 2M \, du \, dv + N \, dv^2$$

where $L = \langle n, \sigma_{uu} \rangle$, $M = \langle n, \sigma_{uv} \rangle$, and $N = \langle n, \sigma_{vv} \rangle$, and n is the unit normal given by $n = \frac{\sigma_u \times \sigma_v}{\|\sigma_u \times \sigma_v\|}$.

We will say more about how this relates to curvature in the coming sections. It's good to know (but not proven in this course) that the two fundamental forms completely determine a smooth oriented connected surface in $\mathbb{R}^3$, up to rigid motion. This is the *fundamental theorem of surfaces in $\mathbb{R}^3$* .

§29.4.2 The Gauss Map and the Shape Operator

We are now going to define what our notion of curvature actually is. This is done using the *Gauss map*, which packages the unit normal into a map to the sphere.

Definition 29.4.2 (Gauss Map)

Let Σ be a smooth oriented surface in $\mathbb{R}^3$. The **Gauss map** is

$$n : \Sigma \rightarrow S^2, \quad p \mapsto n(p),$$

sending each point to its positively oriented unit normal, viewed as a point of the unit sphere.

Lemma 29.4.3

The Gauss map is smooth.

Proof. Smoothness is a local property, so we may check it in an allowable parametrisation σ compatible with the orientation, where

$$n \circ \sigma = \frac{\sigma_u \times \sigma_v}{\|\sigma_u \times \sigma_v\|}.$$

The numerator is smooth and the denominator is smooth and non-vanishing (since σ_u, σ_v are linearly independent), so $n \circ \sigma$ is smooth. $\square$

The reason the Gauss map is so useful is a small miracle of dimension counting. Its derivative at p is a linear map

$$Dn|_p : T_p\Sigma \rightarrow T_{n(p)}S^2,$$

but $T_{n(p)}S^2$ is the plane orthogonal to $n(p)$ in $\mathbb{R}^3$, which is precisely $T_p\Sigma$. So $Dn|_p$ is an *endomorphism of the tangent plane*, and we may take its determinant, its trace, and its eigenvalues.

Definition 29.4.4 (Shape Operator)

The **shape operator** (or Weingarten map) of Σ at p is the linear map

$$S_p = -Dn|_p : T_p\Sigma \rightarrow T_p\Sigma.$$

The sign is a convention chosen so that the sphere with its outward normal has positive curvature. The key algebraic fact is the following.

Lemma 29.4.5

The shape operator is self-adjoint with respect to the first fundamental form, and

$$\Pi_p(w_1, w_2) = \langle S_p(w_1), w_2 \rangle.$$

In particular the second fundamental form is a symmetric bilinear form.

Proof. Work in an allowable parametrisation and abbreviate n for $n \circ \sigma$. Applying the chain rule to a curve $\sigma(u(t), v(t))$ shows that $Dn|_p(\sigma_u) = n_u$ and $Dn|_p(\sigma_v) = n_v$, so it is enough to check the claim on the basis $\{\sigma_u, \sigma_v\}$.

Differentiating the identities $\langle n, \sigma_u \rangle = 0$ and $\langle n, \sigma_v \rangle = 0$ gives

$$\begin{aligned} \langle n_u, \sigma_u \rangle &= -\langle n, \sigma_{uu} \rangle = -L, & \langle n_u, \sigma_v \rangle &= -\langle n, \sigma_{uv} \rangle = -M, \\ \langle n_v, \sigma_u \rangle &= -\langle n, \sigma_{vu} \rangle = -M, & \langle n_v, \sigma_v \rangle &= -\langle n, \sigma_{vv} \rangle = -N. \end{aligned}$$

The two middle expressions agree because mixed partials commute, which gives $\langle Dn|_p \sigma_u, \sigma_v \rangle = \langle \sigma_u, Dn|_p \sigma_v \rangle$: self-adjointness. Reading the same four identities the other way round says exactly that the matrix of Π in the basis $\{\sigma_u, \sigma_v\}$ is the matrix of $\langle S_p(\cdot), \cdot \rangle$. $\square$

The identities in that proof deserve to be displayed on their own, since they are the computational heart of the subject:

$$\begin{pmatrix} L & M \\ M & N \end{pmatrix} = - \begin{pmatrix} \langle n_u, \sigma_u \rangle & \langle n_u, \sigma_v \rangle \\ \langle n_v, \sigma_u \rangle & \langle n_v, \sigma_v \rangle \end{pmatrix} = -(Dn)^\top(D\sigma),$$

in perfect analogy with $I = (D\sigma)^\top(D\sigma)$.

§29.4.3 Normal and Principal Curvatures

The second fundamental form has a direct geometric meaning in terms of curves on the surface.

Definition 29.4.6 (Normal Curvature)

Let γ be a unit speed curve on Σ with $\gamma(0) = p$. The **normal curvature** of γ at p is

$$\kappa_n = \langle \ddot{\gamma}(0), n(p) \rangle,$$

the component of the acceleration in the normal direction.

Proposition 29.4.7

The normal curvature of a unit speed curve γ on Σ at p depends only on the tangent vector $\dot{\gamma}(0)$, and

$$\kappa_n = \Pi_p(\dot{\gamma}(0), \dot{\gamma}(0)).$$

Proof. Along γ we have $\langle n(\gamma(t)), \dot{\gamma}(t) \rangle = 0$. Differentiating at $t = 0$,

$$\langle Dn|_p(\dot{\gamma}(0)), \dot{\gamma}(0) \rangle + \langle n(p), \ddot{\gamma}(0) \rangle = 0,$$

so $\kappa_n = \langle S_p(\dot{\gamma}(0)), \dot{\gamma}(0) \rangle = \Pi_p(\dot{\gamma}(0), \dot{\gamma}(0))$, which depends only on $\dot{\gamma}(0)$. $\square$

This is sometimes called Meusnier's theorem. It says that all curves on Σ through p with the same tangent direction bend away from the tangent plane at the same rate; in particular we may as well compute with the most symmetric such curve.

Definition 29.4.8 (Normal Section)

Given a unit vector $w \in T_p\Sigma$, let Π be the plane through p spanned by w and $n(p)$. Then $\Pi \cap \Sigma$ is, near p , a smooth curve (the two are transversal), called the **normal section** of Σ at p in the direction w .

A normal section is a plane curve lying in Π , and its principal normal at p is $\pm n(p)$; so its signed curvature there is exactly $\Pi_p(w, w)$. Normal curvature is genuinely the curvature of the slice you get by cutting the surface with a plane containing the normal.

Since S_p is self-adjoint, the spectral theorem applies.

Definition 29.4.9 (Principal Curvatures)

The eigenvalues $\kappa_1 \geq \kappa_2$ of the shape operator S_p are the **principal curvatures** of Σ at p , and the corresponding unit eigenvectors are the **principal directions**. A point where $\kappa_1 = \kappa_2$ is called **umbilic**.

Corollary 29.4.10

There is an orthonormal basis $\{e_1, e_2\}$ of $T_p\Sigma$ with $S_p(e_i) = \kappa_i e_i$, and κ_1, κ_2 are the maximum and minimum values of the normal curvature over all unit tangent directions.

Proof. The first statement is the spectral theorem for a self-adjoint operator on a two-dimensional inner product space. For the second, write a unit vector as $w = \cos \theta e_1 + \sin \theta e_2$; then

$$\Pi_p(w, w) = \kappa_1 \cos^2 \theta + \kappa_2 \sin^2 \theta,$$

which is a convex combination of κ_1 and κ_2 , attaining each at $\theta = 0, \pi/2$. $\square$

The formula in that proof is *Euler's theorem*, and it is worth remembering: the normal curvature in the direction making angle θ with the first principal direction is $\kappa_1 \cos^2 \theta + \kappa_2 \sin^2 \theta$.

Definition 29.4.11 (Gaussian and Mean Curvature)

Let Σ be a smooth surface in $\mathbb{R}^3$. The **Gaussian curvature** and **mean curvature** of Σ at p are

$$K(p) = \det S_p = \det (Dn|_p) = \kappa_1 \kappa_2, \quad H(p) = \frac{1}{2} \operatorname{tr} S_p = \frac{1}{2}(\kappa_1 + \kappa_2).$$

Note that reversing the orientation replaces n by $-n$, hence S_p by $-S_p$; so κ_1, κ_2 and H change sign, but K does not. In particular K is well defined even on a non-orientable surface, since every surface is locally orientable. Both are smooth functions of p , being polynomial expressions in the derivatives of a smooth parametrisation.

Remark. The principal curvatures are the roots of $t^2 - 2Ht + K = 0$, so $\kappa_{1,2} = H \pm \sqrt{H^2 - K}$ and in particular $H^2 \geq K$ always, with equality exactly at umbilic points.

§29.4.4 Curvature in Local Coordinates

We can now compute K and H from the two fundamental forms. This is the formula that makes everything computable.

Proposition 29.4.12

In any allowable parametrisation,

$$K = \frac{LN - M^2}{EG - F^2}, \quad H = \frac{LG - 2MF + NE}{2(EG - F^2)}.$$

Proof. Write the matrix of S_p in the basis $\{\sigma_u, \sigma_v\}$ as $A = (a_{ij})$, so that

$$-n_u = a_{11}\sigma_u + a_{21}\sigma_v, \quad -n_v = a_{12}\sigma_u + a_{22}\sigma_v.$$

Taking the inner product of each with σ_u and with σ_v , and using the identities $-\langle n_u, \sigma_u \rangle = L$ and so on, we obtain the matrix identity

$$\begin{pmatrix} L & M \\ M & N \end{pmatrix} = \begin{pmatrix} E & F \\ F & G \end{pmatrix} A,$$

that is, $A = I^{-1}II$. Taking determinants gives

$$K = \det A = \frac{LN - M^2}{EG - F^2},$$

and computing $A = \frac{1}{EG-F^2} \begin{pmatrix} G & -F \\ -F & E \end{pmatrix} \begin{pmatrix} L & M \\ M & N \end{pmatrix}$ explicitly and taking half the trace gives the stated H . $\square$

Example 29.4.13 (The Sphere)

For the unit sphere with outward normal, $n(p) = p$, so $Dn|_p = \operatorname{id}$ and $S_p = -\operatorname{id}$. Hence $\kappa_1 = \kappa_2 = -1$, $K = 1$ and $H = -1$. Every point is umbilic. With the inward normal we would get $\kappa_i = +1$; either way $K = 1$. For the sphere of radius a the same computation gives $K = 1/a^2$: big spheres are less curved.

Example 29.4.14 (The Cylinder)

For the cylinder $\sigma(u, v) = (a \cos u, a \sin u, v)$ we found $E = a^2$, $F = 0$, $G = 1$. Also $\sigma_{uv} = \sigma_{vu} = 0$ and $\sigma_{uu} = (-a \cos u, -a \sin u, 0)$, while $n = (\cos u, \sin u, 0)$ is the outward normal, so

$$L = -a, \quad M = N = 0.$$

Therefore $K = 0$ and $H = -1/(2a)$. The principal curvatures are $-1/a$ (around the cylinder) and 0 (along it). So the cylinder is *flat* – consistent with the fact that it is locally isometric to the plane, as we saw, and a first hint of the Theorema Egregium.

Example 29.4.15 (The Torus)

For the torus $\sigma(u, v) = ((a + r \cos u) \cos v, (a + r \cos u) \sin v, r \sin u)$ we have $E = r^2$, $F = 0$, $G = (a + r \cos u)^2$, and one computes

$$L = r, \quad M = 0, \quad N = (a + r \cos u) \cos u,$$

so

$$K = \frac{r(a + r \cos u) \cos u}{r^2(a + r \cos u)^2} = \frac{\cos u}{r(a + r \cos u)}.$$

Thus the outer half of the torus ($|u| < \pi/2$) has $K > 0$, the inner half has $K < 0$, and the top and bottom circles $u = \pm\pi/2$ have $K = 0$. This matches the intuition that the outside of a doughnut is dome-like and the inside is saddle-like.

Example 29.4.16 (Surfaces of Revolution)

Let $\sigma(u, v) = (f(u) \cos v, f(u) \sin v, g(u))$ with unit speed profile, so $(f')^2 + (g')^2 = 1$ and $I = du^2 + f^2 dv^2$. A short computation gives

$$L = f'g'' - f''g', \quad M = 0, \quad N = fg',$$

and hence

$$K = \frac{(f'g'' - f''g')g'}{f}.$$

Differentiating $(f')^2 + (g')^2 = 1$ gives $f'f'' + g'g'' = 0$, from which $(f'g'' - f''g')g' = -f''$, and so the memorable formula

$$K = -\frac{f''}{f}.$$

§29.4.5 Elliptic, Hyperbolic and Parabolic Points

The sign of the Gaussian curvature controls the local shape of the surface, via the Taylor expansion we used to motivate the second fundamental form.

Definition 29.4.17

A smooth surface in $\mathbb{R}^3$ with $K \equiv 0$ is called **flat**.

Definition 29.4.18

Let Σ be a smooth surface in $\mathbb{R}^3$, and let $p \in \Sigma$. We say p is

- (i) **elliptic** if $K(p) > 0$;
- (ii) **hyperbolic** if $K(p) < 0$;
- (iii) **parabolic** if $K(p) = 0$ but $S_p \neq 0$;
- (iv) **planar** if $S_p = 0$.

elliptic: $K > 0$ hyperbolic: $K < 0$ parabolic: $K = 0$ **Proposition 29.4.19**

Let $p \in \Sigma$ be an elliptic point. Then there is a neighbourhood of p in Σ lying strictly on one side of the affine tangent plane $p + T_p\Sigma$ (apart from p itself). If p is hyperbolic, then every neighbourhood of p contains points on both sides.

Proof. Take an allowable parametrisation with $\sigma(0,0) = p$. From the Taylor expansion at the start of this section, the signed distance from $\sigma(h,\ell)$ to the affine tangent plane is

$$\langle \sigma(h,\ell) - p, n(p) \rangle = \frac{1}{2} (Lh^2 + 2Mh\ell + N\ell^2) + O((h^2 + \ell^2)^{3/2}),$$

that is, $\frac{1}{2}\Pi_p(w, w) + o(\|w\|^2)$ where $w = h\sigma_u + \ell\sigma_v$.

If $K(p) > 0$ then $LN - M^2 > 0$, so the quadratic form Π_p is definite, and hence $|\Pi_p(w, w)| \geq c\|w\|^2$ for some $c > 0$ by compactness of the unit circle. The error term is $o(\|w\|^2)$, so for $\|w\|$ small the sign of the whole expression is that of Π_p , which is constant.

If $K(p) < 0$ then Π_p is indefinite, so there are unit vectors $w_{\pm}$ with $\Pi_p(w_+, w_+) > 0 > \Pi_p(w_-, w_-)$, and the same estimate applied along the two directions produces points on both sides arbitrarily close to p . $\square$

Example 29.4.20 (The Monkey Saddle)

Let Σ be the graph of $z = x^3 - 3xy^2$. At the origin all first and second derivatives of the height function vanish, so $\Pi_0 = 0$ and the origin is a planar point. Writing $x = r \cos \theta$, $y = r \sin \theta$ gives $z = r^3 \cos 3\theta$, so the surface crosses its tangent plane six times around the origin – a saddle with room for two legs and a tail.

§29.4.6 Curvature as Area Distortion

The determinant of a linear map is the factor by which it scales areas, and the Gauss map's derivative is a map between two-dimensional spaces. That gives the following interpretation of K , which is essentially Gauss's original definition.

Theorem 29.4.21

Let Σ be a smooth surface in $\mathbb{R}^3$ and $p \in \Sigma$ with $K(p) \neq 0$. Let (A_i) be a decreasing sequence of neighbourhoods of p shrinking to p , in the sense that for every $\varepsilon > 0$ we have $A_i \subseteq B(p, \varepsilon)$ for all large i . Then

$$|K(p)| = \lim_{i \rightarrow \infty} \frac{\text{area}_{S^2}(n(A_i))}{\text{area}_{\Sigma}(A_i)}.$$

Proof. Fix an allowable parametrisation σ near p . The area element of Σ is $\|\sigma_u \times \sigma_v\|$, and the composite $n \circ \sigma$ parametrises the image on the sphere, with area element $\|n_u \times n_v\|$, both with respect to $du dv$. But $n_u = -S(\sigma_u)$ and $n_v = -S(\sigma_v)$, so

$$n_u \times n_v = \det(S) \sigma_u \times \sigma_v = K \sigma_u \times \sigma_v.$$

Hence

$$\frac{\text{area}_{S^2}(n(A_i))}{\text{area}_{\Sigma}(A_i)} = \frac{\int_{\sigma^{-1}(A_i)} |K| \|\sigma_u \times \sigma_v\|}{\int_{\sigma^{-1}(A_i)} \|\sigma_u \times \sigma_v\|},$$

a weighted average of $|K|$ over a region shrinking to p . Since K is continuous and $K(p) \neq 0$ (so n is a local diffeomorphism near p and the areas above are genuinely areas of the image), this tends to $|K(p)|$. $\square$

Informally, then, the Gaussian curvature is an infinitesimal measure of how much the Gauss map distorts area. On a sphere of radius a a patch of area A maps to a patch of area A/a^2 ; on a cylinder every patch maps into a single curve, of area zero, which is why $K = 0$.

§29.4.7 Compact Surfaces Have an Elliptic Point

Here is a first genuinely global statement, and a good illustration of a technique we will use again: put the surface inside the smallest sphere you can and look at where they touch.

Theorem 29.4.22

Every compact smooth surface $\Sigma \subseteq \mathbb{R}^3$ has an elliptic point. In particular, no compact surface in $\mathbb{R}^3$ has $K \leq 0$ everywhere.

Proof. The function $p \mapsto \|p\|^2$ is continuous on the compact set Σ , so it attains its maximum at some p_0 , at distance $R = \|p_0\|$ from the origin. Then Σ is contained in the closed ball of radius R and touches the sphere S_R of radius R at p_0 .

Let γ be any unit speed curve in Σ with $\gamma(0) = p_0$. The function $h(t) = \|\gamma(t)\|^2$ has a maximum at $t = 0$, so $\dot{h}(0) = 2\langle \gamma(0), \dot{\gamma}(0) \rangle = 0$ – which says p_0 is orthogonal to $T_{p_0}\Sigma$, so the unit normal there is $n(p_0) = \pm p_0/R$; choose the orientation so that $n(p_0) = -p_0/R$ (the inward normal). Also

$$0 \geq \frac{1}{2}\ddot{h}(0) = \langle \dot{\gamma}(0), \dot{\gamma}(0) \rangle + \langle \gamma(0), \ddot{\gamma}(0) \rangle = 1 + \langle p_0, \ddot{\gamma}(0) \rangle.$$

Now the normal curvature of γ at p_0 is $\kappa_n = \langle \ddot{\gamma}(0), n(p_0) \rangle = -\langle \ddot{\gamma}(0), p_0 \rangle/R$, so the

displayed inequality reads $R\kappa_n \geq 1$, i.e.

$$\kappa_n \geq \frac{1}{R}$$

for every unit tangent direction at p_0 . In particular both principal curvatures at p_0 are at least $1/R > 0$, so

$$K(p_0) = \kappa_1\kappa_2 \geq \frac{1}{R^2} > 0,$$

and p_0 is elliptic. □

Remark. This is the germ of several deeper global theorems. For instance, a compact surface with K constant must have $K > 0$ by the above, and one can then show it is a sphere; and Hilbert's theorem states that there is no complete surface in $\mathbb{R}^3$ with constant negative curvature, so the hyperbolic plane of Section 10 can never be realised as a surface in $\mathbb{R}^3$. We will not prove either here.

§29.5 The Theorema Egregium

The Gaussian curvature was defined using the Gauss map, which needs a normal vector, which needs an ambient $\mathbb{R}^3$. So on the face of it K measures how the surface sits inside space. Gauss's remarkable theorem – *theorema egregium* really does mean ‘remarkable theorem’, and he named it himself – says that this appearance is deceptive: K can be computed from the first fundamental form alone, and so is unchanged by any isometry.

The strategy is exactly the one that worked for curves. There we differentiated the Frenet frame and expressed the answer back in the frame; here we differentiate the frame $\{\sigma_u, \sigma_v, n\}$ and express the answer back in that frame. The coefficients which appear are the Christoffel symbols, and the compatibility conditions coming from equality of mixed partials are the Gauss and Codazzi–Mainardi equations.

§29.5.1 Christoffel Symbols

Let $\sigma : V \rightarrow U \subseteq \Sigma$ be an allowable parametrisation. At each point $\{\sigma_u, \sigma_v, n\}$ is a basis of $\mathbb{R}^3$, so we may expand the second derivatives of σ in it.

Definition 29.5.1 (Christoffel Symbols)

The **Christoffel symbols** of Σ in the parametrisation σ are the functions Γ_{ij}^k defined by

$$\begin{aligned}\sigma_{uu} &= \Gamma_{11}^1\sigma_u + \Gamma_{11}^2\sigma_v + Ln, \\ \sigma_{uv} &= \Gamma_{12}^1\sigma_u + \Gamma_{12}^2\sigma_v + Mn, \\ \sigma_{vv} &= \Gamma_{22}^1\sigma_u + \Gamma_{22}^2\sigma_v + Nn.\end{aligned}$$

The normal components are the coefficients of the second fundamental form, by definition. Note that $\sigma_{uv} = \sigma_{vu}$, so the symbols are symmetric in their lower indices, $\Gamma_{12}^k = \Gamma_{21}^k$: there are six of them in all.

The whole point is that the Christoffel symbols are *intrinsic*.

Lemma 29.5.2

The Christoffel symbols are determined by E, F, G and their first partial derivatives.

Proof. Take the inner product of each of the three defining equations with σ_u and with σ_v ; the normal terms drop out. Using

$$\begin{aligned}\langle \sigma_{uu}, \sigma_u \rangle &= \frac{1}{2}E_u, & \langle \sigma_{uu}, \sigma_v \rangle &= F_u - \frac{1}{2}E_v, & \langle \sigma_{uv}, \sigma_u \rangle &= \frac{1}{2}E_v, \\ \langle \sigma_{uv}, \sigma_v \rangle &= \frac{1}{2}G_u, & \langle \sigma_{vv}, \sigma_u \rangle &= F_v - \frac{1}{2}G_u, & \langle \sigma_{vv}, \sigma_v \rangle &= \frac{1}{2}G_v,\end{aligned}$$

each of which follows by differentiating the definitions of E, F, G , we obtain three linear systems

$$\begin{pmatrix} E & F \\ F & G \end{pmatrix} \begin{pmatrix} \Gamma_{11}^1 \\ \Gamma_{11}^2 \end{pmatrix} = \begin{pmatrix} \frac{1}{2}E_u \\ F_u - \frac{1}{2}E_v \end{pmatrix}, \quad \begin{pmatrix} E & F \\ F & G \end{pmatrix} \begin{pmatrix} \Gamma_{12}^1 \\ \Gamma_{12}^2 \end{pmatrix} = \begin{pmatrix} \frac{1}{2}E_v \\ \frac{1}{2}G_u \end{pmatrix},$$

$$\begin{pmatrix} E & F \\ F & G \end{pmatrix} \begin{pmatrix} \Gamma_{22}^1 \\ \Gamma_{22}^2 \end{pmatrix} = \begin{pmatrix} F_v - \frac{1}{2}G_u \\ \frac{1}{2}G_v \end{pmatrix}.$$

Since $EG - F^2 > 0$ the matrix is invertible, and Cramer's rule solves each system in terms of E, F, G and their first derivatives. $\square$

Example 29.5.3 (Orthogonal Parametrisations)

When $F = 0$ the systems above are diagonal and we can read off everything at once:

$$\Gamma_{11}^1 = \frac{E_u}{2E}, \quad \Gamma_{11}^2 = -\frac{E_v}{2G}, \quad \Gamma_{12}^1 = \frac{E_v}{2E}, \quad \Gamma_{12}^2 = \frac{G_u}{2G}, \quad \Gamma_{22}^1 = -\frac{G_u}{2E}, \quad \Gamma_{22}^2 = \frac{G_v}{2G}.$$

§29.5.2 The Gauss and Codazzi–Mainardi Equations

We have written down $\sigma_{uu}, \sigma_{uv}, \sigma_{vv}$ and (from the shape operator) n_u, n_v in terms of the frame. The only constraint left to impose is that mixed partial derivatives commute, and this is where all the content is.

Theorem 29.5.4 (Gauss Equation)

In any allowable parametrisation,

$$EK = (\Gamma_{11}^2)_v - (\Gamma_{12}^2)_u + \Gamma_{11}^1 \Gamma_{12}^2 - \Gamma_{12}^1 \Gamma_{11}^2 + \Gamma_{11}^2 \Gamma_{22}^2 - (\Gamma_{12}^2)^2.$$

Proof. Write $n_u = a_{11}\sigma_u + a_{21}\sigma_v$ and $n_v = a_{12}\sigma_u + a_{22}\sigma_v$; from the previous section the matrix (a_{ij}) of $Dn|_p = -S_p$ is $-\mathbf{I}^{-1}\mathbf{II}$, so

$$a_{21} = \frac{FL - EM}{EG - F^2}, \quad a_{22} = \frac{FM - EN}{EG - F^2}.$$

Now differentiate the first Christoffel identity with respect to v and the second with respect to u :

$$\sigma_{uuv} = (\Gamma_{11}^1)_v \sigma_u + \Gamma_{11}^1 \sigma_{uv} + (\Gamma_{11}^2)_v \sigma_v + \Gamma_{11}^2 \sigma_{vv} + L_v n + L n_v,$$

$$\sigma_{uvu} = (\Gamma_{12}^1)_u \sigma_u + \Gamma_{12}^1 \sigma_{uu} + (\Gamma_{12}^2)_u \sigma_v + \Gamma_{12}^2 \sigma_{uv} + M_u n + M n_u.$$

These are equal. Expanding $\sigma_{uu}, \sigma_{uv}, \sigma_{vv}, n_u, n_v$ in the frame and comparing the coefficients of σ_v (which is legitimate since the frame is a basis) gives

$$(\Gamma_{11}^2)_v + \Gamma_{11}^1 \Gamma_{12}^2 + \Gamma_{11}^2 \Gamma_{22}^2 + L a_{22} = (\Gamma_{12}^2)_u + \Gamma_{12}^1 \Gamma_{11}^2 + (\Gamma_{12}^2)^2 + M a_{21}.$$

Finally

$$M a_{21} - L a_{22} = \frac{M(FL - EM) - L(FM - EN)}{EG - F^2} = \frac{E(LN - M^2)}{EG - F^2} = EK,$$

and rearranging gives the claim. $\square$

Theorem 29.5.5 (Theorema Egregium)

The Gaussian curvature of a smooth surface in $\mathbb{R}^3$ depends only on the first fundamental form. Consequently, if $f : \Sigma \rightarrow \Sigma'$ is an isometry then $K' \circ f = K$; that is, Gaussian curvature is an isometry invariant.

Proof. The right hand side of the Gauss equation involves only Christoffel symbols and their derivatives, hence only E, F, G and their derivatives up to second order. Since $E = \langle \sigma_u, \sigma_u \rangle > 0$ we may divide, and K is expressed intrinsically.

For the second statement, if f is an isometry and σ is an allowable parametrisation of Σ , then $f \circ \sigma$ is an allowable parametrisation of Σ' with the same first fundamental form, so the two curvature computations produce the same function. $\square$

Comparing the coefficients of n instead of σ_v , and doing the same with $\sigma_{uvv} = \sigma_{vvu}$, gives the remaining compatibility conditions.

Theorem 29.5.6 (Codazzi–Mainardi Equations)

In any allowable parametrisation,

$$\begin{aligned} L_v - M_u &= L\Gamma_{12}^1 + M(\Gamma_{12}^2 - \Gamma_{11}^1) - N\Gamma_{11}^2, \\ M_v - N_u &= L\Gamma_{22}^1 + M(\Gamma_{22}^2 - \Gamma_{12}^1) - N\Gamma_{12}^2. \end{aligned}$$

Proof. Compare the coefficients of n in the two expansions of $\sigma_{uvv} = \sigma_{vvu}$ displayed above: this gives $\Gamma_{11}^1 M + \Gamma_{11}^2 N + L_v = \Gamma_{12}^1 L + \Gamma_{12}^2 M + M_u$, which rearranges to the first equation. Expanding $\sigma_{uvv} = \sigma_{vvu}$ in the same way and comparing n coefficients gives $\Gamma_{12}^1 M + \Gamma_{12}^2 N + M_v = \Gamma_{22}^1 L + \Gamma_{22}^2 M + N_u$, which is the second. $\square$

Remark. The Gauss and Codazzi–Mainardi equations are precisely the integrability conditions for the system defining σ , and one can prove a converse: given smooth functions E, F, G (with $E, G, EG - F^2 > 0$) and L, M, N on a simply connected open $V \subseteq \mathbb{R}^2$ satisfying these equations, there is a smooth surface, unique up to a rigid motion of $\mathbb{R}^3$, with these as its fundamental forms. This is the *fundamental theorem of surface theory*, the exact analogue of the fundamental theorem of curve theory from Section 2. We will not prove it.

§29.5.3 Useful Special Cases

In practice one almost always arranges $F = 0$, and then the Gauss equation collapses to something usable.

Corollary 29.5.7 (Orthogonal Gauss Formula)

If σ is an orthogonal parametrisation ($F \equiv 0$) then

$$K = -\frac{1}{2\sqrt{EG}} \left[\left(\frac{E_v}{\sqrt{EG}} \right)_v + \left(\frac{G_u}{\sqrt{EG}} \right)_u \right].$$

Proof. Substitute the orthogonal Christoffel symbols computed above into the Gauss equation and simplify; it is a slightly tedious but entirely mechanical calculation. $\square$

Corollary 29.5.8

If $I = du^2 + G(u, v) dv^2$, then with $h = \sqrt{G}$,

$$K = -\frac{h_{uu}}{h}.$$

Proof. Put $E = 1$ in the orthogonal Gauss formula: the first bracket vanishes and $G_u/\sqrt{G} = 2h_u$, so $K = -(2h_u)_u/(2h) = -h_{uu}/h$. $\square$

Corollary 29.5.9 (Isothermal Case)

If σ is isothermal, so $E = G = \lambda^2$ and $F = 0$, then

$$K = -\frac{1}{\lambda^2} \nabla^2 (\log \lambda),$$

where $\nabla^2 = \partial_u^2 + \partial_v^2$ is the flat Laplacian.

Proof. Here $\sqrt{EG} = \lambda^2$, so $E_v/\sqrt{EG} = 2\lambda_v/\lambda = 2(\log \lambda)_v$ and likewise $G_u/\sqrt{EG} = 2(\log \lambda)_u$. Substituting into the orthogonal Gauss formula gives the result. $\square$

Example 29.5.10 (The Sphere, Intrinsically)

The unit sphere has $I = du^2 + \cos^2 u dv^2$ in latitude-longitude coordinates. So $h = \cos u$ and

$$K = -\frac{h_{uu}}{h} = -\frac{-\cos u}{\cos u} = 1,$$

with not a single normal vector in sight.

Example 29.5.11 (Surfaces of Revolution, Intrinsically)

A surface of revolution with unit speed profile has $I = du^2 + f(u)^2 dv^2$, so immediately $K = -f''/f$, recovering the formula of the previous section by a purely intrinsic route.

Example 29.5.12 (Why the Sphere Cannot be Flattened)

A piece of the plane has $K \equiv 0$ and a piece of the unit sphere has $K \equiv 1$. By the Theorema Egregium no open subset of the sphere is isometric to an open subset of the plane. Every flat map of the world lies about distances – and now we know it is not the cartographers' fault.

Example 29.5.13 (The Cylinder Again)

The cylinder has $I = a^2 du^2 + dv^2$, with constant coefficients, so $K \equiv 0$: the cylinder is intrinsically flat, exactly as its local isometry with the plane demands. Note that the *mean* curvature does not have this property: the plane has $H \equiv 0$ and the cylinder has $H = -1/2a \neq 0$, so H is emphatically not intrinsic.

§29.6 Geodesics

§29.6.1 Length, Energy and Variations

We are now going to discuss a particular geometric phenomenon, *geodesics*, which are curves that are (in some sense) the shortest path between points.

Fix a smooth surface Σ and points $p, q \in \Sigma$, and let $\Omega(p, q)$ denote the set of smooth curves $\gamma : [a, b] \rightarrow \Sigma$ with $\gamma(a) = p$ and $\gamma(b) = q$. We would like to find the critical points of the length functional L on $\Omega(p, q)$. The trouble is that L has a square root in it, which makes differentiating it unpleasant, and it is also insensitive to reparametrisation, so its critical points are never isolated. Both problems are fixed by working with a different functional.

Definition 29.6.1 (Energy)

The **energy** of a curve $\gamma : [a, b] \rightarrow \mathbb{R}^3$ is given by

$$\mathcal{E}(\gamma) = \int_a^b \|\gamma'(t)\|^2 dt.$$

We write $\mathcal{E}$ rather than E to avoid a clash with the first fundamental form. Energy is sensitive to reparametrisation, but the two functionals are related by Cauchy–Schwarz.

Lemma 29.6.2

For any $\gamma \in \Omega(p, q)$ we have $L(\gamma)^2 \leq (b - a)\mathcal{E}(\gamma)$, with equality if and only if γ has constant speed.

Proof. Apply Cauchy–Schwarz to $\|\gamma'\|$ and the constant function 1 on $[a, b]$:

$$L(\gamma)^2 = \left(\int_a^b \|\gamma'\| \cdot 1 dt \right)^2 \leq (b - a) \int_a^b \|\gamma'\|^2 dt = (b - a)\mathcal{E}(\gamma),$$

with equality exactly when $\|\gamma'\|$ is a constant multiple of 1. $\square$

Since every curve can be reparametrised to have constant speed without changing its

length, minimising L is the same problem as minimising $\mathcal{E}$ over constant speed curves, and the latter is the more tractable one.

Definition 29.6.3 (One-Parameter Variation)

Let $\gamma : [a, b] \rightarrow \Sigma$, where Σ is a smooth surface in $\mathbb{R}^3$. A **one-parameter variation** (with fixed endpoints) of γ is a smooth map $\Gamma : (-\varepsilon, \varepsilon) \times [a, b] \rightarrow \Sigma$ such that, writing $\gamma_s = \Gamma(s, \cdot)$, we have $\gamma_0 = \gamma$ and $\gamma_s(a), \gamma_s(b)$ are independent of s .

Definition 29.6.4 (Geodesic)

A smooth curve $\gamma : [a, b] \rightarrow \Sigma$ is a **geodesic** if, for every variation (γ_s) of γ with fixed endpoints, we have $\left. \frac{d}{ds} \right|_{s=0} \mathcal{E}(\gamma_s) = 0$; that is, if γ is a critical point of the energy functional on $\Omega(\gamma(a), \gamma(b))$.

§29.6.2 The Geodesic Equations

So how do we actually find geodesics? It turns out to be *relatively* easy, using the geodesic equations.

Suppose we have some curve γ with image contained in the image of an allowable parametrisation σ . Then for sufficiently small s we can write $\gamma_s(t) = \sigma(u(s, t), v(s, t))$. Let the first fundamental form with respect to σ be

$$E du^2 + 2F du dv + G dv^2.$$

Then by definition,

$$\mathcal{E}(\gamma_s) = \int_a^b (E\dot{u}^2 + 2F\dot{u}\dot{v} + G\dot{v}^2) dt,$$

where the dots are $\partial/\partial t$ and E, F, G are evaluated at $(u(s, t), v(s, t))$. Differentiating under the integral sign and integrating by parts – the boundary terms vanish because the endpoints are fixed – we get

$$\left. \frac{d}{ds} \mathcal{E}(\gamma_s) \right|_{s=0} = \int_a^b \left(A \frac{\partial u}{\partial s} + B \frac{\partial v}{\partial s} \right) dt \Big|_{s=0}$$

where

$$A = E_u \dot{u}^2 + 2F_u \dot{u}\dot{v} + G_u \dot{v}^2 - 2 \frac{d}{dt} (E\dot{u} + F\dot{v}),$$

$$B = E_v \dot{u}^2 + 2F_v \dot{u}\dot{v} + G_v \dot{v}^2 - 2 \frac{d}{dt} (F\dot{u} + G\dot{v}).$$

Since $\partial u/\partial s$ and $\partial v/\partial s$ at $s = 0$ can be prescribed to be any pair of smooth functions vanishing at a and b , the integral vanishes for all variations exactly when $A = B = 0$. These give us the *geodesic equations*.

Theorem 29.6.5 (Geodesic Equations)

A smooth curve $\gamma(t) = \sigma(u(t), v(t))$ is a geodesic if and only if it satisfies the geodesic equations

$$\frac{d}{dt} (E\dot{u} + F\dot{v}) = \frac{E_u \dot{u}^2 + 2F_u \dot{u}\dot{v} + G_u \dot{v}^2}{2},$$

$$\frac{d}{dt}(F\dot{u} + G\dot{v}) = \frac{E_v\dot{u}^2 + 2F_v\dot{u}\dot{v} + G_v\dot{v}^2}{2}.$$

Unlike length, energy is sensitive to reparameterisation, but Cauchy–Schwarz gives us that $L(\gamma)^2 \leq \mathcal{E}(\gamma)(b-a)$, with equality if and only if γ is parametrised proportional to arc length.

Corollary 29.6.6

If γ has constant speed and locally minimises length, then it is a geodesic. Further, if γ minimises energy globally, then it minimises length globally and is parametrised with constant speed.

Expanding the derivatives on the left and using the formulae for the Christoffel symbols, the geodesic equations take an equivalent and often more convenient form.

Corollary 29.6.7

A curve $\gamma(t) = \sigma(u(t), v(t))$ is a geodesic if and only if

$$\begin{aligned}\ddot{u} + \Gamma_{11}^1\dot{u}^2 + 2\Gamma_{12}^1\dot{u}\dot{v} + \Gamma_{22}^1\dot{v}^2 &= 0, \\ \ddot{v} + \Gamma_{11}^2\dot{u}^2 + 2\Gamma_{12}^2\dot{u}\dot{v} + \Gamma_{22}^2\dot{v}^2 &= 0.\end{aligned}$$

In this form the geodesic equations are visibly a second order system of ODEs, with smooth coefficients depending only on the first fundamental form. Picard’s theorem therefore gives us existence, uniqueness and smooth dependence on initial data all at once.

Proposition 29.6.8 (Local Existence and Uniqueness of Geodesics)

Let Σ be a smooth surface, $p \in \Sigma$ and $w \in T_p\Sigma$. Then there is $\varepsilon > 0$ and a unique geodesic $\gamma : (-\varepsilon, \varepsilon) \rightarrow \Sigma$ with $\gamma(0) = p$ and $\dot{\gamma}(0) = w$. Moreover γ depends smoothly on (p, w) .

Proof. Choose an allowable parametrisation about p . In it the geodesic equations are a second order ODE system $\ddot{x} = h(x, \dot{x})$ with h smooth, which is equivalent to a first order system in $(x, \dot{x})$ with smooth right hand side. Picard’s theorem gives a unique local solution with any prescribed initial position and velocity, and the standard theory gives smooth dependence on those initial conditions. $\square$

Note also the important fact that geodesics automatically have constant speed. This will follow immediately from the characterisation in the next subsection.

§29.6.3 Geodesics Are Straightest

In $\mathbb{R}^2$, the geodesics are not just locally shortest, they are also locally *straightest*. We would intuitively expect this to hold on other surfaces too: the change in the tangent vector should be as small as possible subject to the constraint that we lie on the surface. That is, the acceleration should be entirely used up in staying on the surface.

Theorem 29.6.9

Let Σ be a smooth surface in $\mathbb{R}^3$. A smooth curve $\gamma : [a, b] \rightarrow \Sigma$ is a geodesic if and only if $\ddot{\gamma}(t)$ is everywhere normal to the surface Σ , that is, $\ddot{\gamma}(t) \perp T_{\gamma(t)}\Sigma$ for all t .

Proof. Let Γ be a variation of γ with fixed endpoints and put $W(t) = \frac{\partial \Gamma}{\partial s} \Big|_{s=0}$, a vector field along γ tangent to Σ and vanishing at the endpoints. Differentiating under the integral sign,

$$\frac{d}{ds} \Big|_{s=0} \mathcal{E}(\gamma_s) = \int_a^b 2 \left\langle \frac{\partial^2 \Gamma}{\partial s \partial t}, \frac{\partial \Gamma}{\partial t} \right\rangle_{s=0} dt = 2 \int_a^b \langle \dot{W}, \dot{\gamma} \rangle dt = -2 \int_a^b \langle W, \ddot{\gamma} \rangle dt,$$

integrating by parts and using $W(a) = W(b) = 0$.

If $\ddot{\gamma} \perp T_{\gamma}\Sigma$ everywhere then the integrand vanishes for every variation, so γ is a geodesic. Conversely, suppose γ is a geodesic but $\ddot{\gamma}(t_0)$ has a non-zero tangential part Z for some t_0 . Choose a smooth bump function $\chi \geq 0$ supported in a small neighbourhood of t_0 with $\chi(t_0) = 1$, and let W be the tangential vector field along γ obtained by extending χZ (in a parametrisation, take $W = \chi(t)(\alpha\sigma_u + \beta\sigma_v)$ with α, β the constant coordinates of Z). Then W arises from a genuine variation – take $\Gamma(s, t) = \sigma(u(t) + s\alpha\chi(t), v(t) + s\beta\chi(t))$ – and $\int \langle W, \ddot{\gamma} \rangle > 0$ if the support is small enough, contradicting criticality. $\square$

Corollary 29.6.10

Every geodesic has constant speed.

Proof. $\frac{d}{dt} \langle \dot{\gamma}, \dot{\gamma} \rangle = 2 \langle \ddot{\gamma}, \dot{\gamma} \rangle = 0$, since $\ddot{\gamma}$ is normal and $\dot{\gamma}$ is tangent. $\square$

This characterisation makes many examples immediate.

Example 29.6.11 (Geodesics in the Plane)

For a curve in a plane, $\ddot{\gamma}$ is normal to the plane if and only if $\ddot{\gamma} = 0$, so the geodesics are exactly the constant speed straight lines.

Example 29.6.12 (Geodesics on the Sphere)

Let γ be a unit speed geodesic on S^2 . The normal at p is p itself, so $\ddot{\gamma} = \lambda\gamma$ for some function λ ; taking the inner product with γ and using $\langle \gamma, \gamma \rangle = 1$, $\langle \dot{\gamma}, \gamma \rangle = 0$ and $\langle \ddot{\gamma}, \gamma \rangle = -1$ gives $\lambda = -1$. So $\ddot{\gamma} = -\gamma$, whose solutions are

$$\gamma(t) = \cos t \gamma(0) + \sin t \dot{\gamma}(0),$$

which traverses the great circle cut out by the plane through the origin spanned by $\gamma(0)$ and $\dot{\gamma}(0)$. So the geodesics on the sphere are exactly the constant speed parametrisations of great circles.

Example 29.6.13 (Geodesics on the Cylinder)

Since the cylinder is locally isometric to the plane and geodesics are determined by the first fundamental form, the geodesics of the cylinder are the images of straight lines under the rolling-up map. These are the vertical rulings, the horizontal circles, and the helices. Alternatively, unroll: on the cylinder $I = a^2 du^2 + dv^2$ has constant coefficients, so the geodesic equations read $\ddot{u} = \ddot{v} = 0$, giving u, v affine in t .

§29.6.4 Planes of Symmetry

There is a useful symmetry principle which lets us find geodesics with no computation at all.

Proposition 29.6.14

Let Σ be a smooth surface in $\mathbb{R}^3$ and let Π be a plane such that reflection in Π maps Σ to itself. Then every constant speed parametrisation of a connected component of $\Sigma \cap \Pi$ is a geodesic.

Proof. Let R denote reflection in Π and let γ be a unit speed parametrisation of a component of $\Sigma \cap \Pi$. Since R is an isometry of $\mathbb{R}^3$ fixing Σ setwise and fixing γ pointwise, R maps Σ to Σ and hence maps $T_{\gamma(t)}\Sigma$ to itself, and $R(\ddot{\gamma}) = (R\ddot{\gamma}) = \ddot{\gamma}$, so $\ddot{\gamma}$ lies in Π .

Now decompose $\ddot{\gamma}$ into its tangential and normal parts. The tangential part is orthogonal to $\dot{\gamma}$ (as γ has unit speed), and it lies in Π ; but $T_{\gamma(t)}\Sigma \cap \Pi$ is the line spanned by $\dot{\gamma}(t)$, because Σ and Π meet transversally along γ . So the tangential part is both parallel and orthogonal to $\dot{\gamma}$, hence zero, and γ is a geodesic. $\square$

§29.6.5 Surfaces of Revolution

One common family of surfaces is the surfaces of revolution, obtained by rotating $\eta(u) = (f(u), 0, g(u))$ – where η is smooth and injective and $f(u) > 0$ – about the z -axis. We will assume throughout that η has unit speed, so that

$$I = du^2 + f(u)^2 dv^2.$$

Definition 29.6.15

A circle obtained by rotating a point of η is called a **parallel**. A curve obtained by

rotating η itself by a fixed angle about the z -axis is a **meridian**.

Every plane in $\mathbb{R}^3$ containing the z -axis is a plane of symmetry of Σ , and meets Σ exactly in a pair of meridians. So the previous proposition gives:

Corollary 29.6.16

All meridians of a surface of revolution, parametrised at constant speed, are geodesics.

Not all parallels are geodesics however – think of a circle of latitude on the sphere near the north pole, which is visibly not straight.

Lemma 29.6.17

The parallel $u = u_0$, parametrised at constant speed, is a geodesic if and only if $f'(u_0) = 0$.

Proof. With $E = 1$, $F = 0$, $G = f^2$ the geodesic equations become

$$\ddot{u} = f f' \dot{v}^2, \quad \frac{d}{dt} (f^2 \dot{v}) = 0.$$

Along the parallel $u \equiv u_0$ with constant speed, $\dot{v}$ is a non-zero constant, so the second equation holds automatically and the first reduces to $0 = f(u_0) f'(u_0) \dot{v}^2$. As $f > 0$ and $\dot{v} \neq 0$, this holds precisely when $f'(u_0) = 0$: the parallel must sit at a critical radius. $\square$

Now consider a unit speed curve $\gamma(t)$ on Σ , making an angle θ with the parallel through each of its points, and let $\rho = f(u)$ be the radius of that parallel. There is a striking conservation law.

Theorem 29.6.18 (Clairaut's Relation)

If γ is a unit speed geodesic on a surface of revolution, then $\rho \cos \theta$ is constant along γ .

Proof. Write $\gamma(t) = \sigma(u(t), v(t))$, so $\dot{\gamma} = \sigma_u \dot{u} + \sigma_v \dot{v}$. The tangent to the parallel is σ_v , of length $\sqrt{G} = f = \rho$. Since $F = 0$ and $\|\dot{\gamma}\| = 1$,

$$\cos \theta = \frac{\langle \sigma_v, \dot{\gamma} \rangle}{\|\sigma_v\| \|\dot{\gamma}\|} = \frac{G \dot{v}}{\rho} = \rho \dot{v}.$$

So $\rho \cos \theta = \rho^2 \dot{v} = f^2 \dot{v}$, and the second geodesic equation says precisely that this is constant. $\square$

Example 29.6.19 (Trapped Geodesics)

Let γ be a geodesic on an ellipsoid of revolution which is not a meridian, so that $c = \rho \cos \theta > 0$. Since $|\cos \theta| \leq 1$ we always have $\rho \geq c$, so the geodesic can never enter the polar caps where the parallels are narrower than c : it is trapped in a band between two parallels, oscillating between them forever. In particular, any geodesic passing through a pole must have $c = 0$ and hence be a meridian.

§29.6.6 The Covariant Derivative and Parallel Transport

The characterisation ‘ $\ddot{\gamma}$ is normal’ can be phrased more elegantly. The obstruction to $\dot{\gamma}$ being constant is entirely in the tangential direction, so let us give that tangential part a name.

Definition 29.6.20 (Vector Field Along a Curve)

Let $\gamma : I \rightarrow \Sigma$ be a smooth curve. A **vector field along γ** is a smooth map $W : I \rightarrow \mathbb{R}^3$ with $W(t) \in T_{\gamma(t)}\Sigma$ for every t .

Definition 29.6.21 (Covariant Derivative)

The **covariant derivative** of a vector field W along γ is

$$\frac{DW}{dt} = \pi_{T_{\gamma(t)}\Sigma} \left(\frac{dW}{dt} \right),$$

the orthogonal projection of dW/dt onto the tangent plane. We say W is **parallel** along γ if $DW/dt \equiv 0$.

With this language, γ is a geodesic precisely when $D\dot{\gamma}/dt = 0$: a geodesic is a curve whose velocity field is parallel along it. In the plane a vector field is parallel exactly when it is constant, so this really is the right generalisation of ‘moving in a straight line at constant speed’.

Proposition 29.6.22

If V, W are parallel vector fields along γ then $\langle V(t), W(t) \rangle$ is constant. In particular parallel vector fields have constant length, and the angle between two of them is constant.

Proof. $\frac{d}{dt} \langle V, W \rangle = \langle \dot{V}, W \rangle + \langle V, \dot{W} \rangle$. Now $\dot{V}$ differs from $DV/dt = 0$ by a normal vector, and W is tangent, so $\langle \dot{V}, W \rangle = 0$; similarly for the other term. $\square$

The covariant derivative looks as though it depends on the embedding – we projected onto a tangent plane sitting in $\mathbb{R}^3$. It does not.

Lemma 29.6.23

The covariant derivative depends only on the first fundamental form. Explicitly, if

$\gamma(t) = \sigma(u(t), v(t))$ and $W = a\sigma_u + b\sigma_v$, then

$$\begin{aligned} \frac{DW}{dt} &= (\dot{a} + \Gamma_{11}^1 a\dot{u} + \Gamma_{12}^1 (a\dot{v} + b\dot{u}) + \Gamma_{22}^1 b\dot{v}) \sigma_u \\ &\quad + (\dot{b} + \Gamma_{11}^2 a\dot{u} + \Gamma_{12}^2 (a\dot{v} + b\dot{u}) + \Gamma_{22}^2 b\dot{v}) \sigma_v. \end{aligned}$$

Proof. Differentiating $W = a\sigma_u + b\sigma_v$ along γ gives

$$\frac{dW}{dt} = \dot{a}\sigma_u + \dot{b}\sigma_v + a(\sigma_{uu}\dot{u} + \sigma_{uv}\dot{v}) + b(\sigma_{vu}\dot{u} + \sigma_{vv}\dot{v}).$$

Now expand $\sigma_{uu}, \sigma_{uv}, \sigma_{vv}$ using the Christoffel symbols and discard the n components, which is exactly what the projection does. Collecting terms gives the stated formula, and the Christoffel symbols depend only on E, F, G . $\square$

Since $DW/dt = 0$ is a linear first order ODE system in (a, b) , Picard's theorem gives at once:

Proposition 29.6.24

Let $\gamma : I \rightarrow \Sigma$ be a smooth curve, $t_0 \in I$ and $w_0 \in T_{\gamma(t_0)}\Sigma$. Then there is a unique parallel vector field W along γ with $W(t_0) = w_0$, defined on all of I .

Definition 29.6.25 (Parallel Transport)

With notation as above, the map

$$\mathbf{p} : T_{\gamma(t_0)}\Sigma \rightarrow T_{\gamma(t_1)}\Sigma, \quad w_0 \mapsto W(t_1)$$

is called **parallel transport** along γ from $\gamma(t_0)$ to $\gamma(t_1)$.

Parallel transport is linear, since the defining ODE is linear, and it is a linear isometry by the proposition on inner products above. It is emphatically *path dependent*: transporting a vector around a closed loop on the sphere returns it rotated by an angle, and Gauss–Bonnet will tell us that the angle is the enclosed curvature.

§29.6.7 The Exponential Map

Geodesics give us a canonical way to move away from a point in a given direction, and hence a canonical way to put coordinates near a point.

Given $p \in \Sigma$ and $w \in T_p\Sigma$, let γ_w be the unique geodesic with $\gamma_w(0) = p$ and $\dot{\gamma}_w(0) = w$.

Definition 29.6.26 (Exponential Map)

The **exponential map** at p is

$$\exp_p(w) = \gamma_w(1),$$

defined for those $w \in T_p\Sigma$ for which γ_w exists up to time 1, and with $\exp_p(0) = p$.

Proposition 29.6.27

$\exp_p$ is defined and smooth on a neighbourhood of 0 in $T_p\Sigma$.

Proof. By the local existence theorem there is $\varepsilon > 0$ such that γ_w is defined on $(-2, 2)$ for every w in the closed disc $\{\|w\| \leq \varepsilon\}$: indeed, existence for a fixed time on a compact set of initial conditions follows from the local statement plus a compactness argument, and geodesics rescale, $\gamma_{\lambda w}(t) = \gamma_w(\lambda t)$, so shrinking ε buys more time. Smoothness is the smooth dependence of the solution of an ODE on its initial conditions. $\square$

Proposition 29.6.28

$\exp_p$ is a diffeomorphism from a neighbourhood of $0 \in T_p\Sigma$ onto its image.

Proof. By the inverse function theorem it suffices to show $D\exp_p|_0$ is invertible. Fix $w \in T_p\Sigma$ and consider the curve $\alpha(t) = tw$ in $T_p\Sigma$. Then

$$\exp_p(\alpha(t)) = \exp_p(tw) = \gamma_{tw}(1) = \gamma_w(t),$$

so differentiating at $t = 0$ gives $D\exp_p|_0(w) = \dot{\gamma}_w(0) = w$. So $D\exp_p|_0$ is the identity. $\square$

Definition 29.6.29 (Normal Neighbourhood)

The image of such a restriction of $\exp_p$ is a **normal neighbourhood** of p , and $\exp_p^{-1}$ gives **geodesic normal coordinates** on it.

Remark. The name comes from Lie theory. If $X \subseteq M(n)$ is a matrix group, with the inner product $\langle A, B \rangle = \text{tr}(AB^\top)$, then for $A \in T_I X$ the curve $t \mapsto e^{tA}$ satisfies $\ddot{\alpha} = A^2\alpha$, which one checks is normal to X ; so it is a geodesic, and $\exp_I(A) = e^A$ really is the matrix exponential.

§29.6.8 Geodesic Polar Coordinates

Composing the exponential map with polar coordinates on $T_p\Sigma$ gives an especially convenient parametrisation.

Definition 29.6.30 (Geodesic Polar Coordinates)

Choose an orthonormal basis of $T_p\Sigma$ and let $w(\theta)$ be the unit vector at angle θ . For ε small enough that $\exp_p$ is a diffeomorphism on the disc of radius ε , define

$$\sigma(r, \theta) = \exp_p(r w(\theta)) = \gamma_{w(\theta)}(r), \quad 0 < r < \varepsilon.$$

These are **geodesic polar coordinates** centred at p . The curves $\theta = \text{const}$ are the **radial geodesics** and the curves $r = \text{const}$ are the **geodesic circles** about p .

Note that σ is a genuine allowable parametrisation away from $r = 0$ (the origin, as always with polar coordinates, is a removable defect).

**Proposition 29.6.31 (The Gauss Lemma)**

In geodesic polar coordinates the first fundamental form is

$$I = dr^2 + G(r, \theta) d\theta^2,$$

that is, $E \equiv 1$ and $F \equiv 0$. Moreover

$$G(0, \theta) = 0, \quad (\sqrt{G})_r(0, \theta) = 1, \quad K = -\frac{(\sqrt{G})_{rr}}{\sqrt{G}}.$$

Proof. For fixed θ , $r \mapsto \sigma(r, \theta)$ is the unit speed geodesic $\gamma_{w(\theta)}$, so $E = \langle \sigma_r, \sigma_r \rangle = 1$. For F , note σ_{rr} is the acceleration of a geodesic, hence normal to Σ , so $\langle \sigma_{rr}, \sigma_\theta \rangle = 0$, and

$$F_r = \langle \sigma_{rr}, \sigma_\theta \rangle + \langle \sigma_r, \sigma_{\theta r} \rangle = 0 + \frac{1}{2} \frac{\partial}{\partial \theta} \langle \sigma_r, \sigma_r \rangle = \frac{1}{2} E_\theta = 0.$$

So F is independent of r . Writing $\sigma_\theta = r D \exp_p|_{rw(\theta)}(w'(\theta))$, we see $\sigma_\theta \rightarrow 0$ as $r \rightarrow 0$, hence $F \rightarrow 0$; since F is constant in r this gives $F \equiv 0$. The same expression gives $G = r^2 \|D \exp_p|_{rw}(w')\|^2$, so $G(0, \theta) = 0$ and

$$(\sqrt{G})_r(0, \theta) = \|D \exp_p|_0(w'(\theta))\| = \|w'(\theta)\| = 1.$$

Finally the formula for K is the corollary of the Gauss equation for a metric of the form $dr^2 + G d\theta^2$. $\square$

The geometric content of $F \equiv 0$ is worth stating: *geodesic circles meet radial geodesics at right angles*. This is what makes the next result work.

Proposition 29.6.32 (Geodesics Locally Minimise Length)

Let q lie in a normal neighbourhood of p , and let γ be the radial geodesic from p to q . Then every piecewise smooth curve in Σ from p to q has length at least $L(\gamma)$, with equality only if it is a reparametrisation of γ .

Proof. Say $q = \sigma(r_0, \theta_0)$, so $L(\gamma) = r_0$. Let α be any piecewise smooth curve from p to q . Consider first the case that α stays inside the normal neighbourhood; write

$\alpha(t) = \sigma(r(t), \theta(t))$ (away from p). Then by the Gauss lemma

$$L(\alpha) = \int \sqrt{\dot{r}^2 + G\dot{\theta}^2} dt \geq \int |\dot{r}| dt \geq \left| \int \dot{r} dt \right| = r_0,$$

with equality only if $\dot{\theta} \equiv 0$ and $\dot{r}$ never changes sign, i.e. only if α is a monotone reparametrisation of the radial geodesic.

If α leaves the normal neighbourhood, then it must cross the geodesic circle of radius r_1 for every $r_1 < \varepsilon$, and the same estimate applied to the initial segment shows $L(\alpha) \geq r_1$ for all such r_1 , hence $L(\alpha) \geq \varepsilon > r_0$. $\square$

Remark. ‘Locally’ is essential. On the sphere, the major arc of a great circle is a geodesic but is nowhere near the shortest path; and a geodesic on a cylinder can wind around many times. Geodesics are critical points of energy, and critical points need not be minima.

§29.6.9 Surfaces of Constant Curvature

Geodesic polar coordinates let us classify surfaces of constant curvature, locally.

Theorem 29.6.33 (Minding)

Let Σ be a smooth surface in $\mathbb{R}^3$ with constant Gaussian curvature K . Then Σ is locally isometric to

- (i) the plane with $I = du^2 + dv^2$, if $K = 0$;
- (ii) the sphere of radius $1/\sqrt{K}$, with $I = du^2 + \frac{1}{K} \cos^2(\sqrt{K}u) dv^2$, if $K > 0$;
- (iii) the hyperbolic plane of curvature K , with $I = du^2 + \frac{1}{|K|} \cosh^2(\sqrt{|K|}u) dv^2$, if $K < 0$.

In particular any two surfaces with the same constant curvature are locally isometric.

Proof. Work in geodesic polar coordinates about a point, so $I = dr^2 + G d\theta^2$ and, writing $h = \sqrt{G}$, the Gauss lemma gives

$$h_{rr} + Kh = 0, \quad h(0, \theta) = 0, \quad h_r(0, \theta) = 1.$$

This is a linear ODE in r for each fixed θ with prescribed initial data, so its solution is unique and independent of θ :

$$h(r) = \begin{cases} r & K = 0, \\ \frac{1}{\sqrt{K}} \sin(\sqrt{K}r) & K > 0, \\ \frac{1}{\sqrt{|K|}} \sinh(\sqrt{|K|}r) & K < 0. \end{cases}$$

So the first fundamental form in geodesic polar coordinates is completely determined by K , and any two surfaces of the same constant curvature have parametrisations with the same first fundamental form – hence are locally isometric. Identifying the resulting metrics with the standard models (after the substitution taking polar to the coordinates listed) gives the stated forms. $\square$

Remark. Globally the situation is quite different. There are plenty of flat surfaces which are not isometric to the plane – the cylinder and the flat torus, for example – and Gauss–Bonnet will explain why the sphere is the only compact one with $K \equiv 1$. Meanwhile Hilbert’s theorem says that no complete surface in $\mathbb{R}^3$ has constant negative curvature at all, so case (iii) can only ever be realised locally, on pieces such as the pseudosphere.

§29.7 Minimal Surfaces

Geodesics arose as the critical points of the length functional on curves. The obvious two-dimensional analogue is to look for critical points of the *area* functional on surfaces. The Euler–Lagrange equations are now a partial differential equation rather than an ordinary one, which makes the theory harder – but also much richer, because complex analysis turns out to solve it.

The physical model to keep in mind is a soap film spanning a wire loop: surface tension makes it minimise area subject to the boundary condition.

§29.7.1 The First Variation of Area

Let $\sigma : V \rightarrow \Sigma$ be an allowable parametrisation, let $D \subseteq V$ be a bounded domain with $\overline{D} \subseteq V$, and let $h : \overline{D} \rightarrow \mathbb{R}$ be smooth. We deform the surface in the normal direction, with the amount of deformation controlled by h .

Definition 29.7.1 (Normal Variation)

The **normal variation** of $\sigma(\overline{D})$ determined by h is the map

$$\sigma^t(u, v) = \sigma(u, v) + t h(u, v) n(\sigma(u, v)), \quad t \in (-\varepsilon, \varepsilon).$$

For small t the vectors

$$\sigma_u^t = \sigma_u + t h n_u + t h_u n, \quad \sigma_v^t = \sigma_v + t h n_v + t h_v n$$

remain linearly independent, so σ^t parametrises a genuine surface.

Proposition 29.7.2 (First Variation of Area)

With notation as above,

$$\left. \frac{d}{dt} \right|_{t=0} \text{area}(\sigma^t(D)) = -2 \int_D h H \sqrt{EG - F^2} \, du \, dv,$$

where H is the mean curvature of Σ .

Proof. Compute the first fundamental form of σ^t . Using $\langle n, \sigma_u \rangle = \langle n, \sigma_v \rangle = 0$ and the identities $\langle n_u, \sigma_u \rangle = -L$, $\langle n_u, \sigma_v \rangle = \langle n_v, \sigma_u \rangle = -M$, $\langle n_v, \sigma_v \rangle = -N$, we get

$$E^t = E - 2thL + O(t^2),$$

$$F^t = F - 2thM + O(t^2),$$

$$G^t = G - 2thN + O(t^2),$$

where the $O(t^2)$ terms are smooth in (u, v, t) . Hence

$$\begin{aligned} E^t G^t - (F^t)^2 &= EG - F^2 - 2th(EN - 2FM + GL) + O(t^2) \\ &= (EG - F^2)(1 - 4thH) + O(t^2), \end{aligned}$$

using $H = (LG - 2MF + NE)/2(EG - F^2)$. Taking square roots and differentiating under the integral sign at $t = 0$,

$$\left. \frac{d}{dt} \right|_{t=0} \int_D \sqrt{E^t G^t - (F^t)^2} \, du \, dv = \int_D \frac{-4hH}{2} \sqrt{EG - F^2} \, du \, dv,$$

which is the claim. $\square$

Definition 29.7.3 (Minimal Surface)

A smooth surface in $\mathbb{R}^3$ is **minimal** if its mean curvature vanishes identically.

Corollary 29.7.4

A surface is minimal if and only if it is a critical point of area under all normal variations, i.e. the first variation vanishes for every choice of D and h .

Proof. If $H \equiv 0$ the first variation formula gives zero. Conversely, if $H(q) \neq 0$ for some q , choose by continuity a small domain D around $\sigma^{-1}(q)$ on which H does not vanish and put $h = H$; then

$$\left. \frac{d}{dt} \right|_{t=0} \text{area} = -2 \int_D H^2 \sqrt{EG - F^2} \, du \, dv < 0,$$

so the surface is not critical. $\square$

Remark. As with geodesics, ‘minimal’ means *critical*, not minimising. A minimal surface need not minimise area even among nearby competitors, though small enough pieces of one always do.

The condition $H = 0$ says $\kappa_1 = -\kappa_2$, so at every point of a minimal surface the two principal curvatures are equal and opposite: minimal surfaces curve up as much as they curve down. In particular $K = \kappa_1 \kappa_2 = -\kappa_1^2 \leq 0$ everywhere, so every point of a minimal surface is hyperbolic or planar. Combined with the fact that every compact surface has an elliptic point, we get:

Corollary 29.7.5

There are no compact minimal surfaces in $\mathbb{R}^3$.

§29.7.2 Examples

Example 29.7.6 (The Plane)

A plane has $S_p = 0$ and so $H \equiv 0$. It is the trivial minimal surface, and the question that started the subject (asked by Lagrange in 1762) was whether there is any other.

Example 29.7.7 (The Catenoid)

Meusnier answered Lagrange in 1776. Consider the surface of revolution generated by the catenary $x = a \cosh(z/a)$, that is,

$$\sigma(u, v) = (a \cosh v \cos u, a \cosh v \sin u, av).$$

One computes $E = G = a^2 \cosh^2 v$ and $F = 0$, so this parametrisation is isothermal, and

$$L = -a, \quad M = 0, \quad N = a,$$

giving $H = (LG + NE)/2EG = 0$. So the catenoid is minimal. It is in fact the only minimal surface of revolution other than the plane – a fact one can prove by solving $H = 0$ for a profile curve, which reduces to $ff'' = 1 + (f')^2$ and hence to the catenary.

Example 29.7.8 (The Helicoid)

The helicoid is the ruled surface

$$\sigma(u, v) = (a \sinh v \cos u, a \sinh v \sin u, au),$$

swept out by a horizontal line rotating at constant speed as it rises. Again $E = G = a^2 \cosh^2 v$ and $F = 0$, so it too is isothermal with the same first fundamental form as the catenoid – and hence the two are locally isometric. It is minimal for the same reason. Physically, one can bend a catenoid soap film continuously into a helicoid without stretching it anywhere; the pictures of this deformation are worth looking up.

catenoid

helicoid

Example 29.7.9 (Ruled Surfaces)

A **ruled surface** $\sigma(u, v) = \eta(u) + vw(u)$ is a union of straight lines. Every straight line on a surface is a geodesic and has vanishing normal curvature, so at every point of a ruled surface some normal curvature is zero, hence $\kappa_1 \kappa_2 \leq 0$ and $K \leq 0$. The plane and the helicoid are the only ruled minimal surfaces in $\mathbb{R}^3$, a theorem of Catalan.

§29.7.3 Isothermal Coordinates and Harmonicity

The reason complex analysis enters is the following identity.

Proposition 29.7.10

Let σ be an isothermal parametrisation, so $E = G = \lambda^2$ and $F = 0$. Then

$$\nabla^2 \sigma := \sigma_{uu} + \sigma_{vv} = 2\lambda^2 H n.$$

Proof. Differentiating $\langle \sigma_u, \sigma_u \rangle = \langle \sigma_v, \sigma_v \rangle$ with respect to u gives $\langle \sigma_{uu}, \sigma_u \rangle = \langle \sigma_{uv}, \sigma_v \rangle$, and differentiating $\langle \sigma_u, \sigma_v \rangle = 0$ with respect to v gives $\langle \sigma_{uv}, \sigma_v \rangle = -\langle \sigma_u, \sigma_{vv} \rangle$. Adding,

$$\langle \sigma_{uu} + \sigma_{vv}, \sigma_u \rangle = 0,$$

and symmetrically $\langle \sigma_{uu} + \sigma_{vv}, \sigma_v \rangle = 0$. So $\nabla^2 \sigma$ is normal. Its normal component is $L + N$, and in the isothermal case

$$H = \frac{LG + NE}{2EG} = \frac{L + N}{2\lambda^2},$$

so $L + N = 2\lambda^2 H$ as claimed. $\square$

Corollary 29.7.11

An isothermally parametrised surface is minimal if and only if the three coordinate functions of σ are harmonic.

Since every minimal surface admits isothermal coordinates – for minimal surfaces this is much easier than the general theorem – minimal surfaces are locally exactly the harmonic isothermal immersions. Because a non-constant harmonic function on a connected open set has no interior maximum, this gives another proof that no minimal surface is compact.

§29.7.4 The Weierstrass Representation

We can now write down *all* minimal surfaces, locally, in terms of holomorphic data.

Proposition 29.7.12

Let $\sigma(u, v) = (x, y, z)$ be a parametrisation of a surface in $\mathbb{R}^3$ and set

$$\theta_1 = x_u - ix_v, \quad \theta_2 = y_u - iy_v, \quad \theta_3 = z_u - iz_v.$$

Then

- (i) σ is isothermal if and only if $\theta_1^2 + \theta_2^2 + \theta_3^2 = 0$;
- (ii) if σ is isothermal, then the surface is minimal if and only if $\theta_1, \theta_2, \theta_3$ are holomorphic in $\xi = u + iv$.

Proof. For (i), expand:

$$\sum_j \theta_j^2 = \sum_j (x_u^{(j)})^2 - \sum_j (x_v^{(j)})^2 - 2i \sum_j x_u^{(j)} x_v^{(j)} = E - G - 2iF,$$

which vanishes exactly when $E = G$ and $F = 0$.

For (ii), the Cauchy–Riemann equations for $\theta_1 = x_u - ix_v$ are $x_{uu} = -x_{vv}$ and $x_{uv} = x_{vu}$. The second always holds and the first says x is harmonic, so θ_1 is

holomorphic if and only if x is harmonic; likewise for θ_2, θ_3 . Now apply the previous corollary. $\square$

So the problem becomes: describe all triples of holomorphic functions with $\theta_1^2 + \theta_2^2 + \theta_3^2 = 0$. This is a conic, and conics can be rationally parametrised.

Lemma 29.7.13

Let $D \subseteq \mathbb{C}$ be a domain, g meromorphic on D and f holomorphic on D , such that f has a zero of order at least $2k$ wherever g has a pole of order k . Then

$$\theta_1 = \frac{1}{2}f(1 - g^2), \quad \theta_2 = \frac{i}{2}f(1 + g^2), \quad \theta_3 = fg$$

are holomorphic on D and satisfy $\theta_1^2 + \theta_2^2 + \theta_3^2 = 0$. Conversely, every triple of holomorphic functions satisfying this equation arises in this way, apart from the degenerate case $\theta_1 = i\theta_2, \theta_3 = 0$.

Proof. For the first part, the pole conditions make each θ_j holomorphic, and

$$\theta_1^2 + \theta_2^2 = \frac{f^2}{4} [(1 - g^2)^2 - (1 + g^2)^2] = -f^2 g^2 = -\theta_3^2.$$

Conversely, given holomorphic θ_j with $\sum \theta_j^2 = 0$, suppose $\theta_1 \neq i\theta_2$ and set

$$f = \theta_1 - i\theta_2, \quad g = \frac{\theta_3}{f}.$$

Then $fg = \theta_3$, and from $\theta_1^2 + \theta_2^2 = -\theta_3^2$ we get $(\theta_1 - i\theta_2)(\theta_1 + i\theta_2) = -\theta_3^2$, so $\theta_1 + i\theta_2 = -fg^2$; solving the two linear equations for θ_1, θ_2 gives the stated formulae. Holomorphy of $\theta_1 + i\theta_2 = -fg^2$ is exactly the condition on the orders of zeros and poles. $\square$

Proposition 29.7.14

Let $D \subseteq \mathbb{C}$ be simply connected, fix $\xi_0 \in D$, and let $\theta_1, \theta_2, \theta_3$ be holomorphic on D with $\sum \theta_j^2 = 0$. Define

$$x(u, v) = \operatorname{Re} \int_{\xi_0}^{u+iv} \theta_1 \, d\xi, \quad y(u, v) = \operatorname{Re} \int_{\xi_0}^{u+iv} \theta_2 \, d\xi, \quad z(u, v) = \operatorname{Re} \int_{\xi_0}^{u+iv} \theta_3 \, d\xi.$$

Then $x_u - ix_v = \theta_1$, and similarly for y, z . Consequently, wherever $\sigma = (x, y, z)$ is an immersion, its image is a minimal surface.

Proof. Simple connectedness makes the integrals well defined and holomorphic. Write $\chi(\omega) = \int_{\xi_0}^{\omega} \theta_1 \, d\xi = x + i\beta$; the Cauchy–Riemann equations for χ give $\beta_u = -x_v$, so

$$\theta_1(\omega) = \chi'(\omega) = x_u + i\beta_u = x_u - ix_v,$$

as claimed. The previous two results then say that σ is isothermal with harmonic components, hence minimal. $\square$

Definition 29.7.15 (Weierstrass Data)

The pair (f, g) above is the **Weierstrass representation** of the resulting minimal surface.

By the existence of isothermal coordinates, *every* minimal surface has a local Weierstrass representation. Checking that a given (f, g) yields an embedding can be delicate; checking that it yields an immersion is easy, and amounts to asking that the zeros of f occur exactly at the poles of g and with exactly twice the order.

Example 29.7.16 (Enneper's Surface)

Take $D = \mathbb{C}$, $f(\xi) = 1$ and $g(\xi) = \xi$, so $\theta_1 = \frac{1}{2}(1 - \xi^2)$, $\theta_2 = \frac{i}{2}(1 + \xi^2)$, $\theta_3 = \xi$. Integrating from 0 and taking real parts gives

$$\sigma(u, v) = \frac{1}{2} \left(u - \frac{u^3}{3} + uv^2, -v - \frac{v^3}{3} - u^2v, u^2 - v^2 \right),$$

which is an immersion everywhere and an embedding near the origin. Its Gaussian curvature works out to $K = -16/(1 + u^2 + v^2)^4$.

Example 29.7.17 (Scherk's Surface)

Take $D = \{|\xi| < 1\}$, $f(\xi) = 4/(1 - \xi^4)$ and $g(\xi) = \xi$. The resulting surface satisfies the beautiful equation

$$\cos y = e^z \cos x,$$

is defined over the open square $(-\pi/2, \pi/2)^2$, and repeats periodically in a checker-board pattern. It was the first new minimal surface found after the catenoid and helicoid, in 1835.

§29.7.5 Interpreting the Weierstrass Data

The function g has a lovely geometric meaning: it is the Gauss map, read through stereographic projection.

Proposition 29.7.18

Let σ be a minimal immersion with Weierstrass data (f, g) , and let $\pi : S^2 \rightarrow \mathbb{C} \cup \{\infty\}$ be stereographic projection from the north pole. Then

$$g = \pi \circ n \circ \sigma,$$

and the conformal factor is $\lambda = \frac{1}{2}|f|(1 + |g|^2)$.

Proof. Since $\sigma_u - i\sigma_v = (\theta_1, \theta_2, \theta_3)$ and σ is isothermal,

$$\lambda^2 = E = \frac{1}{2} \langle \sigma_u - i\sigma_v, \sigma_u + i\sigma_v \rangle = \frac{1}{2} (|\theta_1|^2 + |\theta_2|^2 + |\theta_3|^2) = \left(\frac{|f|(1+|g|^2)}{2} \right)^2$$

after substituting the formulae for θ_j . A direct computation of the cross product

gives

$$\sigma_u \times \sigma_v = \frac{|f|^2(1 + |g|^2)}{4} (2 \operatorname{Re} g, 2 \operatorname{Im} g, |g|^2 - 1),$$

and normalising, the Gauss map is

$$n \circ \sigma = \frac{1}{1 + |g|^2} (2 \operatorname{Re} g, 2 \operatorname{Im} g, |g|^2 - 1),$$

which is exactly $\pi^{-1}(g)$. □

Corollary 29.7.19

If $K \not\equiv 0$ on a connected minimal surface, then the zeros of K are isolated.

Proof. On the example sheet one computes $K = - (4|g'| / (|f|(1 + |g|^2)^2))^2$, so K vanishes exactly where g' does. Since g is meromorphic and non-constant, g' has isolated zeros by the principle of isolated zeros. □

Theorem 29.7.20

Let σ be a minimal immersion defined on all of $\mathbb{C}$. Then either its image lies in a plane, or its Gauss map omits at most two points of S^2 .

Proof. If the degenerate case $\theta_1 = i\theta_2, \theta_3 = 0$ occurs then z is constant and the surface lies in a plane; so assume the Weierstrass data (f, g) exists. If g is constant then n is constant and again the image is planar. Otherwise $g : \mathbb{C} \rightarrow \mathbb{C} \cup \{\infty\}$ is a non-constant meromorphic function, so by Picard's theorem it omits at most two values of $\mathbb{C} \cup \{\infty\}$. Since $g = \pi \circ n \circ \sigma$ and π is a bijection, the Gauss map omits at most two points of S^2 . □

Example 29.7.21

Enneper's surface has $g(\xi) = \xi$, which omits only ∞ ; its Gauss map misses exactly one point. The catenoid has $g(\xi) = \xi$ on $\mathbb{C} \setminus \{0\}$, whose Gauss map misses two points, the north and south poles. So the bound is achieved.

Remark. For complete non-planar minimal surfaces, Fujimoto proved in 1988 that the Gauss map can omit at most four points, sharpening earlier work of Xavier; and four is attained. This is a striking instance of the general principle that minimal surfaces inherit the rigidity of holomorphic functions.

§29.8 The Gauss–Bonnet Theorem

We come to the theorem the whole course has been building towards. Gauss–Bonnet relates an analytic quantity – the integral of the curvature – to a purely topological one, the Euler characteristic. Curvature is a delicate local invariant which changes if you dent the surface with a finger; the Euler characteristic is a crude count of holes which does not. The theorem says that if you push curvature down in one place, it has to pop

up somewhere else.

We begin with the local statement, for which we need to measure how much a curve on a surface turns.

§29.8.1 Geodesic Curvature

Let Σ be an oriented surface and γ a unit speed curve on it. We have already seen that $\ddot{\gamma}$ splits into a normal part – the normal curvature $\kappa_n = \langle \ddot{\gamma}, n \rangle$ – and a tangential part, and that γ is a geodesic exactly when the tangential part vanishes. Since $\ddot{\gamma} \perp \dot{\gamma}$, the tangential part is a multiple of $n \times \dot{\gamma}$.

Definition 29.8.1 (Geodesic Curvature)

The **geodesic curvature** of a unit speed curve γ on an oriented surface Σ is

$$\kappa_g = \langle \ddot{\gamma}, n \times \dot{\gamma} \rangle.$$

So $\ddot{\gamma} = \kappa_g (n \times \dot{\gamma}) + \kappa_n n$, and therefore

$$\kappa^2 = \|\ddot{\gamma}\|^2 = \kappa_g^2 + \kappa_n^2 :$$

the curvature of a curve on a surface splits into the part forced on it by the surface bending, and the part due to the curve turning within the surface. Immediately from the definitions:

Proposition 29.8.2

A unit speed curve on Σ is a geodesic if and only if $\kappa_g \equiv 0$.

Example 29.8.3

For a curve in a plane, n is constant and κ_g is the signed curvature κ_s of Section 2. On the sphere, a circle of latitude at angle u from the equator has $\kappa_g = \tan u$: zero at the equator (a great circle) and blowing up at the poles.

The sign of κ_g depends on the orientation. More generally, given a unit vector field W along γ , the derivative $\dot{W}$ is orthogonal to W , so its tangential part is a multiple of $n \times W$; we write

$$\left[\frac{DW}{dt} \right] = \langle \dot{W}, n \times W \rangle,$$

the **algebraic value** of the covariant derivative, so that $DW/dt = [DW/dt](n \times W)$. Then $\kappa_g = [D\dot{\gamma}/dt]$. The following lemma is the technical heart of the local Gauss–Bonnet theorem: it says that the algebraic value measures the rate of turning relative to a reference field.

Lemma 29.8.4

Let V, W be smooth unit vector fields along a curve $\gamma : I \rightarrow \Sigma$, and let ψ be a smooth determination of the angle from V to W , that is, a smooth function with

$$W = \cos \psi V + \sin \psi (n \times V).$$

(Such a ψ exists and is unique up to adding a constant in $2\pi\mathbb{Z}$.) Then

$$\left[\frac{DW}{dt} \right] - \left[\frac{DV}{dt} \right] = \dot{\psi}.$$

Proof. Write $W = aV + b(n \times V)$ with $a^2 + b^2 = 1$; existence of a smooth ψ follows by setting $\psi(t) = \psi_0 + \int_{t_0}^t (a\dot{b} - b\dot{a})$ and checking as in the plane curve case. Abbreviate $iV = n \times V$, so that $n \times W = -\sin \psi V + \cos \psi (iV)$. Then

$$\dot{W} = -\dot{\psi} \sin \psi V + \dot{\psi} \cos \psi (iV) + \cos \psi \dot{V} + \sin \psi \frac{d(iV)}{dt},$$

and taking the inner product with $n \times W$, the first two terms contribute $\dot{\psi}(\sin^2 \psi + \cos^2 \psi) = \dot{\psi}$ while the last two contribute

$$\cos^2 \psi \langle \dot{V}, iV \rangle - \sin^2 \psi \langle V, \frac{d}{dt}(iV) \rangle = (\cos^2 \psi + \sin^2 \psi) \left[\frac{DV}{dt} \right],$$

using $\langle V, iV \rangle = 0$. Adding gives the result. $\square$

Proposition 29.8.5

Let σ be an orthogonal parametrisation compatible with the orientation, and let $\gamma(t) = \sigma(u(t), v(t))$ be a unit speed curve in its image. Then

$$\kappa_g = \frac{G_u \dot{v} - E_v \dot{u}}{2\sqrt{EG}} + \dot{\psi},$$

where ψ is a smooth determination of the angle from σ_u to $\dot{\gamma}$.

Proof. Put $e_1 = \sigma_u / \sqrt{E}$ and $e_2 = \sigma_v / \sqrt{G}$, a positively oriented orthonormal frame. By the lemma it is enough to compute $[De_1 / dt] = \langle \dot{e}_1, e_2 \rangle$. Now

$$\langle (e_1)_u, e_2 \rangle = \frac{1}{\sqrt{EG}} \langle \sigma_{uu}, \sigma_v \rangle = \frac{1}{\sqrt{EG}} (F_u - \frac{1}{2}E_v) = -\frac{E_v}{2\sqrt{EG}},$$

using $F \equiv 0$, and similarly

$$\langle (e_1)_v, e_2 \rangle = \frac{1}{\sqrt{EG}} \langle \sigma_{uv}, \sigma_v \rangle = \frac{G_u}{2\sqrt{EG}}.$$

Hence $[De_1 / dt] = \dot{u} \langle (e_1)_u, e_2 \rangle + \dot{v} \langle (e_1)_v, e_2 \rangle$ is the first term, and the lemma supplies the $\dot{\psi}$. $\square$

That first term is exactly the sort of thing Green's theorem eats, and the orthogonal Gauss formula is exactly what comes out. That is the whole proof of the local theorem.

§29.8.2 The Local Gauss–Bonnet Theorem

Definition 29.8.6 (Simple Region)

Let Σ be an oriented surface. A region $\bar{R} \subseteq \Sigma$ is **simple** if it is homeomorphic to

a closed disc and its boundary is the image of a simple closed curve $\alpha : [0, L] \rightarrow \Sigma$, parametrised by arc length, which is smooth except at finitely many points called **vertices**. The **exterior angle** θ_i at a vertex is the angle from the incoming tangent to the outgoing tangent, taken in $(-\pi, \pi)$. We say α is **positively oriented** if $n \times \dot{\alpha}$ points into R .

We will use, without proof, the following fact, which is the surface version of Hopf's Umlaufsatz: if $\bar{R}$ is a simple region contained in the image of a parametrisation whose domain is a disc, and ψ is a piecewise smooth determination of the angle from σ_u to $\dot{\alpha}$ which jumps by θ_i at the i th vertex, then the total change is

$$\psi(L) - \psi(0) = 2\pi.$$

Theorem 29.8.7 (Local Gauss–Bonnet)

Let $\bar{R}$ be a simple region contained in the image of an orthogonal parametrisation compatible with the orientation, whose domain is a disc, and let $\alpha : [0, L] \rightarrow \Sigma$ be a positively oriented arc length parametrisation of ∂R with exterior angles $\theta_1, \dots, \theta_k$. Then

$$\int_0^L \kappa_g \, ds + \int_R K \, dA = 2\pi - \sum_{i=1}^k \theta_i.$$

Proof. Away from the vertices we have, by the proposition above,

$$\kappa_g = \frac{G_u \dot{v} - E_v \dot{u}}{2\sqrt{EG}} + \frac{d\psi}{ds}.$$

Integrating over the smooth arcs and summing, the last term contributes $\psi(L) - \psi(0)$ together with the jumps, that is, $2\pi - \sum_i \theta_i$ by the fact quoted above. For the first term, Green's theorem in the (u, v) -plane gives

$$\int_0^L \frac{G_u \dot{v} - E_v \dot{u}}{2\sqrt{EG}} \, ds = \int_{\sigma^{-1}(R)} \left[\left(\frac{G_u}{2\sqrt{EG}} \right)_u + \left(\frac{E_v}{2\sqrt{EG}} \right)_v \right] \, du \, dv,$$

and by the orthogonal Gauss formula the integrand is $-K\sqrt{EG}$. Since $F = 0$ we have $\sqrt{EG} = \sqrt{EG - F^2}$, so this is $-\int_R K \, dA$. Rearranging gives the theorem. $\square$

Corollary 29.8.8 (Geodesic Triangles)

Let T be a geodesic triangle – a simple region whose three boundary arcs are

geodesics – with interior angles $\alpha_1, \alpha_2, \alpha_3$. Then

$$\int_T K \, dA = \alpha_1 + \alpha_2 + \alpha_3 - \pi.$$

Proof. The geodesic curvature vanishes on the boundary, and the exterior angles are $\theta_i = \pi - \alpha_i$. Substituting, $\int_T K \, dA = 2\pi - \sum(\pi - \alpha_i) = \sum \alpha_i - \pi$. $\square$

So the angle sum of a geodesic triangle exceeds π by exactly the total curvature it encloses. On the unit sphere this recovers the classical formula: the area of a spherical triangle is its angle excess. In the plane we recover Euclid.

§29.8.3 Triangulations and the Euler Characteristic

To globalise, we chop the surface into small pieces and add up.

Definition 29.8.9 (Triangulation)

A **triangulation** of a compact surface Σ (possibly with boundary) is a finite collection of topological triangles $T_1, \dots, T_F$ covering Σ , such that any two distinct triangles are either disjoint, meet in exactly one common vertex, or meet in exactly one common edge.

Definition 29.8.10 (Euler Characteristic)

The **Euler characteristic** of a triangulation is $\chi = V - E + F$, where V, E, F count vertices, edges and faces.

We will use the following facts from topology, which we do not prove.

Fact 29.8.11

Every compact smooth surface admits a triangulation whose edges are smooth curves, and every triangulation can be refined to a smooth one.

Fact 29.8.12 (Classification of Compact Surfaces)

Every compact connected orientable surface without boundary is diffeomorphic to a sphere with $g \geq 0$ handles attached, and this surface has Euler characteristic $2 - 2g$. In particular the Euler characteristic determines the surface up to diffeomorphism.

For the proof we will need triangulations by small triangles. Note first that subdividing a triangle into four by joining the midpoints of its edges adds 3 vertices, 6 edges and 3 faces, so it leaves χ unchanged. Repeating this finitely often makes all triangles as small as we like.

Proposition 29.8.13

Every point of a smooth surface has a neighbourhood admitting an orthogonal parametrisation.

Proof. Fix p and a unit speed geodesic γ through p with $\gamma(0) = p$. For each v , let γ^v be the unit speed geodesic with $\gamma^v(0) = \gamma(v)$ whose initial velocity is orthogonal to $\dot{\gamma}(v)$ and positively oriented. Define

$$\sigma(u, v) = \gamma^v(u).$$

By smooth dependence of solutions of the geodesic equations on initial conditions this is smooth near $(0, 0)$, and $\sigma_u(0, 0), \sigma_v(0, 0)$ are orthonormal, so by the inverse function theorem σ is a parametrisation near p . Finally $E = \|\sigma_u\|^2 = 1$ since the u -curves are unit speed geodesics, and

$$F_u = \langle \sigma_{uu}, \sigma_v \rangle + \langle \sigma_u, \sigma_{uv} \rangle = 0 + \frac{1}{2}E_v = 0,$$

so F is independent of u ; and $F(0, v) = 0$ by construction. Hence $F \equiv 0$. These are called **geodesic normal** (or Fermi) coordinates. $\square$

§29.8.4 The Global Gauss–Bonnet Theorem

Theorem 29.8.14 (Global Gauss–Bonnet)

Let Σ be a compact orientable smooth surface without boundary. Then for any triangulation of Σ with Euler characteristic χ ,

$$\int_{\Sigma} K \, dA = 2\pi\chi.$$

Proof. Cover Σ by finitely many open sets carrying orthogonal parametrisations, using the previous proposition and compactness, and let ε be a Lebesgue number for this cover. Take any smooth triangulation and subdivide repeatedly until every triangle has diameter less than ε ; as noted, this does not change χ . Now every triangle T_i lies inside a single orthogonal patch, so local Gauss–Bonnet applies to it:

$$\int_{T_i} K \, dA + \int_{\partial T_i} \kappa_g \, ds = \alpha_{i,1} + \alpha_{i,2} + \alpha_{i,3} - \pi,$$

with ∂T_i positively oriented. Sum over i . On the left, the curvature integrals add up to $\int_{\Sigma} K \, dA$. The geodesic curvature integrals cancel in pairs: every edge is shared by exactly two triangles and, because Σ is orientable, we may orient all the triangles compatibly, so each edge is traversed once in each direction and κ_g changes sign.

On the right, the angles at each vertex sum to 2π , so $\sum_{i,j} \alpha_{i,j} = 2\pi V$, and we subtract π once per face. Hence

$$\int_{\Sigma} K \, dA = 2\pi V - \pi F.$$

Finally, each face has three edges and each edge lies in two faces, so $3F = 2E$, giving $\pi F = 3\pi F - 2\pi F = 2\pi E - 2\pi F$ and therefore

$$\int_{\Sigma} K \, dA = 2\pi V - 2\pi E + 2\pi F = 2\pi\chi. \quad \square$$

Corollary 29.8.15

The Euler characteristic of a compact orientable smooth surface does not depend on the choice of triangulation.

Proof. The left hand side of Gauss–Bonnet does not mention the triangulation. $\square$

This is a genuinely startling deduction: a fact of pure combinatorial topology, proved by integrating curvature.

Theorem 29.8.16 (Gauss–Bonnet with Boundary)

Let R be a region with compact closure in an oriented surface Σ , whose boundary consists of n piecewise smooth simple closed curves $\alpha_1, \dots, \alpha_n$, positively oriented and parametrised by arc length, with exterior angles θ_j at the vertices. Then

$$\int_R K \, dA + \sum_{i=1}^n \int_{\alpha_i} \kappa_g \, ds = 2\pi\chi(R) - \sum_j \theta_j.$$

Proof. Identical to the previous proof, except that the geodesic curvature integrals along the boundary edges have no partner to cancel with, and the exterior angles at boundary vertices survive. $\square$

§29.8.5 Applications**Example 29.8.17 (Total Curvature of Standard Surfaces)**

The sphere has $\chi = 2$, so $\int_{S^2} K \, dA = 4\pi$ – which we can check directly, since $K \equiv 1$ and the area is 4π . The torus has $\chi = 0$, so $\int K \, dA = 0$: the positive curvature on the outside exactly cancels the negative curvature on the inside, however you deform it. A surface of genus $g \geq 2$ has $\chi = 2 - 2g < 0$, so it must have negative curvature somewhere.

Corollary 29.8.18

A compact orientable surface with $K > 0$ everywhere is diffeomorphic to S^2 .

Proof. By Gauss–Bonnet, $2\pi\chi = \int_{\Sigma} K \, dA > 0$, so $\chi > 0$. But $\chi = 2 - 2g$ for some $g \geq 0$, so $\chi = 2$ and $g = 0$. By the classification of compact surfaces, Σ is diffeomorphic to S^2 . $\square$

Corollary 29.8.19

A compact orientable surface with $K \leq 0$ everywhere has genus at least 1; and if $K < 0$ everywhere it has genus at least 2.

Proof. $2\pi(2 - 2g) = \int K \, dA \leq 0$ forces $g \geq 1$, and the strict inequality forces $2 - 2g < 0$, i.e. $g \geq 2$. $\square$

Proposition 29.8.20

On a compact orientable surface with $K > 0$ everywhere, any two simple closed geodesics must intersect.

Proof. Suppose γ_1, γ_2 are disjoint simple closed geodesics. By the previous corollary Σ is a sphere, and two disjoint simple closed curves on a sphere bound a region R homeomorphic to an annulus, which has $\chi(R) = 0$. Applying Gauss–Bonnet with boundary to R , and noting that $\kappa_g = 0$ along both boundary curves and there are no vertices,

$$\int_R K \, dA = 2\pi \cdot 0 = 0,$$

contradicting $K > 0$. □

Example 29.8.21 (The Catenoid)

The catenoid is homeomorphic to a cylinder and has $K < 0$ everywhere. A similar Gauss–Bonnet argument shows that such a surface carries at most one simple closed geodesic; and indeed the catenoid has exactly one, the circle at its waist.

Remark (Parallel Transport and Holonomy). Local Gauss–Bonnet also computes the angle by which parallel transport around a closed curve rotates a tangent vector. If γ bounds a simple region R and V is parallel along γ , then the lemma above with $W = \dot{\gamma}$ shows that the total turning of V relative to $\dot{\gamma}$ is $\int \kappa_g$, and the computation in the proof shows that transporting once around γ rotates a vector by exactly $\int_R K \, dA$. Carry a vector around a spherical triangle and it comes back rotated by the area of the triangle – this is what a Foucault pendulum is measuring.

§29.9 Total Curvature of Space Curves

We finish with two beautiful applications of the global theory to curves in $\mathbb{R}^3$. Both work by fattening the curve into a surface – a tube – and then applying what we know about the Gauss map.

Definition 29.9.1 (Total Curvature)

The **total curvature** of a closed unit speed curve $\alpha : [0, L] \rightarrow \mathbb{R}^3$ is $\int_0^L \kappa(s) \, ds$.

For a plane curve, the total curvature is $\int |\kappa_s| \geq |\int \kappa_s| = 2\pi$ if the curve is simple, by Hopf’s Umlaufsatz, with equality if and only if κ_s never changes sign, that is, if and only if the curve is convex. Fenchel’s theorem says the same bound holds in space, and that only plane curves achieve it.

§29.9.1 Tubes

Definition 29.9.2 (Tube)

Let $\alpha : [0, L] \rightarrow \mathbb{R}^3$ be a closed unit speed curve with $\kappa > 0$ everywhere, with Frenet frame (T, N, B) . For $r > 0$, the **tube** of radius r about α is the surface parametrised

by

$$\sigma(s, v) = \alpha(s) + r(N(s) \cos v + B(s) \sin v).$$

For r small enough the tube is an embedded surface. Its geometry is entirely explicit.

Lemma 29.9.3

For r small enough that $r\kappa < 1$ everywhere, the tube T_r is a smooth compact surface with

$$EG - F^2 = r^2(1 - r\kappa \cos v)^2, \quad n = -(N \cos v + B \sin v),$$

and Gaussian curvature

$$K = -\frac{\kappa \cos v}{r(1 - r\kappa \cos v)}.$$

Proof. Differentiating and using Frenet–Serret,

$$\sigma_s = (1 - r\kappa \cos v)T + r\tau(-N \sin v + B \cos v), \quad \sigma_v = r(-N \sin v + B \cos v).$$

These are linearly independent when $r\kappa < 1$, and a short computation gives $E = (1 - r\kappa \cos v)^2 + r^2\tau^2$, $F = r^2\tau$, $G = r^2$, whence $EG - F^2 = r^2(1 - r\kappa \cos v)^2$. Also $\sigma_s \times \sigma_v = -r(1 - r\kappa \cos v)(N \cos v + B \sin v)$, giving the stated unit normal. Differentiating n and using Frenet–Serret again gives

$$n_s \times n_v = \kappa \cos v (N \cos v + B \sin v) = -\frac{\kappa \cos v}{r(1 - r\kappa \cos v)} \sigma_s \times \sigma_v,$$

and since $n_s \times n_v = K \sigma_s \times \sigma_v$, the formula for K follows. $\square$

Note that $K \geq 0$ exactly when $\cos v \leq 0$, that is, on the ‘outer’ half of the tube – exactly as for the torus, which is the special case α a circle. We will also use, without proof, the following consequence of the stack of records theorem and Sard’s theorem: for a compact oriented surface Σ in $\mathbb{R}^3$,

$$\int_{\Sigma} |K| \, dA = \int_{S^2} |n^{-1}(y)| \, dy,$$

which is to say that $\int |K|$ counts, with multiplicity, how often the Gauss map covers the sphere.

§29.9.2 Fenchel’s Theorem

Theorem 29.9.4 (Fenchel)

Let α be a simple closed regular curve in $\mathbb{R}^3$ with nowhere vanishing curvature. Then its total curvature is at least 2π , with equality if and only if α is a convex plane curve.

Proof. Form the tube T_r for small r and let $R = \{p \in T_r : K(p) \geq 0\}$, which by the

lemma is the set where $\cos v \leq 0$, i.e. $v \in [\pi/2, 3\pi/2]$. Then

$$\begin{aligned} \int_R K \, dA &= \int_0^L \int_{\pi/2}^{3\pi/2} \frac{-\kappa \cos v}{r(1 - r\kappa \cos v)} \cdot r(1 - r\kappa \cos v) \, dv \, ds \\ &= - \int_0^L \kappa \, ds \int_{\pi/2}^{3\pi/2} \cos v \, dv, \end{aligned}$$

and since $\int_{\pi/2}^{3\pi/2} \cos v \, dv = -2$, this is $2 \int_0^L \kappa \, ds$.

Now the Gauss map restricted to R is surjective onto S^2 : given any unit vector y , the height function $s \mapsto \langle \alpha(s), y \rangle$ attains a maximum, and at that point the corresponding point of the tube in the direction y has outward normal y and non-negative curvature. Hence

$$2 \int_0^L \kappa \, ds = \int_R K \, dA = \int_{S^2} |(n|_R)^{-1}(y)| \, dy \geq \text{area}(S^2) = 4\pi,$$

giving $\int \kappa \geq 2\pi$.

Suppose equality holds. Then n is injective on the set where $K > 0$, so distinct points of that set have distinct normals. It follows that at every such point p the whole tube lies on one side of the tangent plane at p – otherwise, using that n is a local diffeomorphism near p and that the zero set of K is nowhere dense, one produces two distinct points with positive curvature and the same normal. Taking limits, the same holds at the points where $K = 0$, which are exactly the points of the tube in the directions $\pm B$.

Fix s_0 and look at the circle $s = s_0$ of the tube. The two points on it in the directions $\pm B(s_0)$ have parallel tangent planes, and the tube is squeezed between them; hence α lies in the plane Π midway between. (If not, take s_1 maximising the distance from Π ; then $T(s_1)$ is parallel to Π , and the circle $s = s_1$ then pokes out of the slab, a contradiction.) So α is a plane curve, and by the plane case discussed above, equality forces it to be convex. $\square$

§29.9.3 The Fáry–Milnor Theorem

If a closed curve is knotted, it has to bend more. This was conjectured by Borsuk and proved independently by Fáry (1949) and Milnor (1950); Milnor was an undergraduate at the time.

Definition 29.9.5 (Unknotted)

A regular simple closed curve in $\mathbb{R}^3$ is **unknotted** if its image is the boundary of an embedded disc, and **knotted** otherwise.

Theorem 29.9.6 (Fáry–Milnor)

A knotted regular simple closed curve in $\mathbb{R}^3$ with nowhere vanishing curvature has total curvature at least 4π .

Proof. We prove the contrapositive: if the total curvature is less than 4π then the curve is unknotted.

Form the tube T_r as before. Computing $\int_{T_r} |K| \, dA$ exactly as in Fenchel's proof, but now over all of $[0, 2\pi]$ in v and with $|\cos v|$ in place of $-\cos v$, gives

$$\int_{S^2} |n^{-1}(y)| \, dy = \int_{T_r} |K| \, dA = 4 \int_0^L \kappa \, ds.$$

If $\int_0^L \kappa \, ds < 4\pi$ then the right hand side is less than $16\pi = 4 \operatorname{area}(S^2)$, so the average number of preimages is less than 4. By Sard's theorem we may pick a regular value $y \in S^2$ of n with $|n^{-1}(y)| \leq 3$.

Now consider the height function $h(s) = \langle y, \alpha(s) \rangle$. We have $h'(s) = \langle y, T(s) \rangle$, and one checks from the formula for n that $h'(s) = 0$ precisely when the two points of the tube over s in the $\pm$ directions of the plane orthogonal to $T(s)$ hit y ; so h has at most three critical points. But h is a smooth function on a circle, so it has at least one maximum and one minimum, and its critical points alternate between maxima and minima, hence are even in number. So h has exactly two critical points, one maximum and one minimum.

Therefore α consists of exactly two arcs joining the maximum to the minimum, on each of which h is strictly monotone. For each value c strictly between the minimum and the maximum, the plane $h = c$ meets α in exactly two points; joining them by a straight segment and letting c vary sweeps out an embedded disc with boundary α . Hence α is unknotted. $\square$

Remark. Milnor proved the stronger statement that the total curvature of a knotted curve is *strictly* greater than 4π , and that 4π is the best possible bound: a suitably flattened trefoil has total curvature as close to 4π as we please.

§29.10 Abstract Surfaces

So far, the geometry of our surfaces has been induced by the space that surface has been embedded in (which has so far been $\mathbb{R}^3$). Of course, it's possible to do geometry on surfaces that do not arise in this way. One way of specifying the geometry of a surface is with a *Riemannian metric*.

The point of doing this is not merely generality. We saw that constant curvature $K < 0$ is realised locally by pieces of surfaces in $\mathbb{R}^3$, but Hilbert's theorem says that no *complete* surface of constant negative curvature exists in $\mathbb{R}^3$. The hyperbolic plane, one of the three classical two-dimensional geometries, therefore only exists as an abstract surface – and once we allow abstract surfaces, it is easy to write down.

§29.10.1 Riemannian Metrics

Definition 29.10.1 (Riemannian Metric)

Let $V \subseteq \mathbb{R}^2$ be an open set. An (abstract) **Riemannian metric** on V is a smooth

map from V to the set of positive definite symmetric bilinear forms, given by

$$p \mapsto \begin{pmatrix} E(p) & F(p) \\ F(p) & G(p) \end{pmatrix},$$

with $E, G, EG - F^2 > 0$.

If w is a tangent vector at $p \in V$, we can compute its infinitesimal length by

$$\|w\|^2 = w^\top \begin{pmatrix} E(p) & F(p) \\ F(p) & G(p) \end{pmatrix} w.$$

So, if $\gamma : [a, b] \rightarrow V$ is smooth,

$$L(\gamma) = \int_a^b \sqrt{E\dot{u}^2 + 2F\dot{u}\dot{v} + G\dot{v}^2} dt,$$

where $\gamma(t) = (u(t), v(t))$. Areas are computed by $\int \sqrt{EG - F^2} du dv$, exactly as before.

Definition 29.10.2 (Abstract Riemannian Surface)

An **abstract Riemannian surface** is an abstract smooth surface Σ together with a Riemannian metric in each chart, such that the metrics agree on overlaps: if φ is a transition map then

$$\begin{pmatrix} \tilde{E} & \tilde{F} \\ \tilde{F} & \tilde{G} \end{pmatrix} = (D\varphi)^\top \begin{pmatrix} E & F \\ F & G \end{pmatrix} (D\varphi).$$

Everything intrinsic that we have done goes through unchanged: the Christoffel symbols were defined purely in terms of E, F, G , hence so were the covariant derivative, parallel transport, the geodesic equations, and – by the Theorema Egregium – the Gaussian curvature, which we now simply *define* by the Gauss equation. Geodesic polar coordinates, the local and global Gauss–Bonnet theorems, and all their corollaries hold verbatim. What we lose is the second fundamental form, the mean curvature and the Gauss map, all of which needed an ambient space.

Example 29.10.3 (Surfaces in $\mathbb{R}^3$)

A smooth surface in $\mathbb{R}^3$ with its first fundamental form is an abstract Riemannian surface, and the transformation rule above is exactly how E, F, G transform.

Example 29.10.4 (The Flat Torus)

Take $\mathbb{R}^2$ with the Euclidean metric $du^2 + dv^2$ and quotient by the lattice $\mathbb{Z}^2$. The result is a torus with a flat metric, $K \equiv 0$, which is consistent with Gauss–Bonnet since $\chi = 0$. This surface is *not* isometric to any torus of revolution in $\mathbb{R}^3$, since we showed such a torus has points of positive and of negative curvature. Indeed, no compact flat surface embeds in $\mathbb{R}^3$ at all, since compact surfaces in $\mathbb{R}^3$ have an elliptic point.

§29.10.2 The Length Metric

An abstract Riemannian surface carries a genuine metric space structure, obtained in the obvious way.

Definition 29.10.5 (Length Metric)

Let Σ be a connected abstract Riemannian surface. For $p, q \in \Sigma$ define

$$d(p, q) = \inf \{L(\gamma) : \gamma \text{ a piecewise smooth curve in } \Sigma \text{ from } p \text{ to } q\}.$$

Proposition 29.10.6

d is a metric on Σ , and it induces the original topology.

Proof. Symmetry and the triangle inequality are clear from concatenating and reversing curves, and $d(p, p) = 0$. The only issue is that $d(p, q) > 0$ for $p \neq q$. Take geodesic polar coordinates about p on a normal neighbourhood of radius ε small enough not to contain q . Any curve from p to q must cross every geodesic circle about p of radius less than ε , and by the argument used to prove that geodesics locally minimise length, such a curve has length at least ε . So $d(p, q) \geq \varepsilon > 0$. The same argument shows the metric balls of small radius about p are exactly the images under $\exp_p$ of the Euclidean balls, so the topologies agree. $\square$

Remark. A curve realising the infimum, if one exists, is necessarily a geodesic; but such a curve need not exist – delete a point from the plane and there is no shortest path between two points on opposite sides of the hole. The Hopf–Rinow theorem says that this is the only obstruction: if (Σ, d) is complete as a metric space then any two points are joined by a minimising geodesic.

§29.10.3 The Hyperbolic Plane

The simplest abstract Riemannian surface which is not a surface in $\mathbb{R}^3$ is also the most important.

Definition 29.10.7 (The Upper Half-Plane Model)

The **hyperbolic plane** is the upper half plane

$$\mathbb{H} = \{(u, v) \in \mathbb{R}^2 : v > 0\}$$

equipped with the Riemannian metric

$$I = \frac{du^2 + dv^2}{v^2}.$$

This is an isothermal metric with conformal factor $\lambda = 1/v$, so the corollary to the Gauss equation computes its curvature instantly.

Proposition 29.10.8

The hyperbolic plane has constant curvature $K \equiv -1$.

Proof. With $\lambda = 1/v$ we have $\log \lambda = -\log v$, so $\nabla^2 \log \lambda = -\partial_v^2 \log v = 1/v^2$. Hence

$$K = -\frac{1}{\lambda^2} \nabla^2 (\log \lambda) = -v^2 \cdot \frac{1}{v^2} = -1. \quad \square$$

Proposition 29.10.9

The geodesics of $\mathbb{H}$ are the vertical half-lines and the semicircles orthogonal to the real axis.

Proof. Here $E = G = 1/v^2$ and $F = 0$, and the geodesic equations read

$$\frac{d}{dt} \left(\frac{\dot{u}}{v^2} \right) = 0, \quad \frac{d}{dt} \left(\frac{\dot{v}}{v^2} \right) = -\frac{\dot{u}^2 + \dot{v}^2}{v^3}.$$

The vertical line $u \equiv u_0$, $v = e^t$ satisfies both, so vertical lines are geodesics. For the general case, one can either integrate directly, or – more slickly – observe that the Möbius maps $z \mapsto (az + b)/(cz + d)$ with a, b, c, d real and $ad - bc > 0$ act on $\mathbb{H}$ by isometries (a computation with $\text{Im} \left(\frac{az+b}{cz+d} \right) = \frac{\text{Im } z}{|cz+d|^2}$), that this action is transitive on pairs (point, direction), and that such maps take lines and circles to lines and circles preserving angles. Since a vertical line is a geodesic and the images of vertical lines under this group are exactly the vertical lines and the semicircles meeting $\mathbb{R}$ at right angles, these are all the geodesics. $\square$

Theorem 29.10.10 (Area of a Hyperbolic Triangle)

A hyperbolic triangle with interior angles α, β, γ has area $\pi - \alpha - \beta - \gamma$.

Proof. Apply local Gauss–Bonnet to the triangle, whose sides are geodesics so $\kappa_g = 0$, with exterior angles $\pi - \alpha$ and so on:

$$\int_T K \, dA = \alpha + \beta + \gamma - \pi.$$

But $K \equiv -1$, so the left hand side is $-\text{area}(T)$, giving the result. $\square$

In particular the angle sum of a hyperbolic triangle is always less than π , and no hyperbolic triangle has area more than π . Compare the sphere, where $K \equiv 1$ and the area is the angle *excess*, and the plane, where $K \equiv 0$ and the angle sum is exactly π . All three statements are the same statement, with the sign of the curvature switched.

Remark. By Minding's theorem, any surface of constant curvature -1 is locally isometric to $\mathbb{H}$. The pseudosphere – the surface of revolution generated by the tractrix – is such a surface in $\mathbb{R}^3$, but it is incomplete: it has a singular circle where it cannot be continued. Hilbert's theorem says this is unavoidable, and that no complete surface of constant negative curvature exists in $\mathbb{R}^3$. So the hyperbolic plane is an object we can only reach by allowing abstract metrics – which is a fair summary of why one bothers with them.

Where Next

We have really only scratched the surface. The obvious next step is to allow more dimensions: the Christoffel symbols, the covariant derivative and parallel transport all generalise to n -dimensional Riemannian manifolds, with the Gaussian curvature replaced by the Riemann curvature tensor, and this is the subject of Part III Differential Geometry and of General Relativity. In another direction, the Gauss–Bonnet theorem is the first instance of an index theorem, expressing an analytic invariant in terms of a topological one; the Atiyah–Singer index theorem is the vast generalisation. And the complex-analytic side of minimal surface theory opens into the theory of Riemann surfaces. All of these begin exactly where we have stopped.

30 Galois Theory

Galois theory is the study of the symmetries of the solutions of polynomial equations. The central discovery of the subject – and it really is one of the most beautiful discoveries in all of mathematics – is that the messy analytic question ‘can I write down the roots of this polynomial using $+$, $-$, $\times$, $\div$ and $\sqrt[n]{}$?’ is exactly equivalent to a clean, finite, combinatorial question about a group. Galois’ insight was to stop looking at the roots one at a time, and instead to look at the group of symmetries that permutes them without disturbing any of the algebra they satisfy.

Modern treatments phrase all of this in terms of *field extensions*, and the heart of the course is a dictionary – the *Galois correspondence* – translating between the subfields of a field extension and the subgroups of its symmetry group. Once we have that dictionary in hand, an enormous amount falls out: the impossibility of trisecting an angle, the classification of finite fields, the constructibility of the regular 17-gon, the fundamental theorem of algebra, and of course the insolubility of the general quintic.

This article constitutes my notes for the ‘Galois Theory’ course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§30.1 Introduction

§30.1.1 A Bit of History

Historically the subject arose from looking at solutions to polynomial equations in one variable over $\mathbb{C}$. The question arose as to whether polynomials could be solved by a formula involving the coefficients and taking roots (‘soluble by radicals’). From school, we know that we can solve quadratics in this way, with

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}.$$

For a long time it has been known that cubics and quartics have similar, albeit rather more complicated, formulae for their roots. These were studied by Lagrange in the 1770s, who was the first to notice that what really mattered was how certain expressions in the roots behaved when the roots were permuted.

In 1799 Ruffini claimed that there was no general formula in the case of quintics, however there was a gap in his proof. It wasn’t until Abel in 1824 that there was a complete accepted proof, using permutations of roots of polynomials. This was the start of group theory.

Galois gave the first explanation of *when* a quintic was soluble by radicals or not in 1831, using the structure of a group of permutations of the roots, and in particular the importance of normal subgroups. Galois’ work was not known until Liouville published his papers in 1846. Liouville realised the connection with Cauchy’s work on permutations, but didn’t realise the importance of the group-theoretic structure, and in fact few of the contemporary mathematicians did so.

Galois entered his papers for various competitions and also for the entrance process for the École Polytechnique in Paris. He didn't get in however, and went to another university in Paris, where he got involved in politics and was eventually killed in a duel at the age of twenty. The night before the duel he left a $6\frac{1}{2}$ page manuscript setting out his ideas about the future development of the theory. His papers have been carefully studied by Peter Neumann, in *The Mathematical Writings of Évariste Galois* (History of European Mathematics, European Mathematical Society).

There is a historical introduction in I. Stewart's *Galois Theory*, which is very readable but doesn't quite cover the syllabus. Other books worth looking at are Artin's *Galois Theory*, Van der Waerden's *Modern Algebra*, Lang's *Algebra*, and Kaplansky's *Fields and Rings*.

§30.1.2 Solving Cubics and Quartics

Before we get going, it is worth reminding ourselves what these classical formulae actually look like, because the shape of the answer will turn out to be a very good guide to the shape of the theory.

Consider a cubic $f(x) = x^3 + ax^2 + bx + c$. Substituting $x \mapsto x - a/3$ (which is legitimate provided $\text{char } K \neq 3$) we may assume $a = 0$, so

$$f(x) = x^3 + px + q.$$

Cardano's trick is to write a root as $x = u + v$. Then

$$x^3 = u^3 + v^3 + 3uv(u + v) = u^3 + v^3 + 3uvx,$$

so x is a root of f provided that $u^3 + v^3 = -q$ and $3uv = -p$. But then u^3 and v^3 are two numbers with known sum $-q$ and known product $-p^3/27$, so they are the roots of a *quadratic*,

$$t^2 + qt - \frac{p^3}{27} = 0.$$

Solving that quadratic and taking cube roots gives the roots of f . What we should notice here is the intrusion of an auxiliary quadratic – the **resolvent** – and the fact that solving a cubic requires taking a square root and then a cube root, in that order. The quartic behaves similarly: an auxiliary *cubic* appears, and the whole thing unravels into a chain of extractions of roots. The whole point of the course will be to explain *why* such a chain must exist for degrees 2, 3, 4, and why no such chain can exist for degree 5.

§30.1.3 Notation and Revision

Everything we do will take place inside rings and fields, and we will lean quite heavily on the Groups, Rings and Modules course. Let us fix our conventions and remind ourselves of what we need.

In this course a **ring** always means a commutative ring with a 1, and ring homomorphisms are required to send $1 \mapsto 1$. A **field** is a ring in which every non-zero element is a unit, for instance $\mathbb{Q}, \mathbb{R}, \mathbb{C}$ and $\mathbb{F}_p = \mathbb{Z}/p\mathbb{Z}$ for p prime. For a ring R we write $R^\times$ for its group of units, so if K is a field then $K^\times = K \setminus \{0\}$.

We write $R[x]$ for the ring of polynomials in an indeterminate x with coefficients in R , that is, the set of formal sums $\sum_{i \geq 0} r_i x^i$ with all but finitely many r_i equal to zero.¹ If K is a field, then $K(x)$ denotes the **field of fractions** of $K[x]$, whose elements are equivalence classes of formal quotients f/g with $g \neq 0$, where $f/g = r/s$ exactly when $fs = gr$. Its elements are called **rational functions**.

The single most important fact we import from Groups, Rings and Modules is that polynomial rings over a field are as well-behaved as we could possibly hope.

Theorem 30.1.1 (Division Algorithm)

Let K be a field and let $a, b \in K[x]$ with $b \neq 0$. Then there exist $q, r \in K[x]$ with

$$a = qb + r, \quad \deg r < \deg b.$$

In other words, $K[x]$ is a Euclidean domain.

Everything else we need is a formal consequence.

Corollary 30.1.2

Let K be a field. Then:

- (i) $K[x]$ is a principal ideal domain;
- (ii) $K[x]$ is a unique factorisation domain;
- (iii) for $f \in K[x]$ non-constant, f is irreducible $\iff f$ is prime $\iff (f)$ is maximal $\iff K[x]/(f)$ is a field;
- (iv) for $a, b \in K[x]$, the ideal $(a) + (b)$ equals (g) for some g , and this g is a greatest common divisor of a and b , unique up to a unit. In particular $\gcd(a, b) = pa + qb$ for some $p, q \in K[x]$;
- (v) if $f \in K[x] \setminus \{0\}$ then f has at most $\deg f$ roots in K .^a

^aAs usual, α is a **root** of f if $f(\alpha) = 0$, and by the division algorithm this happens if and only if $(x - \alpha) \mid f$.

Proof. All of these were proved in Groups, Rings and Modules; (i) follows by taking a non-zero element of least degree in an ideal and dividing, (ii) follows since every PID is a UFD, (iii) is the standard characterisation of irreducibles in a PID, (iv) is immediate from (i), and (v) follows from (ii) together with the factor theorem. $\square$

The point of (iii) that we will use again and again is the following: *if $f \in K[x]$ is irreducible, then $K[x]/(f)$ is a field*. This is the engine that manufactures new fields out of old ones, and it is where the whole subject starts.

We will also want the standard irreducibility criteria from Groups, Rings and Modules, namely Gauss's lemma (a primitive polynomial in $\mathbb{Z}[x]$ is irreducible in $\mathbb{Z}[x]$ if and only if it is irreducible in $\mathbb{Q}[x]$) and Eisenstein's criterion.

¹It is a good exercise to check that if R is an integral domain then so is $R[x]$, and that in that case $\deg(fg) = \deg f + \deg g$.

§30.2 Field Extensions

§30.2.1 Extensions and Degree

The basic object of the course is not a field but a *pair* of fields, one sitting inside the other.

Definition 30.2.1 (Field Extension)

If $K \subseteq L$ where L is a field and K is a subring of L which is itself a field, then we say L is an **extension** of K , and write L/K .^a

^aThe notation L/K has nothing whatsoever to do with quotients. It is unfortunate, but universal.

For example $\mathbb{C}/\mathbb{R}$, $\mathbb{R}/\mathbb{Q}$ and $K(x)/K$ are all field extensions, as is L/K where $L = K[x]/(f)$ for $f \in K[x]$ irreducible (here we regard K as sitting inside L as the constant polynomials).

Now here is the observation that makes the whole theory work. If L/K is a field extension, then L is in particular a vector space over K : we can add elements of L , and we can multiply them by scalars from K , and all of the vector space axioms are instances of the field axioms in L . So we may bring the whole of linear algebra to bear.

Definition 30.2.2 (Degree)

The **degree** of a field extension L/K is

$$[L : K] = \dim_K L,$$

the dimension of L as a K -vector space. If $[L : K] < \infty$ we say L/K is a **finite** extension, and otherwise an **infinite** extension.

For instance $[\mathbb{C} : \mathbb{R}] = 2$, since $\{1, i\}$ is an $\mathbb{R}$ -basis of $\mathbb{C}$. On the other hand $[\mathbb{R} : \mathbb{Q}] = \infty$, and $[K(x) : K] = \infty$ since $1, x, x^2, \dots$ are linearly independent over K .

Before going further, let us record the smallest subfield that any field contains.

Definition 30.2.3 (Characteristic)

Let K be a field. There is a unique ring homomorphism $\mathbb{Z} \rightarrow K$, sending $1 \mapsto 1$. If it is injective then K contains a copy of $\mathbb{Q}$ and we say K has **characteristic** zero, written $\text{char } K = 0$. Otherwise its kernel is a non-zero prime ideal (p) , so that $\underbrace{1 + 1 + \dots + 1}_p = 0$ in K ; then K contains a copy of $\mathbb{F}_p$ and we say $\text{char } K = p$.

The kernel must be prime because its quotient embeds in the integral domain K . In either case the image of $\mathbb{Z} \rightarrow K$ generates a smallest subfield of K , called the **prime subfield**, which is $\mathbb{Q}$ or $\mathbb{F}_p$ accordingly. For instance $\text{char } \mathbb{F}_p(x) = p$, since $p \cdot 1 = 0$ already in $\mathbb{F}_p$.

We say K is a **finite field** if $\#K < \infty$, where $\#K$ denotes the number of elements of K . Already we can say something about what sizes are possible.

Lemma 30.2.4

If F is a finite field then $\text{char } F = p$ for some prime p , and $\#F = p^n$ where $n = [F : \mathbb{F}_p]$.

Proof. If $\#F < \infty$ then the map $\mathbb{Z} \rightarrow F$ cannot be injective, so $\text{char } F = p$ for some prime p and $\mathbb{F}_p \subseteq F$. Then F is a vector space over $\mathbb{F}_p$, necessarily finite-dimensional, say of dimension n . Choosing a basis gives an isomorphism of $\mathbb{F}_p$ -vector spaces $F \cong \mathbb{F}_p^n$, and hence $\#F = p^n$. $\square$

We will see later that, conversely, for every prime p and every $n \geq 1$ there is a field with p^n elements, and that it is unique up to isomorphism.

§30.2.2 The Tower Law

Degrees behave exactly as you would want them to in a tower of extensions – they multiply. This little fact is used constantly, often several times on the same page.

Theorem 30.2.5 (Tower Law)

Let $M/L/K$ be field extensions. Then M/K is finite if and only if both M/L and L/K are finite, and in that case

$$[M : K] = [M : L][L : K].$$

It is no harder, and rather more useful, to prove the following slightly more general statement about vector spaces.

Proposition 30.2.6

Let L/K be a finite field extension and let V be a vector space over L . Then V is finite dimensional over L if and only if it is finite dimensional over K , and in that case

$$\dim_K V = \dim_L V \cdot [L : K].$$

Proof. Suppose $\dim_L V = d < \infty$, and take an L -basis $\alpha_1, \dots, \alpha_d$ of V and a K -basis $\ell_1, \dots, \ell_n$ of L . We claim that the nd products

$$\{\ell_i \alpha_j : 1 \leq i \leq n, 1 \leq j \leq d\}$$

form a K -basis of V .

They span: any $v \in V$ can be written $v = \sum_j \mu_j \alpha_j$ with $\mu_j \in L$, and each $\mu_j = \sum_i \lambda_{ij} \ell_i$ with $\lambda_{ij} \in K$, so $v = \sum_{i,j} \lambda_{ij} \ell_i \alpha_j$.

They are independent: if $\sum_{i,j} \lambda_{ij} \ell_i \alpha_j = 0$ with $\lambda_{ij} \in K$, then collecting terms gives $\sum_j (\sum_i \lambda_{ij} \ell_i) \alpha_j = 0$, and the inner brackets lie in L , so by L -independence of the α_j each $\sum_i \lambda_{ij} \ell_i = 0$, and then by K -independence of the ℓ_i each $\lambda_{ij} = 0$.

Hence $\dim_K V = nd = \dim_L V \cdot [L : K] < \infty$.

Conversely if $\dim_K V < \infty$ then certainly $\dim_L V < \infty$, since a K -spanning set is

in particular an L -spanning set. $\square$

Proof of the Tower Law. If L/K is infinite then $L \subseteq M$ forces M/K to be infinite, and if M/L is infinite then so is M/K by the same argument applied to a set of elements of M independent over L . Otherwise apply Proposition 30.2.6 with $V = M$. $\square$

It is worth pausing to appreciate how much arithmetic information the tower law encodes. If we can find a subfield of L containing K , its degree over K must divide $[L : K]$; contrapositively, if $[L : K]$ is prime then there are no intermediate fields at all. This kind of numerical reasoning is remarkably powerful, and we will use it immediately.

§30.2.3 Algebraic and Transcendental Elements

Given a field extension L/K and an element $\alpha \in L$, we write $K[\alpha]$ for the smallest subring of L containing both K and α , and $K(\alpha)$ for the smallest subfield. Concretely,

$$K[\alpha] = \left\{ \sum_{i=0}^N r_i \alpha^i : r_i \in K, N \in \mathbb{N} \right\}, \quad K(\alpha) = \{f/g : f, g \in K[\alpha], g \neq 0\}.$$

More generally we write $K(\alpha_1, \dots, \alpha_n)$ for the smallest subfield of L containing K and all the α_i ; note that $K(\alpha, \beta) = (K(\alpha))(\beta)$, so we can adjoin elements one at a time.

Example 30.2.7

Take $L = \mathbb{C}$, $K = \mathbb{Q}$ and $\alpha = i$. Then

$$\mathbb{Q}[i] = \{a_0 + a_1 i + a_2 i^2 + \dots + a_n i^n : a_j \in \mathbb{Q}\} = \{a + bi : a, b \in \mathbb{Q}\},$$

since $i^2 = -1$ lets us collapse all the higher powers. This is already a field, because $(a + bi)^{-1} = (a - bi)/(a^2 + b^2)$, and so $\mathbb{Q}(i) = \mathbb{Q}[i]$.

That last coincidence – that $K[\alpha]$ happened to be a field already – is not an accident, and understanding exactly when it happens is the content of this subsection. The right way to see it is through the evaluation map.

Fix $\alpha \in L$ and consider the ring homomorphism

$$\phi : K[x] \rightarrow L, \quad x \mapsto \alpha,$$

which is to say $\phi(\sum r_i x^i) = \sum r_i \alpha^i$. Its image is exactly $K[\alpha]$. There are then precisely two possibilities, according to whether ϕ is injective.

Definition 30.2.8 (Algebraic and Transcendental)

With notation as above, we say α is **transcendental** over K if ϕ is injective, and **algebraic** over K if ϕ is not injective. Equivalently, α is algebraic over K if and only if $f(\alpha) = 0$ for some non-zero $f \in K[x]$.

Suppose α is algebraic. Then $\ker \phi$ is a non-zero ideal of the PID $K[x]$, so $\ker \phi = (f)$ for some non-zero f , unique up to a unit; normalising so that f is monic pins it down completely.

Definition 30.2.9 (Minimal Polynomial)

Let $\alpha \in L$ be algebraic over K . The **minimal polynomial** of α over K is the unique monic generator f of $\ker(\phi : K[x] \rightarrow L)$. Equivalently, it is the monic polynomial of least degree in $K[x]$ having α as a root, and it divides every polynomial in $K[x]$ with α as a root. We write $\deg_K \alpha = \deg f$ for the **degree** of α over K .

Lemma 30.2.10

The minimal polynomial of α over K is irreducible in $K[x]$.

Proof. Write f for the minimal polynomial, and suppose $f = gh$ with $\deg g, \deg h < \deg f$. Then $g(\alpha)h(\alpha) = f(\alpha) = 0$ in L , and L is a field and hence an integral domain, so $g(\alpha) = 0$ or $h(\alpha) = 0$. Either way we have found a non-zero polynomial of smaller degree than f vanishing at α , contradicting minimality. $\square$

Notice a small but useful consequence: since f is irreducible and $\deg f \geq 1$, its constant term a_0 is non-zero (else $x \mid f$). Writing $f(x) = x^n + a_{n-1}x^{n-1} + \cdots + a_0$ and rearranging $f(\alpha) = 0$ gives

$$\alpha \cdot \left(-\frac{1}{a_0} (\alpha^{n-1} + a_{n-1}\alpha^{n-2} + \cdots + a_1) \right) = 1,$$

so $\alpha^{-1} \in K[\alpha]$. This is the first hint that $K[\alpha]$ is a field whenever α is algebraic; here is the full statement.

Proposition 30.2.11

Let L/K be a field extension and $\alpha \in L$. The following are equivalent:

- (i) α is algebraic over K ;
- (ii) $[K(\alpha) : K] < \infty$;
- (iii) $\dim_K K[\alpha] < \infty$;
- (iv) $K[\alpha] = K(\alpha)$;
- (v) $K[\alpha]$ is a field.

When these hold, $[K(\alpha) : K] = \deg_K \alpha$, and $1, \alpha, \dots, \alpha^{d-1}$ is a K -basis of $K(\alpha)$, where $d = \deg_K \alpha$.

Proof. Suppose (i), and let f be the minimal polynomial of α , of degree d . Since ϕ has kernel (f) , the first isomorphism theorem gives $K[\alpha] \cong K[x]/(f)$, which is a field because f is irreducible; this is (v), and (iv) follows since $K(\alpha)$ is the smallest field containing K and α . Moreover $1, \alpha, \dots, \alpha^{d-1}$ span $K[\alpha]$ (divide by f and take the remainder) and are linearly independent (a linear relation would be a polynomial of degree $< d$ killing α), so $\dim_K K[\alpha] = d$, giving (iii) and (ii).

Conversely suppose (iii), so $\dim_K K[\alpha] = m < \infty$. Then $1, \alpha, \dots, \alpha^m$ are $m+1$ elements of an m -dimensional space, hence linearly dependent over K , and a non-trivial dependence is precisely a non-zero polynomial vanishing at α . So (iii) $\Rightarrow$ (i). Since (ii) $\Rightarrow$ (iii) (as $K[\alpha] \subseteq K(\alpha)$) and (v) $\Rightarrow$ (iv) $\Rightarrow$ (i) (if $K[\alpha]$ is a field then

$\alpha^{-1} \in K[\alpha]$, so $\alpha^{-1} = \sum r_i \alpha^i$ and hence α satisfies $\sum r_i x^{i+1} - 1 = 0$, all five are equivalent. $\square$

The transcendental case is much less interesting, precisely because there is only one of them.

Proposition 30.2.12

α is transcendental over K if and only if $\phi : K[x] \rightarrow K[\alpha]$ is an isomorphism, in which case it extends to an isomorphism $K(x) \rightarrow K(\alpha)$. In particular, any two simple transcendental extensions of K are K -isomorphic, both being isomorphic to the rational function field $K(x)$.

Proof. The map ϕ is surjective onto $K[\alpha]$ by definition, so it is an isomorphism precisely when it is injective, which is the definition of transcendence. An isomorphism of integral domains extends uniquely to their fields of fractions, giving $K(x) \cong K(\alpha)$. $\square$

Remark. Both ‘algebraic’ and ‘transcendental’, and the minimal polynomial itself, depend very much on the base field K , and it is worth being careful about this.

- (i) $2\pi i \in \mathbb{C}$ is algebraic over $\mathbb{R}$, with minimal polynomial $x^2 + 4\pi^2$, but it is transcendental over $\mathbb{Q}$ (this is Lindemann’s theorem, and is decidedly not easy).
- (ii) Let $\alpha = \sqrt{i} = \frac{\sqrt{2}}{2}(1 + i)$. Over $\mathbb{Q}$ the minimal polynomial of α is $x^4 + 1$, whereas over $\mathbb{Q}(i)$ it is $x^2 - i$. Note that

$$[\mathbb{Q}(i) : \mathbb{Q}] = 2, \quad [\mathbb{Q}(\alpha) : \mathbb{Q}(i)] = 2, \quad [\mathbb{Q}(\alpha) : \mathbb{Q}] = 4,$$

which is a first illustration of the tower law in action.

§30.2.4 Working with Degrees

Combining the tower law with Proposition 30.2.11 gives a very effective toolkit. Here is the basic divisibility statement.

Corollary 30.2.13

If L/K is a finite extension and $\alpha \in L$, then α is algebraic over K and $\deg_K \alpha \mid [L : K]$.

Proof. Since $K \subseteq K(\alpha) \subseteq L$ and $[L : K] < \infty$, we get $[K(\alpha) : K] < \infty$, so α is algebraic. The tower law applied to $L/K(\alpha)/K$ gives $[L : K] = [L : K(\alpha)] \cdot \deg_K \alpha$. $\square$

The following picture is the one to keep in mind: an element $\alpha \in L$ interposes an intermediate field, and the two degrees multiply to give the degree of the whole tower.

$$[L : K] \left\{ \begin{array}{l} L \\ | \\ [L : K(\alpha)] \\ K(\alpha) \\ | \\ \deg_K \alpha \\ K \end{array} \right.$$

Example 30.2.14

Let us see the toolkit at work.

- (i) Suppose $[L : K] = p$ is prime. Then for every $\alpha \in L \setminus K$ we have $L = K(\alpha)$. Indeed $[K(\alpha) : K]$ divides p , so is 1 or p ; it is not 1 since $\alpha \notin K$; so $[K(\alpha) : K] = p$ and hence $[L : K(\alpha)] = 1$.
- (ii) Every irreducible polynomial $f \in \mathbb{R}[x]$ has degree 1 or 2. Granting that $\mathbb{C}$ is algebraically closed, f has a root $\alpha \in \mathbb{C}$, and $\deg f = [\mathbb{R}(\alpha) : \mathbb{R}]$ divides $[\mathbb{C} : \mathbb{R}] = 2$.
- (iii) Let $L = \mathbb{Q}(\sqrt[3]{2}, \sqrt[4]{5})$. We claim $[L : \mathbb{Q}] = 12$. Certainly $L \supseteq \mathbb{Q}(\sqrt[3]{2})$, and $x^3 - 2$ is irreducible over $\mathbb{Q}$ by Eisenstein at 2, so $[\mathbb{Q}(\sqrt[3]{2}) : \mathbb{Q}] = 3$ and hence $3 \mid [L : \mathbb{Q}]$. Similarly $x^4 - 5$ is irreducible by Eisenstein at 5, so $4 \mid [L : \mathbb{Q}]$, and therefore $12 \mid [L : \mathbb{Q}]$. On the other hand $\sqrt[4]{5}$ satisfies $x^4 - 5$ over $\mathbb{Q}(\sqrt[3]{2})$, so $[L : \mathbb{Q}(\sqrt[3]{2})] \leq 4$ and hence $[L : \mathbb{Q}] \leq 12$. So $[L : \mathbb{Q}] = 12$.
- (iv) Let p be an odd prime, let $\omega = e^{2\pi i/p}$ and let $\alpha = \omega + \omega^{-1} = 2\cos(2\pi/p)$. What is $\deg_{\mathbb{Q}} \alpha$? Now ω is a root of

$$f(x) = 1 + x + \cdots + x^{p-1} = \frac{x^p - 1}{x - 1},$$

which is irreducible over $\mathbb{Q}$: applying Eisenstein at p to $f(x+1)$ does the job, since $f(x+1) = \frac{(x+1)^p - 1}{x} = x^{p-1} + \binom{p}{1}x^{p-2} + \cdots + \binom{p}{p-1}$. Hence $[\mathbb{Q}(\omega) : \mathbb{Q}] = p-1$. Clearly $\alpha \in \mathbb{Q}(\omega)$, so $\mathbb{Q}(\omega)/\mathbb{Q}(\alpha)/\mathbb{Q}$ is a tower and $\deg_{\mathbb{Q}} \alpha \mid p-1$. Now $\alpha\omega = \omega^2 + 1$, so ω is a root of $x^2 - \alpha x + 1 \in \mathbb{Q}(\alpha)[x]$, giving $[\mathbb{Q}(\omega) : \mathbb{Q}(\alpha)] \leq 2$. It is not 1, since $\alpha \in \mathbb{R}$ but $\omega \notin \mathbb{R}$, so $[\mathbb{Q}(\omega) : \mathbb{Q}(\alpha)] = 2$ and hence

$$\deg_{\mathbb{Q}} \alpha = \frac{p-1}{2}.$$

Next, a fact that ought to be surprising: the algebraic elements are closed under all the field operations, even though there is no obvious way to write down the minimal polynomial of a sum.

Corollary 30.2.15

Let L/K be a field extension.

- (i) Elements $\alpha_1, \dots, \alpha_n \in L$ are all algebraic over K if and only if $[K(\alpha_1, \dots, \alpha_n) : K] < \infty$.
- (ii) If $\alpha, \beta \in L$ are algebraic over K then so are $\alpha \pm \beta$, $\alpha\beta$ and α/β (the last provided $\beta \neq 0$).

Proof. For (i), suppose first that $[K(\alpha_1, \dots, \alpha_n) : K] < \infty$. Each α_i lies in this finite extension, so is algebraic over K by Corollary 30.2.13. Conversely, suppose each α_i is algebraic over K . Then α_n is in particular algebraic over the larger field $K(\alpha_1, \dots, \alpha_{n-1})$ (its minimal polynomial over K is still a polynomial there), so

$$[K(\alpha_1, \dots, \alpha_n) : K(\alpha_1, \dots, \alpha_{n-1})] < \infty,$$

and the result follows by induction and the tower law, as a product of finitely many finite numbers.

For (ii), all four elements lie in $K(\alpha, \beta)$, which is a finite extension of K by (i), so all four are algebraic by Corollary 30.2.13. $\square$

Corollary 30.2.16

The elements of L which are algebraic over K form a subfield of L .

It is instructive to see how one might find an explicit polynomial in a simple case – this is the sort of thing that Galois theory will eventually let us do systematically.

Example 30.2.17

Let $a, b \in K$ and let $\alpha = \sqrt{a}$, $\beta = \sqrt{b}$ in some extension. Put $\gamma = \alpha + \beta$. We compute, using $\alpha^2 = a$ and $\beta^2 = b$:

$$\begin{aligned}\gamma^2 &= a + b + 2\alpha\beta, \\ \gamma^4 &= (a + b)^2 + 4\alpha\beta(a + b) + 4ab,\end{aligned}$$

and $2(a + b)\gamma^2 = 2(a + b)^2 + 4\alpha\beta(a + b)$. Subtracting kills the awkward $\alpha\beta$ term:

$$\gamma^4 - 2(a + b)\gamma^2 = 4ab - (a + b)^2 = -(a - b)^2.$$

So γ is a root of $x^4 - 2(a + b)x^2 + (a - b)^2$.

More generally, if $\deg_K \alpha = m$ and $\deg_{K(\alpha)} \beta = n$, then $K(\alpha, \beta)$ is spanned over K by the mn monomials $\alpha^i \beta^j$ with $0 \leq i < m$, $0 \leq j < n$. So for any $\gamma \in K(\alpha, \beta)$, the $mn + 1$ elements $1, \gamma, \dots, \gamma^{mn}$ must be linearly dependent over K , which produces a polynomial of degree at most mn satisfied by γ . Be warned that the polynomial obtained this way is in general *not* the minimal polynomial.

Exercise 30.2.18. Show that if $m, n, mn \in \mathbb{Q}$ are all non-squares, then $[\mathbb{Q}(\sqrt{m} + \sqrt{n}) : \mathbb{Q}] = 4$.

§30.2.5 Algebraic Extensions

Definition 30.2.19 (Algebraic Extension)

An extension L/K is an **algebraic extension** if every $\alpha \in L$ is algebraic over K .

By Corollary 30.2.13, every finite extension is algebraic. The converse fails.

Example 30.2.20

Let $\overline{\mathbb{Q}} = \{\alpha \in \mathbb{C} : \alpha \text{ is algebraic over } \mathbb{Q}\}$, the field of **algebraic numbers** (a field, by Corollary 30.2.15). Then $\overline{\mathbb{Q}}/\mathbb{Q}$ is algebraic by construction, but it is not finite: $\sqrt[n]{2} \in \overline{\mathbb{Q}}$ has degree n over $\mathbb{Q}$ for every n , so $[\overline{\mathbb{Q}} : \mathbb{Q}] \geq n$ for all n .

Proposition 30.2.21 (i) Every finite extension is algebraic.

(ii) If $M/L/K$ are field extensions, then M/K is algebraic if and only if M/L and L/K are algebraic.

Proof. Part (i) is Corollary 30.2.13.

For (ii), suppose first M/K is algebraic. If $\alpha \in M$ then α is algebraic over K , hence over the larger field L ; and $L \subseteq M$, so every element of L is algebraic over K too.

Conversely suppose M/L and L/K are algebraic, and let $\alpha \in M$. Then α is algebraic over L , so

$$r_0 + r_1\alpha + \cdots + r_d\alpha^d = 0$$

for some $r_0, \dots, r_d \in L$ not all zero. Put $L_0 = K(r_0, \dots, r_d)$. Each r_j is algebraic over K since L/K is algebraic, so $[L_0 : K] < \infty$ by Corollary 30.2.15. Also α is algebraic over L_0 by the displayed equation, so $[L_0(\alpha) : L_0] < \infty$. By the tower law

$$[L_0(\alpha) : K] = [L_0(\alpha) : L_0][L_0 : K] < \infty,$$

and α lies in this finite extension of K , hence is algebraic over K . □

In other words, an extension L/K is algebraic exactly when L is a union of subfields each of which is finite over K .

§30.3 Ruler and Compass Constructions

This section is an interlude, but a very satisfying one. The Greeks asked a number of geometric questions which resisted attack for two thousand years: can we trisect a general angle with ruler and compass? Can we construct a square with the same area as a given circle? Can we construct a cube with double the volume of a given cube? With the tower law in hand, all three become easy.

§30.3.1 What Is Constructible?

We begin with two marked points in the plane, which we declare to be **constructed**. From a set of constructed points we may produce more, as follows: given constructed points we may draw the line through any two of them, and the circle centred at one of them passing through another, and then any point of intersection of two such lines, of two such circles, or of a line and a circle, is again constructed. A point is **constructible** if it can be obtained from the two initial points by finitely many such steps.

In the picture, R is the intersection of the lines P_1Q_1 and P_2Q_2 , and S is one of the two intersections of the line P_1Q_1 with the circle centred at P_2 passing through Q_2 ; both are therefore constructible from P_1, P_2, Q_1, Q_2 .

There are three standard constructions that we shall use freely, all of which are done in school.

- (i) Given a constructed point P and a constructed line ℓ , we may drop or erect the perpendicular to ℓ through P . (Draw a circle centred at P meeting ℓ in two points A, B ; then circles of equal radius centred at A and B meet in two points, and the line through those two points is the required perpendicular.)
- (ii) Given a constructed point P and a constructed line ℓ , we may draw the line through P parallel to ℓ : erect the perpendicular m to ℓ through P , then the perpendicular to m through P .
- (iii) Given constructed points a, b and a constructed point P on a constructed line ℓ , we may mark off the length $|ab|$ along ℓ starting from P : this is what a compass is for.

As a consequence of (i) and (ii) we may set up Cartesian coordinates, declaring our two initial points to be $(0, 0)$ and $(1, 0)$, and constructing the two coordinate axes.

Definition 30.3.1 (Constructible Number)

A real number λ is **constructible** if $|\lambda|$ is the distance between two constructible points.

Lemma 30.3.2

A point $P = (a, b)$ is constructible if and only if a and b are constructible real numbers.

Proof. If P is constructible, drop perpendiculars from P onto the two axes; the feet are constructible points, at distances $|a|$ and $|b|$ from the origin. Conversely, given constructible a and b , mark off a along the x -axis and b along the y -axis, erect perpendiculars there, and take their intersection. $\square$

§30.3.2 Constructible Numbers Form a Field

Proposition 30.3.3

The set of constructible real numbers is a subfield of $\mathbb{R}$, closed moreover under taking square roots of positive elements.

Proof. Let a, b be constructible. Then $a + b$ and $-a$ are constructible by marking off lengths along a line, so we have an additive subgroup containing $\mathbb{Q}$.

For products and quotients we use similar triangles. Draw two rays from a point O . Along the first mark points U and A at distances 1 and a ; along the second mark B at distance b . Draw the line UB , and then the line through A parallel to it, meeting the second ray at C . By similarity $|OC|/|OB| = |OA|/|OU|$, that is $|OC| = ab$.

Exactly the same picture read backwards gives a/b for $b \neq 0$: mark b and 1 on the first ray and a on the second.

Finally, suppose $a > 0$ is constructible. Mark off a segment of length a followed by a segment of length 1 along a line, giving a segment XZ of length $a + 1$ with the intermediate point Y . Draw the semicircle on XZ as diameter, and erect the perpendicular to XZ at Y , meeting the semicircle at W . The angle XWZ is a right angle (angle in a semicircle), so the triangles XYW and WYZ are similar, giving $|YW|^2 = |XY||YZ| = a$, so $|YW| = \sqrt{a}$.

□

That is the easy half. The point of the theory is the other half: nothing else is constructible.

Theorem 30.3.4

A real number λ is constructible if and only if there is a chain of subfields

$$\mathbb{Q} = F_0 \subseteq F_1 \subseteq \cdots \subseteq F_n = F \subseteq \mathbb{R}$$

with $\lambda \in F$, where for each j we have $F_{j+1} = F_j(\sqrt{r_j})$ for some $r_j \in F_j$ with $r_j > 0$.

Proof. If such a chain exists, then every element of F is constructible by the previous proposition (each stage only requires the field operations and one square root).

Conversely, suppose λ is constructible, via a sequence of constructions producing points $P_1, P_2, \dots, P_N$. We build the chain inductively, maintaining the invariant that the coordinates of $P_1, \dots, P_k$ all lie in $F_{j(k)}$ for some field in the chain. Initially the two starting points have coordinates in $\mathbb{Q} = F_0$. At each step, a new point arises in one of three ways.

- As the intersection of two lines through points with coordinates in F : solving two simultaneous linear equations with coefficients in F gives coordinates in F , so no extension is needed.
- As an intersection of a line and a circle, or of two circles, with all data in F . Subtracting the two circle equations reduces the second case to the first, and substituting the equation of the line into that of the circle gives a quadratic over F . Its roots lie in $F(\sqrt{r})$, where $r \in F$ is the discriminant, which is non-negative because the intersection is assumed to exist.

So each construction step either keeps us in the current field or extends it by one square root, and after finitely many steps we obtain the desired chain. $\square$

Corollary 30.3.5

If $\lambda \in \mathbb{R}$ is constructible then λ is algebraic over $\mathbb{Q}$, and $\deg_{\mathbb{Q}} \lambda = 2^m$ for some $m \geq 0$.

Proof. Each step of the chain has $[F_{j+1} : F_j] \in \{1, 2\}$, so by the tower law $[F : \mathbb{Q}] = 2^k$ for some k . Since $\lambda \in F$, Corollary 30.2.13 gives $\deg_{\mathbb{Q}} \lambda \mid 2^k$. $\square$

§30.3.3 The Classical Impossibilities**Example 30.3.6** (Duplicating the cube)

It is impossible to construct a cube of volume 2 from a cube of volume 1; that would require constructing $\sqrt[3]{2}$, and $\deg_{\mathbb{Q}} \sqrt[3]{2} = 3$, which is not a power of 2.

Example 30.3.7 (Trisecting the angle)

It is impossible to trisect a general angle. It suffices to exhibit one angle that cannot be trisected. We can certainly construct 60° , since $\cos 60^\circ = 1/2 \in \mathbb{Q}$. If we could trisect it we could construct 20° and hence $\alpha = \cos 20^\circ$. But the triple angle formula

$\cos 3\theta = 4\cos^3\theta - 3\cos\theta$ with $\theta = 20^\circ$ gives

$$8\alpha^3 - 6\alpha - 1 = 0.$$

The cubic $8x^3 - 6x - 1$ has no rational root (by the rational root test the only candidates are $\pm 1, \pm \frac{1}{2}, \pm \frac{1}{4}, \pm \frac{1}{8}$, and none work), so it is irreducible over $\mathbb{Q}$, and $\deg_{\mathbb{Q}} \alpha = 3$ is not a power of 2.

Example 30.3.8 (Squaring the circle)

It is impossible to construct a square of the same area as a given circle, since this requires constructing $\sqrt{\pi}$ and hence π , which is transcendental over $\mathbb{Q}$ by Lindemann's theorem – unless of course you are in Indiana in 1897.

Example 30.3.9 (Regular polygons)

A regular p -gon, for p an odd prime, is constructible only if $p - 1$ is a power of 2. Constructing the polygon is the same as constructing $\cos(2\pi/p)$, which we computed above to have degree $(p - 1)/2$ over $\mathbb{Q}$; for this to be a power of 2 we need $p - 1$ to be a power of 2.

Notice that Corollary 30.3.5 gives a necessary condition, not a sufficient one – being of degree 2^m over $\mathbb{Q}$ does not obviously produce a chain of quadratic extensions. Remarkably, once we have the Galois correspondence we will be able to prove the converse in the cases of interest, and settle exactly which regular polygons are constructible. That is Gauss's theorem, which we will reach in Section 30.10.

§30.4 Splitting Fields and Normal Extensions

§30.4.1 Adjoining a Root

We now start manufacturing extensions. Let $f \in K[x]$ be irreducible. Then (f) is maximal, so

$$K_f := K[x]/(f)$$

is a field, and K_f/K is a field extension (identifying K with the constant polynomials). Write $\alpha = x + (f)$ for the image of x . If $d = \deg f$, then $1, \alpha, \dots, \alpha^{d-1}$ is a K -basis of K_f , and

$$f(\alpha) = f(x) + (f) = 0 \text{ in } K_f,$$

so α is a root of f in K_f and $K_f = K(\alpha)$. We say that K_f is obtained from K by **adjoining a root of f** .

This is a genuinely magical construction: it produces a root of f out of nothing, by fiat. The price is that the root we get is not canonical – and understanding exactly how non-canonical it is turns out to be the whole of Galois theory.

To speak precisely about this we need a notion of a map that respects the base field.

Definition 30.4.1 (K -homomorphism)

Let L/K and M/K be extensions of the same field K . A **K -homomorphism** is a field homomorphism $\phi : L \rightarrow M$ with $\phi(a) = a$ for all $a \in K$. We write $\text{Aut}(L/K)$ for the group of K -isomorphisms $L \rightarrow L$.

Recall that any homomorphism of fields is automatically injective, since its kernel is an ideal not containing 1, and the only such ideal is $\{0\}$. For instance complex conjugation $\mathbb{C} \rightarrow \mathbb{C}$ is an $\mathbb{R}$ -homomorphism but not a $\mathbb{C}$ -homomorphism.

The following observation, though it takes only a few lines to prove, is the technical heart of the first half of the course. We shall refer to it as the Key Lemma.

Lemma 30.4.2 (Key Lemma)

Let L/K be a field extension and let $f \in K[x]$ be irreducible. Then there is a bijection

$$\{K\text{-homomorphisms } \phi : K_f \rightarrow L\} \longleftrightarrow \{\tilde{\alpha} \in L : f(\tilde{\alpha}) = 0\},$$

given by $\phi \mapsto \phi(\alpha)$ where $\alpha = x + (f)$.

Proof. Giving a K -homomorphism $K[x]/(f) \rightarrow L$ is the same as giving a ring homomorphism $\psi : K[x] \rightarrow L$ with $\psi|_K = \text{id}$ and $\ker \psi \supseteq (f)$. Such a ψ is determined by $\psi(x)$, since $\psi(\sum r_i x^i) = \sum r_i \psi(x)^i$; conversely any choice of $\psi(x) \in L$ determines such a ψ . Note that this formula says exactly that $\psi(g) = g(\psi(x))$ for every $g \in K[x]$.

So $\ker \psi \supseteq (f)$ if and only if $\psi(f) = 0$, that is $f(\psi(x)) = 0$, that is $\psi(x)$ is a root of f in L . (And in that case $\ker \psi = (f)$, since (f) is maximal and $\ker \psi \neq K[x]$.) The bijection sends ϕ to $\phi(\alpha) = \psi(x)$, and distinct roots evidently give distinct homomorphisms. $\square$

In particular the number of K -homomorphisms $K_f \rightarrow L$ is finite and equal to the number of *distinct* roots of f in L , which is at most $\deg f$. The possibility that f has repeated roots is exactly what will later be ruled out by *separability*, and the possibility that f has no roots at all in L is exactly what will be ruled out by *normality*. Those two conditions together will define a Galois extension.

Corollary 30.4.3

Let L/K be an extension and let $\alpha, \beta \in L$ be algebraic over K . Then α and β have the same minimal polynomial over K if and only if there is a K -isomorphism $K(\alpha) \rightarrow K(\beta)$ with $\alpha \mapsto \beta$.

Proof. Let f be the minimal polynomial of α , so that we have a K -isomorphism $K_f \xrightarrow{\sim} K(\alpha)$ sending $x + (f) \mapsto \alpha$. If β has the same minimal polynomial then likewise $K_f \xrightarrow{\sim} K(\beta)$, and composing one with the inverse of the other gives the required K -isomorphism.

Conversely, if $\theta : K(\alpha) \rightarrow K(\beta)$ is a K -isomorphism with $\theta(\alpha) = \beta$, then applying θ to $f(\alpha) = 0$ gives $f(\beta) = 0$, so the minimal polynomial g of β divides f . Applying the same argument to θ^{-1} gives $f \mid g$, and both are monic, so $f = g$. $\square$

Example 30.4.4

Let $f(x) = x^3 - 2 \in \mathbb{Q}[x]$, which is irreducible by Eisenstein. Let $\alpha = \sqrt[3]{2}$ be the real cube root and $\omega = e^{2\pi i/3}$, so that the roots of f in $\mathbb{C}$ are $\alpha, \omega\alpha, \omega^2\alpha$. By the corollary there is a $\mathbb{Q}$ -isomorphism

$$\mathbb{Q}(\alpha) \xrightarrow{\sim} \mathbb{Q}(\omega\alpha), \quad \alpha \mapsto \omega\alpha,$$

even though $\mathbb{Q}(\alpha) \subseteq \mathbb{R}$ while $\mathbb{Q}(\omega\alpha) \not\subseteq \mathbb{R}$. This is not a contradiction: an isomorphism of fields sees only the internal algebraic structure, and knows nothing about how the fields happen to sit inside $\mathbb{C}$. In particular this isomorphism is wildly discontinuous.

§30.4.2 Splitting Fields

Adjoining one root of f need not produce all of them. The right object is the following.

Definition 30.4.5 (Splitting Field)

Let $f \in K[x]$ be non-constant. A **splitting field** for f over K is an extension L/K such that

- (i) f splits into linear factors in $L[x]$, say $f = c(x - \alpha_1) \cdots (x - \alpha_d)$; and
- (ii) $L = K(\alpha_1, \dots, \alpha_d)$.

Equivalently, (ii) says that f does not split in any proper subfield of L containing K .

Example 30.4.6

Take $K = \mathbb{Q}$.

- (i) $f = x^2 + 1 = (x + i)(x - i)$, so $\mathbb{Q}(i)$ is a splitting field for f .
- (ii) $f = x^3 - 2$. A splitting field is $\mathbb{Q}(\alpha, \omega\alpha) = \mathbb{Q}(\alpha, \omega)$, where $\alpha = \sqrt[3]{2}$ and $\omega = e^{2\pi i/3}$. Its degree is divisible by $[\mathbb{Q}(\alpha) : \mathbb{Q}] = 3$ and by $[\mathbb{Q}(\omega) : \mathbb{Q}] = 2$, hence by 6; and it is at most 6 since $\{1, \omega\}\{1, \alpha, \alpha^2\}$ spans. So $[\mathbb{Q}(\alpha, \omega) : \mathbb{Q}] = 6$. Note in particular that adjoining a *single* root of f gives only a degree 3 extension, which is therefore not a splitting field.
- (iii) The splitting field of any quadratic is obtained by adjoining a single root, since if $x^2 + bx + c = (x - \alpha)(x - \alpha')$ then $\alpha' = -b - \alpha$ lies in $K(\alpha)$ automatically.
- (iv) $f = \frac{x^p - 1}{x - 1}$ with $\omega = e^{2\pi i/p}$. The roots are $\omega, \omega^2, \dots, \omega^{p-1}$, all of which lie in $\mathbb{Q}(\omega)$, so $\mathbb{Q}(\omega)$ is a splitting field.

Theorem 30.4.7 (Existence of splitting fields)

Let K be a field and $f \in K[x]$ non-constant. Then a splitting field for f over K exists, and $[L : K] \leq (\deg f)!$.

Proof. We induct on $\deg f$, the statement being for all fields simultaneously. If $\deg f = 1$ then f is already linear and $L = K$ works. Otherwise let g be an irreducible factor of f and put $K_1 = K_g = K(\alpha)$, so that $g(\alpha) = 0$ and hence $f(\alpha) = 0$ in K_1 , with $[K_1 : K] = \deg g \leq \deg f$. Then in $K_1[x]$ we may write $f(x) = (x - \alpha)f_1(x)$ with $\deg f_1 = \deg f - 1$. By induction f_1 has a splitting field $L = K_1(\alpha_2, \dots, \alpha_d)$ over K_1 with $[L : K_1] \leq (\deg f - 1)!$. Then f splits in L as $(x - \alpha)(x - \alpha_2) \cdots (x - \alpha_d)$ (up to the leading coefficient), and $L = K(\alpha, \alpha_2, \dots, \alpha_d)$, so L is a splitting field for f over K . The degree bound follows from the tower law. $\square$

Uniqueness is more delicate, and more interesting. Splitting fields are unique up to isomorphism, but – crucially – *not up to a unique isomorphism*. Here is a very concrete illustration.

Example 30.4.8

Take $K = \mathbb{R}$ and let us build $\mathbb{C}$. On the one hand $f(x) = x^2 + 1$ gives $\mathbb{R}_f = \mathbb{R}[x]/(x^2 + 1)$, with a distinguished element i , the image of x . On the other hand $g(y) = y^2 + 2y + 2 = (y + 1 - i)(y + 1 + i)$ gives $\mathbb{R}_g = \mathbb{R}[y]/(y^2 + 2y + 2)$, with its own distinguished element, the image of y . There are two $\mathbb{R}$ -isomorphisms $\mathbb{R}_g \rightarrow \mathbb{R}_f$, given by $y \mapsto -1 + i$ and $y \mapsto -1 - i$, and there is absolutely no reason to prefer one over the other. The fields are isomorphic; the isomorphism is not canonical.

The following theorem does uniqueness and, at the same time, counts the isomorphisms – and it is that count which we will later turn into the order of the Galois group.

Theorem 30.4.9 (Uniqueness of splitting fields)

Let L be a splitting field for $f \in K[x]$ over K , and let $\phi : K \rightarrow M$ be a field homomorphism such that $\phi(f)$ splits into linear factors in $M[x]$. Then:

- (i) ϕ extends to a homomorphism $\bar{\phi} : L \rightarrow M$;
- (ii) the number of such extensions is at most $[L : K]$, with equality if f has no repeated roots in M ;
- (iii) if M is a splitting field for $\phi(f)$ over $\phi(K)$, then every such $\bar{\phi}$ is an isomorphism.

In particular any two splitting fields for f over K are K -isomorphic.

Proof. We induct on $[L : K]$. If $[L : K] = 1$ then $L = K$ and there is exactly one extension, namely ϕ itself, so (i) and (ii) hold.

Otherwise choose a root $\alpha \in L \setminus K$ of f , and let $g \in K[x]$ be the minimal polynomial of α over K , so that $g \mid f$ and $\deg g = [K(\alpha) : K] > 1$. Since $\phi(f)$ splits in M and $\phi(g) \mid \phi(f)$, the polynomial $\phi(g)$ also splits in M . By the Key Lemma applied to ϕ (that is, regarding M as an extension of $\phi(K) \cong K$), the extensions

of ϕ to $K(\alpha)$ correspond bijectively to the roots of $\phi(g)$ in M ; there are at most $\deg g = [K(\alpha) : K]$ of them, with equality if $\phi(g)$ has no repeated roots.

Now fix one such extension $\tilde{\phi} : K(\alpha) \rightarrow M$. Since L is a splitting field for f over $K(\alpha)$ as well, and $[L : K(\alpha)] < [L : K]$, the inductive hypothesis says that $\tilde{\phi}$ extends to $\bar{\phi} : L \rightarrow M$, in at most $[L : K(\alpha)]$ ways, with equality when there are no repeated roots. Multiplying up and using the tower law, the total number of extensions of ϕ to L is at most

$$[L : K(\alpha)] \cdot [K(\alpha) : K] = [L : K],$$

with equality when f has no repeated roots. This proves (i) and (ii).

For (iii), suppose M is a splitting field for $\phi(f)$, say $M = \phi(K)(\beta_1, \dots, \beta_d)$ where the β_j are the roots of $\phi(f)$. If $\alpha_1, \dots, \alpha_d$ are the roots of f in L , then $\bar{\phi}(\alpha_1), \dots, \bar{\phi}(\alpha_d)$ are roots of $\phi(f)$ in M , and they are distinct since $\bar{\phi}$ is injective; so they are exactly $\beta_1, \dots, \beta_d$. Since $L = K(\alpha_1, \dots, \alpha_d)$, the image $\bar{\phi}(L)$ contains $\phi(K)$ and all the β_j , hence is all of M . So $\bar{\phi}$ is surjective, and it is injective as it is a field homomorphism.

Finally, taking ϕ to be the inclusion $K \hookrightarrow M$ where M is another splitting field gives the last statement. $\square$

We record the count separately, since we will use it constantly.

Corollary 30.4.10

If L is a splitting field for f over K , then $\# \text{Aut}(L/K) \leq [L : K]$, with equality if f has no repeated roots in L .

Proof. Apply Theorem 30.4.9 with $M = L$ and ϕ the inclusion; every extension $\bar{\phi} : L \rightarrow L$ is an isomorphism by part (iii). $\square$

§30.4.3 Normal Extensions

Splitting fields are characterised by an intrinsic property, which does not mention any particular polynomial.

Definition 30.4.11 (Normal Extension)

An algebraic extension L/K is **normal** if for every $\alpha \in L$, the minimal polynomial of α over K splits into linear factors in $L[x]$.

In other words: if an irreducible polynomial over K has *one* root in L , it has *all* of them. For instance $\mathbb{Q}(\sqrt[3]{2})/\mathbb{Q}$ is not normal, since $x^3 - 2$ has one root in $\mathbb{Q}(\sqrt[3]{2}) \subseteq \mathbb{R}$ but its other two roots are not real. On the other hand any extension of degree 2 is normal, by the quadratic case above.

Theorem 30.4.12

Let L/K be a finite extension. Then L/K is normal if and only if L is a splitting field over K for some $f \in K[x]$.

Proof. Suppose L/K is normal. Since L/K is finite we may write $L = K(\alpha_1, \dots, \alpha_n)$. Let f_i be the minimal polynomial of α_i over K ; by normality each f_i splits in L . Then $f = f_1 \cdots f_n$ splits in L , and L is generated over K by some of its roots, hence by all of them. So L is a splitting field for f .

Conversely suppose L is a splitting field for $f \in K[x]$. Let $\alpha \in L$ with minimal polynomial g , and let $M \supseteq L$ be a splitting field for g over L ; take $\beta \in M$ a root of g . We must show $\beta \in L$.

By Corollary 30.4.3 there is a K -isomorphism $\theta : K(\alpha) \rightarrow K(\beta)$ with $\alpha \mapsto \beta$. Now L is a splitting field for f over $K(\alpha)$, and $L(\beta)$ is a splitting field for f over $K(\beta)$. Applying Theorem 30.4.9(iii) to θ , we get an isomorphism $L \rightarrow L(\beta)$, so

$$[L : K(\alpha)] = [L(\beta) : K(\beta)].$$

But $[K(\alpha) : K] = [K(\beta) : K] = \deg g$, so multiplying up gives $[L : K] = [L(\beta) : K]$, whence $[L(\beta) : L] = 1$ and $\beta \in L$. $\square$

Corollary 30.4.13 (Normal closure)

Let L/K be a finite extension. Then there is a finite extension N/L such that N/K is normal, and such that no proper intermediate field $L \subseteq N' \subsetneq N$ is normal over K . Moreover any two such N are L -isomorphic.

Proof. Write $L = K(\alpha_1, \dots, \alpha_n)$, let f_i be the minimal polynomial of α_i over K and set $f = f_1 \cdots f_n$. Let N be a splitting field for f over L . Since the α_i are among the roots of f , in fact N is a splitting field for f over K , so N/K is normal by Theorem 30.4.12.

If $L \subseteq N' \subseteq N$ with N'/K normal, then each $\alpha_i \in N'$, so each f_i splits in N' , so f splits in N' and hence $N' \supseteq N$ by minimality of splitting fields; that is $N' = N$. Uniqueness up to L -isomorphism is Theorem 30.4.9(iii). $\square$

We call N the **normal closure** of L/K ; it is the smallest normal extension of K containing L .

§30.5 Separability

The Key Lemma told us that K -homomorphisms out of $K(\alpha)$ correspond to the *distinct* roots of the minimal polynomial of α . If that polynomial has repeated roots we lose homomorphisms, and everything we are going to build will collapse. So we must understand when an irreducible polynomial can have a repeated root. Over $\mathbb{Q}$ or $\mathbb{R}$ or $\mathbb{C}$ this never happens, and it takes a little imagination to see how it could – but in characteristic p it genuinely does.

§30.5.1 The Derivative Criterion

The tool is differentiation, but of course we cannot take limits in an abstract field, so we define the derivative formally.

Definition 30.5.1 (Formal Derivative)

Let K be a field. The **formal derivative** is the K -linear map $\frac{d}{dx} : K[x] \rightarrow K[x]$ determined by $x^n \mapsto nx^{n-1}$; that is,

$$\left(\sum_i a_i x^i \right)' = \sum_{i \geq 1} i a_i x^{i-1}.$$

Proposition 30.5.2

For $f, g \in K[x]$ we have $(fg)' = f'g + fg'$ and $(f \circ g)' = (f' \circ g) \cdot g'$.

Proof. Both sides of each identity are additive in f (and in g , for the first), so by linearity it suffices to check them on monomials, where they are immediate from the binomial theorem. $\square$

Lemma 30.5.3

Let L/K be a field extension, $f \in K[x]$ and $\alpha \in L$ with $f(\alpha) = 0$. Then α is a simple root of f (that is, $(x - \alpha)^2 \nmid f$ in $L[x]$) if and only if $f'(\alpha) \neq 0$.

Proof. Write $f(x) = (x - \alpha)g(x)$ in $L[x]$. Then $f'(x) = g(x) + (x - \alpha)g'(x)$, so $f'(\alpha) = g(\alpha)$. Now α is a repeated root exactly when $(x - \alpha) \mid g$, that is $g(\alpha) = 0$. $\square$

Corollary 30.5.4

A polynomial $f \in K[x]$ has a repeated root in some extension of K if and only if $\deg \gcd(f, f') > 0$.

Proof. Work in a splitting field L for f . If α is a repeated root then $(x - \alpha)$ divides both f and f' by the lemma, so $\gcd(f, f') \neq 1$. (Note that the gcd may be computed in $K[x]$ or in $L[x]$ with the same answer; see Lemma 30.5.5 below.) Conversely if $\gcd(f, f')$ has positive degree then it has a root α in L , and then $f(\alpha) = f'(\alpha) = 0$, so α is a repeated root of f . $\square$

We should check the claim about the gcd, since it is used repeatedly and is a nice illustration of the power of Bézout.

Lemma 30.5.5

Let L/K be a field extension and $f, g \in K[x]$, not both zero. Then $\gcd(f, g)$ is the same whether computed in $K[x]$ or in $L[x]$. Consequently the same is true of $\text{lcm}(f, g) = fg/\gcd(f, g)$.

Proof. Let $h = \gcd_K(f, g)$ and $h' = \gcd_L(f, g)$, both taken monic. Since $h \mid f$ and $h \mid g$ in $K[x]$, the same divisibilities hold in $L[x]$, so $h \mid h'$. Conversely, by Bézout we may write $h = pf + qg$ with $p, q \in K[x]$; since $h' \mid f$ and $h' \mid g$ in $L[x]$, we get $h' \mid h$. As both are monic, $h = h'$. $\square$

§30.5.2 Separable Polynomials and Perfect Fields

Definition 30.5.6 (Separable Polynomial)

A non-constant polynomial $f \in K[x]$ is **separable** if it has no repeated roots in a splitting field, that is, if it splits into *distinct* linear factors there. Otherwise it is **inseparable**.

Equivalently, by Corollary 30.5.4, f is separable if and only if $\gcd(f, f') = 1$. Note that this does not depend on the choice of splitting field, by uniqueness.

Proposition 30.5.7

Let $f \in K[x]$ be irreducible.

- (i) f is separable if and only if $f' \neq 0$.
- (ii) If $\text{char } K = 0$, then f is separable. Indeed every irreducible polynomial over a field of characteristic zero is separable.
- (iii) If $\text{char } K = p$, then f is inseparable if and only if $f(x) = g(x^p)$ for some $g \in K[x]$.

Proof. (i) We may take f monic. As f is irreducible, $\gcd(f, f')$ is 1 or f , since it divides f . If $f' = 0$ then $\gcd(f, f') = f$, which has positive degree, so f is inseparable. If $f' \neq 0$ then $\deg f' < \deg f$, so $\gcd(f, f') \neq f$ and hence equals 1, so f is separable.

(ii) Write $f = \sum a_i x^i$ with $\deg f = d \geq 1$. If $f' = 0$ then $ia_i = 0$ for all $i \geq 1$; in characteristic zero this forces $a_i = 0$ for all $i \geq 1$, so f is constant, contradicting irreducibility. So $f' \neq 0$ and we are done by (i).

(iii) As above $f' = 0$ if and only if $ia_i = 0$ for all $i \geq 1$, which in characteristic p says precisely that $a_i = 0$ whenever $p \nmid i$. That is exactly the statement that $f(x) = \sum_j a_{pj} x^{pj} = g(x^p)$ with $g(x) = \sum_j a_{pj} x^j$. $\square$

So inseparability is a characteristic p phenomenon, and even there it takes some work to produce. The reason is the following remarkable map.

Proposition 30.5.8 (Frobenius)

Let R be a ring with $\text{char } R = p$ prime. Then

$$\text{Frob} : R \rightarrow R, \quad x \mapsto x^p$$

is a ring homomorphism, called the **Frobenius map**.

Proof. Clearly $\text{Frob}(1) = 1$ and $\text{Frob}(xy) = \text{Frob}(x)\text{Frob}(y)$. For addition, the binomial theorem gives

$$(x + y)^p = x^p + \binom{p}{1} x^{p-1} y + \cdots + \binom{p}{p-1} x y^{p-1} + y^p,$$

and $p \mid \binom{p}{i}$ for $1 \leq i \leq p-1$ (the numerator $p!$ contains a factor p which is not cancelled by $i!(p-i)!$), so all the middle terms vanish. $\square$

In particular, if K is a field of characteristic p then $\text{Frob} : K \rightarrow K$ is injective, so it is an automorphism as soon as K is finite. Fields where it is surjective are exactly the ones with no inseparability.

Definition 30.5.9 (Perfect Field)

A field K is **perfect** if $\text{char } K = 0$, or if $\text{char } K = p$ and every element of K is a p th power.

Proposition 30.5.10

K is perfect if and only if every irreducible polynomial in $K[x]$ is separable. In particular every finite field is perfect, and so is every field of characteristic zero.

Proof. Characteristic zero is Proposition 30.5.7(ii), so suppose $\text{char } K = p$.

Suppose K is perfect and $f \in K[x]$ is irreducible but inseparable. By Proposition 30.5.7(iii), $f(x) = \sum_j a_j x^{pj}$. Write $a_j = b_j^p$, possible by perfection. Then

$$f(x) = \sum_j b_j^p x^{pj} = \left(\sum_j b_j x^j \right)^p$$

by the Frobenius homomorphism applied in $K[x]$, contradicting irreducibility.

Conversely, suppose $b \in K$ is not a p th power, and consider $f(x) = x^p - b$. Let α be a root of f in a splitting field, so $\alpha^p = b$ and

$$x^p - b = x^p - \alpha^p = (x - \alpha)^p,$$

using Frobenius again. So f is very far from separable. It remains to see that f is irreducible. If not, then some monic factor $(x - \alpha)^m$ with $0 < m < p$ lies in $K[x]$; expanding, its coefficient of x^{m-1} is $-m\alpha \in K$, and $m \neq 0$ in K , so $\alpha \in K$ and hence $b = \alpha^p$ is a p th power, a contradiction.

Finally, a finite field K of characteristic p is perfect because Frob is an injective map from the finite set K to itself, hence surjective. $\square$

Example 30.5.11

The smallest imperfect field is $K = \mathbb{F}_p(t)$, the field of rational functions over $\mathbb{F}_p$. Here t is not a p th power in K (a p th power in $\mathbb{F}_p(t)$ is a ratio of polynomials in t^p), so $x^p - t$ is irreducible and inseparable, and

$$\mathbb{F}_p(t^{1/p})/\mathbb{F}_p(t)$$

is a degree p extension in which the minimal polynomial of the generator has a single root of multiplicity p . This is a genuinely strange extension: by the Key Lemma there is exactly one K -homomorphism $K(t^{1/p}) \rightarrow K(t^{1/p})$, namely the identity, even

though the extension has degree p .

§30.5.3 Separable Extensions and the Separable Degree

Definition 30.5.12 (Separable Element and Extension)

Let L/K be an extension and $\alpha \in L$ algebraic over K . We say α is **separable** over K if its minimal polynomial over K is separable. An algebraic extension L/K is **separable** if every $\alpha \in L$ is separable over K .

So by Proposition 30.5.10, every algebraic extension of a perfect field – in particular of $\mathbb{Q}$, of $\mathbb{C}$, or of any finite field – is separable. The reader who is content to work in characteristic zero may safely read ‘separable’ as ‘no condition at all’.

The right way to organise the theory is to count homomorphisms.

Definition 30.5.13 (Separable Degree)

Let L/K be a finite extension and let N be a normal extension of K containing L (for instance a normal closure). The **separable degree** $[L : K]_s$ is the number of K -homomorphisms $L \rightarrow N$.

Proposition 30.5.14

With notation as above:

- (i) $[L : K]_s$ does not depend on the choice of N ;
- (ii) $[K(\alpha) : K]_s$ is the number of distinct roots of the minimal polynomial of α over K , and so $[K(\alpha) : K]_s = [K(\alpha) : K]$ if and only if α is separable over K ;
- (iii) $[L : K]_s \leq [L : K]$;
- (iv) if $M/L/K$ are finite extensions then $[M : K]_s = [M : L]_s [L : K]_s$.

Proof. (ii) is the Key Lemma 30.4.2, once we note that the minimal polynomial of α splits in N by normality.

For (iv), let N be normal over K containing M . Each K -homomorphism $\sigma : L \rightarrow N$ has image in N , and N is normal over $\sigma(L)$ too, so by Theorem 30.4.9(i) (applied to M , which is generated over L by finitely many algebraic elements, so is contained in a splitting field over L) each σ extends to M . The number of extensions of a given σ is $[M : L]_s$: transporting along the isomorphism $L \cong \sigma(L)$, this is the number of $\sigma(L)$ -homomorphisms $\sigma(M) \rightarrow N$. Since every K -homomorphism $M \rightarrow N$ restricts to some σ on L , the count is $[M : L]_s [L : K]_s$.

Now (iii) follows by writing $L = K(\alpha_1, \dots, \alpha_n)$, applying (iv) repeatedly, and using (ii) together with the fact that the number of distinct roots of a polynomial is at most its degree.

Finally (i): the count in (ii) does not depend on N , and the multiplicativity in (iv) then determines $[L : K]_s$ from a chain of simple extensions. $\square$

Theorem 30.5.15

A finite extension L/K is separable if and only if $[L : K]_s = [L : K]$.

Proof. Suppose $[L : K]_s = [L : K]$ and let $\alpha \in L$. By multiplicativity,

$$[L : K(\alpha)]_s [K(\alpha) : K]_s = [L : K(\alpha)] [K(\alpha) : K],$$

and each separable degree is at most the corresponding degree, so we must have equality in each; in particular $[K(\alpha) : K]_s = [K(\alpha) : K]$, so α is separable by Proposition 30.5.14(ii).

Conversely suppose L/K is separable and write $L = K(\alpha_1, \dots, \alpha_n)$. Set $K_i = K(\alpha_1, \dots, \alpha_i)$. Each α_i is separable over K , so its minimal polynomial over K is separable; the minimal polynomial over K_{i-1} divides it, so is separable too. Hence $[K_i : K_{i-1}]_s = [K_i : K_{i-1}]$ for each i , and multiplying up gives the result. $\square$

Corollary 30.5.16 (i) If α is separable over K then $K(\alpha)/K$ is a separable extension.

(ii) If M/L and L/K are finite separable extensions then so is M/K .

(iii) If L/K is finite and $L = K(\alpha_1, \dots, \alpha_n)$ with each α_i separable over K , then L/K is separable.

Proof. All three are immediate from Theorem 30.5.15 and the multiplicativity of both the degree and the separable degree; for (i) and (iii) use the argument in the second paragraph of that proof. $\square$

One further small lemma will be needed when we assemble separable polynomials.

Lemma 30.5.17

The lowest common multiple of finitely many separable polynomials is separable.

Proof. By Lemma 30.5.5 we may compute the lcm in any extension we like, so pass to a field in which all the polynomials split. There each is a product of distinct linear factors, and the lcm is the product of the distinct linear factors occurring in any of them, which is again separable. $\square$

§30.5.4 The Primitive Element Theorem

We now come to a genuinely useful structural theorem: a finite separable extension is always generated by a *single* element. This is not at all obvious, and the proof is a pretty piece of trickery.

Theorem 30.5.18 (Primitive Element Theorem)

Let $L = K(\alpha_1, \dots, \alpha_n, \beta)$ be a finite extension of K in which $\alpha_1, \dots, \alpha_n$ are separable over K (and β is arbitrary). Then $L = K(\gamma)$ for some $\gamma \in L$. Such a γ is called a

primitive element.

Proof. First suppose K is finite. Then L is finite too, so $L^\times$ is a cyclic group (Proposition 30.6.1 below, whose proof does not use this theorem), and taking γ to be a generator gives $L = K(\gamma)$ immediately.

So suppose K is infinite. By induction on n it suffices to treat the case $L = K(\alpha, \beta)$ with α separable over K ; indeed, once we know $K(\alpha_1, \beta) = K(\beta_1)$ for some β_1 , we may write $K(\alpha_1, \alpha_2, \beta) = K(\alpha_2, \beta_1)$ and continue.

We shall show that for all but finitely many $c \in K$, the element $\gamma = \beta + c\alpha$ generates L . It is enough to show $\alpha \in K(\gamma)$, since then $\beta = \gamma - c\alpha \in K(\gamma)$ as well and so $K(\gamma) = L$.

Let $f, g \in K[x]$ be the minimal polynomials of α, β respectively, and let M be a splitting field for fg over L , in which

$$f(x) = (x - \alpha_1) \cdots (x - \alpha_m), \quad g(x) = (x - \beta_1) \cdots (x - \beta_k),$$

with $\alpha = \alpha_1$ and $\beta = \beta_1$. Since α is separable, the α_i are distinct.

Now consider

$$h(x) = g(\gamma - cx) \in K(\gamma)[x].$$

We have $h(\alpha) = g(\gamma - c\alpha) = g(\beta) = 0$, and also $f(\alpha) = 0$, so $(x - \alpha)$ divides $\gcd(f, h)$ in $M[x]$. Suppose we can arrange that

$$\gcd(f, h) = x - \alpha.$$

By Lemma 30.5.5 this gcd may be computed in $K(\gamma)[x]$, so $x - \alpha \in K(\gamma)[x]$ and hence $\alpha \in K(\gamma)$, as required.

So we need $h(\alpha_i) \neq 0$ for $i = 2, \dots, m$. Now $h(\alpha_i) = 0$ if and only if $\gamma - c\alpha_i = \beta_j$ for some j , that is, since $\gamma = \beta + c\alpha$,

$$\beta_j - \beta = c(\alpha_i - \alpha).$$

As $\alpha_i \neq \alpha$ for $i \geq 2$, this says

$$c = \frac{\beta_j - \beta}{\alpha_i - \alpha}$$

for some $i \geq 2$ and some j . There are only finitely many such values, and K is infinite, so we may choose $c \in K$ avoiding them all. $\square$

Corollary 30.5.19

Every finite separable extension is simple. In particular, if $\text{char } K = 0$ and L/K is finite then $L = K(\gamma)$ for some γ .

Example 30.5.20

Take $K = \mathbb{Q}(i, \sqrt[3]{2})$, so $[K : \mathbb{Q}] = 6$. In the notation of the proof, $\beta_1 = i$, $\beta_2 = -i$, and $\alpha_1 = \sqrt[3]{2}$, $\alpha_2 = \omega\sqrt[3]{2}$, $\alpha_3 = \omega^2\sqrt[3]{2}$ where $\omega = e^{2\pi i/3}$. The bad values of c are the

numbers

$$\frac{\pm i - i}{\sqrt[3]{2}(\omega^{\pm 1} - 1)},$$

none of which is a non-zero rational. So $K = \mathbb{Q}(i + c\sqrt[3]{2})$ for *every* non-zero rational c . As one would expect, most elements of K generate it; for instance $i\sqrt[3]{2}$ works too.

Example 30.5.21

Separability really is needed. Let $K = \mathbb{F}_p(x, y)$ and $L = K(x^{1/p}, y^{1/p})$, so $[L : K] = p^2$. We claim that L is not simple. Indeed, if $\gamma \in L$ then we may write $\gamma = \sum_{i,j} a_{ij} x^{i/p} y^{j/p}$ with $a_{ij} \in K$ and $0 \leq i, j < p$, and applying Frobenius,

$$\gamma^p = \sum_{i,j} a_{ij}^p x^i y^j \in K.$$

So γ satisfies $t^p - \gamma^p \in K[t]$, whence $[K(\gamma) : K] \leq p < p^2 = [L : K]$, and $K(\gamma) \neq L$.

§30.6 Finite Fields

We already know that a finite field has p^n elements for some prime p and $n \geq 1$. In this section we prove the converse – for each such $q = p^n$ there is exactly one field with q elements – and work out its subfields. Everything hinges on one polynomial, $x^q - x$.

§30.6.1 The Multiplicative Group

Proposition 30.6.1

Let K be a field and let $G \leq K^\times$ be a finite subgroup. Then G is cyclic.

Proof. G is a finite abelian group, so by the structure theorem

$$G \cong \mathbb{Z}/m_1 \times \mathbb{Z}/m_2 \times \cdots \times \mathbb{Z}/m_r$$

with $m_1 \mid m_2 \mid \cdots \mid m_r$, and $\#G = m_1 m_2 \cdots m_r$. Every element of each factor is killed by m_r , so every $\alpha \in G$ satisfies $\alpha^{m_r} = 1$, that is, every element of G is a root of $x^{m_r} - 1$. But a polynomial of degree m_r over a field has at most m_r roots, so

$$m_1 m_2 \cdots m_r = \#G \leq m_r,$$

forcing $m_1 = \cdots = m_{r-1} = 1$. Hence $G \cong \mathbb{Z}/m_r$ is cyclic. $\square$

Example 30.6.2

$\mathbb{F}_7^\times = \langle 3 \rangle$, since the powers of 3 are 3, 2, 6, 4, 5, 1. Note that there is no canonical generator, and correspondingly no canonical isomorphism $\mathbb{F}_q^\times \cong \mathbb{Z}/(q-1)$; finding a generator (a ‘primitive root’) for a given p is, as you saw in Number Theory, a genuinely awkward computational problem.

Lemma 30.6.3 (Fermat's Little Theorem)

Let K be a finite field with $\#K = q$. Then every $\alpha \in K$ satisfies $\alpha^q = \alpha$. Consequently

$$x^q - x = \prod_{\alpha \in K} (x - \alpha)$$

in $K[x]$; in particular $x^q - x$ splits into distinct linear factors over K .

Proof. This is clear for $\alpha = 0$. Otherwise $\alpha \in K^\times$, a group of order $q - 1$, so $\alpha^{q-1} = 1$ by Lagrange, and hence $\alpha^q = \alpha$. So every one of the q elements of K is a root of the degree q polynomial $x^q - x$, which therefore factors as claimed. $\square$

So a finite field K with q elements is precisely a splitting field for $x^q - x$ over $\mathbb{F}_p$: it contains all q roots, and is generated by them since they are everything. That immediately gives uniqueness, by uniqueness of splitting fields. For existence we must construct the splitting field of $x^q - x$ and check it has the right size – which is where separability earns its keep.

§30.6.2 Existence, Uniqueness and Subfields**Theorem 30.6.4** (Classification of finite fields)

Let p be prime, $n \geq 1$ and $q = p^n$. Then:

- (i) there exists a field $\mathbb{F}_q$ with exactly q elements, namely the splitting field of $x^q - x$ over $\mathbb{F}_p$;
- (ii) any two fields with q elements are isomorphic;
- (iii) $\mathbb{F}_q$ contains a subfield with p^k elements if and only if $k \mid n$, and then that subfield is unique.

Proof. (i) Let K be a splitting field for $f(x) = x^q - x$ over $\mathbb{F}_p$, and let

$$S = \{\alpha \in K : \alpha^q = \alpha\}$$

be the set of roots. We claim S is a subfield. Indeed the map $\alpha \mapsto \alpha^q$ is the n -fold composite Frob^n of the Frobenius homomorphism, hence is itself a ring homomorphism, and S is exactly the set where it agrees with the identity; so S is closed under $+$, $-$, $\times$, contains 0 and 1, and is closed under inverses since $(\alpha^{-1})^q = (\alpha^q)^{-1} = \alpha^{-1}$. Since K is generated over $\mathbb{F}_p$ by S , and S is a field, $K = S$.

It remains to check that $\#S = q$. Now $f'(x) = qx^{q-1} - 1 = -1$, because $q = p^n = 0$ in characteristic p . So $\gcd(f, f') = 1$ and f is separable, hence has exactly q distinct roots in K . So $\#K = \#S = q$.

(ii) If $\#K = q$ then by Lemma 30.6.3 K is a splitting field for $x^q - x$ over its prime subfield $\mathbb{F}_p$, so any two such are isomorphic by Theorem 30.4.9.

(iii) If $K \subseteq \mathbb{F}_q$ is a subfield with p^k elements, then $[\mathbb{F}_q : \mathbb{F}_p] = [\mathbb{F}_q : K][K : \mathbb{F}_p]$ gives $k \mid n$.

Conversely suppose $k \mid n$, say $n = k\ell$. We claim $x^{p^k} - x$ divides $x^{p^n} - x$. First, for

integers $a, b \geq 1$ with $a \mid b$ we have $y^a - 1 \mid y^b - 1$, since $y^a - 1$ divides $(y^a)^{b/a} - 1$ by the factorisation $z^m - 1 = (z - 1)(z^{m-1} + \cdots + 1)$. Applying this with $y = p$, $a = k$, $b = n$ gives $p^k - 1 \mid p^n - 1$; applying it again with $y = x$ gives $x^{p^k-1} - 1 \mid x^{p^n-1} - 1$, and multiplying by x gives the claim.

Hence every root of $x^{p^k} - x$ lies in $\mathbb{F}_q$, and $\{\alpha \in \mathbb{F}_q : \alpha^{p^k} = \alpha\}$ is a subfield with exactly p^k elements by the argument in (i). It is unique, since any subfield of order p^k consists of roots of $x^{p^k} - x$, of which there are only p^k in total. $\square$

The subfield structure is therefore a perfect copy of the divisibility lattice of n . Here it is for $n = 12$.

Note that $\mathbb{F}_{p^4}$ and $\mathbb{F}_{p^6}$ are incomparable, as $4 \nmid 6$ and $6 \nmid 4$; and their intersection is $\mathbb{F}_{p^2}$, matching $\gcd(4, 6) = 2$.

Example 30.6.5

Let us do the two smallest interesting cases explicitly, over $\mathbb{F}_2$.

- $q = 4$: $x^4 - x = x(x-1)(x^2 + x + 1)$, and $x^2 + x + 1$ is irreducible over $\mathbb{F}_2$ (it has no root in $\mathbb{F}_2$), so

$$\mathbb{F}_4 = \mathbb{F}_2[x]/(x^2 + x + 1).$$

- $q = 8$: over $\mathbb{F}_2$ we have

$$x^8 - x = x(x+1)(x^3 + x + 1)(x^3 + x^2 + 1),$$

and the two cubics are precisely the irreducible cubics over $\mathbb{F}_2$. So the six elements of $\mathbb{F}_8 \setminus \mathbb{F}_2$ split into two classes of three, according to which cubic they satisfy. Taking β with $\beta^3 = \beta + 1$, we get $\mathbb{F}_8 = \mathbb{F}_2(\beta)$ with basis $1, \beta, \beta^2$.

Note that $[\mathbb{F}_8 : \mathbb{F}_2] = 3$ and $[\mathbb{F}_4 : \mathbb{F}_2] = 2$, and $2 \nmid 3$, so $\mathbb{F}_4 \not\subseteq \mathbb{F}_8$ – despite $4 < 8$.

§30.6.3 Irreducible Polynomials over $\mathbb{F}_p$

The same divisibility yields a clean description of the irreducible polynomials over a finite field.

Proposition 30.6.6

Let $f \in \mathbb{F}_p[x]$ be monic irreducible of degree d , and let $q = p^n$. Then

$$f \mid x^q - x \iff d \mid n.$$

Consequently $x^{p^n} - x$ is the product of all monic irreducible polynomials in $\mathbb{F}_p[x]$ whose degree divides n , each occurring exactly once.

Proof. Let $K = \mathbb{F}_p[x]/(f) = \mathbb{F}_p(\alpha)$, a field with p^d elements. If $d \mid n$ then K embeds in $\mathbb{F}_q$ by Theorem 30.6.4(iii), so $\alpha \in \mathbb{F}_q$ satisfies $\alpha^q = \alpha$, and f , being the minimal polynomial of α , divides $x^q - x$.

Conversely if $f \mid x^q - x$ then α is a root of $x^q - x$ in some extension, so $\mathbb{F}_p(\alpha)$ is contained in a field with q elements, and $d = [\mathbb{F}_p(\alpha) : \mathbb{F}_p]$ divides n .

For the last statement, $x^q - x$ is separable so has no repeated factors, and every monic irreducible factor has degree dividing n by the above; conversely every monic irreducible of degree dividing n divides it. $\square$

Counting degrees in the last statement gives the pretty identity

$$p^n = \sum_{d \mid n} d \cdot N_d,$$

where N_d is the number of monic irreducible polynomials of degree d over $\mathbb{F}_p$; Möbius inversion then gives $N_n = \frac{1}{n} \sum_{d \mid n} \mu(n/d) p^d$, which is positive for all n . In particular irreducible polynomials of every degree exist over $\mathbb{F}_p$ – though notice how much easier it was to construct $\mathbb{F}_q$ as a splitting field than to write down an irreducible polynomial of degree n by hand.

§30.7 Algebraic Closure

We have been rather carefully constructing splitting fields one polynomial at a time. It is natural to ask for a single field in which *every* polynomial splits.

Definition 30.7.1 (Algebraically Closed)

A field K is **algebraically closed** if every non-constant $f \in K[x]$ has a root in K (and hence, by induction, splits into linear factors in $K[x]$). An **algebraic closure** of K is an algebraic extension $\overline{K}/K$ with $\overline{K}$ algebraically closed.

Lemma 30.7.2

For a field K the following are equivalent:

- (i) K is algebraically closed;
- (ii) whenever L/K is an extension and $\alpha \in L$ is algebraic over K , we have $\alpha \in K$;
- (iii) the only algebraic extension of K is K itself.

Proof. (i) $\Rightarrow$ (ii): the minimal polynomial of α is irreducible over K , but every irreducible polynomial over an algebraically closed field is linear, so $\alpha \in K$. (ii) $\Rightarrow$ (iii) is immediate, and (iii) $\Rightarrow$ (i) follows since for non-constant f the extension K_g/K is algebraic, where g is an irreducible factor of f , so $K_g = K$ and g is linear. $\square$

Two examples we know: $\mathbb{C}$ is algebraically closed (we will prove this in Section 30.14 using Galois theory), and hence so is $\overline{\mathbb{Q}} = \{\alpha \in \mathbb{C} : \alpha \text{ algebraic over } \mathbb{Q}\}$, which is therefore an algebraic closure of $\mathbb{Q}$. Here is a more hands-on construction.

Example 30.7.3 (An algebraic closure of $\mathbb{F}_p$)

Choose integers $r_1 \mid r_2 \mid r_3 \mid \cdots$ such that every $n \in \mathbb{N}$ divides some r_i – for instance $r_i = i!$. By Theorem 30.6.4 we may choose embeddings

$$\mathbb{F}_{p^{r_1}} \hookrightarrow \mathbb{F}_{p^{r_2}} \hookrightarrow \mathbb{F}_{p^{r_3}} \hookrightarrow \cdots$$

and set $\overline{\mathbb{F}}_p = \bigcup_i \mathbb{F}_{p^{r_i}}$, which is a field since the union is increasing. It is algebraic over $\mathbb{F}_p$ since each $\mathbb{F}_{p^{r_i}}$ is finite over $\mathbb{F}_p$.

It is algebraically closed: given non-constant $f \in \overline{\mathbb{F}}_p[x]$, its finitely many coefficients all lie in some $\mathbb{F}_{p^{r_i}}$, and a splitting field for f over $\mathbb{F}_{p^{r_i}}$ is a finite field $\mathbb{F}_{p^N}$ with $r_i \mid N$. Choosing j with $N \mid r_j$, we may embed $\mathbb{F}_{p^N}$ into $\mathbb{F}_{p^{r_j}} \subseteq \overline{\mathbb{F}}_p$ over $\mathbb{F}_{p^{r_i}}$, so f splits in $\overline{\mathbb{F}}_p$.

The general case works the same way, but the induction has to be transfinite.

Theorem 30.7.4

Every field K has an algebraic closure $\overline{K}$. Moreover if L_1, L_2 are two algebraic closures of K then there is a K -isomorphism $L_1 \rightarrow L_2$, though it is very far from unique.

Proof sketch. One way to organise the construction is as follows. Consider the polynomial ring $R = K[x_f : f \in K[x] \text{ monic irreducible}]$ in one indeterminate for each monic irreducible polynomial, and let $I \leq R$ be the ideal generated by all $f(x_f)$. One checks that $I \neq R$ (a relation $\sum g_i f_i(x_{f_i}) = 1$ involves finitely many f_i , and evaluating in a splitting field for $\prod f_i$ gives $1 = 0$), so by Zorn's lemma I is contained in a maximal ideal $\mathfrak{m}$, and $K_1 = R/\mathfrak{m}$ is a field in which every monic irreducible polynomial over K acquires a root. Iterating gives a chain $K \subseteq K_1 \subseteq K_2 \subseteq \cdots$, and the union is algebraically closed; the subfield of elements algebraic over K is then an algebraic closure.

For uniqueness, consider the set of pairs (M, ϕ) where $K \subseteq M \subseteq L_1$ and $\phi : M \rightarrow L_2$ is a K -homomorphism, partially ordered by extension. Every chain has an upper bound (take the union), so by Zorn's lemma there is a maximal element (M, ϕ) . If $M \neq L_1$, pick $\alpha \in L_1 \setminus M$; its minimal polynomial over M has a root in L_2 since L_2 is algebraically closed, so by the Key Lemma ϕ extends to $M(\alpha)$, contradicting maximality. So $M = L_1$, and $\phi(L_1)$ is algebraically closed and L_2 is algebraic over it, so $\phi(L_1) = L_2$. $\square$

We will not use the general existence theorem in what follows; for us ‘a field in which f

splits' is always enough, and that we constructed by hand.

§30.8 The Galois Correspondence

Everything so far has concerned a single element α and the maps out of $K(\alpha)$ determined by the roots of its minimal polynomial. We now ask what happens when we look at all the roots at once, and how they interact. The answer is the Galois correspondence, and it is the heart of the course.

§30.8.1 Automorphism Groups

Recall that for an extension L/K we write

$$\text{Aut}(L/K) = \{\sigma : L \rightarrow L \mid \sigma \text{ is a field isomorphism with } \sigma|_K = \text{id}\},$$

which is a group under composition. It measures precisely the failure of uniqueness in our isomorphism theorems: if $\phi : M \rightarrow L$ is a K -isomorphism and $\sigma \in \text{Aut}(L/K)$, then $\sigma\phi$ is another one; and conversely if $\phi_1, \phi_2 : M \rightarrow L$ are K -isomorphisms then $\phi_1\phi_2^{-1} \in \text{Aut}(L/K)$, and it is non-trivial exactly when $\phi_1 \neq \phi_2$.

Lemma 30.8.1

Let L/K be an extension and $\sigma \in \text{Aut}(L/K)$.

- (i) If $f \in K[x]$ and $\alpha \in L$ with $f(\alpha) = 0$, then $f(\sigma\alpha) = 0$. So σ permutes the roots in L of any polynomial over K .
- (ii) If $L = K(\alpha_1, \dots, \alpha_n)$ and $\sigma\alpha_i = \alpha_i$ for all i , then $\sigma = \text{id}$.
- (iii) If L is a splitting field over K for a polynomial f with roots $\alpha_1, \dots, \alpha_n$, then restriction to $\{\alpha_1, \dots, \alpha_n\}$ gives an injective homomorphism $\text{Aut}(L/K) \hookrightarrow S_n$.

Proof. (i) Applying σ to $\sum a_i \alpha^i = 0$ and using $\sigma(a_i) = a_i$ gives $\sum a_i (\sigma\alpha)^i = 0$.

(ii) The set of elements fixed by σ is a subfield containing K and all the α_i , hence is L .

(iii) By (i) each σ permutes the roots, giving a homomorphism to S_n ; by (ii) it is injective since $L = K(\alpha_1, \dots, \alpha_n)$. $\square$

Part (iii) is worth dwelling on, because it is exactly Galois' original point of view: the Galois group of a polynomial is a group of *permutations of its roots*, and in particular is a rather small and concrete object. Let us compute a few.

Example 30.8.2 (i) Let $[L : K] = 2$ with $\text{char } K \neq 2$, so $L = K(\alpha)$ for any $\alpha \in L \setminus K$, with minimal polynomial $f(x) = x^2 + bx + c = (x - \alpha)(x - \alpha')$ in a splitting field. Since $\alpha + \alpha' = -b \in K$, in fact $\alpha' = -b - \alpha \in L$, so L is already a splitting field for f . By the Key Lemma there is a K -homomorphism $\sigma : L \rightarrow L$ with $\alpha \mapsto \alpha'$, which is an isomorphism, and $\sigma \neq \text{id}$ unless $\alpha = \alpha'$, that is $2\alpha = -b$, that is $\alpha = -b/2 \in K$, which is false. So

$$\text{Aut}(L/K) \cong \mathbb{Z}/2.$$

This covers $\text{Aut}(\mathbb{C}/\mathbb{R})$, $\text{Aut}(\mathbb{Q}(i)/\mathbb{Q})$ and $\text{Aut}(\mathbb{Q}(\sqrt{2})/\mathbb{Q})$. It is worth a warning: $\mathbb{Q}(\sqrt{2}) \subseteq \mathbb{R}$, but the non-trivial automorphism $\sqrt{2} \mapsto -\sqrt{2}$ is wildly discontinuous for the topology induced from $\mathbb{R}$. We are looking at fields as algebraic objects only.

- (ii) Let $L = \mathbb{Q}(\sqrt[3]{2})$. The minimal polynomial of $\alpha = \sqrt[3]{2}$ is $x^3 - 2$, whose other roots $\omega\alpha, \omega^2\alpha$ are not real and hence not in L . So by the Key Lemma the only $\mathbb{Q}$ -homomorphism $L \rightarrow L$ is the identity, and

$$\text{Aut}(L/\mathbb{Q}) = 1,$$

even though $[L : \mathbb{Q}] = 3$. This is the failure of *normality*.

- (iii) If $\text{char } K = p$ and $L = K(t^{1/p})$ with $t \in K$ not a p th power, then again $\text{Aut}(L/K) = 1$ while $[L : K] = p$. This is the failure of *separability*.

- (iv) Let $L = K(x)$. Then $\text{Aut}(L/K) \cong \text{PGL}_2(K)$, acting by Möbius substitutions $x \mapsto \frac{ax+b}{cx+d}$. (A pleasant exercise.)

Example 30.8.3 (Biquadratic extensions)

Suppose $\text{char } K \neq 2$ and $[L : K] = 4$ with $L = K(\alpha, \beta)$, $\alpha^2 = a \in K$, $\beta^2 = b \in K$. Since $L \supseteq K(\alpha)$ and $\beta \notin K(\alpha)$, there is a unique $K(\alpha)$ -automorphism σ_β of L with $\beta \mapsto -\beta$, and similarly σ_α . These commute, both square to the identity, and neither is trivial, so

$$\mathbb{Z}/2 \times \mathbb{Z}/2 \leq \text{Aut}(L/K).$$

Conversely any K -automorphism must send $\alpha \mapsto \pm\alpha$ and $\beta \mapsto \pm\beta$, and is determined by those choices, so

$$\text{Aut}(L/K) \cong \mathbb{Z}/2 \times \mathbb{Z}/2.$$

The standard example is $L = \mathbb{Q}(i, \sqrt{2})$, with $\sigma_1 : i \mapsto -i$ and $\sigma_2 : \sqrt{2} \mapsto -\sqrt{2}$.

§30.8.2 Artin's Theorem

We now reverse the point of view. Instead of starting with an extension and forming its automorphism group, we start with a group of automorphisms and form its fixed field.

Definition 30.8.4 (Fixed Field)

Let L be a field and $G \leq \text{Aut}(L)$ a group of automorphisms. The **fixed field** is

$$L^G = \{\alpha \in L : \sigma\alpha = \alpha \text{ for all } \sigma \in G\},$$

which is easily checked to be a subfield of L .

Throughout this subsection, let $G \leq \text{Aut}(L)$ be a *finite* group of automorphisms and write $K = L^G$. Everything follows from two lemmas about orbits.

Lemma 30.8.5

Let $\gamma \in L$ and let $G\gamma = \{\gamma_1, \dots, \gamma_r\}$ be its orbit (with the γ_i distinct). Then γ is algebraic and separable over K , with minimal polynomial

$$g(x) = \prod_{i=1}^r (x - \gamma_i),$$

and in particular $\deg_K \gamma = \#G\gamma \leq \#G$.

Proof. Each $\sigma \in G$ permutes the orbit $G\gamma$, hence permutes the linear factors of g , hence fixes each coefficient of g . Therefore $g \in L^G[x] = K[x]$. By construction $g(\gamma) = 0$ and g has distinct roots, so γ is algebraic and its minimal polynomial f over K divides g and hence is separable too.

In fact $f = g$, because g is irreducible over K : if $g = g_1 g_2$ non-trivially in $K[x]$, then over L each g_i is a product of some of the $(x - \gamma_i)$, splitting $G\gamma$ into two non-empty sets A, B . But the coefficients of g_1 lie in K , so A is stable under G , which is impossible for a proper non-empty subset of a single orbit.

Finally $\#G\gamma \leq \#G$ by orbit-stabiliser. $\square$

In particular L/K is a separable extension, and every element of L has degree at most $\#G$ over K . That bound is enough to make the primitive element theorem bite.

Lemma 30.8.6

With $K = L^G$ as above, $[L : K] \leq \#G < \infty$, and $L = K(\gamma)$ for some $\gamma \in L$.

Proof. By Lemma 30.8.5 every element of L has degree at most $\#G$ over K , so we may choose $\gamma \in L$ with $[K(\gamma) : K]$ maximal. We claim $K(\gamma) = L$.

Let $\beta \in L$ be arbitrary. Then $[K(\gamma, \beta) : K] \leq [K(\gamma) : K][K(\beta) : K] < \infty$, and $K(\gamma, \beta)/K$ is separable since L/K is. By the Primitive Element Theorem 30.5.18, $K(\gamma, \beta) = K(\delta)$ for some δ . But then

$$[K(\delta) : K] \geq [K(\gamma) : K],$$

and by maximality equality holds, so $K(\delta) = K(\gamma)$ and hence $\beta \in K(\gamma)$. So $L = K(\gamma)$, and $[L : K] = \deg_K \gamma \leq \#G$. $\square$

Theorem 30.8.7 (Artin)

Let L be a field and $G \leq \text{Aut}(L)$ a finite group of automorphisms, and put $K = L^G$. Then

$$[L : K] = \#G \quad \text{and} \quad \text{Aut}(L/K) = G.$$

Proof. By Lemma 30.8.6 we have $L = K(\gamma)$ for some γ , and by Lemma 30.8.5,

$$[L : K] = \deg_K \gamma = \#G\gamma = \frac{\#G}{\#\text{Stab}_G(\gamma)}.$$

But if $\sigma \in \text{Stab}_G(\gamma)$ then σ fixes K and fixes γ , hence fixes $K(\gamma) = L$ pointwise, so

$\sigma = \text{id}$. Therefore $\text{Stab}_G(\gamma)$ is trivial and $[L : K] = \#G$.

For the second claim, certainly $G \leq \text{Aut}(L/K)$ by definition of $K = L^G$. Conversely any $\sigma \in \text{Aut}(L/K)$ is determined by $\sigma(\gamma)$, which must be a root of the minimal polynomial of γ , and there are only $[L : K]$ of those. So

$$\#G \leq \# \text{Aut}(L/K) \leq [L : K] = \#G,$$

forcing $G = \text{Aut}(L/K)$. □

Artin's theorem is a powerful *computational* tool, because it lets us identify fixed fields by a degree count alone.

Example 30.8.8

Let $L = \mathbb{C}(y)$ and let $\sigma, \tau \in \text{Aut}(L)$ be given by $\sigma(y) = i/y$ and $\tau(y) = -y$ (fixing $\mathbb{C}$). One checks $\sigma^2 = \tau^2 = \text{id}$ and $\sigma\tau = \tau\sigma$, so $G = \langle \sigma, \tau \rangle \cong \mathbb{Z}/2 \times \mathbb{Z}/2$. What is $K = L^G$?

The orbit of y is $Gy = \{y, -y, i/y, -i/y\}$, of size 4, so by Lemma 30.8.5 the minimal polynomial of y over K is

$$(x - y)(x + y)(x - i/y)(x + i/y) = (x^2 - y^2)(x^2 + y^{-2}) = x^4 + (y^{-2} - y^2)x^2 - 1.$$

So $\eta = y^2 - y^{-2} \in K$, and $[L : \mathbb{C}(\eta)] \leq 4$ since y satisfies a quartic over $\mathbb{C}(\eta)$. But $[L : K] = \#G = 4$ by Artin, and $\mathbb{C}(\eta) \subseteq K$, so

$$K = \mathbb{C}(y^2 - y^{-2}).$$

Example 30.8.9

Let $L = \mathbb{F}_{q^n}$ and $K = \mathbb{F}_q$, where $q = p^r$. Let $\varphi : L \rightarrow L$ be $\varphi(x) = x^q$, a field automorphism (an iterate of Frobenius). It fixes K pointwise by Fermat's little theorem, so $\varphi \in \text{Aut}(L/K)$. Its order is exactly n : we have $\varphi^n(x) = x^{q^n} = x$ for all x , so the order divides n ; and if $\varphi^m = \text{id}$ for $m < n$ then every element of L satisfies $x^{q^m} = x$, so $\#L \leq q^m < q^n$, a contradiction. Moreover $L^{\langle \varphi \rangle} = \{x : x^q = x\} = \mathbb{F}_q = K$. So by Artin's theorem

$$\text{Aut}(\mathbb{F}_{q^n}/\mathbb{F}_q) = \langle \varphi \rangle \cong \mathbb{Z}/n,$$

generated by the Frobenius. This is a complete description of the symmetries of finite fields, and it is very simple: *cyclic, generated by Frobenius*.

§30.8.3 Galois Extensions

We saw in Example 30.8.2 that $\# \text{Aut}(L/K)$ can be much smaller than $[L : K]$. It can never be larger.

Proposition 30.8.10

Let L/K be a finite extension. Then $\# \text{Aut}(L/K)$ divides $[L : K]$.

Proof. Put $G = \text{Aut}(L/K)$, which is finite (it injects into the roots of the minimal polynomial of a primitive element of any simple subextension; more simply, $\#G \leq [L : K]_s \leq [L : K]$). Let $M = L^G$, so $K \subseteq M \subseteq L$. By Artin's theorem $[L : M] = \#G$, and by the tower law

$$[L : K] = [L : M][M : K] = \# \text{Aut}(L/K) \cdot [M : K]. \quad \square$$

Definition 30.8.11 (Galois Extension)

A finite extension L/K is a **Galois extension** if

$$\# \text{Aut}(L/K) = [L : K].$$

In that case we write $\text{Gal}(L/K) = \text{Aut}(L/K)$ and call it the **Galois group**.

The following theorem gives four different faces of the same idea, and in practice one uses whichever is most convenient.

Theorem 30.8.12

Let L/K be a finite extension. The following are equivalent:

- (i) L/K is Galois;
- (ii) $K = L^G$ for some finite subgroup $G \leq \text{Aut}(L)$;
- (iii) L is a splitting field over K of some separable polynomial in $K[x]$;
- (iv) L/K is normal and separable.

Proof. (i) $\Rightarrow$ (ii). Take $G = \text{Aut}(L/K)$ and $M = L^G$. As in the proof of Proposition 30.8.10, $[L : M] = \#G = [L : K]$, so $[M : K] = 1$ and $K = L^G$.

(ii) $\Rightarrow$ (i). This is Artin's theorem: $[L : K] = \#G = \# \text{Aut}(L/K)$.

(ii) $\Rightarrow$ (iv). Lemma 30.8.5 says that for every $\gamma \in L$ the minimal polynomial over K is $\prod_{\delta \in G\gamma} (x - \delta)$, which is separable and splits in L . So L/K is separable and normal.

(iv) $\Rightarrow$ (iii). Write $L = K(\alpha_1, \dots, \alpha_n)$ and let f_i be the minimal polynomial of α_i over K . By separability each f_i is separable, and by normality each splits in L . Put $f = \text{lcm}(f_1, \dots, f_n)$, which is separable by Lemma 30.5.17 and splits in L ; and L is generated by its roots since the α_i are among them. So L is a splitting field of the separable polynomial f .

(iii) $\Rightarrow$ (i). This is Corollary 30.4.10: if L is a splitting field for f over K and f has no repeated roots, then $\# \text{Aut}(L/K) = [L : K]$. $\square$

Corollary 30.8.13

If L/K is Galois and $K \subseteq M \subseteq L$, then L/M is Galois.

Proof. Property (iv) of Theorem 30.8.12 passes to L/M : the minimal polynomial over M of $\alpha \in L$ divides the minimal polynomial over K , hence is separable and splits in L . $\square$

Corollary 30.8.14

Every finite separable extension L/K sits inside a Galois extension N/K , and there is a smallest such N , namely the normal closure of L/K .

Proof. Let N be the normal closure from Corollary 30.4.13, that is the splitting field of $f = f_1 \cdots f_n$ where f_i is the minimal polynomial of a generator α_i of L . Replacing f by $\text{lcm}(f_1, \dots, f_n)$ makes it separable without changing the splitting field, so N/K is Galois by Theorem 30.8.12(iii). $\square$

Note that M/K need *not* be Galois for intermediate M : for instance $\mathbb{Q} \subseteq \mathbb{Q}(\sqrt[3]{2}) \subseteq \mathbb{Q}(\sqrt[3]{2}, \omega)$, where the big extension is Galois but the middle one is not. Exactly which intermediate fields are Galois over K is the second half of the fundamental theorem.

§30.8.4 The Fundamental Theorem

Theorem 30.8.15 (Fundamental Theorem of Galois Theory)

Let L/K be a finite Galois extension with $G = \text{Gal}(L/K)$. Then there are mutually inverse bijections

$$\{\text{subgroups } H \leq G\} \longleftrightarrow \{\text{fields } M \text{ with } K \subseteq M \subseteq L\},$$

given by $H \mapsto L^H$ and $M \mapsto \text{Gal}(L/M)$. In particular there are only finitely many intermediate fields. Moreover:

- (i) the correspondence is inclusion-reversing: $H \leq H'$ if and only if $L^{H'} \subseteq L^H$;
- (ii) $[L : L^H] = \#H$ and $[L^H : K] = (G : H)$;
- (iii) $H \trianglelefteq G$ if and only if L^H/K is a Galois extension, and in that case restriction gives an isomorphism

$$\text{Gal}(L^H/K) \cong G/H.$$

Proof. First, both maps are well defined: L^H is a field between K and L , and $\text{Gal}(L/M)$ makes sense because L/M is Galois by Corollary 30.8.13. We check both composites are the identity.

Starting from a subgroup: $H \mapsto L^H \mapsto \text{Aut}(L/L^H) = H$, by Artin's Theorem 30.8.7.

Starting from a field: $M \mapsto \text{Gal}(L/M) \mapsto L^{\text{Gal}(L/M)}$. Since L/M is Galois, Theorem 30.8.12(i) $\Rightarrow$ (ii) (applied with base field M) gives $L^{\text{Gal}(L/M)} = M$.

Statement (i) is immediate from the definitions, in both directions (for the 'if', apply the bijection). Statement (ii) is Artin's theorem together with the tower law.

For (iii), suppose first that $H \trianglelefteq G$. For $\sigma \in G$, $\eta \in H$ and $\ell \in L^H$ we have

$$\eta(\sigma\ell) = \sigma(\sigma^{-1}\eta\sigma)(\ell) = \sigma(\eta'\ell) = \sigma\ell,$$

where $\eta' = \sigma^{-1}\eta\sigma \in H$ by normality. So $\sigma(L^H) \subseteq L^H$, and by applying the same to σ^{-1} , in fact $\sigma(L^H) = L^H$. Hence restriction gives a homomorphism

$$\rho : G \rightarrow \text{Aut}(L^H/K), \quad \sigma \mapsto \sigma|_{L^H},$$

whose kernel is $\{\sigma \in G : \sigma|_{L^H} = \text{id}\} = \text{Gal}(L/L^H) = H$. So $G/H \hookrightarrow \text{Aut}(L^H/K)$, giving

$$\#\text{Aut}(L^H/K) \geq (G : H) = [L^H : K].$$

The reverse inequality is Proposition 30.8.10, so we have equality: L^H/K is Galois with $\text{Gal}(L^H/K) \cong G/H$.

Conversely suppose $M = L^H$ is Galois over K . Let $\sigma \in G$ and $\alpha \in M$. The minimal polynomial of α over K splits in M by normality of M/K , and $\sigma\alpha$ is one of its roots by Lemma 30.8.1(i), so $\sigma\alpha \in M$. Hence $\sigma(M) = M$ for all $\sigma \in G$. But then for $\eta \in H$ and $\alpha \in M$ we get $\sigma^{-1}\eta\sigma(\alpha) = \sigma^{-1}\sigma\alpha = \alpha$, so $\sigma^{-1}H\sigma$ fixes M pointwise, that is $\sigma^{-1}H\sigma \leq \text{Gal}(L/M) = H$. So $H \trianglelefteq G$. $\square$

Remark. It is worth recording the mnemonic: *big subgroups correspond to small fields*. The whole group G corresponds to K , and the trivial subgroup to L . A subgroup of index 2 gives a quadratic subextension of K , not of L .

§30.8.5 Worked Examples

Example 30.8.16

If $\text{Gal}(L/K) \cong \mathbb{Z}/p$ with p prime, then there are no proper intermediate fields, since $\mathbb{Z}/p$ has no proper non-trivial subgroups.

Example 30.8.17 (Finite fields)

Let $L = \mathbb{F}_{q^n}$ and $K = \mathbb{F}_q$. We saw in Example 30.8.9 that L/K is Galois with $\text{Gal}(L/K) = \langle \varphi \rangle \cong \mathbb{Z}/n$. The subgroups of $\mathbb{Z}/n$ are $\langle \varphi^m \rangle$ for $m \mid n$, of order n/m , so the intermediate fields are exactly the

$$L^{\langle \varphi^m \rangle} = \{x : x^{q^m} = x\} = \mathbb{F}_{q^m}, \quad m \mid n,$$

recovering Theorem 30.6.4(iii) at a stroke.

Example 30.8.18

Let $L = \mathbb{Q}(i, \sqrt{2})$ over $K = \mathbb{Q}$. By Example 30.8.3, $G = \mathbb{Z}/2 \times \mathbb{Z}/2 = \{1, \sigma_1, \sigma_2, \sigma_1\sigma_2\}$ where $\sigma_1 : i \mapsto -i$ and $\sigma_2 : \sqrt{2} \mapsto -\sqrt{2}$. The proper non-trivial subgroups are $\langle \sigma_1 \rangle, \langle \sigma_2 \rangle, \langle \sigma_1\sigma_2 \rangle$, so there are exactly three intermediate fields, namely

$$L^{\langle \sigma_1 \rangle} = \mathbb{Q}(\sqrt{2}), \quad L^{\langle \sigma_2 \rangle} = \mathbb{Q}(i), \quad L^{\langle \sigma_1\sigma_2 \rangle} = \mathbb{Q}(i\sqrt{2}).$$

Since G is abelian all subgroups are normal, so all three are Galois over $\mathbb{Q}$ – as they

must be, being quadratic.

The Galois correspondence also gives a very efficient way to compute minimal polynomials: by Lemma 30.8.5, the minimal polynomial of γ over K is $\prod_{\delta \in G\gamma} (x - \delta)$.

Example 30.8.19

In $L = \mathbb{Q}(i, \sqrt{2})$, take $\gamma = 1 + i + \sqrt{2}$. Its orbit under G is $\{1 \pm i \pm \sqrt{2}\}$, so its minimal polynomial is

$$(x - 1 - i - \sqrt{2})(x - 1 + i - \sqrt{2})(x - 1 - i + \sqrt{2})(x - 1 + i + \sqrt{2}) \in \mathbb{Q}[x],$$

which expands to $x^4 - 4x^3 + 4x^2 + 4x - 7$. Doing this by elimination would be painful; knowing the Galois group makes it a two-line computation.

Now let us do the example properly – the one that is worth committing to memory.

Example 30.8.20 (The subfields of $\mathbb{Q}(\sqrt[4]{2}, i)$)

Let $\alpha = \sqrt[4]{2} \in \mathbb{R}$ and $L = \mathbb{Q}(\alpha, i)$. Since $x^4 - 2$ has roots $\pm\alpha, \pm i\alpha$, the field L is a splitting field for $x^4 - 2$ over $\mathbb{Q}$, hence Galois (characteristic zero, so separability is automatic). Its degree is 8: indeed $[\mathbb{Q}(\alpha) : \mathbb{Q}] = 4$ by Eisenstein, and $i \notin \mathbb{R} \supseteq \mathbb{Q}(\alpha)$ so $[L : \mathbb{Q}(\alpha)] = 2$.

So $\#G = 8$ where $G = \text{Gal}(L/\mathbb{Q})$, and G embeds into S_4 as permutations of the four roots. Let

$$r : \alpha \mapsto i\alpha, \quad i \mapsto i, \quad s : \alpha \mapsto \alpha, \quad i \mapsto -i.$$

Then r cycles the roots as $\alpha \rightarrow i\alpha \rightarrow -\alpha \rightarrow -i\alpha$, so has order 4, while s is complex conjugation, fixing $\pm\alpha$ and swapping $\pm i\alpha$, so has order 2. One checks $srs^{-1} = r^{-1}$, and so

$$G = \langle r, s \mid r^4 = s^2 = 1, srs = r^{-1} \rangle \cong D_8,$$

the dihedral group of order 8 (the symmetries of a square, the square in question having the four roots as its vertices in $\mathbb{C}$).

Now D_8 has exactly ten subgroups: itself, the trivial one, three of order 4 (namely $\langle r \rangle$, $\langle r^2, s \rangle$ and $\langle r^2, rs \rangle$) and five of order 2 (namely $\langle r^2 \rangle$, $\langle s \rangle$, $\langle r^2s \rangle$, $\langle rs \rangle$ and $\langle r^3s \rangle$). So L has exactly ten subfields, and we can name them all:

$$\begin{aligned} L^{\langle s \rangle} &= \mathbb{Q}(\alpha), & L^{\langle r^2s \rangle} &= \mathbb{Q}(i\alpha), & L^{\langle r^2 \rangle} &= \mathbb{Q}(\sqrt{2}, i), \\ L^{\langle rs \rangle} &= \mathbb{Q}((1+i)\alpha), & L^{\langle r^3s \rangle} &= \mathbb{Q}((1-i)\alpha), & L^{\langle r \rangle} &= \mathbb{Q}(i), \\ L^{\langle r^2, s \rangle} &= \mathbb{Q}(\sqrt{2}), & L^{\langle r^2, rs \rangle} &= \mathbb{Q}(\sqrt{-2}). \end{aligned}$$

Each is easily verified: for instance rs sends $\alpha \mapsto i\alpha$ and $i \mapsto -i$, so it fixes $(1+i)\alpha \mapsto (1-i)(i\alpha) = (1+i)\alpha$, and $\mathbb{Q}((1+i)\alpha)$ has degree 4 over $\mathbb{Q}$, matching $[L : L^{\langle rs \rangle}] = 2$.

Here are the two lattices. The subgroup lattice has been drawn *upside down*, with G at the bottom, so that corresponding objects sit in corresponding places; remember that the correspondence reverses inclusions.

Reading off part (iii) of the fundamental theorem: the normal subgroups of D_8 are $\{1\}$, $\langle r^2 \rangle$, the three subgroups of index 2, and D_8 itself. Correspondingly, the subfields Galois over $\mathbb{Q}$ are exactly

$$\mathbb{Q}, \quad \mathbb{Q}(\sqrt{2}), \quad \mathbb{Q}(i), \quad \mathbb{Q}(\sqrt{-2}), \quad \mathbb{Q}(\sqrt{2}, i), \quad L,$$

and the four degree-4 fields $\mathbb{Q}(\alpha), \mathbb{Q}(i\alpha), \mathbb{Q}((1 \pm i)\alpha)$ are *not* normal over $\mathbb{Q}$ – as we can see directly, since for instance $x^4 - 2$ has only two of its four roots inside $\mathbb{Q}(\alpha)$. Note also that $\langle s \rangle$ and $\langle r^2s \rangle$ are conjugate in D_8 (indeed $r\langle s \rangle r^{-1} = \langle r^2s \rangle$), which matches the fact that $\mathbb{Q}(\alpha)$ and $\mathbb{Q}(i\alpha)$ are abstractly isomorphic fields sitting differently inside L .

This example repays study. Almost every phenomenon in the subject is visible in it: non-normal intermediate fields, conjugate subgroups giving isomorphic-but-distinct subfields, and the way that a single degree-8 extension can hide ten different fields.

§30.9 Galois Groups of Polynomials

We now return to Galois' original setting: a polynomial and the permutations of its roots.

Definition 30.9.1 (Galois Group of a Polynomial)

Let $f \in K[x]$ be a separable polynomial and let L be a splitting field for f over K . Then L/K is Galois, and we write

$$\text{Gal}(f/K) = \text{Gal}(L/K).$$

If f has roots $\alpha_1, \dots, \alpha_n$ in L , then by Lemma 30.8.1 we may regard $\text{Gal}(f/K) \leq S_n$ as a group of permutations of the roots.

The identification with a subgroup of S_n depends on the ordering of the roots; changing the ordering conjugates the subgroup. So $\text{Gal}(f/K)$ is well defined as a subgroup of S_n only up to conjugacy, which is all we shall ever need.

Proposition 30.9.2

Let $f \in K[x]$ be separable of degree n . Then f is irreducible over K if and only if $\text{Gal}(f/K)$ acts transitively on the roots of f .

Proof. Suppose f is irreducible and let α, β be roots. By Corollary 30.4.3 there is a K -isomorphism $K(\alpha) \rightarrow K(\beta)$ with $\alpha \mapsto \beta$, and by Theorem 30.4.9(i) it extends to $\sigma : L \rightarrow L$, which is an automorphism. So the action is transitive.

Conversely if $f = gh$ non-trivially, then no automorphism can carry a root of g to a root of h , by Lemma 30.8.1(i), so the action is not transitive. $\square$

§30.9.1 Symmetric Polynomials

The coefficients of a polynomial are symmetric functions of its roots, so any expression in the roots that is invariant under all permutations ought to be expressible in the coefficients. That vague statement has a clean and useful theorem behind it.

Let R be a ring, and let S_n act on $R[z_1, \dots, z_n]$ by permuting the variables, $w \cdot z_i = z_{w(i)}$. The invariant ring $R[z_1, \dots, z_n]^{S_n}$ consists of the **symmetric polynomials**. Among them are the **elementary symmetric polynomials**

$$e_1 = \sum_i z_i, \quad e_2 = \sum_{i < j} z_i z_j, \quad \dots, \quad e_n = z_1 z_2 \cdots z_n.$$

Theorem 30.9.3 (Fundamental Theorem of Symmetric Polynomials)

The ring homomorphism

$$R[w_1, \dots, w_n] \rightarrow R[z_1, \dots, z_n]^{S_n}, \quad w_i \mapsto e_i$$

is an isomorphism. That is, every symmetric polynomial is a polynomial in $e_1, \dots, e_n$, uniquely so.

Proof. For $\lambda = (\lambda_1, \dots, \lambda_n) \in \mathbb{N}^n$ write $z^\lambda = z_1^{\lambda_1} \cdots z_n^{\lambda_n}$; these monomials form an R -basis of $R[z_1, \dots, z_n]$. Order $\mathbb{N}^n$ lexicographically. If λ is *decreasing*, meaning $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n$, then $\lambda \geq w\lambda$ for all $w \in S_n$, so every S_n -orbit in $\mathbb{N}^n$ contains a unique decreasing element, which is its maximum. It follows that the orbit sums $\sum_{\mu \in S_n \lambda} z^\mu$, indexed by decreasing λ , form an R -basis of the ring of symmetric polynomials.

Surjectivity. Let f be symmetric and non-zero, and let z^λ be its lexicographically

largest monomial, with coefficient c ; by symmetry λ is decreasing. Consider

$$E_\lambda = e_1^{\lambda_1 - \lambda_2} e_2^{\lambda_2 - \lambda_3} \cdots e_{n-1}^{\lambda_{n-1} - \lambda_n} e_n^{\lambda_n}.$$

Expanding, the lexicographically largest monomial of e_k is $z_1 z_2 \cdots z_k$, so the lexicographically largest monomial of E_λ is

$$z_1^{\lambda_1 - \lambda_2} (z_1 z_2)^{\lambda_2 - \lambda_3} \cdots (z_1 \cdots z_n)^{\lambda_n} = z^\lambda.$$

Hence $f - cE_\lambda$ is symmetric with strictly smaller leading monomial, and the process terminates by induction (there are finitely many monomials of any given degree).

Injectivity. We induct on n ; for $n = 1$ there is nothing to prove. Suppose $g \in R[w_1, \dots, w_n]$ is non-zero of minimal degree with $g(e_1, \dots, e_n) = 0$. Setting $z_n = 0$ turns e_i into the i th elementary symmetric polynomial in $z_1, \dots, z_{n-1}$ for $i < n$, and turns e_n into 0. So

$$g(e'_1, \dots, e'_{n-1}, 0) = 0 \text{ in } R[z_1, \dots, z_{n-1}],$$

whence by induction $g(w_1, \dots, w_{n-1}, 0) = 0$ identically, so $w_n \mid g$, say $g = w_n h$. Then $e_n h(e_1, \dots, e_n) = 0$, and $e_n = z_1 \cdots z_n \neq 0$ in the integral domain $R[z_1, \dots, z_n]$ (if R is a domain; in general compare coefficients), so $h(e_1, \dots, e_n) = 0$ with $\deg h < \deg g$, contradicting minimality. $\square$

Now let $f \in K[x]$ be monic of degree n with roots $\alpha_1, \dots, \alpha_n$ in a splitting field, so that

$$f(x) = x^n - a_1 x^{n-1} + a_2 x^{n-2} - \cdots + (-1)^n a_n$$

with $a_i = e_i(\alpha_1, \dots, \alpha_n)$. The theorem says that *any* symmetric expression in the roots is a polynomial in the coefficients $a_1, \dots, a_n$, with the same coefficient ring. This is the machine we now use.

§30.9.2 The Discriminant

Definition 30.9.4 (Discriminant)

Let $f \in K[x]$ be monic of degree n with roots $\alpha_1, \dots, \alpha_n$ in a splitting field. The **discriminant** of f is

$$\text{Disc}(f) = \prod_{i < j} (\alpha_i - \alpha_j)^2.$$

We also write $\delta = \prod_{i < j} (\alpha_i - \alpha_j)$, so that $\text{Disc}(f) = \delta^2$.

Proposition 30.9.5

With notation as above, and assuming $\text{char } K \neq 2$:

- (i) $\text{Disc}(f) \in K$, and indeed $\text{Disc}(f)$ is a universal polynomial with integer coefficients in the coefficients of f ;
- (ii) $\text{Disc}(f) \neq 0$ if and only if f is separable;
- (iii) if f is separable, then $\text{Gal}(f/K) \leq A_n$ if and only if $\text{Disc}(f)$ is a square in K .

Proof. (i) $\text{Disc}(f)$ is a symmetric polynomial in $\alpha_1, \dots, \alpha_n$ with integer coefficients, so by Theorem 30.9.3 it is a polynomial with integer coefficients in $e_1, \dots, e_n$, that is in the coefficients of f .

(ii) is immediate, as $\text{Disc}(f) = 0$ if and only if two roots coincide.

(iii) Let $G = \text{Gal}(f/K) \leq S_n$. Any $\sigma \in G$ permutes the α_i and hence permutes the factors $(\alpha_i - \alpha_j)$ up to sign, with the sign being $\text{sign}(\sigma)$; that is,

$$\sigma(\delta) = \text{sign}(\sigma)\delta.$$

So $G \leq A_n$ if and only if $\sigma\delta = \delta$ for all $\sigma \in G$, which by the Galois correspondence holds if and only if $\delta \in L^G = K$, that is, if and only if $\text{Disc}(f) = \delta^2$ is a square in K . (We used $\text{char } K \neq 2$ to know that $\delta \neq -\delta$.) $\square$

There is a slicker formula for the discriminant in terms of the derivative, which is often the quickest way to compute it.

Proposition 30.9.6

Let f be monic of degree n with roots $\alpha_1, \dots, \alpha_n$. Then

$$\prod_{i=1}^n f'(\alpha_i) = (-1)^{n(n-1)/2} \text{Disc}(f).$$

Proof. Differentiating $f(x) = \prod_j (x - \alpha_j)$ by the product rule gives

$$f'(x) = \sum_i \prod_{j \neq i} (x - \alpha_j),$$

and evaluating at α_i kills all the terms but one:

$$f'(\alpha_i) = \prod_{j \neq i} (\alpha_i - \alpha_j).$$

Multiplying over i gives $\prod_{i \neq j} (\alpha_i - \alpha_j)$. Pairing off (i, j) with (j, i) introduces a factor (-1) for each of the $\binom{n}{2}$ pairs, giving $(-1)^{n(n-1)/2} \prod_{i < j} (\alpha_i - \alpha_j)^2$. $\square$

Example 30.9.7

For a quadratic $f = x^2 + bx + c$ we have $\text{Disc}(f) = (\alpha_1 - \alpha_2)^2 = (\alpha_1 + \alpha_2)^2 - 4\alpha_1\alpha_2 = b^2 - 4c$, as it should be. Then $\text{Gal}(f/K) \leq A_2 = 1$ if and only if $b^2 - 4c$ is a square, which is exactly the condition for the roots to lie in K .

Example 30.9.8

For a cubic $f = x^3 + px + q$ we claim

$$\text{Disc}(f) = -4p^3 - 27q^2.$$

One can get this cheaply. Since $e_1 = 0$, the discriminant is a polynomial in $e_2 = p$

and $e_3 = -q$ only; and Disc is homogeneous of degree 6 in the roots, while p has degree 2 and q degree 3, so

$$\text{Disc}(f) = cp^3 + dq^2$$

for some integers c, d . Taking $f = (x - \alpha)^2(x + 2\alpha)$, which has $p = -3\alpha^2$, $q = 2\alpha^3$ and discriminant 0, gives $-27c\alpha^6 + 4d\alpha^6 = 0$, so $4d = 27c$. Taking $f = x^3 - x$, with roots $0, \pm 1$, gives $\text{Disc} = (0 - 1)^2(0 + 1)^2(1 + 1)^2 = 4$, so $-c = 4$; hence $c = -4$ and $d = -27$.

§30.9.3 Cubics

Let $f \in K[x]$ be a separable cubic with $\text{char } K \neq 2, 3$; after substituting $x \mapsto x - a_1/3$ we may take $f = x^3 + px + q$. Let L be a splitting field and $G = \text{Gal}(f/K) \leq S_3$.

If f is reducible then G is trivial (three roots in K) or $\cong S_2$ (one root in K and an irreducible quadratic factor). So suppose f is irreducible. Then G acts transitively on three points, so $3 \mid \#G$, forcing $G = A_3$ or $G = S_3$; and by Proposition 30.9.5, $G = A_3$ exactly when $\text{Disc}(f) = -4p^3 - 27q^2$ is a square in K .

The Galois correspondence for the intermediate field $K(\delta) = K(\sqrt{\text{Disc } f})$ then reads as follows.

$$\begin{array}{ccc}
 L = K(\alpha_1, \alpha_2, \alpha_3) & \longleftrightarrow & \{1\} \\
 \downarrow 3 & & \downarrow \text{index 3} \\
 K(\delta) = L^{G \cap A_3} & \longleftrightarrow & G \cap A_3 \\
 \downarrow 1 \text{ or } 2 & & \downarrow \text{index 1 or 2} \\
 K & \longleftrightarrow & G
 \end{array}$$

So the splitting field of an irreducible cubic is obtained from K by first adjoining a square root (of the discriminant) and then a cube root – which is exactly the shape of Cardano's formula. Let us see the cube root appear.

Example 30.9.9

Suppose $f = x^3 + px + q$ is irreducible over K , that $\text{char } K \neq 2, 3$, and that K contains $\delta = \sqrt{\text{Disc } f}$ and a primitive cube root of unity ω . Then $G = \text{Gal}(L/K) = A_3 = \langle \sigma \rangle \cong \mathbb{Z}/3$, where we may take σ to be the 3-cycle $\alpha_1 \rightarrow \alpha_2 \rightarrow \alpha_3 \rightarrow \alpha_1$. Define the **Lagrange resolvents**

$$\beta = \alpha_1 + \omega\alpha_2 + \omega^2\alpha_3, \quad \gamma = \alpha_1 + \omega^2\alpha_2 + \omega\alpha_3.$$

Then $\sigma\beta = \alpha_2 + \omega\alpha_3 + \omega^2\alpha_1 = \omega^{-1}\beta$ and similarly $\sigma\gamma = \omega\gamma$, so $\sigma(\beta^3) = \beta^3$ and $\sigma(\gamma^3) = \gamma^3$; hence $\beta^3, \gamma^3 \in L^G = K$. Also $\alpha_1 + \alpha_2 + \alpha_3 = 0$, so

$$\alpha_1 = \frac{1}{3}(\beta + \gamma), \quad \alpha_2 = \frac{1}{3}(\omega^2\beta + \omega\gamma), \quad \alpha_3 = \frac{1}{3}(\omega\beta + \omega^2\gamma).$$

It remains to compute β^3 and γ^3 . Using $\sum \alpha_i = 0$, $\sum_{i < j} \alpha_i \alpha_j = p$ and $1 + \omega + \omega^2 = 0$:

$$\beta\gamma = \sum_i \alpha_i^2 + (\omega + \omega^2) \sum_{i < j} \alpha_i \alpha_j = \left(\sum_i \alpha_i \right)^2 - 3 \sum_{i < j} \alpha_i \alpha_j = -3p,$$

so $\beta^3\gamma^3 = -27p^3$. A similar (slightly longer) expansion gives $\beta^3 + \gamma^3 = -27q$. Hence β^3, γ^3 are the roots of

$$t^2 + 27qt - 27p^3 = 0,$$

that is $\beta^3 = \frac{1}{2}(-27q + 3\sqrt{-3\text{Disc } f})$, and then $\gamma = -3p/\beta$. This is Cardano's formula, derived rather than guessed.

§30.9.4 Quartics and the Resolvent Cubic

Now let $f \in K[x]$ be an irreducible separable quartic, with $\text{char } K \neq 2, 3$, splitting field L and $G = \text{Gal}(f/K) \leq S_4$. Translating, we may assume $\sum \alpha_i = 0$, so

$$f(x) = x^4 + px^2 + qx + r.$$

Since G is transitive, $4 \mid \#G$, and the transitive subgroups of S_4 are (up to conjugacy)

$$S_4, \quad A_4, \quad D_8 = \langle (1234), (13) \rangle, \quad \mathbb{Z}/4 = \langle (1234) \rangle,$$

$$V = \{e, (12)(34), (13)(24), (14)(23)\}.$$

The key structural fact is that the Klein four-group V is normal in S_4 , with $S_4/V \cong S_3$; concretely, S_4 acts on the three partitions

$$(12 \mid 34), \quad (13 \mid 24), \quad (14 \mid 23)$$

of $\{1, 2, 3, 4\}$ into two pairs, and the kernel of the resulting homomorphism $S_4 \rightarrow S_3$ is exactly V . Since $\#V \cdot \#S_3 = 24$, the map is surjective.

Under the Galois correspondence, $G \cap V \trianglelefteq G$ corresponds to an intermediate field $M = L^{G \cap V}$ with $\text{Gal}(M/K) = G/(G \cap V) \hookrightarrow S_4/V \cong S_3$. So M should be the splitting field of a *cubic*, and we can find it.

Put

$$y_{12} = \alpha_1 + \alpha_2 = -(\alpha_3 + \alpha_4) = -y_{34},$$

and similarly y_{13}, y_{14} . Each element of V either fixes y_{12} or sends it to $y_{34} = -y_{12}$, so $y_{12}^2, y_{13}^2, y_{14}^2$ are fixed by V and hence lie in M . They are distinct: if $y_{12}^2 = y_{13}^2$ then either $y_{12} = y_{13}$, giving $\alpha_2 = \alpha_3$, or $y_{12} = -y_{13}$, giving $2\alpha_1 + \alpha_2 + \alpha_3 = 0$ and hence $\alpha_1 = \alpha_4$; both contradict separability. Finally S_4 permutes $\{y_{12}^2, y_{13}^2, y_{14}^2\}$, so their elementary symmetric functions lie in K .

Definition 30.9.10 (Resolvent Cubic)

The **resolvent cubic** of $f = x^4 + px^2 + qx + r$ is

$$g(x) = (x - y_{12}^2)(x - y_{13}^2)(x - y_{14}^2) \in K[x].$$

Proposition 30.9.11

With notation as above, $g(x) = x^3 + 2px^2 + (p^2 - 4r)x - q^2$, and $M = L^{G \cap V}$ is a splitting field for g over K . Moreover $L = M(y_{12}, y_{13})$, and $\alpha_1 = \frac{1}{2}(y_{12} + y_{13} + y_{14})$ with $y_{12}y_{13}y_{14} = -q$.

Proof. The formula for g is a direct expansion using the symmetric function identities $\sum \alpha_i = 0$, $\sum_{i < j} \alpha_i \alpha_j = p$, $\sum_{i < j < k} \alpha_i \alpha_j \alpha_k = -q$, $\alpha_1 \alpha_2 \alpha_3 \alpha_4 = r$; for instance

$$y_{12}^2 + y_{13}^2 + y_{14}^2 = -((\alpha_1 + \alpha_2)(\alpha_3 + \alpha_4) + \dots) = -2p.$$

That $M \supseteq K(y_{12}^2, y_{13}^2, y_{14}^2)$ we have already seen; equality follows from Artin's theorem, since $\text{Aut}(L/K(y_{12}^2, y_{13}^2, y_{14}^2)) = G \cap V$ (an automorphism fixing all three squares must preserve each partition, hence lie in V).

For the last statements, $\alpha_1 = \frac{1}{2}((\alpha_1 + \alpha_2) + (\alpha_1 + \alpha_3) + (\alpha_1 + \alpha_4))$ since $\sum \alpha_i = 0$, and $y_{12}y_{13}y_{14} = -q$ by another expansion. Hence $L = K(\alpha_1, \dots, \alpha_4) = M(y_{12}, y_{13}, y_{14}) = M(y_{12}, y_{13})$. $\square$

So a quartic is solved by first solving its resolvent cubic and then extracting two square roots – and the whole tower is

$$K \subseteq K(\delta) \subseteq M \subseteq L$$

of degrees dividing 2, 3, 4 respectively. Comparing G with $G \cap A_4$ and $G \cap V$ lets us determine G completely.

Proposition 30.9.12

Let f be an irreducible separable quartic over K with resolvent cubic g . Then $\text{Gal}(f/K)$ is determined by the following table, where $\delta = \sqrt{\text{Disc } f}$.

g irreducible over K ?	$\delta \in K$?	G
yes	yes	A_4
yes	no	S_4
no, splits completely	yes	V
no, one root in K	no	D_8 or $\mathbb{Z}/4$

Proof. We have $[M : K] = \#(G/(G \cap V))$, which is the order of the image of G in S_3 , and this image is $\text{Gal}(g/K)$. Also $\delta \in K$ if and only if $G \leq A_4$. Running through the five transitive subgroups: $G = S_4$ gives image S_3 and $\delta \notin K$; $G = A_4$ gives image A_3 (so g is irreducible) and $\delta \in K$; $G = V$ gives trivial image, so g splits, and $V \leq A_4$ so $\delta \in K$; $G = D_8$ or $\mathbb{Z}/4$ gives image of order 2, so g has exactly one root in K , and neither is contained in A_4 . $\square$

Distinguishing D_8 from $\mathbb{Z}/4$ requires slightly more work (one asks whether f remains irreducible over $K(\delta)$), and we shall not pursue it.

§30.9.5 Reduction Modulo a Prime

For polynomials over $\mathbb{Z}$ there is a beautiful and very practical technique: reduce mod p , where finite field theory tells us everything, and transfer the information back.

Recall from Example 30.8.9 that $\text{Gal}(\bar{f}/\mathbb{F}_p)$ is cyclic, generated by Frobenius. Its cycle type is easy to read off.

Proposition 30.9.13

Let $\bar{f} \in \mathbb{F}_p[x]$ be separable of degree n with irreducible factors of degrees $n_1, \dots, n_r$. Then $\text{Gal}(\bar{f}/\mathbb{F}_p)$ is cyclic, generated by an element of cycle type $(n_1, \dots, n_r)$, and so has order $\text{lcm}(n_1, \dots, n_r)$.

Proof. Let L be a splitting field. Then $\text{Gal}(L/\mathbb{F}_p) = \langle \varphi \rangle$ with $\varphi(x) = x^p$. If α is a root of the irreducible factor g_i , then the roots of g_i are exactly the φ -orbit of α , which therefore has size $\deg g_i = n_i$. So φ acts on the n roots as a product of disjoint cycles of lengths $n_1, \dots, n_r$. $\square$

Theorem 30.9.14 (Dedekind)

Let $f \in \mathbb{Z}[x]$ be monic and separable of degree n , and let p be a prime such that the reduction $\bar{f} \in \mathbb{F}_p[x]$ is also separable. Then $\text{Gal}(\bar{f}/\mathbb{F}_p)$ is (conjugate in S_n to) a subgroup of $\text{Gal}(f/\mathbb{Q})$.

Proof sketch. Let L be a splitting field for f over $\mathbb{Q}$, with roots $\alpha_1, \dots, \alpha_n$, and put $R = \mathbb{Z}[\alpha_1, \dots, \alpha_n]$. Since f is monic, R is finitely generated as a $\mathbb{Z}$ -module. It is torsion-free, so it is free, say $R \cong \mathbb{Z}^M$. Choose a maximal ideal $P \supseteq pR$ of R ; then $F = R/P$ is a finite field of characteristic p , generated by the images $\bar{\alpha}_i$, and in $F[x]$ we have

$$\bar{f} = \prod_i (x - \bar{\alpha}_i).$$

As $\bar{f}$ is separable the $\bar{\alpha}_i$ are distinct, so F is a splitting field for $\bar{f}$.

The group $G = \text{Gal}(f/\mathbb{Q})$ permutes the α_i and hence acts on R ; let $H = \text{Stab}_G(P)$. Then H acts on $F = R/P$, permuting the $\bar{\alpha}_i$ exactly as it permutes the α_i , giving an injection $H \hookrightarrow \text{Gal}(F/\mathbb{F}_p)$. A counting argument using the Chinese remainder theorem on the G -orbit of P shows this injection is onto, which gives the result. $\square$

Corollary 30.9.15

With f and p as above, if $\bar{f}$ factors into distinct irreducibles of degrees $n_1, \dots, n_r$ over $\mathbb{F}_p$, then $\text{Gal}(f/\mathbb{Q})$ contains a permutation of cycle type $(n_1, \dots, n_r)$.

Example 30.9.16

Let $f = x^4 - 3x + 1$.

- Mod 2: $\bar{f} = x^4 + x + 1$, which has no root in $\mathbb{F}_2$ and is not divisible by $x^2 + x + 1$ (the only irreducible quadratic), so it is irreducible. Hence $\text{Gal}(f/\mathbb{Q})$ contains a 4-cycle.
- Mod 5: $\bar{f} = (x + 1)(x^3 - x^2 + x + 1)$, a product of an irreducible linear and an irreducible cubic. Hence $\text{Gal}(f/\mathbb{Q})$ contains a 3-cycle.

So $12 \mid \# \text{Gal}(f/\mathbb{Q})$, and $\text{Gal}(f/\mathbb{Q}) \leq S_4$, so it is A_4 or S_4 . But a 4-cycle is odd, so it is not in A_4 . Hence $\text{Gal}(f/\mathbb{Q}) = S_4$.

Note also that reduction mod p is a good irreducibility test: if $\bar{f}$ is irreducible for some p then f is irreducible over $\mathbb{Z}$ and hence over $\mathbb{Q}$. More subtly, a factorisation over $\mathbb{Z}$ must refine to a factorisation over $\mathbb{F}_p$ for every p , so if the factorisation shapes mod two different primes are incompatible, f is irreducible. For example $f = x^4 + 5x^2 - 2x - 3$ factors as $(x^2 + x + 1)^2 \pmod{2}$ and as $x(x^3 + 2x + 1) \pmod{3}$; a factorisation over $\mathbb{Z}$ would have to have a factor of degree 2 (from mod 2) and a factor of degree 1 (from mod 3) compatible with each other, which is impossible, so f is irreducible.

§30.9.6 The Generic Polynomial

Finally, symmetric functions let us produce a polynomial whose Galois group is as large as possible.

Theorem 30.9.17

Let k be a field and let $L = k(z_1, \dots, z_n)$ be the field of rational functions, with S_n acting by permuting the variables. Then

$$L^{S_n} = k(e_1, \dots, e_n),$$

and L/L^{S_n} is a Galois extension of degree $n!$ with Galois group S_n .

Proof. Certainly $k(e_1, \dots, e_n) \subseteq L^{S_n}$. Conversely let $\gamma = f/g \in L^{S_n}$ with $f, g \in R = k[z_1, \dots, z_n]$. Put $\mu = \prod_{\sigma \in S_n} \sigma g$, which is symmetric, so $\mu \in R^{S_n} = k[e_1, \dots, e_n]$ by Theorem 30.9.3. Then

$$\gamma = \frac{f}{g} = \frac{f \prod_{\sigma \neq 1} \sigma g}{\mu},$$

whose numerator is $\gamma\mu$, a symmetric element of R (it is symmetric since γ and μ are, and it lies in R). So $\gamma \in \text{Frac}(R^{S_n}) = k(e_1, \dots, e_n)$.

Since S_n acts faithfully on L , Artin's Theorem 30.8.7 gives $[L : L^{S_n}] = n!$ with $\text{Gal}(L/L^{S_n}) = S_n$. $\square$

Taking $K = k(e_1, \dots, e_n)$ and $f(x) = x^n - e_1 x^{n-1} + \dots + (-1)^n e_n \in K[x]$, we have $f(x) = \prod_i (x - z_i)$ in L , so L is a splitting field for f and

$$\text{Gal}(f/K) = S_n.$$

Informally: *the general polynomial of degree n has Galois group S_n* . This will be exactly what we need for the insolubility of the quintic.

Corollary 30.9.18

Every finite group G occurs as the Galois group of some Galois extension of fields.

Proof. By Cayley's theorem G embeds in S_n for some n (acting on itself by left

multiplication). Take $L = k(z_1, \dots, z_n)$ and apply Artin's theorem to $G \leq S_n \leq \text{Aut}(L)$: then L/L^G is Galois with group G . $\square$

Whether every finite group occurs as $\text{Gal}(L/\mathbb{Q})$ is the **inverse Galois problem**, and it is open. It is known for all soluble groups (Shafarevich) and for most finite simple groups, including – thanks to Thompson – the Monster.

§30.10 Cyclotomic Extensions

We now study the extension obtained by adjoining roots of unity. These are the simplest interesting Galois extensions of $\mathbb{Q}$, and they are also the raw material out of which radical extensions are built, so we shall need to understand them thoroughly.

§30.10.1 Roots of Unity

Let K be a field and $n \geq 1$ with $n \neq 0$ in K (so $\text{char } K = 0$, or $\text{char } K = p \nmid n$). Then $x^n - 1$ has derivative nx^{n-1} , and $\gcd(x^n - 1, nx^{n-1}) = 1$, so $x^n - 1$ is separable. Let L be a splitting field and

$$\mu_n = \{\zeta \in L : \zeta^n = 1\},$$

a group of order exactly n under multiplication. By Proposition 30.6.1 it is cyclic.

Definition 30.10.1 (Primitive Root of Unity)

A generator of μ_n is called a **primitive n th root of unity**, usually written ζ_n . There are $\phi(n)$ of them, namely ζ_n^a for $\gcd(a, n) = 1$.

Over $\mathbb{C}$ we can draw the picture: the n th roots of unity are the vertices of a regular n -gon inscribed in the unit circle, and the primitive ones are those ‘visible from the origin’ in the sense of being $e^{2\pi ia/n}$ with a coprime to n . Here is $n = 12$, with the four primitive twelfth roots of unity drawn as solid dots.

Proposition 30.10.2

Let $\zeta = \zeta_n$ be a primitive n th root of unity in a splitting field L of $x^n - 1$ over K . Then $L = K(\zeta)$, the extension L/K is Galois, and there is an injective group homomorphism

$$\chi : \text{Gal}(L/K) \hookrightarrow (\mathbb{Z}/n\mathbb{Z})^\times.$$

In particular $\text{Gal}(L/K)$ is abelian.

Proof. Every n th root of unity is a power of ζ , so $L = K(\zeta)$; and L is the splitting field of the separable polynomial $x^n - 1$, so L/K is Galois. Any $\sigma \in \text{Gal}(L/K)$ sends ζ to another root of $x^n - 1$, and must send a generator of μ_n to a generator, so $\sigma(\zeta) = \zeta^{a_\sigma}$ for a unique $a_\sigma \in (\mathbb{Z}/n\mathbb{Z})^\times$. If $\tau(\zeta) = \zeta^{a_\tau}$ then

$$\sigma\tau(\zeta) = \sigma(\zeta^{a_\tau}) = \zeta^{a_\sigma a_\tau},$$

so $\chi(\sigma) = a_\sigma$ is a homomorphism, and it is injective since σ is determined by $\sigma(\zeta)$. $\square$

For general K the map χ need not be surjective – for instance if K already contains ζ then $\text{Gal}(L/K)$ is trivial. The whole content of the next subsection is that over $\mathbb{Q}$ it is surjective.

§30.10.2 Cyclotomic Polynomials

If $d \mid n$ then $x^d - 1$ divides $x^n - 1$. Each $\zeta \in \mu_n$ is a primitive d th root of unity for exactly one $d \mid n$, namely $d = \text{ord}(\zeta)$. This suggests dividing out all the obvious factors.

Definition 30.10.3 (Cyclotomic Polynomial)

The n th **cyclotomic polynomial** is

$$\Phi_n(x) = \prod_{\substack{\zeta \in \mu_n \\ \text{ord}(\zeta)=n}} (x - \zeta) = \prod_{\substack{1 \leq a \leq n \\ \gcd(a,n)=1}} (x - \zeta_n^a),$$

a monic polynomial of degree $\phi(n)$.

Partitioning μ_n by the order of its elements gives

$$x^n - 1 = \prod_{d \mid n} \Phi_d(x), \quad \text{equivalently} \quad \Phi_n(x) = \frac{x^n - 1}{\prod_{d \mid n, d \neq n} \Phi_d(x)},$$

which is an inductive recipe for computing Φ_n .

Proposition 30.10.4

$\Phi_n(x) \in \mathbb{Z}[x]$.

Proof. Induct on n . For $n = 1$, $\Phi_1 = x - 1$. In general $g = \prod_{d \mid n, d \neq n} \Phi_d$ lies in $\mathbb{Z}[x]$ by induction and is monic, so dividing $x^n - 1$ by g using the division algorithm in $\mathbb{Z}[x]$ (legitimate as g is monic) gives a quotient in $\mathbb{Z}[x]$; and that quotient must be Φ_n , since the division is the same computed in any larger ring. $\square$

Example 30.10.5

The first few are $\Phi_1 = x - 1$, $\Phi_2 = x + 1$, $\Phi_3 = x^2 + x + 1$, $\Phi_4 = x^2 + 1$. For p prime,

$\Phi_p = 1 + x + \cdots + x^{p-1}$. For $n = 8$ and $n = 6$:

$$\begin{aligned} x^8 - 1 &= \underbrace{(x-1)}_{\Phi_1} \underbrace{(x+1)}_{\Phi_2} \underbrace{(x^2+1)}_{\Phi_4} \underbrace{(x^4+1)}_{\Phi_8}, \\ x^6 - 1 &= \underbrace{(x-1)}_{\Phi_1} \underbrace{(x+1)}_{\Phi_2} \underbrace{(x^2+x+1)}_{\Phi_3} \underbrace{(x^2-x+1)}_{\Phi_6}. \end{aligned}$$

It is tempting to guess that the coefficients of Φ_n are always $0, \pm 1$. This is true for $n < 105$, and false for $n = 105$.

Theorem 30.10.6 (Gauss, Dedekind)

Φ_n is irreducible in $\mathbb{Q}[x]$.

Proof. By Gauss's lemma, since $\Phi_n \in \mathbb{Z}[x]$ is monic, it suffices to show Φ_n does not factor properly in $\mathbb{Z}[x]$. Suppose $\Phi_n = fg$ with $f, g \in \mathbb{Z}[x]$ monic and f irreducible of positive degree.

Let ξ be a root of f ; it is a primitive n th root of unity, and every primitive n th root of unity is ξ^a with $\gcd(a, n) = 1$. Since every such a is a product of primes not dividing n , it is enough to prove:

$$\text{if } f(\xi) = 0 \text{ and } p \text{ is a prime with } p \nmid n, \text{ then } f(\xi^p) = 0.$$

Granting this, every root of Φ_n is a root of f , so $\deg f = \phi(n)$ and g is constant, as required.

Suppose not, so $f(\xi^p) \neq 0$. Since ξ^p is a primitive n th root of unity, $\Phi_n(\xi^p) = 0$, so $g(\xi^p) = 0$. Thus ξ is a root of both $f(x)$ and $g(x^p)$; as f is irreducible and monic it is the minimal polynomial of ξ over $\mathbb{Q}$, so

$$f(x) \mid g(x^p) \text{ in } \mathbb{Z}[x]$$

(the quotient lies in $\mathbb{Z}[x]$ by Gauss's lemma, as f is monic).

Now reduce modulo p , writing $\bar{h}$ for the image of h in $\mathbb{F}_p[x]$. By the Frobenius homomorphism, $\bar{g}(x^p) = \bar{g}(x)^p$. So

$$\bar{f} \mid \bar{g}^p \text{ in } \mathbb{F}_p[x].$$

Let γ be an irreducible factor of $\bar{f}$; then $\gamma \mid \bar{g}$, so $\gamma^2 \mid \bar{f}\bar{g} = \overline{\Phi_n}$, and hence $\overline{\Phi_n}$ has a repeated root. But $\overline{\Phi_n} \mid x^n - 1$ in $\mathbb{F}_p[x]$, and $x^n - 1$ is separable over $\mathbb{F}_p$ because $p \nmid n$. This is a contradiction. $\square$

Corollary 30.10.7

$[\mathbb{Q}(\zeta_n) : \mathbb{Q}] = \phi(n)$, and

$$\chi : \text{Gal}(\mathbb{Q}(\zeta_n)/\mathbb{Q}) \xrightarrow{\sim} (\mathbb{Z}/n\mathbb{Z})^\times$$

is an isomorphism.

Proof. Φ_n is the minimal polynomial of ζ_n over $\mathbb{Q}$ by Theorem 30.10.6, so $[\mathbb{Q}(\zeta_n) : \mathbb{Q}] = \phi(n) = \#(\mathbb{Z}/n\mathbb{Z})^\times$. The map χ of Proposition 30.10.2 is injective between groups of the same finite order, hence bijective. $\square$

§30.10.3 Subfields of Cyclotomic Fields

Since $(\mathbb{Z}/n\mathbb{Z})^\times$ is abelian, every subgroup is normal, so *every* subfield of $\mathbb{Q}(\zeta_n)$ is Galois over $\mathbb{Q}$ with abelian Galois group. (The converse – that every abelian extension of $\mathbb{Q}$ lies inside a cyclotomic field – is the Kronecker–Weber theorem, well beyond this course.) The Galois correspondence therefore turns questions about subfields of $\mathbb{Q}(\zeta_n)$ into questions about subgroups of $(\mathbb{Z}/n\mathbb{Z})^\times$.

Lemma 30.10.8

Let $n \geq 3$. Then the fixed field of complex conjugation in $\mathbb{Q}(\zeta_n)$ is the maximal real subfield

$$\mathbb{Q}(\zeta_n + \zeta_n^{-1}) = \mathbb{Q}(2 \cos(2\pi/n)),$$

and $[\mathbb{Q}(\zeta_n) : \mathbb{Q}(\zeta_n + \zeta_n^{-1})] = 2$. In particular $2 \mid \phi(n)$.

Proof. Complex conjugation restricts to an element of $\text{Gal}(\mathbb{Q}(\zeta_n)/\mathbb{Q})$ corresponding to $-1 \in (\mathbb{Z}/n\mathbb{Z})^\times$, which is not the identity since $n \geq 3$; so it has order 2 and its fixed field has index 2. Now $\eta = \zeta + \zeta^{-1} = 2 \cos(2\pi/n)$ is real, so $\mathbb{Q}(\eta)$ lies in that fixed field; and ζ is a root of $x^2 - \eta x + 1 \in \mathbb{Q}(\eta)[x]$, so $[\mathbb{Q}(\zeta) : \mathbb{Q}(\eta)] \leq 2$, with equality since $\zeta \notin \mathbb{R}$. Comparing degrees, $\mathbb{Q}(\eta)$ is exactly the fixed field. $\square$

Remark. When $\text{Gal}(\mathbb{Q}(\zeta_n)/\mathbb{Q})$ is not cyclic there may be several subfields of index 2; for instance $\mathbb{Q}(\zeta_8)$ has degree 4 over $\mathbb{Q}$ and contains all three of $\mathbb{Q}(i)$, $\mathbb{Q}(\sqrt{2})$ and $\mathbb{Q}(\sqrt{-2})$. The maximal real subfield is the one fixed by conjugation, here $\mathbb{Q}(\sqrt{2})$.

Example 30.10.9 ($n = 5$)

Here $(\mathbb{Z}/5)^\times \cong \mathbb{Z}/4$, so there is a unique intermediate field of degree 2 over $\mathbb{Q}$, namely $\mathbb{Q}(\eta)$ with $\eta = \zeta_5 + \zeta_5^{-1}$. Since $\zeta + \zeta^2 + \zeta^3 + \zeta^4 = -1$, we get $\eta + \eta' = -1$ where $\eta' = \zeta^2 + \zeta^3$, and $\eta\eta' = -1$, so η satisfies $x^2 + x - 1$ and

$$\eta = \frac{-1 + \sqrt{5}}{2}, \quad \mathbb{Q} \subsetneq \mathbb{Q}(\sqrt{5}) \subsetneq \mathbb{Q}(\zeta_5).$$

Example 30.10.10 ($n = 7$)

Now $(\mathbb{Z}/7)^\times \cong \mathbb{Z}/6$, generated by 3; write $\sigma = \chi^{-1}(3)$, so $\sigma(\zeta) = \zeta^3$. The subgroups of $\mathbb{Z}/6$ are $\{1\}$, $\langle \sigma^3 \rangle \cong \mathbb{Z}/2$, $\langle \sigma^2 \rangle \cong \mathbb{Z}/3$ and the whole group, so $\mathbb{Q}(\zeta_7)$ has exactly four subfields.

The subgroup $\langle \sigma^3 \rangle$ has order 2, so its fixed field has degree 3. Since $\sigma^3(\zeta) = \zeta^{27} = \zeta^{-1}$, this is $\mathbb{Q}(\eta)$ with $\eta = \zeta + \zeta^{-1}$, and the orbit of η under $\langle \sigma \rangle$ is $\{\eta_1, \eta_2, \eta_3\}$ where $\eta_j = \zeta^j + \zeta^{-j}$. So the minimal polynomial of η is

$$(x - \eta_1)(x - \eta_2)(x - \eta_3) = x^3 + x^2 - 2x - 1.$$

The subgroup $\langle \sigma^2 \rangle$ has order 3, so its fixed field is quadratic. Put $\varepsilon = \zeta + \zeta^2 + \zeta^4$ (the orbit of ζ under $\langle \sigma^2 \rangle$, since $\sigma^2(\zeta) = \zeta^2$). Then $\varepsilon' = \zeta^3 + \zeta^5 + \zeta^6$ is its conjugate, and

$$\varepsilon + \varepsilon' = -1, \quad \varepsilon\varepsilon' = 2,$$

so ε satisfies $x^2 + x + 2$, whose discriminant is -7 . Hence the quadratic subfield is $\mathbb{Q}(\sqrt{-7})$.

The pattern in these examples is general.

Proposition 30.10.11

Let p be an odd prime. Then the unique quadratic subfield of $\mathbb{Q}(\zeta_p)$ is $\mathbb{Q}(\sqrt{p^*})$, where

$$p^* = (-1)^{(p-1)/2}p.$$

Proof. Since $\text{Gal}(\mathbb{Q}(\zeta_p)/\mathbb{Q}) \cong \mathbb{Z}/(p-1)$ is cyclic of even order, it has a unique subgroup of index 2, so there is a unique quadratic subfield F .

Now apply Proposition 30.9.6 to $f(x) = x^p - 1$, whose roots are the p th roots of unity and whose derivative is px^{p-1} :

$$\text{Disc}(f) = (-1)^{p(p-1)/2} \prod_{j=0}^{p-1} p\zeta^j = (-1)^{(p-1)/2} p^p \zeta^{(p-1) \cdot \frac{p(p-1)}{2}} = (-1)^{(p-1)/2} p^p,$$

using that p is odd and $\zeta^p = 1$. Since p is odd, p^p and p differ by the square p^{p-1} , so

$$\mathbb{Q}(\sqrt{\text{Disc } f}) = \mathbb{Q}\left(\sqrt{(-1)^{(p-1)/2}p}\right) = \mathbb{Q}(\sqrt{p^*}).$$

But $\delta = \sqrt{\text{Disc } f}$ lies in the splitting field $\mathbb{Q}(\zeta_p)$ and generates a quadratic extension of $\mathbb{Q}$ (it is irrational since p^* is not a square). By uniqueness, $F = \mathbb{Q}(\sqrt{p^*})$. $\square$

Corollary 30.10.12

$\text{Gal}(\mathbb{Q}(\zeta_p)/\mathbb{Q}) \not\cong A_p$, when regarded as permutations of the p th roots of unity.

This proposition is the first step of one of the standard Galois-theoretic proofs of quadratic reciprocity, which you may have seen in Number Theory.

§30.10.4 Constructible Polygons

We can now settle the question left open in Section 30.3.

Theorem 30.10.13 (Gauss)

The regular n -gon is constructible with ruler and compass if and only if

$$n = 2^k p_1 p_2 \cdots p_r$$

where the p_i are distinct primes of the form $2^{2^\ell} + 1$.

Primes of the form $2^m + 1$ are called **Fermat primes**; note that m must itself be a power of 2, since if m has an odd factor $t > 1$ then $2^{m/t} + 1$ divides $2^m + 1$. The only known Fermat primes are 3, 5, 17, 257 and 65537.

Proof. Constructing the regular n -gon is equivalent to constructing $\cos(2\pi/n)$, and since $[\mathbb{Q}(\zeta_n) : \mathbb{Q}(\cos(2\pi/n))] = 2$ by Lemma 30.10.8, this is equivalent to constructing ζ_n , that is, to every element of $\mathbb{Q}(\zeta_n)$ being constructible.

($\Rightarrow$) If ζ_n is constructible then by Corollary 30.3.5 its degree over $\mathbb{Q}$ is a power of 2, that is $\phi(n) = 2^s$. Writing $n = \prod_i p_i^{\alpha_i}$ we have $\phi(n) = \prod_i p_i^{\alpha_i-1}(p_i - 1)$, so no odd prime may occur with $\alpha_i \geq 2$, and each odd p_i must have $p_i - 1$ a power of 2. That is exactly the stated form.

($\Leftarrow$) Suppose $\phi(n) = 2^s$, so $G = \text{Gal}(\mathbb{Q}(\zeta_n)/\mathbb{Q})$ is an abelian group of order 2^s . Any such group has a chain of subgroups

$$\{1\} = A_0 < A_1 < \cdots < A_s = G$$

with $A_j/A_{j-1} \cong \mathbb{Z}/2$ (take a chain through the factors given by the structure theorem, or simply induct: an abelian 2-group has a subgroup of index 2). By the Galois correspondence this gives a tower

$$\mathbb{Q} = F_0 \subset F_1 \subset \cdots \subset F_s = \mathbb{Q}(\zeta_n)$$

with each $[F_j : F_{j-1}] = 2$, so each $F_j = F_{j-1}(\sqrt{r_j})$ for some $r_j \in F_{j-1}$. By Theorem 30.3.4, everything in $\mathbb{Q}(\zeta_n)$ is constructible. $\square$

Example 30.10.14 (The 17-gon)

Here $(\mathbb{Z}/17)^\times \cong \mathbb{Z}/16$, which has the chain $\{1\} < \mathbb{Z}/2 < \mathbb{Z}/4 < \mathbb{Z}/8 < \mathbb{Z}/16$, so

$$\mathbb{Q} \subset K_1 \subset K_2 \subset K_3 \subset \mathbb{Q}(\zeta_{17})$$

with each step quadratic, and $K_3 = \mathbb{Q}(\cos(2\pi/17))$. So $\cos(2\pi/17)$ is obtained from $\mathbb{Q}$ by extracting four successive square roots, and the regular 17-gon is constructible. Gauss discovered this at the age of nineteen, and it is said to have decided him on a career in mathematics.

§30.11 Kummer Theory and Cyclic Extensions

Cyclotomic extensions are the extensions generated by roots of $x^n - 1$. We now consider the general $x^n - a$, and discover that – once enough roots of unity are present – these are exactly the cyclic extensions. This is the last piece of machinery we need for the insolubility of the quintic.

§30.11.1 Linear Independence of Characters

Theorem 30.11.1 (Dedekind, Artin)

Let G be a group, L a field, and $\sigma_1, \dots, \sigma_n : G \rightarrow L^\times$ distinct group homomorphisms. Then $\sigma_1, \dots, \sigma_n$ are linearly independent over L as functions $G \rightarrow L$.

Proof. Induct on n ; the case $n = 1$ is clear since σ_1 is nowhere zero. Suppose $y_1, \dots, y_n \in L$ satisfy

$$y_1\sigma_1(g) + \dots + y_n\sigma_n(g) = 0 \quad \text{for all } g \in G. \quad (*)$$

As $\sigma_1 \neq \sigma_n$, choose $h \in G$ with $\sigma_1(h) \neq \sigma_n(h)$. Substituting hg for g in $(*)$ and using multiplicativity,

$$y_1\sigma_1(h)\sigma_1(g) + \dots + y_n\sigma_n(h)\sigma_n(g) = 0.$$

Subtracting $\sigma_n(h)$ times $(*)$ kills the last term:

$$\sum_{i=1}^{n-1} y_i(\sigma_i(h) - \sigma_n(h))\sigma_i(g) = 0 \quad \text{for all } g.$$

By induction all the coefficients vanish; in particular $y_1(\sigma_1(h) - \sigma_n(h)) = 0$, so $y_1 = 0$. Now $(*)$ has only $n - 1$ terms, and induction finishes the job. $\square$

Corollary 30.11.2 (Linear independence of embeddings)

Let K, L be fields and $\sigma_1, \dots, \sigma_n : K \rightarrow L$ distinct field homomorphisms. Then they are linearly independent over L .

Proof. Apply the theorem with $G = K^\times$; a field homomorphism restricts to a group homomorphism $K^\times \rightarrow L^\times$, and distinct field homomorphisms restrict to distinct group homomorphisms. $\square$

§30.11.2 Kummer Extensions

Throughout this subsection, let $n > 1$ with $n \neq 0$ in K , and suppose K contains a primitive n th root of unity $\zeta = \zeta_n$.

Theorem 30.11.3

Let $L = K(y)$ where $y^n = a \in K^\times$. Then L is a splitting field for $x^n - a$ over K , the extension L/K is Galois, and $\text{Gal}(L/K)$ is cyclic. Moreover $[L : K]$ is the least $m \geq 1$ with $y^m \in K$.

Proof. The roots of $x^n - a$ are $y, \zeta y, \dots, \zeta^{n-1}y$, which are n distinct elements of L since $\zeta \in K$. So $x^n - a$ is separable and L is its splitting field, hence L/K is Galois.

For $\sigma \in G = \text{Gal}(L/K)$ we have $\sigma(y)^n = a$, so $\sigma(y)/y \in \mu_n$. Define

$$\theta : G \rightarrow \mu_n, \quad \theta(\sigma) = \sigma(y)/y.$$

This is a homomorphism: since $\mu_n \subseteq K$ is fixed pointwise by G ,

$$\theta(\tau\sigma) = \frac{\tau\sigma(y)}{y} = \tau\left(\frac{\sigma(y)}{y}\right) \cdot \frac{\tau(y)}{y} = \theta(\sigma)\theta(\tau).$$

It is injective, since $\theta(\sigma) = 1$ means $\sigma(y) = y$, and σ is determined by $\sigma(y)$ as $L = K(y)$. So G embeds in the cyclic group $\mu_n \cong \mathbb{Z}/n$, hence is cyclic.

Finally, since L/K is Galois, $y^m \in K$ if and only if $\sigma(y^m) = y^m$ for all σ , if and only if $\theta(\sigma)^m = 1$ for all σ , if and only if $\#G = \#\theta(G)$ divides m . So the least such m is $\#G = [L : K]$. $\square$

Corollary 30.11.4

Let $a \in K^\times$. Then $x^n - a$ is irreducible over K if and only if a is not a d th power in K for any $d > 1$ dividing n .

Proof. Let y be a root and $L = K(y)$; then $x^n - a$ is irreducible if and only if $[L : K] = n$. Write $n = md$ with $d > 1$. Since $\zeta_n \in K$, one checks that a is a d th power in K if and only if $y^m \in K$: indeed if $y^m = c \in K$ then $a = y^n = c^d$, and conversely if $a = b^d$ then $(y^m/b)^d = 1$ so $y^m = \zeta_d^j b \in K$. By the theorem this holds if and only if $[L : K] \mid m$, that is $[L : K] < n$. $\square$

Remark. The hypothesis $\zeta_n \in K$ is essential here. Over $\mathbb{Q}$, the polynomial $x^4 + 4$ is reducible ($x^4 + 4 = (x^2 - 2x + 2)(x^2 + 2x + 2)$) even though -4 is not a square or fourth power in $\mathbb{Q}$.

The converse of Theorem 30.11.3 is where the Lagrange resolvent comes into its own.

Theorem 30.11.5

Let K contain a primitive n th root of unity ζ , and let L/K be Galois with $\text{Gal}(L/K)$ cyclic of order n . Then $L = K(y)$ for some y with $y^n \in K$.

Proof. Write $\text{Gal}(L/K) = \langle \sigma \rangle$ with σ of order n . For $z \in L$ define the **Lagrange resolvent**

$$R(z) = \sum_{j=0}^{n-1} \zeta^{-j} \sigma^j(z) \in L.$$

Then, since $\zeta \in K$ is fixed by σ and $\sigma^n = 1$,

$$\sigma(R(z)) = \sum_{j=0}^{n-1} \zeta^{-j} \sigma^{j+1}(z) = \zeta \sum_{k=0}^{n-1} \zeta^{-k} \sigma^k(z) = \zeta R(z).$$

Hence $\sigma(R(z)^n) = \zeta^n R(z)^n = R(z)^n$, so $R(z)^n \in L^{\langle \sigma \rangle} = K$.

By Corollary 30.11.2 the distinct automorphisms $1, \sigma, \dots, \sigma^{n-1}$ are linearly independent over L , and the coefficients ζ^{-j} are not all zero, so R is not identically zero; choose z with $y = R(z) \neq 0$.

Then $\sigma^i(y) = \zeta^i y$ for each i , and these are n distinct elements, so the orbit of y has

size n and hence $[K(y) : K] = \deg_K y = n = [L : K]$ by Lemma 30.8.5. Therefore $L = K(y)$, and $y^n \in K$. $\square$

Definition 30.11.6 (Kummer Extension)

An extension of the form $L = K(y)$ with $y^n = a \in K$ and $\zeta_n \in K$ is called a **Kummer extension**.

So, in the presence of enough roots of unity, *cyclic* = *Kummer*. The two theorems above are exactly the bridge between the group theory (cyclic groups) and the algebra (extracting n th roots) that we will use to prove the theorem of Galois.

Example 30.11.7

With $n = 2$ and $\text{char } K \neq 2$, we have $\zeta_2 = -1 \in K$ automatically, and the theorems say: every quadratic extension of K is $K(\sqrt{a})$ for some non-square $a \in K^\times$. This we knew.

Example 30.11.8

Let $L/\mathbb{Q}$ be Galois of degree 3, for instance the splitting field of $x^3 - 3x + 1$ (whose discriminant is 81, a square, so its Galois group is A_3). Since $\zeta_3 \notin \mathbb{Q}$, this is *not* a Kummer extension, and indeed L is not of the form $\mathbb{Q}(\sqrt[3]{a})$ – such a field is not even normal over $\mathbb{Q}$. To apply Kummer theory one must first adjoin ζ_3 , which is exactly what we did in Example 30.9.9.

§30.11.3 Artin–Schreier Extensions

Kummer theory says nothing about cyclic extensions of degree p in characteristic p , since there are no primitive p th roots of unity there ($x^p - 1 = (x - 1)^p$). That case has its own, equally clean, description.

Theorem 30.11.9 (Artin–Schreier)

Let $\text{char } K = p$.

- (i) Let $a \in K$ and $f(x) = x^p - x - a$. Then either f splits completely in K , or f is irreducible; in the latter case $K(\alpha)/K$ is Galois of degree p with cyclic Galois group, where $f(\alpha) = 0$.
- (ii) Conversely, if L/K is Galois with $\text{Gal}(L/K) \cong \mathbb{Z}/p$, then $L = K(\alpha)$ where $\alpha^p - \alpha = a$ for some $a \in K$.

Proof. (i) If α is a root of f in a splitting field, then for $c \in \mathbb{F}_p \subseteq K$ we have

$$(\alpha + c)^p - (\alpha + c) - a = \alpha^p + c^p - \alpha - c - a = f(\alpha) = 0,$$

using $c^p = c$. So the roots of f are $\alpha, \alpha+1, \dots, \alpha+p-1$, all distinct, and f is separable with splitting field $K(\alpha)$. Hence $K(\alpha)/K$ is Galois. Any $\sigma \in \text{Gal}(K(\alpha)/K)$ sends $\alpha \mapsto \alpha + c_\sigma$ for some $c_\sigma \in \mathbb{F}_p$, and $\sigma \mapsto c_\sigma$ is an injective homomorphism into $(\mathbb{F}_p, +) \cong \mathbb{Z}/p$. So the Galois group is trivial or all of $\mathbb{Z}/p$; in the first case $\alpha \in K$

and f splits in K , and in the second $[K(\alpha) : K] = p$ so f is irreducible.

(ii) Write $\text{Gal}(L/K) = \langle \sigma \rangle$ of order p , and consider the trace map $\text{Tr} = \sum_{j=0}^{p-1} \sigma^j : L \rightarrow K$. By Corollary 30.11.2 the σ^j are linearly independent, so Tr is not identically zero; and it is K -linear, so there is $\theta \in L$ with $\text{Tr}(\theta) = 1$. Put

$$\alpha = \sum_{j=0}^{p-1} j \sigma^j(\theta).$$

Then, reindexing and using $\sigma^p = 1$,

$$\sigma(\alpha) = \sum_{j=0}^{p-1} j \sigma^{j+1}(\theta) = \sum_{k=1}^{p-1} (k-1) \sigma^k(\theta) + (p-1)\theta = \alpha - \sum_{k=0}^{p-1} \sigma^k(\theta) = \alpha - 1.$$

Hence $\sigma(\alpha^p - \alpha) = (\alpha - 1)^p - (\alpha - 1) = \alpha^p - 1 - \alpha + 1 = \alpha^p - \alpha$, so $a := \alpha^p - \alpha \in L^{\langle \sigma \rangle} = K$. Finally $\sigma(\alpha) \neq \alpha$, so $\alpha \notin K$, and since $[L : K] = p$ is prime, $L = K(\alpha)$. $\square$

§30.12 Solubility by Radicals

We have arrived at the theorem the subject was invented for. The plan is:

- define precisely what a ‘formula involving radicals’ is;
- define the corresponding class of groups;
- prove that the two match up;
- exhibit a quintic whose Galois group is not in the class.

Throughout this section we work in characteristic zero, which spares us a certain amount of fuss about separability and about $\text{char } K$ dividing the degrees involved. Everything goes through if one assumes $\text{char } K = 0$ or $\text{char } K > \deg f$.

§30.12.1 Soluble Groups

Definition 30.12.1 (Soluble Group)

A finite group G is **soluble** if there is a chain of subgroups

$$\{1\} = G_r \trianglelefteq G_{r-1} \trianglelefteq \dots \trianglelefteq G_1 \trianglelefteq G_0 = G$$

such that each G_{i+1} is normal in G_i and each quotient G_i/G_{i+1} is abelian. (We do *not* require $G_i \trianglelefteq G$.)

Lemma 30.12.2

A finite group G is soluble if and only if it admits such a chain with all quotients *cyclic*.

Proof. Cyclic groups are abelian, so one direction is trivial. Conversely, given a chain with abelian quotients, refine it: if $A = G_i/G_{i+1}$ is abelian then by the

structure theorem $A \cong \mathbb{Z}/a_1 \times \cdots \times \mathbb{Z}/a_m$, and

$$1 \leq \mathbb{Z}/a_1 \leq \mathbb{Z}/a_1 \times \mathbb{Z}/a_2 \leq \cdots \leq A$$

is a chain of subgroups (all normal, as A is abelian) with cyclic quotients. Pulling back along $G_i \rightarrow A$ inserts extra terms into the original chain, with cyclic quotients. $\square$

Example 30.12.3

Every abelian group is soluble. S_3 is soluble via $S_3 \triangleright A_3 \triangleright 1$, with quotients $\mathbb{Z}/2$ and $\mathbb{Z}/3$. S_4 is soluble via

$$S_4 \triangleright A_4 \triangleright V \triangleright 1,$$

with quotients $\mathbb{Z}/2$, $\mathbb{Z}/3$ and $\mathbb{Z}/2 \times \mathbb{Z}/2$. Every p -group is soluble, since a p -group has a non-trivial centre.

Here are the two derived pictures we care about, side by side. On the left is S_4 , which is soluble; on the right is S_5 , which as we shall see is not, because the chain grinds to a halt at the simple non-abelian group A_5 .

$$\begin{array}{ccc} S_4 & & S_5 \\ | \mathbb{Z}/2 & & | \mathbb{Z}/2 \\ A_4 & & A_5 \\ | \mathbb{Z}/3 & & \vdots A_5, \text{ simple and non-abelian} \\ V & & \{1\} \\ | \mathbb{Z}/2 \times \mathbb{Z}/2 & & \\ \{1\} & & \end{array}$$

Proposition 30.12.4

Let G be a finite group.

- (i) If G is soluble and $H \leq G$, then H is soluble.
- (ii) If G is soluble and $N \trianglelefteq G$, then G/N is soluble.
- (iii) If $N \trianglelefteq G$ with N and G/N soluble, then G is soluble.

Proof. (i) Let $G = G_0 \triangleright G_1 \triangleright \cdots \triangleright G_r = 1$ have abelian quotients and put $H_i = H \cap G_i$. If $h \in H_i$ then $hG_{i+1}h^{-1} \subseteq G_{i+1}$ and $hHh^{-1} = H$, so $H_{i+1} \trianglelefteq H_i$. Moreover the map

$$H_i/H_{i+1} \rightarrow G_i/G_{i+1}, \quad hH_{i+1} \mapsto hG_{i+1}$$

is a well-defined injective homomorphism (its kernel is $(H \cap G_i) \cap G_{i+1}/H_{i+1}$, which is trivial), so H_i/H_{i+1} is abelian.

(ii) Let $\pi : G \rightarrow G/N$ be the quotient map. Then $\pi(G_{i+1}) \trianglelefteq \pi(G_i)$, and G_i/G_{i+1} surjects onto $\pi(G_i)/\pi(G_{i+1})$, which is therefore abelian.

(iii) Concatenate a chain for N with the preimage under $G \rightarrow G/N$ of a chain for G/N ; the quotients are unchanged by the third isomorphism theorem. $\square$

Corollary 30.12.5

For $n \geq 5$, the groups A_n and S_n are insoluble.

Proof. Both contain a copy of A_5 , so by Proposition 30.12.4(i) it suffices to show A_5 is insoluble. But A_5 is simple (proved in Groups, Rings and Modules) and non-abelian, so the only chain available is $A_5 \triangleright 1$, whose quotient A_5 is not abelian. $\square$

§30.12.2 Radical Extensions**Definition 30.12.6** (Radical Extension)

An extension L/K is a **radical extension** if there is a chain

$$K = L_0 \subseteq L_1 \subseteq \cdots \subseteq L_r = L$$

with $L_i = L_{i-1}(y_i)$ for some y_i with $y_i^{n_i} \in L_{i-1}$, for some $n_i \geq 1$.

Definition 30.12.7 (Soluble by Radicals)

A polynomial $f \in K[x]$ is **soluble by radicals** over K if its splitting field L is contained in some radical extension of K .

That is the correct formalisation of ‘there is a formula for the roots involving only the field operations and extraction of n th roots’. Note that we allow the radical extension to be strictly bigger than L : Cardano’s formula for a cubic with three real roots famously passes through complex numbers, so we must permit detours.

Lemma 30.12.8 (i) If L/K is radical and $\sigma : L \rightarrow M$ is a K -homomorphism, then $\sigma(L)/K$ is radical.

(ii) If L_1/K and L_2/K are radical subextensions of some M/K , then L_1L_2/K is radical, where L_1L_2 denotes the subfield of M generated by both.

(iii) If L/K is radical and N is a normal closure of L/K , then N/K is radical.

Proof. (i) Apply σ to the chain: $\sigma(L_i) = \sigma(L_{i-1})(\sigma y_i)$ and $(\sigma y_i)^{n_i} = \sigma(y_i^{n_i}) \in \sigma(L_{i-1})$.

(ii) Concatenate: take a chain for L_1/K , then adjoin the generators of a chain for L_2/K one at a time on top.

(iii) The normal closure N is generated over K by the images $\sigma(L)$ as σ ranges over the (finitely many) K -homomorphisms $L \rightarrow N$, since N is a splitting field for the product of the minimal polynomials of generators of L . Each $\sigma(L)/K$ is radical by (i), so N/K is radical by (ii). $\square$

§30.12.3 Galois’ Theorem**Theorem 30.12.9** (Galois)

Let $\text{char } K = 0$, let $f \in K[x]$ and let L be a splitting field for f over K . Then f is soluble by radicals over K if and only if $\text{Gal}(L/K)$ is a soluble group.

Proof. ($\Leftarrow$) Suppose $G = \text{Gal}(L/K)$ is soluble, and let $n = \#G$. Adjoin a primitive n th root of unity: $K(\zeta_n)/K$ is radical (it is $K(\zeta_n)$ with $\zeta_n^n = 1 \in K$).

Consider $L(\zeta_n)/K(\zeta_n)$. It is the splitting field of f over $K(\zeta_n)$, hence Galois, and restriction gives a homomorphism

$$\text{Gal}(L(\zeta_n)/K(\zeta_n)) \rightarrow \text{Gal}(L/K), \quad \sigma \mapsto \sigma|_L,$$

which makes sense because σ permutes the roots of f and so preserves L . It is injective: if $\sigma|_L = \text{id}$ then σ fixes L and $K(\zeta_n)$, hence fixes $L(\zeta_n)$. So $H := \text{Gal}(L(\zeta_n)/K(\zeta_n))$ embeds in G and is therefore soluble by Proposition 30.12.4(i).

By Lemma 30.12.2 choose a chain $H = H_0 \triangleright H_1 \triangleright \cdots \triangleright H_s = 1$ with cyclic quotients, and let $F_i = L(\zeta_n)^{H_i}$, so that

$$K(\zeta_n) = F_0 \subseteq F_1 \subseteq \cdots \subseteq F_s = L(\zeta_n)$$

and, by the fundamental theorem applied to the Galois extension $L(\zeta_n)/F_i$, each F_{i+1}/F_i is Galois with cyclic Galois group of order $m_i = \#(H_i/H_{i+1})$. Now m_i divides $\#H$, which divides n , so $\zeta_{m_i} \in K(\zeta_n) \subseteq F_i$. By Kummer's Theorem 30.11.5, $F_{i+1} = F_i(y_i)$ with $y_i^{m_i} \in F_i$.

So $L(\zeta_n)/K(\zeta_n)$ is radical, and hence so is $L(\zeta_n)/K$. As $L \subseteq L(\zeta_n)$, the polynomial f is soluble by radicals.

($\Rightarrow$) Suppose $L \subseteq M$ with M/K radical, via a chain with exponents $n_1, \dots, n_r$; put $n = \text{lcm}(n_i)$. Replacing M by $M(\zeta_n)$ (still radical) and then by its normal closure over K (still radical by Lemma 30.12.8(iii)), we may assume that M/K is Galois, radical, and contains ζ_n . Rearranging the chain so that ζ_n is adjoined first, we have

$$K = M_0 \subseteq M_1 = K(\zeta_n) \subseteq M_2 \subseteq \cdots \subseteq M_t = M,$$

with $M_i = M_{i-1}(y_i)$ and $y_i^{n_i} \in M_{i-1}$ for $i \geq 2$, and $n_i \mid n$.

Now M_1/M_0 is Galois with abelian Galois group, by Proposition 30.10.2. And for $i \geq 2$, since $\zeta_{n_i} \in M_1 \subseteq M_{i-1}$, Kummer's Theorem 30.11.3 says M_i/M_{i-1} is Galois with cyclic Galois group.

Set $G_i = \text{Gal}(M/M_i)$, so

$$\text{Gal}(M/K) = G_0 \supseteq G_1 \supseteq \cdots \supseteq G_t = \{1\}.$$

Applying the fundamental theorem to the Galois extension M/M_{i-1} : since M_i/M_{i-1} is Galois, $G_i \trianglelefteq G_{i-1}$ with

$$G_{i-1}/G_i \cong \text{Gal}(M_i/M_{i-1}),$$

which is abelian. So $\text{Gal}(M/K)$ is soluble.

Finally, L/K is normal (being a splitting field), so $\text{Gal}(M/L) \trianglelefteq \text{Gal}(M/K)$ with

$$\text{Gal}(L/K) \cong \text{Gal}(M/K) / \text{Gal}(M/L),$$

a quotient of a soluble group, hence soluble by Proposition 30.12.4(ii). $\square$

§30.12.4 The Insolubility of the Quintic

Theorem 30.12.10

Let k be a field of characteristic zero and $n \geq 5$. The general polynomial of degree n ,

$$f(x) = x^n - e_1x^{n-1} + e_2x^{n-2} - \cdots + (-1)^ne_n \in K[x], \quad K = k(e_1, \dots, e_n),$$

is not soluble by radicals over K .

Proof. By Theorem 30.9.17, $\text{Gal}(f/K) = S_n$, which is insoluble for $n \geq 5$ by Corollary 30.12.5. Now apply Theorem 30.12.9. $\square$

So there is no formula, in the coefficients, for the roots of the general quintic. But this leaves open the possibility that every *particular* quintic with rational coefficients might still be soluble – after all, the general quadratic, cubic and quartic all are. It is not so.

Theorem 30.12.11

The polynomial $f(x) = x^5 - 6x + 3 \in \mathbb{Q}[x]$ has Galois group S_5 , and hence is not soluble by radicals over $\mathbb{Q}$.

Proof. First, f is irreducible over $\mathbb{Q}$ by Eisenstein at 3. So $G = \text{Gal}(f/\mathbb{Q})$ acts transitively on the five roots, and hence $5 \mid \#G$ by orbit-stabiliser. By Cauchy's theorem G contains an element of order 5, which in S_5 must be a 5-cycle.

Next we count real roots. We have $f'(x) = 5x^4 - 6$, which vanishes at $x = \pm(6/5)^{1/4} \approx \pm 1.047$. Evaluating, $f(-1.047) \approx 8.02 > 0$ and $f(1.047) \approx -2.02 < 0$, while $f(x) \rightarrow \pm\infty$ as $x \rightarrow \pm\infty$. So f has exactly three real roots and one pair of complex conjugate roots.

Complex conjugation restricts to an element of G which fixes the three real roots and swaps the two complex ones – that is, a transposition.

Finally, a 5-cycle and a transposition generate S_5 . (Relabelling, the 5-cycle is $\sigma = (12345)$ and the transposition is $\tau = (ab)$; replacing σ by a suitable power we may assume $\tau = (12)$, and then $\sigma^j \tau \sigma^{-j}$ gives all the transpositions $(i, i+1)$, which generate S_5 .) So $G = S_5$, which is insoluble, and Theorem 30.12.9 applies. $\square$

Remark. Note how much the argument used: irreducibility (an algebraic input), the intermediate value theorem (an analytic input) and the classification of transitive subgroups of S_5 (a group-theoretic input). This mixture is entirely typical of Galois theory in practice.

§30.13 Trace and Norm

There are two very useful maps attached to a finite extension, obtained by remembering that L is a vector space over K and that multiplication by an element of L is a K -linear map.

Definition 30.13.1 (Trace and Norm)

Let L/K be a finite extension of degree n and let $\alpha \in L$. Multiplication by α ,

$$U_\alpha : L \rightarrow L, \quad U_\alpha(y) = \alpha y,$$

is K -linear. We define the **trace** and **norm** of α relative to L/K by

$$\mathrm{Tr}_{L/K}(\alpha) = \mathrm{tr}(U_\alpha) \in K, \quad \mathrm{N}_{L/K}(\alpha) = \det(U_\alpha) \in K,$$

and the **characteristic polynomial** of α by $f_{\alpha, L/K}(x) = \det(x \mathrm{id} - U_\alpha) \in K[x]$.

Example 30.13.2

Take $L = \mathbb{Q}(\sqrt{d})$ over $K = \mathbb{Q}$, with basis $1, \sqrt{d}$, and $\alpha = a + b\sqrt{d}$. Then $\alpha \cdot 1 = a + b\sqrt{d}$ and $\alpha \cdot \sqrt{d} = bd + a\sqrt{d}$, so

$$U_\alpha = \begin{pmatrix} a & bd \\ b & a \end{pmatrix},$$

giving $\mathrm{Tr}(\alpha) = 2a$ and $\mathrm{N}(\alpha) = a^2 - db^2$. For $d = -1$ this is the familiar $|a + bi|^2$.

Lemma 30.13.3

Let L/K be finite of degree n , $\alpha, \beta \in L$ and $c \in K$. Then

- (i) $\mathrm{Tr}_{L/K}$ is K -linear, and $\mathrm{Tr}_{L/K}(c) = nc$;
- (ii) $\mathrm{N}_{L/K}(\alpha\beta) = \mathrm{N}_{L/K}(\alpha)\mathrm{N}_{L/K}(\beta)$ and $\mathrm{N}_{L/K}(c\alpha) = c^n \mathrm{N}_{L/K}(\alpha)$;
- (iii) $\mathrm{N}_{L/K}(\alpha) = 0$ if and only if $\alpha = 0$, so $\mathrm{N}_{L/K} : L^\times \rightarrow K^\times$ is a group homomorphism.

Proof. The map $\alpha \mapsto U_\alpha$ is a K -algebra homomorphism from L to $\mathrm{End}_K(L)$, so (i) and (ii) follow from linearity and multiplicativity of trace and determinant. For (iii), $\det U_\alpha \neq 0$ if and only if U_α is invertible, which holds if and only if $\alpha \neq 0$ since L is a field. $\square$

Proposition 30.13.4

Let $L = K(\alpha)$ with minimal polynomial $m(x) = x^n + c_{n-1}x^{n-1} + \cdots + c_0$. Then $f_{\alpha, L/K} = m$, and

$$\mathrm{Tr}_{L/K}(\alpha) = -c_{n-1}, \quad \mathrm{N}_{L/K}(\alpha) = (-1)^n c_0.$$

Proof. In the basis $1, \alpha, \dots, \alpha^{n-1}$, the matrix of U_α is the companion matrix of m

(multiplication sends $\alpha^i \mapsto \alpha^{i+1}$ for $i < n-1$, and $\alpha^{n-1} \mapsto -c_0 - c_1\alpha - \cdots - c_{n-1}\alpha^{n-1}$), whose characteristic polynomial is m . The formulae for the trace and determinant are the standard expressions for the coefficients of a characteristic polynomial. $\square$

For a Galois extension there is a much more useful description.

Proposition 30.13.5

Let L/K be a finite separable extension of degree n , and let $\sigma_1, \dots, \sigma_n : L \rightarrow N$ be the distinct K -homomorphisms into a normal closure N . Then for all $\alpha \in L$,

$$\mathrm{Tr}_{L/K}(\alpha) = \sum_{i=1}^n \sigma_i(\alpha), \quad \mathrm{N}_{L/K}(\alpha) = \prod_{i=1}^n \sigma_i(\alpha), \quad f_{\alpha, L/K}(x) = \prod_{i=1}^n (x - \sigma_i(\alpha)).$$

In particular, if L/K is Galois then $\mathrm{Tr}_{L/K}(\alpha) = \sum_{\sigma \in \mathrm{Gal}(L/K)} \sigma(\alpha)$ and $\mathrm{N}_{L/K}(\alpha) = \prod_{\sigma} \sigma(\alpha)$.

Proof. It suffices to prove the statement about the characteristic polynomial. Let $e_1, \dots, e_n$ be a K -basis of L and let $P = (\sigma_i(e_j)) \in \mathrm{Mat}_n(N)$. Then P is invertible: otherwise there is a non-zero row vector (y_i) over N with $\sum_i y_i \sigma_i(e_j) = 0$ for all j , and hence $\sum_i y_i \sigma_i = 0$ on all of L by K -linearity, contradicting Corollary 30.11.2.

Let $A = (a_{ij})$ be the matrix of U_α , so $\alpha e_j = \sum_r a_{rj} e_r$. Applying σ_i ,

$$\sigma_i(\alpha) \sigma_i(e_j) = \sum_r \sigma_i(e_r) a_{rj},$$

which says $SP = PA$ where $S = \mathrm{diag}(\sigma_1(\alpha), \dots, \sigma_n(\alpha))$. So A and S are conjugate, hence have the same characteristic polynomial, namely $\prod_i (x - \sigma_i(\alpha))$. $\square$

Proposition 30.13.6 (Transitivity)

Let $M/L/K$ be finite extensions. Then for all $\alpha \in M$,

$$\mathrm{Tr}_{L/K}(\mathrm{Tr}_{M/L}(\alpha)) = \mathrm{Tr}_{M/K}(\alpha), \quad \mathrm{N}_{L/K}(\mathrm{N}_{M/L}(\alpha)) = \mathrm{N}_{M/K}(\alpha).$$

Proof. We do the trace. Let $u_1, \dots, u_m$ be an L -basis of M and $v_1, \dots, v_n$ a K -basis of L , so the $u_i v_j$ form a K -basis of M . Let (a_{ik}) be the matrix of $U_{\alpha, M/L}$ over L , so $\alpha u_k = \sum_i a_{ik} u_i$, and let $A_{ik} \in \mathrm{Mat}_n(K)$ be the matrix of multiplication by a_{ik} on L . Then, with respect to the basis $\{u_i v_j\}$ ordered by i first, the matrix of $U_{\alpha, M/K}$ is the block matrix $(A_{ik})_{i,k}$. Taking traces,

$$\mathrm{Tr}_{M/K}(\alpha) = \sum_i \mathrm{tr}(A_{ii}) = \sum_i \mathrm{Tr}_{L/K}(a_{ii}) = \mathrm{Tr}_{L/K} \left(\sum_i a_{ii} \right) = \mathrm{Tr}_{L/K}(\mathrm{Tr}_{M/L}(\alpha)).$$

The norm is similar, using multiplicativity of the determinant of a block matrix. $\square$

The trace is a K -linear map $L \rightarrow K$, so it is either identically zero or surjective. Which one happens is exactly a question of separability.

Theorem 30.13.7

Let L/K be a finite extension. Then L/K is separable if and only if $\text{Tr}_{L/K}$ is surjective (equivalently, not identically zero).

Proof. Suppose L/K is separable, with K -homomorphisms $\sigma_1, \dots, \sigma_n$ into a normal closure. By Proposition 30.13.5, $\text{Tr}_{L/K} = \sum_i \sigma_i$, which is not identically zero by linear independence of embeddings (Corollary 30.11.2).

Conversely suppose L/K is inseparable, so $\text{char } K = p$ and there is $\alpha \in L$ with $\alpha \notin K(\alpha^p)$. Put $F = K(\alpha^p)$ and $F' = F(\alpha)$, so $[F' : F] = p$ (the minimal polynomial of α over F is $x^p - \alpha^p$). For any $\beta \in F'$ we have $\beta^p \in F$, so either $\beta \in F$, in which case $\text{Tr}_{F'/F}(\beta) = p\beta = 0$, or $F(\beta) = F'$ and the minimal polynomial of β over F is $x^p - \beta^p$, whose x^{p-1} coefficient is 0, so again $\text{Tr}_{F'/F}(\beta) = 0$ by Proposition 30.13.4. So $\text{Tr}_{F'/F} \equiv 0$, and by transitivity

$$\text{Tr}_{L/K} = \text{Tr}_{F/K} \circ \text{Tr}_{F'/F} \circ \text{Tr}_{L/F'} \equiv 0. \quad \square$$

Example 30.13.8

For the extension $\mathbb{F}_{q^n}/\mathbb{F}_q$, which is separable, there is therefore some α with $\text{Tr}(\alpha) = 1$. Concretely $\text{Tr}_{\mathbb{F}_{q^n}/\mathbb{F}_q}(\alpha) = \alpha + \alpha^q + \dots + \alpha^{q^{n-1}}$, and this map is surjective; the fibres all have size q^{n-1} .

Remark. This gives a second proof that a tower of separable extensions is separable: if M/L and L/K are separable then $\text{Tr}_{M/L}$ and $\text{Tr}_{L/K}$ are surjective, hence so is their composite $\text{Tr}_{M/K}$.

§30.14 Some Further Results**§30.14.1 The Fundamental Theorem of Algebra**

We have used several times that $\mathbb{C}$ is algebraically closed. Here is a proof which is essentially algebraic; the only analysis used is the intermediate value theorem, which is unavoidable since the real numbers are defined analytically. This subsection is non-examinable.

Theorem 30.14.1 (Fundamental Theorem of Algebra)

$\mathbb{C}$ is algebraically closed.

Proof. We use four facts:

- (a) every polynomial of odd degree over $\mathbb{R}$ has a real root (intermediate value theorem);
- (b) every element of $\mathbb{C}$ has a square root in $\mathbb{C}$, so every quadratic over $\mathbb{C}$ splits;
- (c) every finite group G has a subgroup H with $(G : H)$ odd and $\#H$ a power of 2 (a Sylow 2-subgroup);

- (d) every non-trivial finite p -group has a subgroup of index p (as it has non-trivial centre, one may induct).

It suffices to show that $\mathbb{C}$ has no non-trivial finite extension. So let $K/\mathbb{C}$ be finite; enlarging K , let L be a normal closure of $K/\mathbb{R}$, so that $L/\mathbb{R}$ is Galois (we are in characteristic zero, so separability is free) and $\mathbb{C} \subseteq L$. Put $G = \text{Gal}(L/\mathbb{R})$.

Let $H \leq G$ be a Sylow 2-subgroup, and consider L^H . By the fundamental theorem, $[L^H : \mathbb{R}] = (G : H)$, which is odd. But if $\alpha \in L^H$, then the minimal polynomial of α over $\mathbb{R}$ has odd degree (it divides $[L^H : \mathbb{R}]$), so by (a) it has a real root; being irreducible, it must be linear, so $\alpha \in \mathbb{R}$. Hence $L^H = \mathbb{R}$, so $H = G$ and G is a 2-group.

Now let $G_1 = \text{Gal}(L/\mathbb{C}) \leq G$, also a 2-group. If G_1 were non-trivial, by (d) it would have a subgroup G_2 of index 2, and then $[L^{G_2} : \mathbb{C}] = 2$, giving a quadratic extension of $\mathbb{C}$ – impossible by (b). So $G_1 = \{1\}$ and $L = \mathbb{C}$. Hence $K = \mathbb{C}$. $\square$

§30.14.2 Invariant Theory and the Inverse Galois Problem

Artin's theorem 30.8.7 is a machine for producing Galois extensions from the top down: fix a big field L and a finite group G of automorphisms, and L/L^G is automatically Galois with group G . Theorem 30.9.17 was the prototype, with $L = k(z_1, \dots, z_n)$ and $G = S_n$. Studying R^G for a ring R and a group $G \leq \text{Aut}(R)$ is the subject of **invariant theory**.

Example 30.14.2

For $G = A_n$ acting on $R = k[z_1, \dots, z_n]$ with $\text{char } k \neq 2$, one has

$$R^{A_n} = k[e_1, \dots, e_n, \delta], \quad \delta = \prod_{i < j} (z_i - z_j),$$

which is why the discriminant is the right tool for detecting whether a Galois group lies in A_n .

Example 30.14.3

Let $R = k[z_1, z_2]$ with $\text{char } k \neq 2$ and let $G = \{1, \sigma\}$ with $\sigma(z_i) = -z_i$. Then

$$R^G = k[z_1^2, z_2^2, z_1 z_2] \cong k[Y_1, Y_2, Y_3]/(Y_1 Y_2 - Y_3^2).$$

Over $\mathbb{R}$ the surface $Y_1 Y_2 = Y_3^2$ is a double cone, and the point where the two cones meet is a *singularity*. Invariant rings are a standard source of interesting singularities in algebraic geometry.

Given K and G , one cannot always find a Galois extension L/K with $\text{Gal}(L/K) \cong G$: if K is algebraically closed there are no non-trivial Galois extensions at all, and if $K = \mathbb{F}_p$ then every Galois group is cyclic. Over $\mathbb{Q}$, the **inverse Galois problem** asks whether every finite group arises. This is open. It is known for every finite soluble group (Shafarevich), for every abelian group (an exercise, using cyclotomic fields and Dirichlet's theorem), and for most finite simple groups.

A better question may be to understand the single enormous group $\text{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$, the

absolute Galois group of $\mathbb{Q}$; the inverse Galois problem is the question of whether every finite group is a quotient of it. Understanding its representations is one of the central goals of the Langlands programme.

§30.14.3 A Geometric Postscript

Finally, here is a hint of what Galois theory looks like in geometry. Let $K = \mathbb{C}(x)$, the field of rational functions, whose elements we may regard as functions $\mathbb{C} \setminus P \rightarrow \mathbb{C}$ for a finite set of poles P . Consider

$$L = K(\sqrt{x^3 - x}) = \mathbb{C}(x)[y]/(y^2 - x^3 + x),$$

a quadratic extension, so L/K is Galois with group $\mathbb{Z}/2$ generated by $\sigma : y \mapsto -y, x \mapsto x$.

Now $L = \text{Frac}(R)$ where $R = \mathbb{C}[x, y]/(y^2 - x^3 + x)$, and R is the ring of polynomial functions on the curve

$$E = \{(x, y) \in \mathbb{C}^2 : y^2 = x^3 - x\}.$$

The inclusion $\mathbb{C}[x] \hookrightarrow R$ corresponds to the projection $p : E \rightarrow \mathbb{C}, (x, y) \mapsto x$. For each $x \notin \{0, \pm 1\}$ there are exactly two square roots of $x^3 - x$, so p is two-to-one away from three points, and the Galois group $\langle \sigma \rangle$ acts on E by deck transformations with $E/\langle \sigma \rangle = \mathbb{C}$.

In other words, the Galois correspondence for function fields is the theory of covering spaces in disguise, with the Galois group playing the role of the group of deck transformations, and the ramification points $\{0, \pm 1\}$ playing the role of the branch points. This analogy – fields and covering spaces, Galois groups and fundamental groups – runs very deep, and is the starting point of a great deal of modern algebraic geometry and number theory.

31 Graph Theory

Graph theory is an area of combinatorics which has lots of fun problems and plenty of interesting theorems.

This article constitutes my notes for the ‘Graph Theory’ course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§31.1 Introduction

For many people, ‘Graph Theory’ is a first course in combinatorics. It’s an area with a big focus on problem solving, and it can give a perspective on many other areas of mathematics.

§31.1.1 Definitions

We will begin this handout on graph theory naturally by defining what a graph is.

Definition 31.1.1 (Graph)

A **graph** is an ordered pair $G = (V, E)$ where V is the set of **vertices**, and $E \subseteq \{\{x, y\} \mid x, y \in V, x \neq y\}$ is a set of unordered pairs of vertices called **edges**.

We have a natural way of drawing a graph. For each vertex we have a point in the plane, and for each edge we draw a line between the corresponding pair of vertices.

Example 31.1.2 (Example of a Graph)

The ordered pair (V, E) where $V = \{1, 2, \dots, 6\}$ and $E = \{\{1, 2\}, \{2, 3\}, \dots, \{5, 6\}\}$ is a graph.

This graph is known as P_6 , a path on 6 vertices.

Common Graphs

There are some graphs that will appear repeatedly when working on problems involving graph theory, and we will define them now.

Definition 31.1.3 (Path)

We define P_n to be the graph $V = \{1, \dots, n\}$, $E = \{\{1, 2\}, \{2, 3\}, \dots, \{n-1, n\}\}$ as shown.

We call this a **path** on n vertices, and say it has **length** $n - 1$.

Definition 31.1.4 (Cycle)

We define C_n (for $n \geq 3$) to be the graph $V = \{1, \dots, n\}$, $E = \{\{1, 2\}, \dots, \{n - 1, n\}, \{n, 1\}\}$ as shown.

We call this the **cycle** on n vertices.

Definition 31.1.5 (Complete Graph)

The **complete graph** on n vertices K_n is the graph $\{1, \dots, n\}$ and $E = \{\{i, j\} \mid i \neq j \in V\}$.

Note that there is an edge between every pair of vertices.

Definition 31.1.6 (Empty Graph)

We define the **empty graph** on n vertices $\overline{K}_n$ to have $V = \{1, \dots, n\}$ but $E = \emptyset$.

Remark. In our definition of a graph, we *don't allow*¹ loops, and there *cannot* be multiple edges between the same set of vertices.

You can define graphs where such things are allowed, but for now we will outlaw them. We also note that edges are *unordered pairs*, so for now edges have no direction.

To be slightly more succinct, we will use some shorthand notation.

Notation. If $G = (V, E)$ is a graph, and we have some edge $\{x, y\} \in E$, we will denote

¹These limitations are inherent in our definition, where we use sets rather than multisets.

it by xy . We will also define $|G| = |V|$, and $e(G) = |E|$.

Example 31.1.7 (Vertices and Edges of K_n)

Consider the graph K_n . We have $|K_n| = n$, and $e(K_n) = \binom{n}{2}$, as there is an edge between any pair of vertices.

Subgraphs

Now we will define the notion of a *subgraph*, in the natural way.

Definition 31.1.8 (Subgraph)

We say that $H = (V', E')$ is a **subgraph** of $G = (V, E)$ if $V' \subseteq V$ and $E' \subseteq E$.

Informally, H is a subgraph of G if we can remove vertices and edges from G to get H . Let's look at some examples.

Example 31.1.9 (Example of a Subgraph)

The graph on the right is a subgraph of the graph on the left.

We are also going to use some notation for removing an edge or a vertex from a graph. Of course, when removing a vertex you also have to remove the edges connecting to it.

Notation (Adding/Removing Vertices & Edges). For an edge xy or a vertex x , we define $G - xy$ to be the graph G with the edge xy removed, and $G - x$ to be G with vertex x removed, along with all edges incident to x . We will also define $G + xy$ to be G with the edge xy , and $G + x$ to be G with the vertex x .

An easy way to get a subgraph is by taking a subset of the vertices and seeing what edges you get from the original graph.

Definition 31.1.10 (Induced Subgraph)

If $G = (V, E)$ is a graph and $X \subseteq V$, the **subgraph induced by X** is defined to be $G[X] = (X, \{xy \in E \mid x, y \in X\})$.

Graph Isomorphism

Now that we have defined graphs, it's natural to define some notion of isomorphism.

Definition 31.1.11 (Graph Isomorphism)

Let $G = (V, E)$ and $H = (V', E')$ be graphs. We say that $f : V \rightarrow V'$ is a **graph isomorphism** if $f(u)f(v) \in E' \iff uv \in E$.

If there is a graph isomorphism between G and H then we say they are **isomorphic**.

Now for the following discussion, fix some graph $G = (V, E)$, and let $x \in V$.

Definition 31.1.12 (Neighbourhood)

If $xy \in E$, then we say that x and y are **adjacent**. We define the **neighborhood** of x to be the set $N(x) = \{y \in V \mid xy \in E\}$ of all vertices adjacent to x .

Note that as in the diagram below, x is not in its own neighborhood.

Definition 31.1.13 (Degree)

We define the **degree** of a vertex x to be $d(x) = |N(x)|$. This is equal to the number of edges that are incident to x .

Definition 31.1.14 (Regularity)

A graph G is said to be **regular** if all of the degrees are the same. We say G is k -regular if $d(x) = k$ for all $x \in V$.

Example 31.1.15 (Regular and Non-Regular Graphs)

The graphs K_n is $n - 1$ regular, and C_n is 2-regular. The graph P_n is not regular.

Connectivity

We now want to define some notion of *connectivity*, where a vertex u is connected to vertex v if you can follow some path in the graph to get from u to v .

For example, in the graph above we want to say somehow that u and v are connected, but u and v' are not. To do this, we will introduce some more definitions.

Definition 31.1.16 (uv Path)

A **uv path** is a sequence $x_1, x_2, \dots, x_l$ where $x_1, \dots, x_l$ are distinct, $x_1 = u$, $x_l = v$ and $x_i x_{i+1} \in E$.

In the example above, ux_1x_2v is a uv path.

The slight subtlety in this condition is the *distinctness* condition. For example, if $x_1 \dots x_l$ is a uv path and $y_1 \dots y_{l'}$ is a vw path, then $x_1 \dots x_l y_1 \dots y_{l'}$ may *not* be a uw path since we may have reused an edge. Of course, we can just not reuse edges by avoiding cycles.

Proposition 31.1.17 (Joining Paths)

If $x_1 \dots x_l$ is a uv path and $y_1 \dots y_{l'}$ is a vw path, then $x_1 \dots x_l y_1 \dots y_{l'}$ contains a uw path.

Proof. Choose a minimal subsequence $w_1 \dots w_r$ of $x_1 \dots x_l y_1 \dots y_{l'}$ such that

1. $w_i w_{i+1} \in E$.
2. $w_1 = u, w_r = w$.

We now claim that $w_1 \dots w_r$ is a uw path. If this was not the case, then it must fail on distinctness, so there would exist some z such that the sequence is

$$w_1 \dots w_a z w_{a+2} \dots w_b z w_{b+2} \dots w_r,$$

but now note that

$$w_1 \dots w_a z w_{b+2} \dots w_r$$

also satisfies the conditions for the subsequence, but is strictly shorter length. This contradicts the minimality condition. $\square$

Now given $G = (V, E)$, let's define an equivalence relation $\sim$ on V , where

$$x \sim y \iff \text{there exists an } xy \text{ path in } G.$$

Proposition 31.1.18

$\sim$ is an equivalence relation.

Proof. Note that $\sim$ is reflexive and symmetric, and we get transitivity from our previous proposition. $\square$

Example 31.1.19

In the graph below, the vertices that are the same colour are in the same equivalence class under $\sim$.

Definition 31.1.20 (Connected Graph)

If there is a path between any two vertices in G then we say that G is **connected**.

Definition 31.1.21 (Connected Components)

We call the equivalence classes of $\sim$ on G the **components** or **connected components** of G .

Edges and Distance

We can also introduce some useful definitions relating to the edges of a graph.

Definition 31.1.22 (Minimum/Maximum Degree)

Let G be a graph. The **maximum degree** of G , $\Delta(G)$ is defined to be $\Delta(G) = \max_{x \in V} d(x)$. Similarly, we define the **minimum degree** of G , $\delta(G)$ to be $\delta(G) = \min_{x \in V} d(x)$.

In a k -regular graph as mentioned above, we have $\Delta(G) = \delta(G) = k$.

Definition 31.1.23 (Graph Distance)

Let $G = (V, E)$ be a graph. The associated **graph distance** $d : V \times V \rightarrow \mathbb{R}^{\geq 0} \cup \{\infty\}$ is defined so that $d(x, y)$ is the minimum path length from x to y if it exists, and ∞ otherwise.

Proposition 31.1.24 (Graph Distance is a Metric)

Let $G = (V, E)$ be a connected graph and let d be the associated graph distance. Then (V, d) defines a metric space.

Proof Sketch. We have $d(x, y) = 0$, and $d(x, y) = d(y, x)$ (taking the shortest path in the opposite direction), and $d(x, z) \leq d(x, y) + d(y, z)$ as we can find path from x to z by taking paths from x to y and y to z and adjoining them, and this puts an upper bound on $d(x, z)$. $\square$

§31.1.2 Trees

We will now discuss a special class of graph called *trees*. This class is quite restrictive (yet is quite useful), and they have some nice properties.

To define what a tree is, we first need a notion of when a graph is acyclic.

Definition 31.1.25 (Acyclic)

A graph G is said to be **acyclic** if it does not contain any subgraph isomorphic to a cycle, C_n .

Example 31.1.26 (Example of Acyclic/Non-Acyclic Graphs)

In the example below, the two graphs are both *acyclic*.

Two *non-acyclic* graphs are shown below. The subgraphs isomorphic to C_4 and C_3 are highlighted.

Definition 31.1.27 (Tree)

A **tree** is a connected, acyclic graph.

Example 31.1.28 (Examples of Trees)

The following three graphs are trees.

Proposition 31.1.29 (Characterising Trees)

The following are equivalent.

- (a) G is a tree.
- (b) G is a maximal acyclic graph (adding any edge creates a cycle).
- (c) G is a minimal connected graph (removing any edge disconnects the graph).

Proof. (a) $\implies$ (b). By definition G is acyclic. Let $x, y \in V$ such that $xy \notin E$. As G is connected, there is an xy path P . So xPy then defines a cycle.

(b) $\implies$ (a). By definition G is acyclic. So for a contradiction assume G is not connected and let x, y be vertices from different components. Now note $G + xy$ is

acyclic, but this contradicts the claim that G is maximally acyclic.

(a) $\implies$ (c). By definition G is connected. Suppose, for a contradiction, that there exists some vertices $x, y \in E$ with $x \neq y$ and $G - xy$ is connected. But then there is some xy path P that does not use the edge xy , so xPy is then a cycle, contradicting that G is acyclic.

(c) $\implies$ (a). By definition G is connected. Again for a contradiction, assume that G contains a cycle C . Then let xy be an edge on C . We claim $G - xy$ is still connected. If $u, v \in V(G - xy)$ then let P be a path in G from u to v . If xy does not appear as consecutive vertices on this path, then u is connected to v . Otherwise, we can consider a new path where we replace x, y with the other vertices in $C - xy$ in order. Thus u and v are still connected. This contradicts the minimal connectedness of G .

□

Definition 31.1.30 (Leaf)

Let G be a graph. A vertex $v \in V(G)$ is a **leaf** if $d(v) = 1$.

For example, the tree below has three leaves.

In general, trees has a leaf.

Proposition 31.1.31 (Trees Have Leaves)

Every tree T with $|T| \geq 2$ has a leaf.

Proof. Let T be a tree with $|T| \geq 2$, and let P be a path of maximum length in T , with $P = x_1 \dots x_k$. We claim that $d(x_k) = 1$. Observe that $\deg(x_k) \geq 1$, since $x_k x_{k-1} \in E$. If x_k is adjacent to another vertex $y \neq x_{k-1}$, then either $y \in \{x_1, \dots, x_{k-2}\}$, which would imply that T contains a cycle, or $y \notin \{x_1, \dots, x_{k-2}\}$, then $x_1 \dots x_k y$ is a path longer than P , which violates its maximality. □

Remark. This proof gives us two leaves in T , which is the best we can hope for considering P_n is a tree with exactly two leaves.

Proposition 31.1.32 (Edges of a Tree)

Let T be a tree. Then $e(T) = |T| - 1$.

Proof. We will do induction on $n = |T|$. If $n = 1$, this is trivial as there is only one edge. Now given T with at least 2 vertices, let x be a leaf in T , and define $T' = T - x$.

T' must be acyclic, since we have only removed vertices. T' must also be connected since for all $u, v \in V(T')$ there exists a path from u to v in T that does not use x , so it is also a path from u to v in T' . Thus T' is a tree. Thus by induction, T' has $n - 2$ edges, and $e(T) = e(T') + 1 = |T| - 1$. $\square$

Now let's think about trees as subgraphs of other graphs.

Definition 31.1.33 (Spanning Tree)

Let G be a graph. We say T is a **spanning tree** of G if T is a tree on $V(G)$ and is a subgraph of G .

Spanning trees are useful in a number of contexts, one of which is giving a sensible ordering to the vertices of a graph. They are particularly useful because of the following result.

Proposition 31.1.34 (Connected Graphs have Spanning Trees)

Every connected graph contains a spanning tree.

Proof. A tree is a minimal connected graph. So take the connected graph and remove edges until it becomes a minimal connected graph. Then this will be a subgraph of the original graph, and will thus be a spanning tree. $\square$

§31.1.3 Bipartite Graphs

The next type of graph we will look at is *bipartite* graphs.

Definition 31.1.35 (Bipartite Graphs)

A graph $G = (V, E)$ is **bipartite** if $V = A \cup B$ where $A \cap B = \emptyset$ and all edges $xy \in E$ have either $x \in A, y \in B$ or $x \in B, y \in A$.

Example 31.1.36 (Example of Bipartite Graphs)

The graph below is bipartite, with vertices in the set A being coloured red and vertices in the set B being coloured blue.

An example of a non-bipartite graph is C_5 . To see this, we can start by choosing a vertex to be in A (without loss of generality), then the adjacent vertices must be in B , but then their adjacent vertices must be in A , but then there is an edge between two vertices in A . This is shown below.

The argument given for C_5 works in general.

Proposition 31.1.37 (Bipartite Cyclic Graphs)

The cycle C_{2k+1} is *not* bipartite, and the cycle C_{2k} is bipartite.

Proof. Assume that C_{2k+1} is bipartite. Then there must be disjoint sets A and B , and as $2k + 1$ is odd, we must have (without loss of generality), $|A| > |B|$. Now let's count the edges between A and B . This must be $2|A|$ and also $2|B|$, as every vertex has degree 2. But then $|A| = |B|$, which is a contradiction.

For C_{2n} , we can let $v_i \in A$ if i is even and $v_i \in B$ if i is odd. Then a vertex i only has edges to vertices $i - 1$ and $i + 1 \pmod{2}$, which have opposite parity. Thus all edges are between A and B , as required. $\square$

There is then a natural question: given some arbitrary graph G , how do we determine if a given graph is bipartite? It turns out that there is a nice check for 'bipartness'. We will state the result and then do some setup before we prove it.

Proposition 31.1.38 (Bipartite Criterion)

A graph G is bipartite if and only if G contains no odd cycles.

We need to first develop some theory regarding *circuits*. Informally, a circuit is like a cycle where we can revisit vertices.

Definition 31.1.39 (Circuit)

A circuit is a sequence $x_1 \dots x_l$ where $x_1 = x_l$ and $x_i x_{i+1} \in E$. The **length** of the circuit is $l - 1$, the number of edges traversed in the circuit.

Definition 31.1.40 (Odd Circuits)

If the length of a circuit is odd, then we say it is an **odd circuit**.

Proposition 31.1.41

An odd circuit contains an odd cycle.

Proof. We will prove this by induction on the length of the circuit. For a circuit of length 3, the circuit must be a cycle. In general, let $C = x_1 \dots x_l$ be our circuit. If $x_1, \dots, x_{l-1}$ are distinct, then C is a cycle and we are done.

Otherwise, there exists some $z \in C$ that is repeated. We write

$$C = x_1 \dots x_a z x_{a+2} \dots x_b z x_{b+2} \dots x_l.$$

We define $C' = x_1 \dots x_a z x_{b+2} \dots x_l$ and $C'' = z x_{a+2} \dots x_b z$. The length of C' and C'' is strictly less than the length of C . One of these circuits must have odd length, and by induction that odd circuit contains an odd cycle. $\square$

We can now prove our original bipartiteness criterion, that a graph is bipartite if and only if it contains no odd cycles.

Proof (Bipartite Criterion). If G was bipartite and contained an odd cycle, then there exists an odd cycle that is bipartite. But this is a contradiction.

Now if G is not bipartite, we can induct on the number of vertices. For $|G| = 1$, this holds. Now if G is not connected, let $C_1, \dots, C_k$ be the components of G . We may now apply our induction to each component of G to obtain a bipartition $V(C_i) = A_i \cup B_i$ for each $i \in 1, \dots, k$. Then $A = A_1 \cup \dots \cup A_k$ and $B = B_1 \cup \dots \cup B_k$ is a bipartition for the whole graph.

We may now assume without loss of generality that G is connected. Fix some vertex $v \in V$, and define

$$A = \{u \in V \mid d(u, v) \text{ is odd}\}$$

$$B = \{u \in V \mid d(u, v) \text{ is even}\}$$

We claim that $A \cup B$ is a bipartition.

Assume (for a contradiction) that u_1 is adjacent to u_2 and $d(u_1, v) \not\equiv d(u_2, v) \pmod{2}$. Then there exists paths P_1 from v to u_1 and P_2 from u_2 to v with $|P_1| \equiv |P_2| \pmod{2}$. But this implies that $vP_1u_1u_2P_2v$ defines an odd circuit in G . Therefore, by our previous proposition, G contains an odd cycle, which is a contradiction. $\square$

§31.2 Hall's Theorem

In this section, we will build up our knowledge of *matchings* so that we can prove the first theorem of the course – Hall's theorem.

§31.2.1 Matchings

An appropriate place to start is probably by defining what a matching is.

Definition 31.2.1 (Matching)

A **matching** of G is a collection of edges $M \subseteq E$ so that $\forall e_1, e_2 \in M$ with $e_1 \neq e_2$ has $e_1 \cap e_2 = \emptyset$.

Definition 31.2.2 (Saturated)

Given a graph $G = (V, E)$ and a matching M in G , we say that a vertex $v \in V$ is **saturated by M** if there exists an edge in M containing v .

A matching where every vertex is saturated (such as the above) is known as a **perfect matching**. However, there is no restriction in general on how many vertices are saturated by a matching.

§31.2.2 Matching in Bipartite Graphs

Matchings are particularly interesting in bipartite graphs. We will be interested in the following question: given a bipartite graph $G = (A \cup B, E)$, when can I find a matching saturating A ?

This question is the same as asking when is there a function $f : A \rightarrow B$ where $xf(x) \in E$ that is an injection.

In trying to answer this question, we might try and think about why it may not be possible. The simplest reason is when B isn't large enough to have an injection, when $|B| \leq |A|$. In a similar way, we might have a graph is big enough, but that isn't true for a small part of the graph, like below.

What Hall's theorem says is that this issue is the only obstruction to creating such a matching.

Definition 31.2.3 (Neighbourhood of a Vertex Set)

If $X \subseteq V$, then we define $N(X)$, the **neighbourhood of X** to be $N(X) = \bigcup_{x \in X} N(x)$.

With the notion of the neighborhood of a set of vertices, we can rephrase the issue mentioned about as $|N(A')| < |A'|$ for some subset $A' \subseteq A$. We will use this notation in our statement for Hall's theorem.

Before we prove the theorem, we will need to prepare a little bit.

Definition 31.2.4 (M -Alternating Path)

Let $G = (V, E)$ be a graph with a matching M in G . We say that a path $P = x_1 \dots x_l$ is **M -alternating** if $x_i x_{i+1}$ is alternately in M and not in M .

Another example of an M -alternating path is the one below.

If we saw the path above in the graph, and we knew that the end vertices were not saturated, then we could change the edges that are in M , so we would still have a matching. This move will be key in our proof of Hall's theorem.

We are going to call this configuration an *augmented path*.

Definition 31.2.5 (M -Augmenting Path)

Given a graph $G = (V, E)$ and a matching M in G , an M -alternating path $P = x_1 \dots x_l$ is said to be **M -augmenting** if x_1 and x_l are not saturated.

Proposition 31.2.6

If M is a matching in G of maximum size, then there are no M -augmenting paths.

Proof. If there is an M -augmenting path in G , then we can flip the edges of M along P to find a strictly larger matching. $\square$

An important observation is that an M -alternating path in a bipartite graph $G = (A \cup B, E)$ with $P = x_1 \dots x_l$, with $x_1 \in A$ and $x_1x_2 \in M$, then $x_{2k+1}x_{2k+2} \in M$, and vice versa.

§31.2.3 Hall's Theorem

We are now ready to state and prove Hall's matching theorem, which formalises the ideas mentioned in the previous section.

Theorem 31.2.7 (Hall's Theorem)

Let $G = (A \cup B, E)$ be a bipartite graph. Then there exists a matching saturating A if and only if every subset $A' \subseteq A$ satisfies $|N(A')| \geq |A'|$.

Proof. First we prove the forward (and easy) direction. Let $A' = \{x_1, \dots, x_t\} \subseteq A$. We have matching edges $x_1y_1, \dots, x_ty_t \in M \subseteq E$, and thus $\{y_1, \dots, y_t\} \subseteq N(A')$, and thus $|N(A')| \geq |A'|$.

Now for the other (harder) direction, which is that this condition implies the existence of such a matching. Choose a matching M in G with $|M|$ maximized. For a contradiction, assume there is some vertex $a_0 \in A$ that is not saturated by M .

We inductively define sets $A_i \subseteq A$, $B_t \subseteq B$ by setting $A_0 = \{a_0\}$, $B_0 = \emptyset$. We will maintain, for all t , that

1. $|A_t| = t + 1$, $|B_t| = t$.
2. Every vertex in $A_t \cup B_t$ is the endpoint of an alternating path that started at a_0 .
3. $A_t \setminus \{a_0\}$ is matched to B_t .

So given A_t, B_t , we need to define A_{t+1}, B_{t+1} .

First consider $N(A_t)$. We have $|N(A_t)| \geq |A_t| = t + 1 > |B_t|$. So $N(A_t) \setminus B_t$ is non-empty. So let $b_{t+1} \in N(A_t) \setminus B_t$. Observe that b_{t+1} can be reached along an alternating path which started at a_0 . Call $y \in A_t$ such that $y b_{t+1} \in E$. Then y can be reached along an alternating path starting at a_0 . Let $P = a_0 x_1 \dots x_l y$ be such an alternating path. Since $a_0 x_1 \notin M$, $x_l y \in M$. Hence $P b_{t+1}$ is a alternating path.

Now, b_{t+1} is saturated by M , as otherwise $P b_{t+1}$ would be an M -augmenting path, which is a contradiction. So let $a_{t+1} b_{t+1} \in M$. We claim $a_{t+1} \notin A_t$, since A_t is matched to B_t , and $b_{t+1} \notin B_t$. So we may define $A_{t+1} = A_t \cup \{a_{t+1}\}$ and $B_{t+1} = B_t \cup \{b_{t+1}\}$. We can check that what we claimed before holds.

Since $a_{t+1} \notin A_t$, and $b_{t+1} \notin B_t$, we have $|A_{t+1}| = |A_t| + 1$ and $|B_{t+1}| = |B_t| + 1$. Also every vertex is the endpoint of an alternating path starting at a_0 by construction. Also $A_{t+1} \setminus \{a_0\}$ is matched to B_{t+1} since $A_t \setminus \{a_0\}$ is matched to B_t , and by construction.

This completes the construction of A_t, B_t for all t . Then if $t > |A|$, then $|A_t| > |A|$, but $A_t \subseteq A$, which is a contradiction. $\square$

§31.2.4 Corollaries of Hall's Theorem

So Hall's theorem gives us a nice way to guarantee the existence of matchings that saturate a part of a bipartite graph. We are going to use Hall's theorem to prove some interesting results.

Corollary 31.2.8

A k -regular bipartite graph contains a perfect matching.

Proof. Let $G = (A \cup B, E)$, and let $A' \subseteq A$. We want to show that $|N(A')| \geq |A'|$ so that we may apply Hall's theorem.

We will count the number of edges between A' and $N(A')$ in two different ways. We know that each vertex in A' has degree k , so there is $k|A'|$ edges. But on the other hand, the number of edges in $N(A')$ is $|N(A')|k$. Thus $|N(A')|k \geq |A'|k$, so $|N(A')| \geq |A'|$, and by Hall's theorem there exists a matching saturating A' .

We claim that $|B| = |A|$. Indeed, the number of edges between A and B is $k|A|$ and is also $k|B|$, and thus $|A| = |B|$. So a matching saturating A also saturates B . So there exists a perfect matching. $\square$

We can also consider an extension of Hall's theorem. Hall's theorem tells us when, in a bipartite graph $G = (A \cup B, E)$, there is a matching saturating A , but what if we only wanted a matching of size k ?

Let's say that a matching in G has **deficiency** d if it saturates $|A| - d$ vertices.

Corollary 31.2.9

Let G be a bipartite graph. Then G contains a matching saturating $|A| - d$ vertices in A if and only if for all $A' \subseteq A$, we have $|N(A')| \geq |A'| - d$.

Proof. If we have a matching with deficiency d , then this clearly holds.

Now if this condition holds for some graph $G = (A \cup B, E)$, we define a new graph $\tilde{G}$ by setting $\tilde{B} = B \cup \{z_1, \dots, z_d\}$ where $z_1, \dots, z_d$ are distinct from $x \in A \cup B$, and we define $\tilde{E} = E \cup \{e_i a \mid i \in \{1, \dots, d\}, a \in A\}$. So $\tilde{G} = (A \cup \tilde{B}, \tilde{E})$.

This is a bipartite graph, and we observe that it satisfies Hall's condition. Thus $\tilde{G}$ has a matching M saturating A . So if we define M' by removing all of the edges with an endpoint in $\{z_1, \dots, z_d\}$, then M' saturates all but at most d vertices in G . $\square$

Another way of stating Hall's theorem is with set systems.

Definition 31.2.10 (System of Distinct Representatives)

Given sets $S_1, \dots, S_n \subset X$ where S_i is finite for all i . Then we say that $x_1, \dots, x_n \in X$ is a **system of distinct representatives** (or SDR) if they are distinct and $x_i \in S_i$.

The question is, for what set systems does there exist a system of distinct representatives? The answer is if they satisfy some Hall-like condition.

Corollary 31.2.11 (Existence of SDRs)

Given $S_1, \dots, S_n \subseteq X$, with S_i finite, then $S_1, \dots, S_n$ has a system of distinct representatives if and only if

$$\left| \bigcup_{i \in I} S_i \right| \geq |I|,$$

for all $I \in \{1, \dots, n\}$.

Proof. If such an SDR exists, then this condition clearly holds.

In the other direction, given that this condition holds, we define a graph G by setting $A = \{S_1, \dots, S_n\}$ and $B = \bigcup_{i=1}^n S_i$, with $E = \{\{S_i, x\} \mid x \in A, i \in \{1, \dots, n\}, x \in S_i\}$. Then $G = (A \cup B, E)$. Now observe that a SDR is exactly a matching in G that saturates A .

We check Hall's condition. Given $A' \subseteq A$, then $N(A') = \bigcup_{S_i \in A'} S_i$. Thus

$$|N(A')| = \left| \bigcup_{S_i \in A'} S_i \right| \geq |A'|,$$

by our condition. So such a matching exists. $\square$

Remark. The existence of SDRs is equivalent to Hall's theorem.

The last example of using Hall's theorem will be an application to group theory.

Example 31.2.12 (Left and Right Coset Representatives)

Let G be a group and let $H < G$, with G finite. We have the left cosets $g_1H, \dots, g_kH$ and right cosets $Hg'_1, \dots, Hg'_k$.

We want to know does there exists $h_1, \dots, h_k$ such that $h_1H, \dots, h_kH$ are all of the left cosets and $Hh_1, \dots, Hh_k$ are all of the right cosets. It turns out that this question is entirely combinatorial, and we can use Hall's theorem.

Let's form the bipartite graph $(A \cup B, E)$ with $A = \{g_1H, \dots, g_kH\}$ and $B = \{Hg'_1, \dots, Hg'_k\}$ so that there is an edge between g_iH and Hg'_j if the cosets have non empty intersection.

If we had a perfect matching in this graph, then we could pick an element h_i in the (non-empty) intersection of the matched left and right cosets, and then $h_1, \dots, h_k$ would be a set of coset representatives for all of the k left and right cosets.

So we want to show that Hall's theorem is satisfied. Given $I \subseteq \{1, \dots, k\}$, we want to show that the number of right cosets intersecting $\bigcup_{i \in I} g_iH$ is at least $|I|$.

Observe that $|\bigcup_{i \in I} g_iH| = |H||I|$. Since the right cosets partition G , and each coset has size $|H|$, so the number of right cosets intersecting $\bigcup g_iH$ is at least $|I|$. Thus $|N(\{g_iH \mid i \in I\})| \geq |I|$, and thus Hall's theorem is satisfied, and we have a perfect matching in the graph.

§31.3 Connectivity

We have already defined what it means for a graph to be connected, but consider the following connected graphs:

Clearly these are connected, but they are all ‘connected to different extents’. For example, in the first graph, removing any vertex disconnects the graph. In the second graph, any vertex could be removed and the graph would stay connected. We can also see that in the first graph, there’s only one path from one vertex to another, whereas in the third graph there is many. This also seems to correlate with ‘how connected’ a graph is.

§31.3.1 Measuring Connectivity

So looking at the graphs above, we two natural notions for ‘how connected a graph is’ can be informally described as

1. A ‘deletion notion’ of connectivity, where we consider how connected the graph is after some vertices are removed.
2. A ‘paths notion’ of connectivity, where we consider how many independent paths there is between vertices.

One of the main goals of this section will be turning this vague notion into a concrete concept, and proving an interesting result about how the two notions relate to each other.

Notation (Removing Vertex Sets). In this section (and for the rest of this article), if $G = (V, E)$ is a graph and $S \subseteq V$, we define $G - S = G - x_1 - x_2 - \cdots - x_l$ where $S = \{x_1, \dots, x_l\}$.

We will begin with a definition.

Definition 31.3.1 (Cut Vertex)

Let $G = (V, E)$ be a connected graph. We say that $v \in V$ is a **cut vertex** if $G - v$ is disconnected.

Definition 31.3.2 (Separator)

If $G = (G, V)$ is a connected graph, we say that a subset $S \subseteq V$ is a **separator** (or separating set) if $G - S$ is disconnected.

With these concepts defined, we can define our ‘deletion’ notion of connectivity.

Definition 31.3.3 (Connectivity)

Let $G = (V, E)$ be a graph. The **connectivity** of G , denoted $\kappa(G)$, is the size of the smallest set $S \subseteq V$ such that $G - S$ is disconnected, or just a single vertex^a.

^aThis is needed for the case of a complete graph.

Example 31.3.4 (Connectivity of C_n)

Consider the graph C_n for $n \geq 3$.

Removing one vertex will never disconnect C_n .
However, removing two vertices can disconnect it.

$$\implies \kappa(C_n) = 2$$

Example 31.3.5 (Connectivity of the Petersen Graph)

We define the **Petersen graph** with 10 vertices and 15 edges as shown below.

We can see that the connectivity is at most 3, since that is the degree of each vertex, and also removing two vertices won't disconnect the graph. Thus the connectivity of the Petersen graph is exactly 3.

Definition 31.3.6 (k -Connected)

We say that a graph G is **k -connected** if $\kappa(G) \geq k$. In particular, any set $S \subseteq V(G)$ with $|S| < k$ will have $G - S$ connected.

We note this immediately implies that G is 1-connected if and only if it's connected, and it is 2-connected if and only if it has no cut vertex.

We can note some basic properties of connectivity.

Lemma 31.3.7 (Increasing/Reducing Connectivity)

If $G = (V, E)$ is a k -connected graph and $v \in V$ then $G - v$ is $(k - 1)$ -connected^a. Also, if we have some $e \in E$, then $G - e$ is $(k - 1)$ -connected.

^aNote that it is also possible that $G - v$ is $(k + 1)$ -connected, so connectivity can also increase by deleting a vertex.

Proof Sketch. Check definitions. □

§31.3.2 Preparing for Menger's Theorem

We are going to prove Menger's theorem about connectivity measures, but we have to do some setting up beforehand.

Definition 31.3.8 (ab -Seperator)

If $G = (V, E)$ is a graph and $a, b \in V$ are distinct vertices, we say that S is an **ab seperator** if a and b lie in different components of $G - S$ (so $a, b \notin S$).

Definition 31.3.9 (Seperator)

If $G = (V, E)$ is a graph and $F \subseteq E$, we say that F is a **seperator** of G if $G - F$ is disconnected.

We then have a number of useful lemmas, that we will employ later on.

Notation. We let $\kappa_{a,b}(G)$ be the minimum size of an ab seperator.

Lemma 31.3.10

Let $G = (V, E)$ be a graph. Then $\kappa_{a,b}(G) \geq \kappa_{a,b}(G - v)$, where $v \in V$ and $v \neq a, b$.

Proof. If $G - v$ has an ab seperator S then $S \cup \{v\}$ is an ab seperator in G . □

Lemma 31.3.11

For a graph $G = (V, E)$, $\kappa_{a,b}(G - e) \geq \kappa_{a,b}(G) = 1$, for $e \in E$ and $a \sim b$.

Proof. If $G - e$ has an ab separator S then $S \cup \{x\}$ and $S \cup \{y\}$ are ab separators in G , where $e = xy$. $\square$

Lemma 31.3.12

Let $G = (V, E)$ be a graph with distinct non-adjacent vertices $a, b \in V$. Also let $\kappa_{a,b}(G) \geq k$. Let S be an ab separator in G , and say $G - S = A \cup C$, where A is the connected component containing a . Then define $\tilde{G}$ as the induced graph $G[A \cup S]$ with a vertex x joined to all of S . Then $\kappa_{a,x}(\tilde{G}) \geq k$.

Proof Sketch. Check definitions. $\square$

We can now formalize our ‘independent paths’ notion of connectivity.

Definition 31.3.13 (Independent Paths)

We say that $P_1, \dots, P_k$ are **independent ab paths** if each of $P_1, \dots, P_k$ are ab -paths and all of the vertices in these paths are distinct, apart from a and b .

§31.3.3 Actually Menger’s Theorem

Finally, we can state and prove Menger’s theorem.

Theorem 31.3.14 (Menger’s Theorem, First Form)

Let $G = (V, E)$ be a graph, with distinct and non-adjacent $a, b \in V$. If every ab separator in G has size at least k then we can find k independent ab paths.

Proof. Suppose for a contradiction, assume this is false and let G be the counterexample that

- (1) Minimizes $\kappa_{a,b}(G)$
- (2) Subject to (1), minimizes the number of edges in the graph.

Then we observe that $\kappa_{a,b}(G - e) = \kappa_{a,b}(G) - 1$ for any edge $e \in E$. We will let $k = \kappa_{a,b}(G)$.

Claim. There exists an ab separator S with $|S| = k$ so that $S \not\subseteq N(a)$ and $S \not\subseteq N(b)$.

We first observe that $N(a) \cap N(b)$ is empty. To see this, let $x \in N(a) \cap N(b)$ and $G' = G - x$. Then $\kappa_{a,b}(G') \geq \kappa_{a,b}(G) - 1$, thus there are $k - 1$ independent paths $P_1, \dots, P_{k-1}$ in G' , then $P_1, \dots, P_{k-1}, axb$ are k independent paths in G , and our graph would then not be a counterexample.

Now choose a shortest path $P = ax_1 \dots x_l b$. Let $G' = G - x_1 x_2$. We know that $\kappa_{a,b}(G') = k - 1$. Therefore there exists an ab separator S' of size $k - 1$. Let A be the component of a in $G' - S'$, and B be the component of b in $G' - S'$. Note that $x_1 x_2$ must have $x_1 \in A$ and $x_2 \in B$.

Note $x_1 \sim a$, and $x_2 \not\sim a$ since P is the shortest path. Also note that $x_2 \neq b$, since $N(a) \cap N(b) = \emptyset$.

If $S' \subseteq N(a)$, then $S' \cup \{x_2\}$ is an ab separator of size k , and $S \not\subseteq N(a), N(b)$. If $S' \subseteq N(b)$, then $S = S' \cup \{x_1\}$ is an ab separator of size k , and $S \not\subseteq N(b), N(a)$. Lastly, if $S' \not\subseteq N(a)$ and $S' \not\subseteq N(b)$, then $S = S' \cup \{x_1\}$ is an ab separator of size k that is not in $N(a)$ or $N(b)$. So our claim holds.

So let S be an ab separator with $|S| = k$ and $S \not\subseteq N(a), N(b)$. Define A, B to be the components containing a and b in $G - S$. We also define $\tilde{G}_a$ as $G[A \cup S]$ with a vertex x that joins to all of S . define $\tilde{G}_b$ likewise. We now have

$$e(\tilde{G}_a) < e(G), \quad e(\tilde{G}_b) < e(G).$$

We also have $\kappa_{a,x}(\tilde{G}_a) = k = \kappa_{b,x}(\tilde{G}_b)$. Thus $\tilde{G}_a$ and $\tilde{G}_b$ satisfy the theorem, by minimality.

So we can find independent ax paths $P_1, \dots, P_k \in \tilde{G}_a$ and yb paths $Q_1, \dots, Q_k \in \tilde{G}_b$. Thus we can find k independent ab paths by concatenation and reordering in G , as desired. $\square$

Remark. It should be noted that we need the non-adjacent condition, otherwise there is no ab separator. Before we write down the proof, we will isolate some notable facts about connectivity. Also, this result implies Hall's theorem.

Another form of Menger's theorem is more common.

Theorem 31.3.15 (Menger's Theorem, Second Form)

Let $G = (V, E)$ be a graph. Then G is k -connected if and only for all $u, v \in V$ with $u \neq v$, there exists k independent uv -paths.

Proof. If u is not adjacent to v , then apply Menger's theorem (first form) to find k -independent uv paths. If they are adjacent, then $G' = G - uv$ is $k - 1$ connected, thus Menger's theorem (first form) tells us that there are uv independent paths $P_1, \dots, P_{k-1}$ in $G - uv$. Thus $P_1, \dots, P_{k-1}, uv$ are k independent paths. The other direction is straightforward. $\square$

§31.3.4 Edge Connectivity

We have so far been looking at connectivity related to removing vertices and considering independent paths. We will now look at connectivity related to removing edges, and we will see that Menger's theorem is still useful.

Notation. If $G = (V, E)$ is a graph and $F \subseteq E$, define $G - F = (V, E \setminus F)$.

Definition 31.3.16 (Edge Cut)

An **edge cut** in a graph $G = (V, E)$ is a set $F \subseteq E$ so that $G - F$ is disconnected.

Definition 31.3.17 (Cut Edge)

A **cut edge** $e \in E$ is an edge so that $G - e$ is disconnected.

Now similarly to how we had independent paths before (that didn't share vertices), we can define a notion of edge independent paths.

Definition 31.3.18 (Edge Disjoint Paths)

We say that the uv paths $P_1, \dots, P_k$ are **edge disjoint** if $E(P_i) \cap E(P_j) = \emptyset$ for all $i \neq j$.

The **blue** and **red** paths are edge disjoint

We can then define edge connectivity (our deletion notion).

Definition 31.3.19 (Edge Connectivity)

Define the **edge connectivity** of G , $\lambda(G)$ to be the smallest $|S|$ with $S \subseteq E$ such that $G - S$ is disconnected.

Definition 31.3.20 (k -Edge-Connected)

We say a graph G is **k -edge-connected** if $\lambda(G) \geq k$. In other words, $G - F$ is connected for all $|F| \leq k - 1$, with $F \subseteq E$.

We note that G is 1-edge-connected if and only if it is connected, and it is 2-edge-connected if and only if there is no cut edge.

We have a Menger's theorem for this notion of connectivity also.

Theorem 31.3.21 (Menger's Theorem, Edge Version)

Let $G = (V, E)$ be a graph, and u, v be distinct vertices of G . If every set of edges $F \subseteq E$ that separates u from v has size greater than or equal to k , then there exists k edge disjoint paths from u to v .

We also have a similar second version.

Theorem 31.3.22 (Menger's Theorem, Edge Version Two)

Let $G = (V, E)$ be a graph. Then G is k -edge-connected if and only if for every

$u, v \in V$ with $u \neq v$ there exists k edge disjoint uv -paths $P_1, \dots, P_k$.

We are going to prove this by constructing a graph that we can then get the required result from by applying vertex Menger. The construction will be based on the idea of a *line graph*.

Definition 31.3.23 (Line Graph)

Given a graph $G = (V, E)$, we define $L(G)$ to be the **line graph** as follows. $V(L(G)) = E$, and for $e, f \in E$, we have $ef \in E(L(G))$ if $e \cap f \neq \emptyset$.

An example of a graph and its corresponding line graph is shown below.

We can now prove the edge version of Menger's theorem.

Proof (Menger's Theorem, Edge Version). We are given a graph $G = (V, E)$ and distinct vertices $u, v \in V$ such that every u, v separator has size $\geq k$.

Construct the graph $\tilde{G}$ which is $L(G)$ along with vertices u and v with u joined to all $e \in V(L(G))$ such that $u \in e$, and likewise for v .

Then applying Menger's theorem (the vertex version, from one) to $\tilde{G}$ with u, v as the distinguished vertices. $\square$

§31.4 Planar Graphs

Informally, a graph is **planar** if it can be drawn in the plane without any pair of edges crossing.

For example the cube graph we mentioned earlier is planar, as we can draw it as below.

Of course, a graph is planar only if *there is some drawing* where the edges don't intersect. For example, we could draw the cube graph as below (where edges intersect), and the graph would still be planar.

§31.4.1 Defining Planar Graphs

Let's formalize the notion of 'planar graphs' a bit. First we will define (a somewhat obvious notion) what we mean for a graph to be in a plane.

Definition 31.4.1 (Plane Graph)

A **plane graph** is a finite set of points $V \subseteq \mathbb{R}^2$ and a collection of disjoint polygonal curves (representing the edges) with start and endpoints in V .

Then we can define what it means for a graph to be *planar*.

Definition 31.4.2 (Planar Graph)

A graph G is **planar** if there exists a graph isomorphism from G to some plane graph.

And again, informally this says that a graph is planar if there is some way to draw it in the plane so that edges don't intersect.

We can also define the notion of 'faces' of a plane graph, by looking at the components.

Definition 31.4.3 (Faces)

The **faces** of a plane graph G are the connected components of $\mathbb{R}^2 - G$.

With this we get a nice relation between the vertices, edges and faces of a plane graph.

Theorem 31.4.4 (Euler's Formula)

Let G be a connected plane graph with V vertices, E edges and F faces. Then

$$V - E + F = 2.$$

Proof. We apply induction on the number of edges of G . The base case is $E = 0$, and then since G is connected, $V = 1$, and $F = 1$, and the formula holds. Now if G contains a cycle C , then let e be on C . Then $G' = G - e$ is still connected, and the number of faces increases by 1. The face enclosed is lost. So considering G' and applying Euler's formula, $V - (E - 1) + (F - 1) = 2$, and $V - E + F = 2$, as required.

If G does not contain a cycle, then G is acyclic and connected and is then a tree. Then $E = V - 1$, $F = 1$, and $V - E + F = 2$, as required. $\square$

Corollary 31.4.5 (Planar Graphs are Sparse)

Let $G = (V, E)$ be a planar graph, with $|V| \geq 3$. Then $|E| \leq 3|V| - 6$. This bound is also sharp^a.

^aBy considering plane graphs where every face is a triangle.

Proof. We may assume without loss of generality that G is connected (if not, then we can add edges until it is connected). Also draw G in the plane so that there is no edge crossings. Then by Euler's formula we have $V - E + F = 2$.

Now since every face has at least three edges on its boundary and every edge on the boundary is incident to at most two faces, we obtain

$$3F \leq |\{(e', f') \mid e' \in E, f' \text{ is a face, and } e' \text{ is on the boundary of } f'\}| \leq 2E.$$

Thus $3F \leq 2E$, so $3(2 - V + E) \leq 2E$, and $E \leq 3V - 6$, as required. $\square$

§31.4.2 Which Graphs are Planar?

In this section we really care about the following question:

Which graphs are planar?

The theorems proved at the end of the last section already give us a small amount of control over planar graphs. For example, we can show that K_5 is not planar.

Example 31.4.6 (K_5 is Non-Planar)

We will show that K_5 is not planar. Since the number of edges is 10, and the number of vertices is 5, by the previous result we would need $10 \leq 3 \cdot 5 - 6$, which is not the case.

Let's consider another type of graph.

Definition 31.4.7 (Bipartite Complete Graph)

Define the **bipartite complete graph** $K_{n,m}$ to be the graph with vertex set $V = A \cup B$ where $A \cap B = \emptyset$ so that $|A| = n$, $|B| = m$, and $E(K_{n,m}) = \{ab \mid a \in A, b \in B\}$.

If you play around a bit, you can see that $K_{3,2}$ is planar, but we get a problem if we try use $K_{3,3}$.

Example 31.4.8 ($K_{3,3}$ is Non-Planar)

We will show that $K_{3,3}$ is not planar. Note that there is 9 edges, and 6 vertices. Then by the result in the previous section, we would need $9 \leq 3 \cdot 6 - 6$, which holds.

However, recall in the proof that of our result that we had each face having at least three edges on its boundary. But that for bipartite graphs, we can get something stronger, as each face has at least four edges on its boundary (since there is no cycles of length 3).

So if we repeat the proof of the previous theorem with the stronger bound, we obtain $E \leq 2V - 4$, which does not hold for this graph. Thus $K_{3,3}$ is not planar.

Now these two examples were interesting, but of course we care about whether *any* graph is planar. It turns out though that these are (in some sense) the *only* fundamentally non-planar graphs, in that any non planar graph will have one of these graphs ‘behind it’.

To look at this formally, we need to look at the idea of a subdivision.

Definition 31.4.9 (Subdivision)

A **subdivision** of a graph G is a graph $\tilde{G}$, obtained by replacing the edges of G with disjoint paths.

Lemma 31.4.10

If G is non-planar, then a subdivision of G is non-planar also.

Proof. Given a plane drawing of the subdivided graph, then by disregarding the vertices on the subdivided paths, we obtain a plane drawing of G (which is a contradiction). $\square$

Corollary 31.4.11

Subdivisions of $K_{3,3}$ and K_5 are non-planar.

Proof. Follows directly from the previous lemma. $\square$

What ties all of this together is Kuratowski’s theorem, which gives us a nice necessary and sufficient condition for a graph to be planar.

Theorem 31.4.12 (Kuratowski’s Theorem)

A graph G is planar if and only if G contains no subdivisions of $K_{3,3}$ or K_5 .

Proof. Omitted.

We will leave the topic of planar graphs here (for now), but we note that there are some other interesting notions that are related to planarity. For example, for what graphs is it possible to draw on a torus with no edge crossings?

§31.5 Graph Colouring

Informally, a graph colouring is just a way of colouring in different vertices of a graph, so that adjacent vertices are different colours. An example of a graph colouring is shown below.

§31.5.1 Basic Concepts

Of course, we need to define what this means in a slightly more mathematical sense, so we will define a colouring as follows.

Notation. We will write $[n] = \{1, 2, \dots, n\}$.

Definition 31.5.1 (r -Colouring)

Let $G = (V, E)$ be a graph. An r -colouring of G is a function $c : V \rightarrow [r]$ that satisfies $xy \in E \implies c(x) \neq c(y)$.

An r -colouring divides up a graph into r different colour classes, where there is only edges between the different colour classes.

Definition 31.5.2 (Chromatic Number)

The **chromatic number** of a graph G , denoted $\chi(G)$ is the smallest r for which there exists an r -colouring.

Example 31.5.3 (Examples of Chromatic Numbers)

In the graph P_n , we have $\chi(P_n) = 2$ for $n \geq 2$, and $\chi(P_1) = 1$.

The graph C_n has $\chi(C_n) = 2$ if n is even, and $\chi(C_n) = 3$ if n is odd.

The complete graph K_n has $\chi(K_n) = n$.

The case for C_{2n} follows from a more general fact about bipartite graphs.

Proposition 31.5.4 (Chromatic Number of Bipartite Graphs)

If G is a bipartite graph, then $\chi(G) \leq 2$, and indeed $\chi(G) = 2$ unless $E = \emptyset$.

Proof Sketch. Colour the vertices in each part separately. □

Indeed, one way to think about chromatic number is as a generalization of bipartite graphs to multiple parts.

A straightforward observation to make is that the maximum degree of a graph (Δ) puts a bound on the chromatic number.

Proposition 31.5.5 (Degree Bound for Chromatic Number)

For a graph G , we have $\chi(G) \leq \Delta(G) + 1$. This bound is also sharp^a.

^aTake the complete graph or odd cycles. These are the only such examples though

To prove this, we are going to use a type of greedy algorithm.

Definition 31.5.6 (Greedy Colouring)

Given a graph $G = (V, E)$ with vertices $V = \{v_1, v_2, \dots, v_n\}$, the **greedy colouring** of G is a function $c_g : V \rightarrow \mathbb{N}$ defined inductively by

- $c_g(v_1) = 1$,
- Given coloured $v_1, \dots, v_t$, we have $c_g(v_{t+1}) = \min(\mathbb{N} \setminus \{c(v_i) \mid v_i \sim v_{t+1}, i \leq t\})$.

Proof of Proposition 31.5.5. Apply the greedy colouring to G with an arbitrary vertex ordering $v_1, \dots, v_n$. Then we note that

$$|\{c(v_i) \mid v_i \sim v_{t+1}, i \leq t\}| \leq \Delta(G),$$

and thus $c_g(v_{t+1}) \in [\Delta + 1]$. □

The ‘greedy’ approach need not give you any colouring that’s in any way optimal. For example, if we have the graph P_4 with vertices labelled as below, we get the following colouring from our greedy approach.

This is clearly not optimal.

§31.5.2 Brooks’ Theorem

One step up from the greedy approach to obtaining a colouring comes in the form of Brooks’ Theorem. Before we look at that, we will make an observation.

Proposition 31.5.7

Let G be a connected graph for which $\delta(G) < \Delta(G)$. Then $\chi(G) \leq \Delta(G)$.

Proof. We find a better ordering to apply the greedy colouring to. First define $v_n = v$, where $d(v) \leq \Delta(G) - 1$. Now choose an ordering of $v_1, \dots, v_{n-1}$ so that

$$d(v_1, v) \geq d(v_2, v) \geq \dots \geq d(v_{n-1}, v).$$

We claim that each vertex v_i with $i \in [n-1]$ has at most $\Delta(G) - 1$ neighbors in $v_1, \dots, v_{i-1}$.

This is true for v_n by definition. For v_i with $i \neq n$, we observe that a shortest path P from v_i to v_n contains a neighbor v_j of v_i with $d(v_j, v) < d(v_i, v)$. Thus v_j comes later in the ordering (that is, $j > i$).

So the greedy colouring gives each vertex one of $\Delta(G)$ colours. $\square$

We can now extend this idea to prove Brook's theorem.

Theorem 31.5.8 (Brooks' Theorem)

Let G be a connected graph that is not complete or an odd cycle. Then $\chi(G) \leq \Delta(G)$.

Proof. Let G be a counterexample with a minimal number of edges. We may assume G is a regular graph (Δ -regular), and also that $\Delta \geq 3$.

Since G is not complete, there exists a vertex v so that $G[N(v)]$ is not complete, so let $x, y \in N(v)$ where $x \not\sim y$. Colour these two vertices x, y the same colour.

If G is 3-connected then $G' = G - x - y$ is connected. In this case, we order the vertices of G' , labelled $v_3, \dots, v_n = v$ so that

$$d_{G'}(v_3, v) \geq d_{G'}(v_4, v) \geq \dots \geq d_{G'}(v_{n-1}, v).$$

The greedy colouring with the ordering $v_3, \dots, v_n$ will give us a Δ -colouring of G . Additionally, it's possible to ensure that each $w \in G'$ adjacent to either v_1 or v_2 is coloured differently from their common colour (check!). The key idea is that keeping G' connected allows the sequence of decreasing distances to be constructed.

If G has a cut vertex $w \in V$, then let $G - w = C_1 \cup \dots \cup C_k$ be the components, and $G_i = G[C_i \cup \{w\}]$. The maximum degree in G_i is bounded by Δ , and therefore G_i has a Δ -colouring for each i , by the minimality of the counter example. Note that G_i cannot be a complete graph on $\Delta + 1$ vertices since $d_{G_i}(w) \leq \Delta - 1$. By permuting the colours, we can assume each colouring gives the vertex w colour 1. Thus we have a colouring of G with Δ colours, which is a contradiction.

If $G - \{w_1, w_2\}$ is disconnected for $w_1 \neq w_2$ with $w_1, w_2 \in V$, then let $C_1, \dots, C_k$ be the components of $G - \{w_1, w_2\}$. We may assume that G has no cut vertex by the previous case. Now let $G_i = G[C_i \cup \{w_1, w_2\}] + w_1 w_2$. Note that $e(G_i) < e(G)$ since w_1, w_2 both send at least one edge to each component $C_1, \dots, C_k$. Also $d_{G_i}(w_1) \leq \Delta$ and likewise $d_{G_i}(w_2) \leq \Delta$, thus the maximum degree $G_i \leq \Delta$ and thus we can find a Δ -colouring of G_i for each i . That gives w_1, w_2 different colours. After permuting

these colours, I can assume w_1 is coloured 1 in each, and w_2 is coloured 2 in each. Thus we can put all of the colourings together to obtain a colouring of G . $\square$

§31.5.3 Colouring Planar Graphs

We will now consider colourings on graphs that are planar. It is in this section that the theorem ever-present in the popular maths psyche is kept (without proof).

Theorem 31.5.9 (Four-Colour Theorem)

Let G be a planar graph. Then $\chi(G) \leq 4$.

Or informally: any map can be coloured with only four colours, where neighboring regions have different colours. Note that this is the dual form of the theorem above. This theorem was proved in 1976 by Appel & Haken and centers around reducing the theorem to a large number of cases, that were checked by computer.

We are going to prove two slightly weaker versions, that are still quite interesting.

Theorem 31.5.10 (Six Colour Theorem – Warmup)

Let G be a planar graph. Then $\chi(G) \leq 6$.

Proof. We will use induction on $n = |G|$. For $n = 1$, this is trivial. Now inductively, we claim that there is a vertex v with $\deg(v) \leq 5$. We note

$$\frac{1}{n} \left[\sum_{x \in V} d(x) \right] = \frac{2E}{n} \leq 6 - \frac{12}{n} < 6.$$

Thus there is a vertex v with $\deg(v) \leq 5$. By induction, $G - v$ is 6-colourable, and since v has at most 5 neighbors, there is a colour in $[6]$ that does not appear in $N(v)$. Colouring v with this colour, we get that the graph is 6-colourable. $\square$

Now we are going to kick it up a notch shortly, by introducing one more ingredient.

Definition 31.5.11

Given a graph G and an r -colouring of G , let $v \in V(G)$, and define the **$\{i, j\}$ -component of v** to be all of the vertices that can be reached starting at v along a path using only colours i and j .

We make the following observation, which gives us an extra ‘move’ to use in the stronger proof

Proposition 31.5.12

Given a graph G with an r -colouring c , and for $i, j \in [r]$ with $i \neq j$, we can *swap* the colour on an $\{i, j\}$ -component to obtain a new colouring.

Proof Sketch. This works because of the ‘being reached’ condition in the $\{i, j\}$ -component definition. $\square$

Now we can prove the five colour theorem, using a lot of the ideas from the proof of the six colour theorem.

Theorem 31.5.13 (Five Colour Theorem)

Let G be a planar graph. Then $\chi(G) \leq 5$.

Proof. By induction on $n = |G|$, we note $n = 1$ is trivial. Now we proceed with the induction step. Let v be a vertex with $d(v) \leq 5$. Then apply induction to get a 5-colouring of $G - v$. Let $N(v) = \{x_1, \dots, x_5\}$, where $x_1, \dots, x_5$ are arranged in a clockwise manner. We may assume that $c(x_i) = i$ (otherwise we can colour v with the missing colour).

Now consider the $\{1, 3\}$ -component containing x_1 . If x_3 is not in this component, we can swap colours on this $\{1, 3\}$ component so that x_1 is colored with 3, and then colour v with 1.

So we may assume there exists a path $x_1 \rightarrow x_3$ using colours 1 and 3 only. By the same argument there exists a path $x_2 \rightarrow x_4$ using colours 2 and 4 only. But then these paths must share a vertex, which is a contradiction. $\square$

§31.5.4 Colouring Graphs on (Other) Surfaces

Following on from the last section, we will consider a related guiding question:

If G is a graph, drawn on the torus, what can we say about $\chi(G)$?

More generally, if G is a graph drawn on a surface of genus g , what can we say about $\chi(G)$? For example, the graph K_7 can be drawn on a torus without edge crossings.

We may wonder if there is an Euler's formula for surfaces, and indeed there is, but instead of equality, we get a bound.

Theorem 31.5.14 (Euler's Formula for Surfaces)

If G is drawn in a surface of genus g , then $V - E + F \geq 2 - 2g$, where F is the number of connected components of $(\text{Surface} - G)$.

Proof Sketch. A similar inductive proof to the planar case. $\square$

Remark. By a surface of genus g , we mean a compact orientable surface of genus g . Informally this is the surface formed from taking a sphere and adding g ‘handles’ to it. Also note that $2 - 2g$ is the **Euler characteristic** of a surface of genus g .

We can then use this to get a bound on the edges of a graph drawn on a surface with no edge crossings.

Proposition 31.5.15

If $G = (V, E)$ is a graph drawn on a surface of genus g , then $|E| \leq 3(|G| - (2 - 2g))$.

Proof Sketch. We have $3F \leq 2E$, then apply Euler’s formula for surfaces. $\square$

We can now get a bound (similarly to the planar case) on the chromatic number of a graph drawn on a surface.

Theorem 31.5.16 (Heawood’s Theorem)

If G is a graph drawn on a surface of Euler characteristic E , with $E \leq 0^a$, then

$$\chi(G) \leq \left\lfloor \frac{7 + \sqrt{49 - 24E}}{2} \right\rfloor.$$

^aThis condition really is needed, as otherwise for the planar case we get $\chi(G) \leq 4$, which is correct but this is not a proof for it!

Proof. Let $G = (V, E)$ be a given graph with $\chi(G) = k$. We may assume that G has the minimum number of edges, subject to $\chi(G) = k$. Observe that $\delta(G) \geq k - 1$, as otherwise there would be a vertex v with $d(v) = k - 1$, and thus $\chi(G - v) = k - 1$, and thus $\chi(G) = k - 1$. Also $k \leq n$, where $n = |V|$. Now the average degree of each vertex is

$$\frac{1}{n} \left[\sum_{v \in V} d(v) \right] = \frac{2e}{n} \leq 6 \left(1 - \frac{E}{n} \right),$$

where e is the number of edges and E is the Euler characteristic.

Thus

$$k - 1 \leq \delta(G) \leq \text{avg degree} \leq 6 \left(1 - \frac{E}{n} \right) \leq 6 \left(1 - \frac{E}{k} \right),$$

and so $k^2 - k \leq 6(k - E)$, then solving gives the required result. $\square$

Remark. It turns out that this estimate is sharp. Calling $H(E) = \left\lfloor \frac{7 + \sqrt{49 - 24E}}{2} \right\rfloor$, we find that $K_{H(E)}$ can be drawn on a surface of Euler characteristic E .

§31.5.5 Edge Colouring

Now instead of assigning vertices colours, we will assign them to edges.

Definition 31.5.17 (Edge Colouring)

Let $G = (V, E)$ be a graph. A **k -edge colouring** is a function $c : E \rightarrow [k]$ so that $c(e) \neq c(f)$ for all $e, f \in E$ such that $e \cap f \neq \emptyset$.

We have a similar notion to chromatic number for edge colourings.

Definition 31.5.18 (Edge Chromatic Number/Chromatic Index)

The **edge chromatic number** or **chromatic index** of a graph G is $\chi'(G)$, the minimum k for which a k -edge colouring exists.

Example 31.5.19 (Examples of Edge Chromatic Number)

The graph C_n has $\chi'(C_n) = 2$ if n is even, and $\chi'(C_n) = 3$ for n odd.

The Petersen graph G has $\chi'(G) = 4$.

In contrast to the chromatic number, it is much easier to get a handle on the edge chromatic number, as we will see in the following theorem.

Theorem 31.5.20 (Vizing's Theorem)

Let G be a graph. Then $\Delta(G) \leq \chi'(G) \leq \Delta(G) + 1$.

Proof. We proceed by induction on $e(G)$. The basis step is trivial, then for the inductive step we are given a graph G , and let's assume for a contradiction that $\chi'(G) > \Delta + 1$.

By induction, $G - e$ has a $\Delta + 1$ colouring, so let's write $e = xy$ with $x \neq y \in G$. We define vertices $y_1, \dots, y_k$ inductively by setting $y_1 = y$. Now assume $y_1, \dots, y_t$ are defined, and the colours missing from $y_1, \dots, y_t$ are $c_1, \dots, c_t$ respectively. Then if $c_t \notin \{c_1, \dots, c_{t-1}\}$, then let y_{t+1} be so that xy_{t+1} receives colour c_t . Note that such a vertex exists as otherwise we could recolour xy_1 with c_1 , xy_2 with c_2 , and so on until xy_t is with c_t , to obtain a $\Delta + 1$ colouring, which is a contradiction.

Now if $c_t \in \{c_1, \dots, c_{t-1}\}$, then stop. Say we stop after k steps, so I have defined $y_1, \dots, y_k$ with missing colours $c_1, \dots, c_k$ and $c_k = c_i$ for some $i < k$. We may assume that $i = 1$ (otherwise uncolour the edge xy_i and recolour xy_1 with c_1 , and so on until xy_{i-1} with c_{i-1}).

Let's call the colour missing at x , c_0 . Consider the $\{c_0, c_1\}$ component C , containing y_1 . If $x \notin C$, then we can flip colours on C so that c_0 is missing at y_1 , then colour xy_1 with c_0 . Likewise, the $\{c_0, c_1\}$ -component containing y_k must contain x , as otherwise we flip colours on this component so that the colour c_0 is missing at y_k . Then recolour xy_k to c_0 and xy_i to c_i for $i < k$.

Thus $x, y_1, y_k \in C$, the $\{c_0, c_1\}$ -component. But this is impossible since x, y_1, y_k all have one of the colours $\{c_0, c_1\}$ missing, thus $d_C(x), d_C(y_1), d_C(y_k) \leq 1$. But this is impossible for a path or cycle. $\square$

Remark. This theorem is *not* true if we generalize to multigraphs, which are graphs that have multiple edges between vertices.

§31.6 Extremal Graph Theory

Welcome to the section on extremal graph theory, where we think about problems involving things with an 'extreme' flavour.

§31.6.1 Eulerian Circuits and Hamiltonian Cycles

We are going to begin our chapter on extremal graph theory with something that's not *really* extremal graph theory. Still, it will lead us nicely into the more extreme parts of this chapter and the course. Let's state a definition.

Definition 31.6.1 (Eulerian Circuit)

An **Eulerian circuit** is a circuit in a graph G that crosses each edge exactly once. If a G has an Eulerian circuit, we say that the graph is **Eulerian**.

What's nice is that there is a straightforward characterisation of Eulerian graphs.

Theorem 31.6.2 (Euler's Theorem)

A connected graph has an Eulerian circuit if and only if every vertex has even degree.

Proof. If a graph G has an Eulerian circuit, then the degree of each vertex must be even. This is because a fixed vertex x is entered and exited a fixed number of times.

Now if each vertex of a graph G has even degree, we will apply induction on $e(G)$. If $e(G) = 0$, then we are done. Now if $d(x) \geq 1$ for all vertices x , then $d(x) \geq 2$, and G contains a cycle C . Define $G' = G - E(C)$. Let $G_1, \dots, G_k$ be the components of G' . The degree of each G_i has all degrees even. Thus by induction, there is an Eulerian circuit $W_1, \dots, W_k$ for each $G_1, \dots, G_k$ respectively. Thus we can combine

C with $W_1, \dots, W_k$ to obtain an Eulerian circuit for all of G . $\square$

Now we are going to define a similar looking notion, but it will not end up being so well behaved as Eulerian circuits.

Definition 31.6.3 (Hamiltonian Cycle)

Let G be a graph, then a **Hamiltonian cycle** in G is a cycle that visits each vertex exactly once. We say G is **Hamiltonian** if it contains a Hamiltonian cycle.

Our first question might be ‘is there an iff type condition for Hamiltonian cycles’, and so far there is no such property known. However there are some results that give us information about whether a graph is Hamiltonian.

Theorem 31.6.4 (Dirac’s Theorem)

Let G be a graph with $n \geq 3$ such that $\delta(G) \geq n/2$. Then G contains a Hamiltonian cycle.

Proof. For a contradiction, assume that G is a counterexample to the theorem. Note that G is connected, since $x \not\sim y$ then $N(x), N(y) \subset V \setminus \{x, y\}$ and $|N(x)|, |N(y)| \geq \frac{n}{2}$, and thus $N(x) \cap N(y) \neq \emptyset$, and thus $d(x, y) \leq 2$.

Let $x_1, \dots, x_\ell$ be the longest path in G . Note that $x_1, \dots, x_\ell$ does not form a cycle, as otherwise if $\ell = n$, then we have a contradiction, and if $\ell < n$ then there exists $y \notin \{x_1, \dots, x_\ell\}$ that is $y \sim x_i$. Thus we can find a longer path (which is also a contradiction).

Now if there exists $i \in \{1, \dots, \ell - 1\}$ so that $x_i \sim x_\ell$ and $x_{i+1} \sim x_1$, then the vertices $x_1, \dots, x_\ell$ form a cycle. This contradicts the above.

Define

$$N^+(x_\ell) = \{x_i \mid x_{i-1} \in N(x_\ell), 2 \leq i \leq \ell\}.$$

We have $N^+(x_\ell) \cap N(x_1) = \emptyset$, but this is impossible since $|N^+(x_\ell)| \geq n/2$, $|N(x_1)| \geq n/2$, and $N^+(x_\ell), N(x_1) \subseteq \{x_2, \dots, x_\ell\}$. Thus we have a contradiction. $\square$

Remark. We never *really* used this $\delta(G) \geq n/2$ condition fully. It suffices to have $d(x) + d(y) \geq n$ for $x \not\sim y$.

We can use this same argument to prove a more general result about paths.

Proposition 31.6.5

Let G be a connected graph. Let $k < n$ and assume $\delta(G) \geq k/2$. Then $G \geq P_{k+1}$.

Proof Sketch. Similar to Dirac's theorem. Choose a longest path $x_1, \dots, x_\ell$ in G . They don't form a cycle, and then we can force a configuration like $x_1 \sum x_{i+1}$, $x_\ell \sum x_i$ by using the minimum degree condition. $\square$

We may wonder in the above if it's possible to replace 'path' with 'cycle' in the above. The answer is, sadly, no.

A natural question is to wonder how many edges are needed to 'force' a (for example) triangle. For a Hamilton cycle, this sort of question would have been a bit strange, and a more natural question would be what is the minimum value of $\delta(G)$ to ensure that G contains a Hamilton cycle. In the next theorem, we will give a result that answers a simpler sort of question.

Theorem 31.6.6

Let G be a graph. If $e(G) > \frac{n}{2}(k-1)$, then G contains a path of length k .

Proof. We will prove the contrapositive: If G is P_{k+1} free, then $e(G) \leq \frac{n}{2}(k-1)$.

We will apply induction on n . This is true for $n = 2$. Then given a graph G on $|G| = n \geq 3$ vertices, if G is disconnected let $G_1, \dots, G_k$ be the components of G . Then each of these has $G_i \not\supseteq P_{k+1}$. Then by induction we have $e(G_i) \leq \frac{n(G_i)(k-1)}{2}$. Thus

$$e(G) = \sum_{i=1}^k e(G_i) \leq \sum \frac{n(G_i)(k-1)}{2} = \left(\frac{k-1}{2}\right)n,$$

and we are done.

Now if there is a vertex v with $d(v) \leq \frac{k-1}{2}$, then consider $G - v$. Then $e(G - v) = e(G) - d(v)$, and also $G - v$ does not contain P_{k+1} . Thus $e(G - v) \leq \frac{n-1}{2}(k-1)$. So

$$e(G) = e(G - v) + d(v) \leq \frac{n-1}{2}(k-1) + \frac{k-1}{2} \leq \frac{n}{2}(k-1).$$

Thus we can assume G is connected and $d(v) \geq \frac{k}{2}$. We can apply [Proposition 31.6.5](#) to find a path of length k , that is, $P_{k+1} \subseteq G$, which is a contradiction.

[We may also assume $k < n$ for if $k = n$ then $e(G) \leq \frac{k}{2}(n-1)$, which reduces to showing $e(G) \leq \binom{n}{2}$, which is trivial]. $\square$

§31.6.2 Complete Subgraphs and Turan's Theorem

Let's return to the question of how many edges are needed in a graph to guarantee the existence of a triangle. Later on, we will look more generally at the question of the number of edges needed to guarantee a K_n subgraph.

Theorem 31.6.7 (Mantel's Theorem)

If $e(G) > \frac{n^2}{4}$, then $G \supset K_3$, and this is sharp.

Proof. Given a K_3 -free graph G and $x, y \in V$ such that $x \sim y$ and $d(x) + d(y) \leq n$,

and let $m = e(G)$. Then summing we get

$$\sum_{xy \in E} d(x) + d(y) \leq mn.$$

We have that this is $\sum_x \sum_y d(x) \mathbb{1}(xy \in E) = \sum_{x \in V} (d(x))^2$. Now $\sum_{x \in V} d(x) = 2m$, and by Cauchy-Schwarz we have $(\sum d(x))^2 \leq n \sum d(x)^2$, and thus

$$mn^2 \geq (2m)^2 \implies \frac{n^2}{4} = e(G).$$

To see that this is sharp, consider the complete bipartite graph with n vertices. Then this has $n^2/4$ edges, but no triangle. Thus this is sharp. $\square$

The next question we are going to answer is how many edges are needed to guarantee the existence of a K_n subgraph. In the previous theorem, to see that our result was sharp, we considered the complete bipartite graph on n vertices. To discuss this more general question, a natural thing to look at is a generalisation of bipartite graphs.

Definition 31.6.8 (r -Partite Graph)

An **r -partite graph** is a graph of the form $G = (V, E)$ where the vertices are partitioned into r subsets $V = V_1 \cup \dots \cup V_r$ with $V_i \cap V_j = \emptyset$ if $i \neq j$, and $xy \notin E$ for all $x, y \in V_i$.

For example, the graph below is 3-partite.

It's worth noting that saying a graph is r -partite is the same as saying the graph has chromatic number of at most r . We care particularly about the case of an r -partite graph where all possible edges are included.

Definition 31.6.9 (Complete r -Partite Graph)

We say an r -partite graph is **complete** if no edge can be added with the graph remaining r -partite.

Now if we consider a complete r -partite graph G on n vertices, with all parts of size n/r , then we would have

$$e(G) = \binom{n}{r} \binom{r}{2} = \left(1 - \frac{1}{r}\right) \frac{n^2}{2}.$$

The graph G can also have no K_{r+1} subgraph, since that would imply there's an edge between two vertices in the same part. This gives us a lower bound on the number of edges needed to have a K_{r+1} subgraph, and it turns out that bound is sharp.

Theorem 31.6.10 (Turan's Theorem)

If $e(G) > \left(1 - \frac{1}{r}\right) \frac{n^2}{2}$, then $G \supset K_{r+1}$, and this is sharp.

Proof. Suppose we have some graph G on n vertices that had no K_{r+1} subgraph, and also that the result holds up to n, r . If $r \geq n$ then we are clearly done, so we may suppose that $n > r$. Let A be a K_r subgraph in G , which must exist by our assumption. Let $B = V - A$. Then we have $e(G) = e(A) + e(B) + e(A, B)$, where $e(A, B)$ denotes the number of edges between vertices in A and B . We have an upper bound of

$$e(G) \leq \binom{r}{2} + \left(1 - \frac{1}{r}\right) \frac{(n-r)^2}{2} + (n-r)(r-1),$$

where $e(A, B) \leq (n-r)(r-1)$ since each vertex in B has at most $r-1$ neighbours in A . We can rewrite this as

$$e(G) \leq \frac{1}{2} \left(1 - \frac{1}{r}\right) (r^2 + (n-r)^2 + (n-r)r) = \frac{1}{2} \left(1 - \frac{1}{r}\right) n^2,$$

as required. □

There's another non-examinable proof called Zykov Symmetrisation

§31.6.3 The Zarankiewicz Problem

Turan's theorem answers the question 'how many edges can a graph have without having a K_t subgraph'. A natural follow on question is 'how many edges can a bipartite graph have without having a $K_{t,t}$ subgraph'. This is the Zarankiewicz problem, and unfortunately does not yet have a definite answer like the previous question. We can however obtain some bounds.

Definition 31.6.11

We define $Z(n, t)$ to be the maximum number of edges in a bipartite graph with n vertices in each part and no $K_{t,t}$ subgraph.

We really care about $Z(n, t)$ where t is fixed and n is large. We will prove the following theorem.

Theorem 31.6.12

We have $Z(n, t) \leq t^{1/t} n^{2-1/t} + tn$ for all n .

Proof. Given a graph $G = (A \cup B, E)$ where $|A| = |B| = n$, and $G \not\supset K_{t,t}$, we want to show that $m = e(G) \leq t^{1/t} n^{2-1/t} + tn$.

For some set $S \subseteq A$, and $|S| = t$, we have

$$\left| \bigcap_{x \in S} N(x) \right| \leq t - 1,$$

as otherwise we would have a $K_{t,t}$ subgraph. Then averaging over such subsets S , we have

$$\binom{n}{t}^{-1} \sum_{\substack{S \subseteq A, \\ |S|=t}} \left| \bigcap_{x \in S} N(x) \right| \leq t - 1.$$

This sum can be written as

$$\begin{aligned} \sum_{\substack{S \subseteq A, \\ |S|=t}} \left| \bigcap_{x \in S} N(x) \right| &= \sum_{\substack{S=\{x_1, \dots, x_t\}, \\ S \subseteq A}} \sum_y \mathbb{1}(y \sim x_1, y \sim x_2, \dots, y \sim x_t) \\ &= \sum_y \sum_{\substack{S=\{x_1, \dots, x_t\}, \\ S \subseteq A}} \mathbb{1}(y \sim x_1, y \sim x_2, \dots, y \sim x_t) \\ &= \sum_y \binom{d(y)}{t}. \end{aligned}$$

We may assume that $d(y) \geq t - 1$ for all y , as otherwise we can add an edge incident with y and not create a $K_{t,t}$ subgraph. Then by convexity and since $d(y) \geq t - 1$, we have

$$\sum_y \binom{d(y)}{t} \geq \sum_{y \in B} \binom{d}{t} = n \binom{d}{t},$$

where $d = \frac{1}{n} \sum_{y \in B} d(y) = m/n$. Combining this inequality with what we obtained previously, we get the bound

$$t - 1 \geq \frac{n \binom{d}{t}}{\binom{n}{t}} = n \frac{d(d-1) \cdots (d-t+1)}{(n-1) \cdots (n-t+1)} \geq \frac{(d-t+1)^t}{n^{t-1}},$$

thus $(t-1)^{1/t} n^{t-1} \geq d-t+1$, and $t^{1/t} n^{2-1/t} + tn \geq m$, as required. $\square$

While we do have this upper bound, we don't know $Z(n, t)$ for most values of n . We do know, for example, that

$$\begin{aligned} cn^{3/2} &\leq Z(n, 2) \leq 2n^{3/2}, \\ c'n^{5/2} &\leq Z(n, 3) \leq 2n^{5/3}, \end{aligned}$$

for all large n , and some constants c, c' . Still we don't even know $t = 4$. The constructions are based on finite geometry. As an example, we will sketch the construction that shows the bound $cn^{3/2} \leq Z(n, 2)$.

Theorem 31.6.13

For infinitely many n we have $Z(n, 2) \geq cn^{3/2}$ for $c > 0$.

Proof Sketch. Let p be a prime, and consider^a $(\mathbb{Z}/p\mathbb{Z})^2$. Define a line $L = \{(x, ax + b) \mid x \in \mathbb{Z}/p\mathbb{Z}\}$, for some $a, b \in \mathbb{Z}/p\mathbb{Z}$ with $a \neq 0$.

We need the following straightforward facts:

1. Two distinct lines intersect in at most one point.
2. Each line contains p points.
3. There are p^2 points, $p(p-1) \approx p^2$ lines^b.

We are going to construct a graph bipartite graph $G = (A \cup B, E)$ where every vertex in A corresponds to a line and every vertex in B corresponds to a point. There's approximately p^2 vertices in each of these parts, so we will take n to be about p^2 . Then for $\ell \in A$ and $x \in B$, we define $\ell \sim x$ if $x \in \ell$. Then $e(G) \approx p^2 \cdot p = p^3 = n^{3/2}$. To see this graph works, if G contained a $K_{2,2}$ then there would exist two lines ℓ_1, ℓ_2 with $|\ell_1 \cap \ell_2| \geq 2$, which is a contradiction. $\square$

^aYou can consider this to be like a torus.

^bTo make this a proper proof, we would have to fix all of the approximations

§31.6.4 The Erdős-Stone Theorem

So far we have been interested in questions of the form ‘how many edges do I need in a graph before I force a subgraph H ’. We’ve been able to prove a variety of interesting but relatively scattered results of this form, but it turns out that if we consider the question asymptotically, we can obtain a more general unifying result.

We begin by defining the following function.

Definition 31.6.14 (Extremal Function)

Let H be a fixed graph. We define the **extremal function** $\text{ex}(n, H)$ to be

$$\text{ex}(n, H) = \max\{e(G) \mid |G| = n, G \not\supseteq H\}.$$

Using this function we can restate some of the results we previously obtained, such as Mantel’s theorem giving us $\text{ex}(n, K_3) \leq n^2/4$, and Turan’s theorem giving us $\text{ex}(n, K_{r+1}) \leq (1 - 1/r)n^2/2$.

Looking a bit more at Turan’s theorem, if we consider things asymptotically on the scale of n^2 , we get a weaker version of Turan that looks like

$$\lim_{n \rightarrow \infty} \frac{\text{ex}(n, K_{r+1})}{\binom{n}{2}} = \left(1 - \frac{1}{r}\right).$$

The Erdős-Stone Theorem allows us to get these types of results generally, using just the chromatic number of the graph.

Theorem 31.6.15 (Erdős-Stone Theorem)

Let H be a graph with $\chi(G) = r$, and $r \geq 2$. Then

$$\lim_{n \rightarrow \infty} \frac{\text{ex}(n, H)}{\binom{n}{2}} = \left(1 - \frac{1}{r-1}\right).$$

Proof. Omitted

§31.7 Ramsey Theory

We are going to jump into Ramsey theory, an area of graph theory that has a similar flavour to previous section. Ramsey theory is often described as the collection of results showing ‘complete disorder is impossible’, but its easiest to see what we study with an example.

Proposition 31.7.1 (Monochromatic Triangles)

Colour each of the edges of K_6 red or blue^a. Then there must be a monochromatic triangle.

^aNote that we don't have any restrictions on the colouring.

Proof. Consider some vertex v in the graph. We know that at least three incident edges must be the same colour, so suppose (without loss of generality) that they are red, with endpoints v_1, v_2, v_3 . Then either $v_1v_2v_3$ is a monochromatic blue triangle, or some v_iv_j is red, in which case vv_iv_j is a monochromatic red triangle. $\square$

Straight away we might wonder about K_4 . Does there exist some large enough n such that every 2-colouring of K_n contains a monochromatic K_4 ? This is the type of problem we will consider in Ramsey theory.

§31.7.1 Ramsey Numbers

We will begin our discussion of Ramsey theory by introducing the *Ramsey numbers*.

Definition 31.7.2 (Ramsey Numbers)

For $t \in \mathbb{N}$, we define $R(t)$ the **t th Ramsey number** to be the smallest n for which every 2-colouring of K_n contains a monochromatic K_t .

We already know that $R(3) = 6$ (since we showed there's always a monochromatic

triangle in K_6 , and it's not hard to find a colouring of K_5 that doesn't have one). We haven't yet proved though that such an $R(t)$ exists though, so we will clear this up first.

Theorem 31.7.3 (Ramsey's Theorem)

For all $t \in \mathbb{N}$, $R(t)$ is finite and $R(t) \leq 4^t$.

Proof. We will begin by proving a small lemma. For $s, t \geq 2$, we define the Ramsey number $R(s, t)$ to be the smallest n such that every red/blue colouring of K_n either contains a red K_s or a blue K_t .

We will prove that for all $s, t \geq 2$,

$$R(s, t) \leq \binom{s+t-2}{s-1}. \quad (\dagger)$$

Claim. Assume that $R(s-1, t)$ and $R(s, t-1)$ exist. Then $R(s, t)$ exists and $R(s, t) \leq R(s-1, t) + R(s, t-1)$.

Let $a = R(s-1, t)$ and $b = R(s, t-1)$ and let c be a red/blue colouring of K_{a+b} . Let x be a vertex in this graph, and we note $d(x) = a + b - 1$. Then x has either

- (i) a red neighbors
- (ii) b blue neighbors.

In case (i), let N_r be the red neighbors of x , and note $|N_r| \geq a$. Then the colouring induced on N_r contains either a K_{s-1} in red or a K_t in blue. In the latter case we are done, and in the former case we can add x to K_{s-1} to finish. Case (ii) is symmetric, and thus our claim is true.

Now we can return to showing $(\dagger)$. We are going to induct on $s+t$. Note that $R(s, 2) = s$ and $R(2, t) = t$. Inductively assume that $R(s-1, t), R(s, t-1)$ exist and satisfy this relation, then

$$R(s, t) \leq R(s-1, t) + R(s, t-1) \leq \binom{s+t-2}{s-2} + \binom{s+t-3}{s-1} \leq \binom{s+t-2}{s-1},$$

as desired. Taking $R(t) = R(t, t)$ gives $R(t) \leq \binom{2t-2}{t-1} \leq 4^t$. $\square$

Ramsey numbers are generally quite mysterious. We know for example that $R(3, 3) = 6$, $R(4, 4) = 18$, and $R(3, 7) = 23$, but even something like $R(5, 5)$ is unknown, and our best bounds are $43 \leq R(5, 5) \leq 48$. The numbers $R(3, t)$ are quite well understood, and for $\epsilon > 0$ we have (for sufficiently large t)

$$\left(\frac{1}{4} + \epsilon\right) \frac{t^2}{\log t} \leq R(3, t) \leq (1 + \epsilon) \frac{t^2}{\log t}.$$

A big question though is getting a lower bound on $R(t)$, which is currently nowhere as close as our upper bound.

§31.7.2 Infinite Ramsey

Now instead of finite complete graphs, we are going to consider an infinite graph.

Definition 31.7.4 (Complete Countable Graph)

We define the **complete countable graph** $G = (\mathbb{N}, \mathbb{N}^{(2)})$.

Notation. For a set X , we let $X^{(r)} = \{A \subseteq X \mid |A| = r\}$, the set of r element subsets of X .

Our motivating question will be the following: given a 2-colouring of the complete countable graph, what can we say about the monochromatic structures that appear in the colouring? Obviously by Ramsey's theorem we can find arbitrarily large monochromatic complete graphs, but is it possible to find a monochromatic complete countable subgraph?

Example 31.7.5 (Complete Countable Graph with Complete Countable Subgraph)

Consider the colouring of a complete countable graph where xy is red if $x + y$ is even, and blue if $x + y$ is odd. Then the subgraph induced on the vertices $\{2, 4, 8, \dots\}$ is a monochromatic complete countable subgraph.

Now consider instead the colouring where $x + y$ is red if it has an even number of prime factors, and $x + y$ is blue if it has an odd number of prime factors. Can you find a monochromatic complete countable subgraph?

It turns out that by another theorem of Ramsey, it is always possible to find such a subgraph.

Theorem 31.7.6 (Infinite Ramsey's Theorem)

Let $G = (\mathbb{N}, \mathbb{N}^{(2)})$, the complete countable graph. Then for every 2-colouring of G there exists an infinite set $X \subseteq \mathbb{N}$ so that $X^{(2)}$ is monochromatic.

Proof. We begin by inductively defining vertices $x_1, x_2, \dots, x_t$ and colours $c_1, c_2, \dots, c_t$ such that $N_{c_i}(x_i) \supset \{x_{i+1}, \dots, x_t\}$, and $\bigcap_{i=1}^t N_{c_i}(x_i)$ is infinite, where $N_{c_i}(x_i)$ is the neighborhood of x_i in the colour c_i .

We can do this by taking $x_1, \dots, x_t$ and then choosing any $x_{t+1} \in \bigcap_{i=1}^t N_{c_i}(x_i)$. Then we can define c_i accordingly, since at least one of $N_{\text{red}}(x_{t+1}) \cap \left(\bigcap_{i=1}^t N_{c_i}(x_i)\right)$ is infinite, or $N_{\text{blue}}(x_{t+1}) \cap \left(\bigcap_{i=1}^t N_{c_i}(x_i)\right)$ is infinite.

This then gives us an infinite collection $x_1, x_2, \dots$ so that $x_i x_j$ with $i < j$ are given colour c_i . Then since both

$$\{x_i \mid c_i = \text{red}\} \quad \text{and} \quad \{x_i \mid c_i = \text{blue}\}$$

are monochromatic cliques, at least one of them is infinite, giving a monochromatic complete countable subgraph. $\square$

Remark. By keeping track of the sizes of sets at each step, we can adapt this proof to give us a different proof of the finite case.

§31.7.3 Ramsey Numbers for Hypergraphs

Before, we were colouring $X^{(2)}$, the pairs of a set X (the vertices of a graph). Of course, we might wonder what happens when we colour r -sets?

Definition 31.7.7 (Hypergraph Ramsey Numbers)

We define $R^{(r)}(s, t)$ to be the smallest n such that every red/blue colouring of $[n]^{(r)}$ either contains a set $X \subseteq [n]$ with $|X| = s$ and $X^{(r)}$ red, or there exists $Y \subseteq [n]$ with $|Y| = t$ and $Y^{(r)}$ blue.

And of course, it's not guaranteed that these exist, but it is possible to show that they do.

Theorem 31.7.8 (Hypergraph Ramsey Theorem)

For all $r, s, t \geq 2$, $R^{(r)}(s, t)$ exists.

Proof. Omitted.

§31.7.4 Lower Bounds for Ramsey Numbers

We said at the end of [subsection 31.7.1](#) that we were left to get a good lower bound on the Ramsey numbers $R(t)$. One way to do that might be by considering the following extremal-seeming construction:

This clearly doesn't have a monochromatic K_t subgraph, and we can compute the number of vertices is $(t-1)^2$, giving

$$R(t) \geq (t-1)^2.$$

However, it turns out that this quadratic bound is, quite frankly, awful. To show something better, we are going to need a new idea – considering random graphs and using probability.

Theorem 31.7.9 (Erdős)

$$R(t) \geq 2^{\frac{t}{2}}.$$

Proof. We will show that for a random colouring of the edges of K_n ,

$$\mathbb{P}(\text{there exists a monochromatic } K_t \subset K_n) \leq 2 \binom{n}{t} 2^{-\binom{t}{2}}.$$

Once we have shown this, we will then note for $n = 2^{t/2}$ that the RHS of this inequality is strictly less than 1, which implies that is *some* colouring of K_n with no monochromatic K_t .

To prove this inequality, we first fix some $A \subseteq K_n$ with $|A| = t$, and note that

$$\mathbb{P}(A^{(2)} \text{ is monochromatic}) = 2 \cdot 2^{-\binom{t}{2}}.$$

Applying the union bound then gives us our desired result

$$\mathbb{P}(\text{there exists a monochromatic } K_t \subset K_n) \leq \sum_{A \in K_n^{(t)}} 2 \cdot 2^{-\binom{t}{2}} = 2 \binom{n}{t} 2^{-\binom{t}{2}}.$$

Then to show that this is less than 1 for $n = 2^{t/2}$, we can take

$$2 \binom{n}{t} 2^{-\binom{t}{2}} \leq 2 \frac{n^t}{t!} 2^{-\frac{t(t-1)}{2}} = \left(\frac{2^{1/t}}{t^{1/t}} \cdot n 2^{-\frac{t-1}{2}} \right)^t,$$

and thus it is indeed less than 1 for $n = 2^{t/2}$. □

The proof idea we employed is known as the *probabilistic method*, and is an immensely powerful technique that can be used to show all kinds of interesting results.

Getting much better bounds on $R(t)$ is still a major open problem, and surprisingly the bounds we have proved so far aren't far from state of the art – the base of the exponential term is still the same in best known results. Also, there's currently no known construction that gives an exponential lower bound directly.

§31.8 The Probabilistic Method

At the end of our discussion on Ramsey numbers, we used an argument that combines probability and random graphs to prove a result. In this section we are going to look a bit more closely at the type of argument that we used.

§31.8.1 Random Graphs

We first are going to come up with a probability space involving a graph where each edge is included independently at random with probability p .

Definition 31.8.1 (Binomial Random Graph)

Let $n \in \mathbb{N}$ and $p \in [0, 1]$, let $\mathcal{G}(n, p)$ be the probability space on all graphs with vertex set $\{1, 2, \dots, n\}$, with $\mathbb{P}(ij \in E(\mathcal{G})) = p$, and every edge included/excluded independently.

Remark. For our ' $R(t) \geq 2^{t/2}$ ' result, we were working with $G(n, 1/2)$, which is the same as sampling uniformly on a graph on $\{1, \dots, n\}$.

Another use of random graphs is in the Zarankiewicz problem. Recall our definition of $Z(n, t)$. We proved already that $Z(n, t) \leq 2n^{2-1/t}$, and we hadn't yet proved a lower bound. We are able to come up with one using the probabilistic method.

Theorem 31.8.2

We have $Z(n, t) \geq \frac{1}{4}n^{2-\frac{2}{t+1}}$.

Proof. Let G be a random bipartite graph with parts A, B and $|A| = |B| = n$. Then, define $\widetilde{G}$ to be G with an edge removed from each $K_{t,t}$ in G . Then

$$e(\widetilde{G}) \geq e(G) - \#(K_{t,t}\text{'s in } G),$$

and by linearity of expectation

$$\mathbb{E}[e(\widetilde{G})] \geq \mathbb{E}[e(G)] - \mathbb{E}[\#(K_{t,t}\text{'s in } G)].$$

We have $\mathbb{E}[e(G)] = pn^2$, and also $\mathbb{E}[\#(K_{t,t}\text{'s in } G)]$ can be written using indicator functions as

$$\mathbb{E}\left[\sum_{A', B'} \mathbb{1}(A', B' \text{ induce a } K_{t,t})\right] = \binom{n}{t}^2 p^{t^2},$$

where we sum over $A' \leq A$, $B' \leq B$ with $|A'| = |B'| = t$. Thus

$$\mathbb{E}[e(\widetilde{G})] \geq pn^2 - \binom{n}{t}^2 p^{t^2}. \quad (*)$$

We want the RHS of this to be positive, so it's enough to have

$$pn^2 \geq n^{2t}p \iff n^{-\frac{2}{t+1}} \geq p,$$

so if $p = n^{-2/(t+1)}$ then $(*) \geq pn^2/2 \geq n^2/2 - 2/(t+1)$, as desired. $\square$

This proof is an example of the ‘modification method’.

§31.8.2 Random Graphs and Chromatic Number

One big picture question in graph theory is ‘what makes $\chi(G)$ large?’ A possible answer is that G contains a large clique, but that’s not the whole story. For example, there’s a triangle free graph with arbitrarily large χ . Another possible answer is that G has lots of short cycles, but it turns out that this is false too.

Definition 31.8.3 (Girth)

The **girth** of a graph G is the length of the shortest cycle in G , denoted $\text{girth}(G)$.

Definition 31.8.4 (Independent Set)

An **independent set** in a graph is a subset of vertices no two of which are adjacent. We will denote the size of the largest independent set $\alpha(G)$.

We can prove that graphs with large girth can also have arbitrarily large chromatic number. We will first need to note that if G is a graph, then

$$\chi(G) \geq \frac{n}{\alpha(G)}.$$

Theorem 31.8.5

For every $k, G \in \mathbb{N}$, there exists a graph G with $\text{girth}(G) \geq g$ and $\chi(G) \geq k$.

Proof. Let G be a random graph sampled from $\mathcal{G}(n, p)$ where $p = n^{\frac{1}{g}-1}$. We form the new graph $\widetilde{G}$ be the graph where we remove a vertex from each cycle of length $g - 1$.

We are going to do a few steps.

1. We want to show that $\mathbb{P}(|\widetilde{G}| \geq n/2) \rightarrow 1$ as $n \rightarrow \infty$.
2. We want to use $\chi(\widetilde{G}) \geq |\widetilde{G}|/\alpha(\widetilde{G})$, noting that $\alpha(\widetilde{G}) \leq \alpha(G)$. To do this, we will prove $\mathbb{P}(\alpha(G) \leq n/2k) \rightarrow 1$ as $n \rightarrow \infty$.

Step 1. Let X_i be the number of cycles of length i in G , and let $X = \sum_{i=1}^{g-1} X_i$. We can write

$$X_i = \sum_{x_1, \dots, x_i \in [n]} \mathbb{1}(x_1 \dots x_i \text{ are a cycle in } G).$$

Taking expectations,

$$\mathbb{E}[X_i] = \sum_{x_1, \dots, x_i \in [n]} \mathbb{P}(x_1 \dots x_i \text{ are a cycle in } G) \leq n^i p^i.$$

Using this we have

$$\mathbb{E}[\# \text{ of cycles of length } \leq g-1] = \mathbb{E}[X] = \sum_{i=1}^{g-1} (np)^i \leq gn^{\frac{g-1}{g}}.$$

Using Markov's inequality,

$$\mathbb{P}(X > n/2) \leq \frac{\mathbb{E}[X]}{n/2} \rightarrow 0 \quad \text{as } n \rightarrow \infty,$$

thus $\mathbb{P}(|\widetilde{G}| \geq n/2) \rightarrow 1$, as we needed.

Step 2. Let Y_t be the number of independent sets of size $t = n/2k$. Then

$$Y_t = \sum_{I \in [n]^{(t)}} \mathbb{1}(I \text{ is independent}),$$

and taking expectations

$$\mathbb{E}[Y_t] = \sum_{I \in [n]^{(t)}} \mathbb{P}(I \text{ is independent}) = \binom{n}{t} (1-p)^{\binom{t}{2}} \leq n^t e^{-p \binom{t}{2}} = \left(n e^{-p \frac{t-1}{2}} \right)^t,$$

and with $p = n^{1/g-1}$ and $t = n/2k$, so the RHS tends to 0 as n tends to infinity. Then

$$\mathbb{P}(Y_t \geq 1) \leq \mathbb{E}[Y_t] \rightarrow 0,$$

and $\mathbb{P}(Y_t \geq 1) = \mathbb{P}(\alpha(G) \geq t) = \mathbb{P}(\alpha(G) \geq n/2k)$. Putting that together, $\chi(\widetilde{G}) \geq \frac{|\widetilde{G}|}{\alpha(\widetilde{G})} \geq \frac{|\widetilde{G}|}{\alpha(G)} \geq \frac{n/2}{n/2k} \geq k$ holds with probability tending to 1 as n tends to infinity, finishing our proof. $\square$

§31.8.3 Structure of Random Graphs

So what does a typical graph sampled from $\mathcal{G}(n, p)$ look like? What does its structure look like as p varies from 0 to 1? As a first example, we will consider the following more precise question:

For what p does G sampled from $\mathcal{G}(n, p)$ contain a K_t ?

Theorem 31.8.6

Let G be sampled from $\mathcal{G}(n, p(n))$, and let $t \in \mathbb{N}$. Then $\lim_{n \rightarrow \infty} \mathbb{P}(G \text{ contains a } K_t) \rightarrow 1$ if $p(n)n^{\frac{2}{t-1}} \rightarrow \infty$. Moreover, $\lim_{n \rightarrow \infty} \mathbb{P}(G \text{ contains } K_t) \rightarrow 0$ if $p(n)n^{\frac{2}{t-1}} \rightarrow 0$.

Proof. Define X_t to be the number of K_t s in G . Then

$$X_t = \sum_{A \in [n]^{(t)}} \mathbb{1}(G[A] \text{ is complete}),$$

and

$$\mathbb{E}[X_t] = \sum_{A \in [n]^{(t)}} \mathbb{P}(G[A] \text{ is complete}) = \binom{n}{t} p^{\binom{t}{2}}.$$

We note that $\binom{n}{t} p^{\binom{t}{2}} \leq n^t p^{\binom{t}{2}} = \left(n^{\frac{2}{t-1}} p\right)^{\binom{t}{2}}$, and this tends to 0 or ∞ if $n^{\frac{2}{t-1}} p$ tends to 0 or ∞ respectively. So

$$\mathbb{P}(G \text{ contains a } K_t) = \mathbb{P}(X_t \geq 1) \leq \mathbb{E}[X_t] \rightarrow 0 \quad \text{if} \quad n^{\frac{2}{t-1}} p \rightarrow 0.$$

We now need to show that $\mathbb{P}(G \supseteq K_t) \rightarrow 1$ if $p n^{\frac{2}{t-1}} \rightarrow \infty$. We will use $\mathbb{P}(G \not\supseteq K_t) = \mathbb{P}(X_t = 0) \leq \mathbb{P}(|X_t - \mathbb{E}[X_t]| \geq \mathbb{E}[X_t])$. By Chebyshev, we have

$$\mathbb{P}(|X_t - \mathbb{E}[X_t]| \geq \mathbb{E}[X_t]) \leq \frac{\text{Var}(X_t)}{\mathbb{E}[X_t]^2},$$

so it suffices to show that this tends to 0.

We calculate the variance as

$$\begin{aligned} \text{Var}(X_t) &= \mathbb{E}[X_t^2] - (\mathbb{E}[X_t])^2 \\ &= \sum_{A, B \in [n]^{(t)}} [\mathbb{P}(G[A], G[B] \text{ complete}) - \mathbb{P}(G[A] \text{ complete})\mathbb{P}(G[B] \text{ complete})], \end{aligned}$$

which we calculate by hand as

$$\text{Var}(X_t) = \sum_{s=1}^t \binom{n}{t} \binom{t}{s} \binom{n-t}{t-s} \left[p^{2\binom{t}{2} - \binom{s}{2} - \binom{t-s}{2}} - p^{2\binom{t}{2}} \right],$$

and noting that $\binom{n-t}{t-s}/\binom{n}{t} \leq t!/n^s$ for n large, we have

$$\begin{aligned} \frac{\text{Var}(X_t)}{(\mathbb{E}[X])^2} &= \sum_{s=1}^t \frac{\binom{n}{t} \binom{t}{s} \binom{n-t}{t-s} [p^{2\binom{t}{2}-\binom{s}{2}} - p^{2\binom{t}{2}}]}{\binom{n}{t} p^{2\binom{t}{2}}}, \\ &\leq 2^{t+1} t! \sum_{s=1}^t \frac{1}{n^s} \cdot \frac{1}{p^{\binom{s}{2}}} \\ &\leq (t!)^2 \sum_{s=1}^t \left(\frac{1}{n^{\frac{s}{s-1}}} p \right)^{\binom{s}{2}}. \end{aligned}$$

Since $n^{\frac{2}{t-1}} p \rightarrow \infty$, then $n^{\frac{2}{s-1}} p \rightarrow \infty$ for each $s \leq t$, this goes to zero as required. $\square$

This is an example of a threshold result, where almost suddenly when p goes to a certain value, we start to see some consistent structure in the random graphs. Another somewhat similar question is:

What is the threshold for the graph to be connected?

We will find that this ‘transition’ will be much faster than with the previous example.

Theorem 31.8.7

Let G be sampled from $\mathcal{G}(n, p(n))$, then $\lim_{n \rightarrow \infty} \mathbb{P}(G \text{ is connected}) = 1$ if $p > (1 + \epsilon) \frac{\log n}{n}$ and $\lim_{n \rightarrow \infty} \mathbb{P}(G \text{ is disconnected}) = 0$ if $p < (1 - \epsilon) \frac{\log n}{n}$.

Proof. For the ‘first direction’ we will show that there is an isolated vertex with probability going to 1 if $p < (1 - \epsilon) \frac{\log n}{n}$. Let I be the number of isolated vertices. We are going to use a similar strategy to before, where we calculate the variance and apply Chebyshev.

We have

$$\mathbb{E}[I] = n(1-p)^{n-1} \quad \text{and} \quad \mathbb{E}[I^2] = \sum_{u,v \in [n]} \mathbb{P}(u, v \text{ are isolated}),$$

which gives us the variance

$$\begin{aligned} \text{Var}(I) &= \sum_{u,v \in [n]} [\mathbb{P}(u, v \text{ isolated}) - \mathbb{P}(u \text{ isolated})\mathbb{P}(v \text{ isolated})] \\ &= \left(\sum_{u \in [n]} \mathbb{P}(u \text{ iso}) - \mathbb{P}(u \text{ iso})^2 \right) + \left(\sum_{u \neq v \in [n]} \mathbb{P}(u, v \text{ iso}) - \mathbb{P}(u \text{ iso})\mathbb{P}(v \text{ iso}) \right) \\ &= (n(1-p)^{n-1}) + \left(\sum_{u \neq v \in [n]} (1-p)^{2(n-1)-1} - (1-p)^{2(n-1)} \right) \\ &= n(1-p)^{n-1} + n(n-1)(1-p)^{2(n-1)-1} p. \end{aligned}$$

Then we can apply Chebyshev to get

$$\begin{aligned}\mathbb{P}(I = 0) &\leq \mathbb{P}(|I - \mathbb{E}[I]| \geq \mathbb{E}[I]) \leq \frac{\text{Var}(I)}{\mathbb{E}[I]^2} \\ &= \frac{n(1-p)^{n-1} + n(n-1)(1-p)^{2(n-1)-1}}{n^2(1-p)^{2(n-1)}} \\ &= \frac{1}{(1-p)^{n-1}n} + p \rightarrow 0,\end{aligned}$$

as required.

Now for the ‘other direction’, we want to show that the $\mathbb{P}(G \text{ is disconnected}) \rightarrow 0$. We can write

$$\begin{aligned}\mathbb{P}(G \text{ is disconnected}) &= \mathbb{P}\left(\bigcup_{A \subseteq [n], 0 < |A| \leq n/2} \{\text{no edges between } A \text{ and } A'\}\right) \\ &\leq \sum_{A \subseteq [n], 0 < |A| \leq n/2} \mathbb{P}(\text{no edges between } A \text{ and } A') \\ &= \sum_{s=1}^{n/2} \binom{n}{s} (1-p)^{s(n-s)},\end{aligned}$$

so we want to show that this tends to zero. We can break up this sum as

$$\begin{aligned}\sum_{s=1}^{n/2} \binom{n}{s} (1-p)^{s(n-s)} &\leq \sum_{s=1}^{\epsilon n/2} \left(ne^{-p(n-s)}\right)^s + \sum_{\epsilon n/2 \leq s \leq n/2} \binom{n}{s} e^{-ps(n-s)} \\ &\leq \sum_{s=1}^{\epsilon n/2} \left(\frac{1}{n^{\epsilon/4}}\right)^s + \left(\sum_{\epsilon n/2 \leq s \leq n/2} \binom{n}{s}\right) e^{-\epsilon n \log n/8} \\ &\leq \sum_{s=1}^{\epsilon n/2} \left(\frac{1}{n^{\epsilon/4}}\right)^s + \left(2e^{-\epsilon \log n/8}\right)^n \rightarrow 0,\end{aligned}$$

thus $\mathbb{P}(G \text{ is disconnected}) \rightarrow 0$, as required. $\square$

§31.9 Algebraic Methods in Graph Theory

The final aspect of graph theory we are going to look at is the use of linear algebraic methods to solve problems. This is a naturally occurring technique, as will be shown by the problem below.

§31.9.1 A Motivating Problem

The **diameter** of a graph is the maximum distance between two vertices in a graph. We are going to try and attack the problem below:

How many vertices can a graph with fixed Δ have, given its diameter is at most 2?

By just thinking a little bit, it's not hard to come up with the bound

$$n \leq 1 + \Delta + (\Delta - 1)\Delta = 1 + \Delta^2,$$

but is it possible to have a graph that attains this bound? We are going to call such graphs *Moore graphs*.

Definition 31.9.1 (Moore Graph)

A **Moore graph** is a k -regular graph on $k^2 + 1$ vertices that has diameter 2.

Example 31.9.2 (Examples of Moore Graphs)

Below are Moore graphs for $k = 2$ and $k = 3$.

$k = 2$

$k = 3$

Note that the graph for $k = 3$ is the Petersen graph. Playing around a bit, you might find that such a graph for $k = 4$ *does not exist*, so it seems that Moore graphs are somewhat special.

Remark. A Moore graph is a k -regular graph for which any $x \neq y$ with $x, y \in V(G)$ has exactly one path of length ≤ 2 between x and y .

So Moore graphs don't always exist, leading to a natural question – does there exist infinitely many of them?

§31.9.2 The Adjacency Matrix

One way to encode a graph is using an adjacency matrix.

Definition 31.9.3 (Adjacency Matrix)

Given a graph $G = (V, E)$ on n vertices, we define the **adjacency matrix** of G to be the $n \times n$ matrix

$$A_{ij} = \begin{cases} 1 & \text{if } ij \in E, \\ 0 & \text{otherwise.} \end{cases}$$

Example 31.9.4 (Example of an Adjacency Matrix)

An graph and its associated adjacency matrix are given below.

Adjacency Matrix

$$A = \begin{pmatrix} 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 & 1 \\ 1 & 1 & 0 & 1 & 0 \end{pmatrix}$$

Now while this is just a straightforward representation of a graph, the fact that it's a matrix means that we can start asking questions about it, even if it's not immediately obvious that they have any meaning. For example, what do the eigenvalues of this matrix look like? What about the eigenvectors?

We can observe that the adjacency matrix is symmetric, which we know implies that it has real eigenvalues $\lambda_1 \geq \dots \geq \lambda_n$, and an associated eigenbasis $v_1, \dots, v_n$ which is orthonormal.

We can also observe that for a graph G with adjacency matrix A , since there's no edge between a vertex and itself, that there is only zeros along the diagonal of A , so it has zero trace and

$$\sum_{i=1}^n \lambda_i = \text{tr}(A) = 0.$$

Also, if we call $\lambda_1 = \lambda_{\max}$ and $\lambda_n = \lambda_{\min}$, then

$$\lambda_{\max} = \max_{x:|x|^2=1} x^T A x, \quad \text{and} \quad \lambda_{\min} = \min_{x:|x|^2=1} x^T A x$$

Somewhat surprisingly, we are going to be able to connect all of these algebraic facts back to our original graph.

Proposition 31.9.5

Let $G = (V, E)$ be a graph with adjacency matrix A . Then

- (i) $\frac{1}{n} \sum_{x \in V} d(x) \leq \lambda_{\max}(G) \leq \Delta(G)$.
- (ii) $\lambda_{\max}(G) = \Delta(G)$ if and only if G is Δ -regular.
- (iii) $\lambda_{\min}(G) = \Delta(G)$ if and only if G is Δ -regular and bipartite.

Proof. Part (i). For the lower bound, let $w = \frac{1}{\sqrt{n}}(1, \dots, 1)$. Then we observe by interpreting the adjacency matrix in a graph theoretic sense that

$$\lambda_{\max} = \max_{x:|x|^2=1} x^T A x \geq w^T A w = \frac{1}{n} \sum_{x \in V} d(x).$$

For the upper bound, let $x = (x_1, \dots, x_n)$ be an eigenvector corresponding to $\lambda_{\max}$. Assume WLOG that $|x_1| \geq |x_i|$, for all i . Then

$$\lambda x_1 = (\lambda_{\max} x)_1 = (Ax)_1 = \sum_{i: v_i \sim v_1} x_i,$$

which gives us

$$|\lambda_{max}x_1| \leq \sum_{i:v_i \sim v_1} |x_i| \leq |x_1|\Delta,$$

so $|\lambda_{max}| \leq \Delta$, and $\lambda_{max} \leq \Delta$.

Part (ii). If G is Δ -regular, then consider $\mathbb{1} = (1, \dots, 1)$. Then

$$A\mathbb{1} = \Delta\mathbb{1},$$

thus $\lambda_{max} \geq \Delta$, so $\lambda_{max} = \Delta$ by our previous result.

If $\lambda_{max} = \Delta$, then let $x = (x_1, \dots, x_n)$ be an associated eigenvector, and as before assume $|x_1| \geq |x_i|$ for all i . Then

$$\Delta x_1 = (\Delta x)_1 = (Ax)_1 = \sum_{i:v_i \sim v_1} x_i,$$

therefore $x_i = x$ for all i where $v_i \sim v_1$. So now we repeat the argument for all $v_i \in N(v_1)$ to learn that all x_j with $d(v_j, v_1) \leq 2$ has $x_j = x_1$ and so on, until we get $x_1 = x_i$ for all v_j in the component of v_i . We then repeat for each component, to see that x is constant on each component, and thus G must be a regular graph.

Part (iii). Omitted. □

Another fact that will bring us closer to Moore graphs concerns the interpretation of the square of an adjacency matrix.

Proposition 31.9.6

Let G be a graph and let A be its adjacency matrix. Then $(A^2)_{ij}$ is the number of walks of length 2 between i, j .

Proof Sketch. Consider how A^2 is calculated. □

§31.9.3 Moore Graphs

Now we can apply our newfound algebraic tools to our question about Moore graphs and graph diameter. We will see that our result really does show that Moore graphs are pretty special.

Lemma 31.9.7 (Necessary Condition for the Existence of Moore Graphs)

Let G be a Moore graph of degree k , then

$$\frac{1}{2} \left(k^2 \pm \frac{k^2 - 2k}{\sqrt{4k - 3}} \right) \text{ are integers.}$$

Proof. Let G be a Moore graph of degree k on n vertices, and let A be the adjacency

matrix of G . Then we have

$$(A^2)_{ij} = \begin{cases} k & \text{if } i = j, \\ 1 & \text{if } i \neq j \text{ and } ij \notin E, \\ 0 & \text{if } ij \in E. \end{cases}$$

Thus $A^2 = (J - A) + (k - 1)I$, where J is the matrix of all 1s. So we have

$$A^2 + A - (k - 1)I = J.$$

Now let $\lambda_{\max}$ be a maximum eigenvalue of A , and let x be a corresponding eigenvector. Since G is k -regular, $\mathbb{1}$ is an eigenvector of A , and thus we know that $x \perp \mathbb{1}$, since $\lambda_{\max} \neq \Delta$. Then

$$(A^2 + A - (k - 1)I)x = Jx \implies (\lambda_{\max}^2 + \lambda_{\max} - (k - 1))x = 0,$$

so $\lambda_{\max}^2 + \lambda_{\max} - (k - 1) = 0$. Thus

$$\lambda_{\max} = \left(\frac{-1 \pm \sqrt{1 + 4(k - 1)}}{2} \right) = \left(\frac{-1 \pm \sqrt{4k - 3}}{2} \right).$$

So A has eigenvalues k with multiplicity 1, $\lambda_{\max}$ with multiplicity say r , and μ with multiplicity s , with $r + s = n - 1$. We also know that

$$\sum_{i=1}^n \lambda_i = 0 = k + r\lambda + s\mu,$$

and solving this for integers r and s and using $n = k^2 + 1$ gives the desired result. $\square$

With this lemma, we can heavily restrict the possible Moore graphs.

Theorem 31.9.8 (Hoffman-Singleton Theorem)

Let G be a Moore graph of degree k . Then $k \in \{2, 3, 7, 57\}$.

Proof. We need to find out when

$$\frac{1}{2} \left(k^2 \pm \frac{k^2 - 2k}{\sqrt{4k - 3}} \right)$$

are integers. One case is when $k^2 - 2k = 0$, implying that $k = 2$. Another case is when $4k - 3 = t^2$, where $t \mid k^2 - 2k$. Then we have

$$t \mid \left(\frac{t^2 + 3}{4} \right)^2 - 2 \left(\frac{t^3 + 3}{4} \right),$$

and multiplying by 16,

$$t \mid t^4 - 2t^2 - 15,$$

so $t \mid 15$, and thus $t \in \{3, 5, 15\}$, and since $4k - 3 = t^2$, this shows that $k \in \{3, 7, 57\}$. $\square$

Remark. For $k = 2, 3$ and 7 , the graphs are known to exist, but a graph for $k = 57$ is

has not yet been found.

32 Integrable Systems

Most differential equations cannot be solved. This is not a statement about our own cleverness – it is a statement about differential equations, the overwhelming majority of which have solutions that admit no description more economical than the equation itself. Every so often, though, we stumble across an equation that can be ‘integrated up’: one whose solutions can be written down in closed form, or reduced to quadratures, or generated from nothing by an algebraic recipe. Such equations are called *integrable*, and they are the subject of this course.

There is a curious tension here. On the one hand, integrable systems ought to be vanishingly rare, in the same way that a randomly chosen polynomial is unlikely to factorise nicely. On the other hand, integrable equations turn up all over physics – the harmonic oscillator, the Kepler problem, the spinning top, waves in shallow water, light in an optical fibre. Nature seems unreasonably fond of them. The explanation, when we find it, is always the same: integrability is a symptom of hidden structure. An integrable system has more conserved quantities than it has any right to have, and those conserved quantities conspire to fill up phase space with tori on which the motion is nothing more than uniform rotation.

The plan of the course is to take this idea and push it as far as it will go. We begin with ordinary differential equations, where the story is essentially complete: the Arnold–Liouville theorem tells us precisely what it means for a Hamiltonian system to be integrable, and how to integrate it. We then move to partial differential equations, which we can think of as infinite-dimensional dynamical systems. Here the theory is much wilder and much more beautiful. We will meet the Korteweg–de Vries equation and its *solitons* – solitary waves that collide and emerge unscathed, behaving far more like particles than like waves – and we will spend the heart of the course developing the *inverse scattering transform*, an extraordinary machine which solves a nonlinear PDE by turning it into a linear scattering problem, letting the scattering data evolve trivially, and then reconstructing the answer.

This article constitutes my notes for the ‘Integrable Systems’ course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered¹.

§32.1 Integrability of Ordinary Differential Equations

We begin with ordinary differential equations. The eventual goal of this section is the Arnold–Liouville theorem, which says that a Hamiltonian system possessing enough conserved quantities can be solved completely, and moreover tells us how. Before we get there we need to set up some machinery: flows, Poisson brackets, and canonical transformations.

¹We will lean fairly heavily on IB Variational Principles (Hamilton’s equations, the Legendre transform, Noether’s theorem) and on IB Methods (Fourier transforms, Green’s functions, Sturm–Liouville theory). A passing acquaintance with IB Quantum Mechanics – specifically reflection and transmission coefficients for a one-dimensional potential – will make Section 3 feel much more familiar.

§32.1.1 Vector Fields and Flow Maps

An m -dimensional first-order ODE is specified by a **vector field** $\mathbf{V} : \mathbb{R}^m \rightarrow \mathbb{R}^m$ together with an initial condition $\mathbf{x}_0 \in \mathbb{R}^m$. We look for a curve $\mathbf{x}(t) \in \mathbb{R}^m$, defined for t in some interval containing 0, satisfying

$$\dot{\mathbf{x}} = \mathbf{V}(\mathbf{x}), \quad \mathbf{x}(0) = \mathbf{x}_0.$$

Restricting to first-order equations costs us nothing: an n th order ODE in one variable becomes a first-order system in n variables in the usual way, by treating the derivatives as new coordinates.

Throughout this course we will be cavalier about regularity, and assume that all our vector fields are as nice as we need them to be.

Fact 32.1.1

For a sufficiently nice vector field $\mathbf{V}$ and any initial condition $\mathbf{x}_0$, the problem $\dot{\mathbf{x}} = \mathbf{V}(\mathbf{x})$, $\mathbf{x}(0) = \mathbf{x}_0$ has a unique solution, and that solution depends smoothly on both t and $\mathbf{x}_0$.

Because the solution is unique, it is legitimate to package all of the solutions together into a single object.

Definition 32.1.2 (Flow map)

The **flow map** of a vector field $\mathbf{V}$ is the family of maps $g^t : \mathbb{R}^m \rightarrow \mathbb{R}^m$ defined by

$$\mathbf{x}(t) = g^t \mathbf{x}_0,$$

where $\mathbf{x}(t)$ solves $\dot{\mathbf{x}} = \mathbf{V}(\mathbf{x})$ with $\mathbf{x}(0) = \mathbf{x}_0$.

The flow map is smooth, and satisfies exactly the properties one would hope for.

Proposition 32.1.3

The flow map obeys

- (i) $g^0 = \text{id}$;
- (ii) $g^{t+s} = g^t g^s$;
- (iii) $(g^t)^{-1} = g^{-t}$.

Proof. The first is immediate from the definition, and the third follows from the first two on setting $s = -t$. For the second, fix $\mathbf{x}_0$ and s , and regard both $t \mapsto g^{t+s} \mathbf{x}_0$ and $t \mapsto g^t(g^s \mathbf{x}_0)$ as functions of t . Both solve

$$\dot{\mathbf{x}} = \mathbf{V}(\mathbf{x}), \quad \mathbf{x}(0) = g^s \mathbf{x}_0,$$

and so by uniqueness of solutions they coincide. □

In the language of IA Groups, this says that $t \mapsto g^t$ is a homomorphism from $(\mathbb{R}, +)$ into the group of diffeomorphisms of $\mathbb{R}^m$. We say that $\mathbf{V}$ is the **infinitesimal generator** of

the flow, which is justified by Taylor expanding:

$$g^\varepsilon \mathbf{x}_0 = \mathbf{x}(0) + \varepsilon \dot{\mathbf{x}}(0) + o(\varepsilon) = \mathbf{x}_0 + \varepsilon \mathbf{V}(\mathbf{x}_0) + o(\varepsilon).$$

So to first order in ε , flowing for time ε is just moving along $\mathbf{V}$.

Suppose now that we have two vector fields $\mathbf{V}_1, \mathbf{V}_2$ generating flows g_1^t and g_2^s . A natural question is whether the flows *commute*, that is, whether

$$g_1^t g_2^s \mathbf{x}_0 = g_2^s g_1^t \mathbf{x}_0$$

for all $\mathbf{x}_0, s, t$. Asked directly this is a hopeless question, since it requires us to solve both ODEs. But there is an infinitesimal criterion, and infinitesimal criteria are always easier.

Definition 32.1.4 (Commutator)

Given vector fields $\mathbf{V}_1, \mathbf{V}_2 : \mathbb{R}^m \rightarrow \mathbb{R}^m$, their **commutator** is the vector field

$$[\mathbf{V}_1, \mathbf{V}_2] = \left(\mathbf{V}_1 \cdot \frac{\partial}{\partial \mathbf{x}} \right) \mathbf{V}_2 - \left(\mathbf{V}_2 \cdot \frac{\partial}{\partial \mathbf{x}} \right) \mathbf{V}_1,$$

where $\frac{\partial}{\partial \mathbf{x}} = (\partial_{x_1}, \dots, \partial_{x_m})^T$. Componentwise,

$$[\mathbf{V}_1, \mathbf{V}_2]_i = \sum_{j=1}^m \left((\mathbf{V}_1)_j \frac{\partial (\mathbf{V}_2)_i}{\partial x_j} - (\mathbf{V}_2)_j \frac{\partial (\mathbf{V}_1)_i}{\partial x_j} \right).$$

Proposition 32.1.5

Let $\mathbf{V}_1, \mathbf{V}_2$ be vector fields generating flows g_1^t, g_2^s . Then

$$[\mathbf{V}_1, \mathbf{V}_2] = 0 \iff g_1^t g_2^s = g_2^s g_1^t \text{ for all } s, t.$$

We will not prove this (it is a standard exercise, and appears on the first example sheet), but the idea is worth recording: expanding $g_1^{-t} g_2^{-s} g_1^t g_2^s \mathbf{x}_0$ to second order in the small parameters, everything cancels except a term $st [\mathbf{V}_1, \mathbf{V}_2](\mathbf{x}_0)$. The commutator measures precisely the failure of the two flows to commute, and it does so at the level of the vector fields, where we can compute.

§32.1.2 Hamiltonian Systems

We now specialise to a very particular class of ODEs. In IB Variational Principles we met Hamilton's equations, obtained from a Lagrangian by a Legendre transform; here we take them as our starting point.

The setting is a **phase space** $M = \mathbb{R}^{2n}$, with coordinates

$$(\mathbf{q}, \mathbf{p}) = (q_1, \dots, q_n, p_1, \dots, p_n),$$

which we think of as generalised positions and generalised momenta. We will usually write

$$\mathbf{x} = (\mathbf{q}, \mathbf{p})^T \in M.$$

The crucial point is that M is not just $\mathbb{R}^{2n}$: the coordinates come *paired up*, with q_i married to p_i . This pairing is the extra structure that distinguishes a phase space from a bare vector space, and we encode it in the $2n \times 2n$ antisymmetric matrix

$$J = \begin{pmatrix} 0 & I_n \\ -I_n & 0 \end{pmatrix},$$

called the **symplectic form**. Note that $J^T = -J$ and $J^2 = -I_{2n}$.

Almost everything in this section can be phrased in terms of J alone. The first example is the Poisson bracket.

Definition 32.1.6 (Poisson bracket)

For smooth $f, g : M \rightarrow \mathbb{R}$, the **Poisson bracket** is

$$\{f, g\} = \frac{\partial f}{\partial \mathbf{x}} \cdot J \frac{\partial g}{\partial \mathbf{x}} = \frac{\partial f}{\partial \mathbf{q}} \cdot \frac{\partial g}{\partial \mathbf{p}} - \frac{\partial f}{\partial \mathbf{p}} \cdot \frac{\partial g}{\partial \mathbf{q}}.$$

The two expressions agree by direct computation with the block form of J . The Poisson bracket has a list of properties, most of which are obvious and one of which is not.

Proposition 32.1.7

The Poisson bracket satisfies, for all smooth $f, g, h : M \rightarrow \mathbb{R}$:

- (i) it is bilinear;
- (ii) it is antisymmetric, $\{f, g\} = -\{g, f\}$;
- (iii) it obeys the Leibniz rule $\{f, gh\} = \{f, g\}h + \{f, h\}g$;
- (iv) it obeys the Jacobi identity

$$\{f, \{g, h\}\} + \{g, \{h, f\}\} + \{h, \{f, g\}\} = 0;$$

- (v) on the coordinate functions,

$$\{q_i, q_j\} = \{p_i, p_j\} = 0, \quad \{q_i, p_j\} = \delta_{ij}.$$

Proof. All of these are immediate from the definition except the Jacobi identity, which one proves by writing out all twenty-four terms and watching them cancel. The only structural remark worth making is that each of the three double brackets contains second derivatives of exactly one of f, g, h , and these second-derivative terms cancel in pairs because J is antisymmetric and second partial derivatives commute. $\square$

The last of these is called the **canonical commutation relation**, and it is the algebraic shadow of the pairing between q_i and p_i .

Definition 32.1.8 (Hamilton's equations)

Given a function $H : M \rightarrow \mathbb{R}$, called the **Hamiltonian**, **Hamilton's equations**

are

$$\dot{\mathbf{q}} = \frac{\partial H}{\partial \mathbf{p}}, \quad \dot{\mathbf{p}} = -\frac{\partial H}{\partial \mathbf{q}}. \quad (*)$$

In terms of J these collapse into the single equation

$$\dot{\mathbf{x}} = J \frac{\partial H}{\partial \mathbf{x}}.$$

This is worth pausing over. To specify a general ODE on $\mathbb{R}^{2n}$ we must supply a vector field, which is $2n$ functions. To specify a Hamiltonian system we need only supply the *single* function H . The symplectic structure does the rest of the work. This is our first hint that Hamiltonian systems are special.

Definition 32.1.9 (Hamiltonian vector field)

Given $f : M \rightarrow \mathbb{R}$, the associated **Hamiltonian vector field** is

$$\mathbf{V}_f = J \frac{\partial f}{\partial \mathbf{x}}.$$

Thus Hamilton's equations say precisely that the motion is the flow of $\mathbf{V}_H$.

Now suppose we are watching a particle move according to $(*)$, and we are interested in some observable $f : M \rightarrow \mathbb{R}$ – its energy, its angular momentum, its distance from the origin. How does f change along the motion? The chain rule gives

$$\frac{df}{dt} = \frac{d}{dt}f(\mathbf{x}(t)) = \frac{\partial f}{\partial \mathbf{x}} \cdot \dot{\mathbf{x}} = \frac{\partial f}{\partial \mathbf{x}} \cdot J \frac{\partial H}{\partial \mathbf{x}} = \{f, H\}.$$

We record this, because it is the single most useful formula in the subject.

Proposition 32.1.10

If $\mathbf{x}(t)$ evolves according to Hamilton's equations with Hamiltonian H , then for any smooth $f : M \rightarrow \mathbb{R}$,

$$\frac{df}{dt} = \{f, H\}.$$

In other words – f is conserved if and only if it Poisson commutes with H . This is genuinely powerful. Without it, deciding whether some quantity is conserved means solving the equations of motion and staring at the answer, or else differentiating and hoping that things cancel. With it, we simply compute a bracket. And immediately we get one conserved quantity for free:

$$\frac{dH}{dt} = \{H, H\} = 0$$

by antisymmetry. Energy is conserved.

Example 32.1.11 (Particle in a potential)

Consider a particle of unit mass with Cartesian position $\mathbf{q} = (q_1, q_2, q_3)$ moving in a potential $U(\mathbf{q})$. Newton's second law reads

$$\ddot{\mathbf{q}} = -\frac{\partial U}{\partial \mathbf{q}}.$$

Introducing $\mathbf{p} = \dot{\mathbf{q}}$, we have

$$\dot{\mathbf{x}} = \begin{pmatrix} \dot{\mathbf{q}} \\ \dot{\mathbf{p}} \end{pmatrix} = \begin{pmatrix} \mathbf{p} \\ -\partial U/\partial \mathbf{q} \end{pmatrix} = J \frac{\partial H}{\partial \mathbf{x}}, \quad H = \frac{1}{2}|\mathbf{p}|^2 + U(\mathbf{q}),$$

since $\partial H/\partial \mathbf{p} = \mathbf{p}$ and $\partial H/\partial \mathbf{q} = \partial U/\partial \mathbf{q}$. So Newtonian mechanics in a potential is a Hamiltonian system, and the Hamiltonian is the total energy.

Example 32.1.12 (Angular momentum in the two-body problem)

Fix the Sun at the origin and let a planet have Cartesian coordinates $\mathbf{q}$. The equation of motion is

$$\ddot{\mathbf{q}} = -\frac{\mathbf{q}}{|\mathbf{q}|^3},$$

which by the previous example is Hamiltonian with $\mathbf{p} = \dot{\mathbf{q}}$ and

$$H = \frac{1}{2}|\mathbf{p}|^2 - \frac{1}{|\mathbf{q}|}.$$

The angular momentum is $\mathbf{L} = \mathbf{q} \wedge \mathbf{p}$, or in components $L_i = \varepsilon_{ijk} q_j p_k$. Let us check that it is conserved, using summation convention throughout:

$$\begin{aligned} \{L_i, H\} &= \frac{\partial L_i}{\partial q_\ell} \frac{\partial H}{\partial p_\ell} - \frac{\partial L_i}{\partial p_\ell} \frac{\partial H}{\partial q_\ell} \\ &= \varepsilon_{ijk} \delta_{j\ell} p_k \cdot p_\ell - \varepsilon_{ijk} q_j \delta_{k\ell} \cdot \frac{q_\ell}{|\mathbf{q}|^3} \\ &= \varepsilon_{ijk} \left(p_j p_k - \frac{q_j q_k}{|\mathbf{q}|^3} \right) \\ &= 0, \end{aligned}$$

since in each term we are contracting the antisymmetric ε_{ijk} against something symmetric in $j \leftrightarrow k$. So all three components of $\mathbf{L}$ are conserved, as is H : this system has rather a lot of conserved quantities, which is exactly why the Kepler problem can be solved.

There is one more piece of structure worth recording. We now have two ways of combining functions to produce vector fields: we can take the Poisson bracket $\{f, g\}$ and then form its Hamiltonian vector field, or we can form $\mathbf{V}_f$ and $\mathbf{V}_g$ and take their commutator. These agree up to sign.

Proposition 32.1.13

For smooth $f, g : M \rightarrow \mathbb{R}$ we have $[\mathbf{V}_f, \mathbf{V}_g] = -\mathbf{V}_{\{f, g\}}$.

The proof is a computation using the Jacobi identity, and is left to the first example sheet. The content of the statement is that $f \mapsto \mathbf{V}_f$ is (up to a sign) a homomorphism of Lie algebras, from functions-under-Poisson-bracket to vector-fields-under-commutator. We will use it in the proof of the Arnold–Liouville theorem, where it will tell us that flows generated by commuting conserved quantities themselves commute.

§32.1.3 First Integrals and Liouville Integrability

Definition 32.1.14 (First integral)

Let (M, H) be a Hamiltonian system. A function $f : M \rightarrow \mathbb{R}$ is a **first integral** if

$$\{f, H\} = 0,$$

equivalently, if f is constant along every trajectory.

The terminology is historical. When we solve a differential equation by successive integrations, each integration produces a constant; the constant produced by the first integration was called the first integral. For our purposes, a first integral is simply a constant of the motion.

Our goal for the rest of this section is the following. If a Hamiltonian system has *enough* first integrals, then there is a change of coordinates in which the equations of motion become trivial, and we can integrate them up by inspection. To make ‘enough’ precise we need two conditions.

Definition 32.1.15 (Involution)

Two first integrals F, G are **in involution** if $\{F, G\} = 0$. We also say that they **Poisson commute**.

Definition 32.1.16 (Independence)

Functions $f_1, \dots, f_n : M \rightarrow \mathbb{R}$ are **independent** if at each point $\mathbf{x} \in M$ the gradients $\frac{\partial f_i}{\partial \mathbf{x}}$, $i = 1, \dots, n$, are linearly independent vectors in $\mathbb{R}^{2n}$.

Definition 32.1.17 (Liouville integrable)

A $2n$ -dimensional Hamiltonian system (M, H) is **integrable** (in the Liouville sense) if there exist n first integrals $f_1, \dots, f_n$ which are independent and in involution, that is $\{f_i, f_j\} = 0$ for all i, j .

By convention we always take $f_1 = H$, which is legitimate since $\{H, H\} = 0$.

The independence requirement is what stops the definition being vacuous. Without it we could always cheat, taking $f_1 = H$, $f_2 = H^2$, $f_3 = e^H$, and so on: these all Poisson commute with everything in sight, but they carry no information beyond H itself. Independence says that each new first integral genuinely cuts down the available motion.

The involutivity requirement is subtler and less obviously natural, but it is exactly what makes the proof of the Arnold–Liouville theorem work. It is worth noting that a system can have many first integrals without being integrable in this sense, if the integrals refuse to Poisson commute.

Example 32.1.18

Every two-dimensional Hamiltonian system ($n = 1$) is integrable: we need one first integral, and H itself will do. This is a restatement of the familiar fact that a single particle moving in one dimension in a potential can always be solved by energy

conservation and a quadrature.

Example 32.1.19

Consider the two-body problem above. We have H , and the three components of $\mathbf{L}$. However

$$\{L_1, L_2\} = L_3 \neq 0,$$

so the L_i are not in involution with each other, and we cannot simply take all four. But H , L_3 and $|\mathbf{L}|^2$ are pairwise in involution and independent, and the system is six-dimensional, so $n = 3$ and the Kepler problem is integrable.

§32.1.4 Canonical Transformations

We want to find coordinates in which an integrable system becomes trivial. But we cannot use arbitrary coordinates: the whole structure above depended on the pairing of q_i with p_i , and a general change of variables will destroy it. So we must decide which coordinate changes are allowed. There are several equivalent ways to do this; we take the most pragmatic, and simply demand that Hamilton's equations keep their form.

Definition 32.1.20 (Canonical transformation)

A coordinate change $(\mathbf{q}, \mathbf{p}) \mapsto (\mathbf{Q}(\mathbf{q}, \mathbf{p}), \mathbf{P}(\mathbf{q}, \mathbf{p}))$ is **canonical** if it preserves the form of Hamilton's equations: that is, if

$$\dot{\mathbf{q}} = \frac{\partial H}{\partial \mathbf{p}}, \quad \dot{\mathbf{p}} = -\frac{\partial H}{\partial \mathbf{q}} \quad \Longleftrightarrow \quad \dot{\mathbf{Q}} = \frac{\partial \tilde{H}}{\partial \mathbf{P}}, \quad \dot{\mathbf{P}} = -\frac{\partial \tilde{H}}{\partial \mathbf{Q}},$$

where $\tilde{H}(\mathbf{Q}, \mathbf{P}) = H(\mathbf{q}, \mathbf{p})$.

Writing $\mathbf{x} = (\mathbf{q}, \mathbf{p})$ and $\mathbf{y} = (\mathbf{Q}, \mathbf{P})$, this says

$$\dot{\mathbf{x}} = J \frac{\partial H}{\partial \mathbf{x}} \quad \Longleftrightarrow \quad \dot{\mathbf{y}} = J \frac{\partial \tilde{H}}{\partial \mathbf{y}}.$$

Example 32.1.21

Swapping $\mathbf{q}$ and $\mathbf{p}$ is *not* canonical: it introduces a sign error, turning $\dot{\mathbf{Q}} = \partial \tilde{H} / \partial \mathbf{P}$ into $\dot{\mathbf{Q}} = -\partial \tilde{H} / \partial \mathbf{P}$. The map $(\mathbf{q}, \mathbf{p}) \mapsto (\mathbf{p}, -\mathbf{q})$, on the other hand, is canonical.

Let us do the linear case honestly, since it tells us what the general answer must look like.

Example 32.1.22 (Linear canonical transformations)

Consider $\mathbf{x} \mapsto \mathbf{y} = A\mathbf{x}$ for a constant matrix A . We claim this is canonical if and only if $AJA^T = J$, in which case A is called **symplectic**.

Indeed, by linearity $\dot{\mathbf{y}} = A\dot{\mathbf{x}} = AJ \frac{\partial H}{\partial \mathbf{x}}$. Setting $\tilde{H}(\mathbf{y}) = H(\mathbf{x})$ and using the chain

rule,

$$\frac{\partial H}{\partial x_i} = \frac{\partial y_j}{\partial x_i} \frac{\partial \tilde{H}}{\partial y_j} = A_{ji} \frac{\partial \tilde{H}}{\partial y_j} = \left[A^T \frac{\partial \tilde{H}}{\partial \mathbf{y}} \right]_i.$$

Substituting back,

$$\dot{\mathbf{y}} = A J A^T \frac{\partial \tilde{H}}{\partial \mathbf{y}},$$

which is Hamilton's equation for $\tilde{H}$ precisely when $A J A^T = J$.

Since a differentiable map is locally linear, and Hamilton's equations are a local condition, the general statement is the obvious one.

Proposition 32.1.23

A smooth map $\mathbf{x} \mapsto \mathbf{y}(\mathbf{x})$ is canonical if and only if its Jacobian $D\mathbf{y}$ is symplectic at every point:

$$D\mathbf{y} J (D\mathbf{y})^T = J.$$

This is a clean criterion, but it is a criterion for *checking* that a transformation is canonical, not for *producing* one. For that we use generating functions.

Generating Functions

There are four standard flavours of generating function, differing in which pair of old and new variables one takes as independent. We will need only one of them.

Let $S : \mathbb{R}^{2n} \rightarrow \mathbb{R}$ be a function which we write as $S(\mathbf{q}, \mathbf{P})$ – old positions and new momenta – and define a transformation implicitly by

$$\mathbf{p} = \frac{\partial S}{\partial \mathbf{q}}, \quad \mathbf{Q} = \frac{\partial S}{\partial \mathbf{P}}.$$

These equations are to be read as follows. The first is n equations relating $\mathbf{p}, \mathbf{q}, \mathbf{P}$; we solve them for $\mathbf{P}$ in terms of $(\mathbf{q}, \mathbf{p})$. The second then delivers $\mathbf{Q}$ in terms of $(\mathbf{q}, \mathbf{P})$, hence in terms of $(\mathbf{q}, \mathbf{p})$. Checking that the result is always canonical is another careful application of the chain rule, which we omit.

In practice we usually already have a candidate for $\mathbf{P}$ in mind – typically some collection of first integrals – and we hunt for an S making the first equation hold. The second equation then *tells* us what the conjugate variable $\mathbf{Q}$ has to be. This is exactly how the Arnold–Liouville theorem will proceed.

Example 32.1.24

Take $S(\mathbf{q}, \mathbf{P}) = \mathbf{q} \cdot \mathbf{P}$. Then

$$\mathbf{p} = \frac{\partial S}{\partial \mathbf{q}} = \mathbf{P}, \quad \mathbf{Q} = \frac{\partial S}{\partial \mathbf{P}} = \mathbf{q},$$

so S generates the identity transformation.

Example 32.1.25

In two dimensions, take $S(q, P) = qP + q^2$. Then

$$p = \frac{\partial S}{\partial q} = P + 2q, \quad Q = \frac{\partial S}{\partial P} = q,$$

so the transformation is $(Q, P) = (q, p - 2q)$, or in matrix form

$$\begin{pmatrix} Q \\ P \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ -2 & 1 \end{pmatrix} \begin{pmatrix} q \\ p \end{pmatrix} = A \begin{pmatrix} q \\ p \end{pmatrix}.$$

We can verify directly that this is canonical:

$$AJA^T = \begin{pmatrix} 1 & 0 \\ -2 & 1 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \begin{pmatrix} 1 & -2 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = J,$$

as promised.

§32.1.5 The Arnold–Liouville Theorem

We can now state the central result about integrable ODEs. Informally it says: if a Hamiltonian system is integrable, then there is a canonical transformation $(\mathbf{q}, \mathbf{p}) \mapsto (\phi, \mathbf{I})$ after which the new Hamiltonian depends only on $\mathbf{I}$. If we can achieve this then Hamilton's equations become

$$\dot{\mathbf{I}} = -\frac{\partial \tilde{H}}{\partial \phi} = 0, \quad \dot{\phi} = \frac{\partial \tilde{H}}{\partial \mathbf{I}},$$

so $\mathbf{I}(t) = \mathbf{I}_0$ is constant, and since the right-hand side of the second equation depends on $\mathbf{I}$ alone, $\dot{\phi}$ is constant too. Hence

$$\phi(t) = \phi_0 + \Omega t, \quad \Omega = \frac{\partial \tilde{H}}{\partial \mathbf{I}}(\mathbf{I}_0),$$

and we have solved the system completely. All the difficulty has been pushed into finding the transformation.

Before proving anything, let us see what the transformation looks like in the simplest possible example, where we can produce it by divine inspiration and then reverse-engineer where it came from.

Example 32.1.26 (Harmonic oscillator, first pass)

Take the harmonic oscillator on $M = \mathbb{R}^2$, with

$$H(q, p) = \frac{1}{2}p^2 + \frac{1}{2}\omega^2 q^2.$$

This is a two-dimensional system, so it is automatically integrable, with the single first integral $f_1 = H$. The level sets of H are ellipses:

Each of these is homeomorphic to a circle S^1 , and this is not an accident – it is the first half of the Arnold–Liouville theorem in miniature.

Now introduce new coordinates (ϕ, I) by

$$q = \sqrt{\frac{2I}{\omega}} \sin \phi, \quad p = \sqrt{2I\omega} \cos \phi.$$

One can check by computing the Jacobian that this is canonical. In these coordinates,

$$\tilde{H}(\phi, I) = \frac{1}{2} \cdot 2I\omega \cos^2 \phi + \frac{1}{2}\omega^2 \cdot \frac{2I}{\omega} \sin^2 \phi = \omega I.$$

There is no ϕ ! So Hamilton's equations read

$$\dot{\phi} = \frac{\partial \tilde{H}}{\partial I} = \omega, \quad \dot{I} = -\frac{\partial \tilde{H}}{\partial \phi} = 0,$$

giving $\phi(t) = \phi_0 + \omega t$ and $I(t) = I_0$. The oscillator goes round its ellipse at constant angular rate ω , which is of course the right answer.

Where could that transformation have come from? Here is a clue. Let us compute, for no obvious reason, the area enclosed by a level set of H , divided by 2π :

$$\begin{aligned} \frac{1}{2\pi} \oint p \, dq &= \frac{1}{2\pi} \int_0^{2\pi} p(\phi, I) \left(\frac{\partial q}{\partial \phi} d\phi + \frac{\partial q}{\partial I} dI \right) \\ &= \frac{1}{2\pi} \int_0^{2\pi} p(\phi, I) \frac{\partial q}{\partial \phi} d\phi \\ &= \frac{1}{2\pi} \int_0^{2\pi} \sqrt{2I\omega} \cos \phi \cdot \sqrt{\frac{2I}{\omega}} \cos \phi d\phi \\ &= \frac{2I}{2\pi} \int_0^{2\pi} \cos^2 \phi d\phi = I, \end{aligned}$$

using $dI = 0$ along a level set. So the new momentum I is nothing but the enclosed area over 2π – a quantity we could have computed knowing nothing whatsoever about the transformation.

There are two lessons here, and they are exactly the two halves of the theorem: the motion takes place on a circle, and the right momentum coordinate is $\frac{1}{2\pi} \oint p \, dq$.

Theorem 32.1.27 (Arnold–Liouville)

Let (M, H) be an integrable $2n$ -dimensional Hamiltonian system with independent, involutive first integrals $f_1, \dots, f_n$, where $f_1 = H$. For $\mathbf{c} \in \mathbb{R}^n$ set

$$M_{\mathbf{c}} = \{(\mathbf{q}, \mathbf{p}) \in M : f_i(\mathbf{q}, \mathbf{p}) = c_i, i = 1, \dots, n\}.$$

Then:

- (i) $M_{\mathbf{c}}$ is a smooth n -dimensional surface in M , invariant under the flow. If $M_{\mathbf{c}}$ is compact and connected, it is diffeomorphic to the n -torus

$$T^n = \underbrace{S^1 \times \dots \times S^1}_n.$$

- (ii) If $M_{\mathbf{c}}$ is compact and connected, then locally there is a canonical transformation $(\mathbf{q}, \mathbf{p}) \mapsto (\boldsymbol{\phi}, \mathbf{I})$ to **action–angle coordinates**, in which the ϕ_k are angular coordinates on $M_{\mathbf{c}}$, the actions I_k are first integrals, and $\tilde{H}$ is independent of $\boldsymbol{\phi}$. Consequently

$$\dot{\mathbf{I}} = 0, \quad \dot{\boldsymbol{\phi}} = \frac{\partial \tilde{H}}{\partial \mathbf{I}} = \text{constant}.$$

The first part is pure differential geometry, and the second is where the work is. We give the argument in outline; readers who have not met the preimage theorem or the orbit–stabiliser theorem in this setting may take the geometric steps on faith.

Proof sketch. Part (i). That $M_{\mathbf{c}}$ is a smooth n -dimensional surface is the preimage theorem (a consequence of the inverse function theorem from IB Analysis and Topology) applied to $\mathbf{f} = (f_1, \dots, f_n) : M \rightarrow \mathbb{R}^n$. What makes it apply is precisely the independence of the f_i , which says that $\mathbf{c}$ is a regular value.

Next we show that $M_{\mathbf{c}}$ is a torus when compact and connected. Consider the Hamiltonian vector fields

$$\mathbf{V}_{f_i} = J \frac{\partial f_i}{\partial \mathbf{x}}.$$

We claim each is tangent to $M_{\mathbf{c}}$. It suffices to show that the derivative of each f_j along $\mathbf{V}_{f_i}$ vanishes, and indeed

$$\left(\mathbf{V}_{f_i} \cdot \frac{\partial}{\partial \mathbf{x}} \right) f_j = \frac{\partial f_j}{\partial \mathbf{x}} \cdot J \frac{\partial f_i}{\partial \mathbf{x}} = \{f_j, f_i\} = 0$$

by involutivity. So the flows g_i^t generated by the $\mathbf{V}_{f_i}$ map $M_{\mathbf{c}}$ into itself. Moreover these flows commute, since

$$[\mathbf{V}_{f_i}, \mathbf{V}_{f_j}] = -\mathbf{V}_{\{f_i, f_j\}} = -\mathbf{V}_0 = 0.$$

So writing $\mathbf{t} = (t_1, \dots, t_n) \in \mathbb{R}^n$ and

$$g^{\mathbf{t}} = g_1^{t_1} g_2^{t_2} \dots g_n^{t_n},$$

commutativity gives $g^{\mathbf{t}_1 + \mathbf{t}_2} = g^{\mathbf{t}_1} g^{\mathbf{t}_2}$, so we have an action of the group $(\mathbb{R}^n, +)$ on $M_{\mathbf{c}}$.

Fix $\mathbf{x} \in M_{\mathbf{c}}$ and let

$$\text{Stab}(\mathbf{x}) = \{\mathbf{t} \in \mathbb{R}^n : g^{\mathbf{t}}\mathbf{x} = \mathbf{x}\}.$$

By the orbit–stabiliser theorem, $\mathbf{t} \mapsto g^{\mathbf{t}}\mathbf{x}$ descends to a bijection $\mathbb{R}^n / \text{Stab}(\mathbf{x}) \rightarrow \text{Orb}(\mathbf{x})$, and one checks that the orbit of $\mathbf{x}$ is the connected component of $\mathbf{x}$ in $M_{\mathbf{c}}$ – so if $M_{\mathbf{c}}$ is connected, the orbit is everything. Now $\text{Stab}(\mathbf{x})$ is a subgroup of $\mathbb{R}^n$, and (provided the flows are non-degenerate) it is discrete, hence isomorphic to $\mathbb{Z}^k$ for some $0 \leq k \leq n$. Therefore

$$M_{\mathbf{c}} \cong \mathbb{R}^n / \mathbb{Z}^k \cong T^k \times \mathbb{R}^{n-k}.$$

If $M_{\mathbf{c}}$ is compact there can be no $\mathbb{R}$ factors, so $k = n$ and $M_{\mathbf{c}} \cong T^n$.

Part (ii). We construct the action–angle coordinates. For clarity of presentation we take $n = 2$; the general case is identical except that we need a higher-dimensional version of Green’s theorem, which we do not have to hand.

It is trivially easy to find *some* coordinates $(\mathbf{Q}, \mathbf{P})$ with $\mathbf{P}$ constant along the flow and $\mathbf{Q}$ angular: just set $\mathbf{P} = \mathbf{c}$ and use the diffeomorphism $M_{\mathbf{c}} \cong T^n$ to get angles. The problem is that such a transformation will almost never be canonical. So we must be cleverer about the choice of $\mathbf{P}$.

On the torus T^n there are n topologically distinct ‘basic’ loops $\Gamma_1, \dots, \Gamma_n$ – under the identification $M_{\mathbf{c}} \cong S^1 \times \dots \times S^1$, the loop Γ_j runs once around the j th factor and is constant on the others. For $n = 2$ these are the two obvious circles:

We now define the **actions**

$$I_j = \frac{1}{2\pi} \oint_{\Gamma_j} \mathbf{p} \cdot d\mathbf{q},$$

generalising the formula we found for the harmonic oscillator. The first thing to check is that this is well defined, since Γ_j is really a whole homotopy class of loops rather than a single one. So suppose Γ_2 and Γ'_2 are two such loops, bounding between them an annular region A on the torus.

On $M_{\mathbf{c}}$ the equations $f_i(\mathbf{q}, \mathbf{p}) = c_i$ hold identically, and we assume we may invert them locally to write $\mathbf{p} = \mathbf{p}(\mathbf{q}, \mathbf{c})$; the condition for this is $\det(\partial f_i / \partial p_j) \neq 0$. Differentiating the identity $f_i(\mathbf{q}, \mathbf{p}(\mathbf{q}, \mathbf{c})) = c_i$ with respect to q_k gives

$$\frac{\partial f_i}{\partial q_k} + \frac{\partial f_i}{\partial p_\ell} \frac{\partial p_\ell}{\partial q_k} = 0$$

on $M_{\mathbf{c}}$. Now use involutivity: on $M_{\mathbf{c}}$,

$$0 = \{f_i, f_j\}$$

$$\begin{aligned}
&= \frac{\partial f_i}{\partial q_k} \frac{\partial f_j}{\partial p_k} - \frac{\partial f_i}{\partial p_k} \frac{\partial f_j}{\partial q_k} \\
&= \left(-\frac{\partial f_i}{\partial p_\ell} \frac{\partial p_\ell}{\partial q_k} \right) \frac{\partial f_j}{\partial p_k} - \frac{\partial f_i}{\partial p_k} \left(-\frac{\partial f_j}{\partial p_\ell} \frac{\partial p_\ell}{\partial q_k} \right) \\
&= \frac{\partial f_i}{\partial p_k} \left(\frac{\partial p_\ell}{\partial q_k} - \frac{\partial p_k}{\partial q_\ell} \right) \frac{\partial f_j}{\partial p_\ell},
\end{aligned}$$

where in the last line we relabelled dummy indices in the first term. Since the matrices $\partial f_i/\partial p_k$ are invertible, the matrix in the middle must vanish:

$$\frac{\partial p_\ell}{\partial q_k} = \frac{\partial p_k}{\partial q_\ell}.$$

For $n = 2$ the only content of this is $\partial p_1/\partial q_2 = \partial p_2/\partial q_1$. But then by Green's theorem

$$\left(\oint_{\Gamma_2} - \oint_{\Gamma'_2} \right) \mathbf{p} \cdot d\mathbf{q} = \oint_{\partial A} \mathbf{p} \cdot d\mathbf{q} = \iint_A \left(\frac{\partial p_2}{\partial q_1} - \frac{\partial p_1}{\partial q_2} \right) dq_1 dq_2 = 0.$$

So I_j depends only on the homotopy class of Γ_j , and hence $\mathbf{I} = \mathbf{I}(\mathbf{c})$ is a function of $\mathbf{c}$ alone. These are our new momenta. We assume $\mathbf{I}(\mathbf{c})$ is invertible, so that we may also write $\mathbf{c} = \mathbf{c}(\mathbf{I})$.

It remains to produce the conjugate angles, and for this we use a generating function. Pick a base point $\mathbf{x}_0 \in M_{\mathbf{c}}$ and set

$$S(\mathbf{q}, \mathbf{I}) = \int_{\mathbf{x}_0}^{\mathbf{x}} \mathbf{p}(\mathbf{q}', \mathbf{c}(\mathbf{I})) \cdot d\mathbf{q}',$$

where $\mathbf{x} = (\mathbf{q}, \mathbf{p}(\mathbf{q}, \mathbf{c}(\mathbf{I})))$ and the integral is along any path in $M_{\mathbf{c}}$. Is this well defined? If we deform the path slightly, sweeping out a region B , then S changes by $\oint_{\partial B} \mathbf{p} \cdot d\mathbf{q}$, which vanishes by exactly the Green's theorem computation above. But we are on a torus, and there are paths that cannot be deformed into one another: a path may wind around one of the cycles Γ_j on its way. Adding such a loop changes S by $\oint_{\Gamma_j} \mathbf{p} \cdot d\mathbf{q} = 2\pi I_j$. So the total ambiguity is

$$S(\mathbf{q}, \mathbf{I}) \mapsto S(\mathbf{q}, \mathbf{I}) + 2\pi m_j I_j, \quad m_j \in \mathbb{Z},$$

and nothing worse. Differentiating with respect to $\mathbf{I}$, we conclude that

$$\phi = \frac{\partial S}{\partial \mathbf{I}}$$

is well defined *modulo* 2π . These are the angles, and the ambiguity is exactly the ambiguity one expects of an angular coordinate.

Finally we should check that S really is a generating function in the sense of the previous subsection, i.e. that $\partial S/\partial \mathbf{q} = \mathbf{p}$. Writing $S = \int_{\mathbf{x}_0}^{\mathbf{x}} \mathbf{F} \cdot d\mathbf{x}'$ with $\mathbf{F} = (\mathbf{p}, \mathbf{0})$, the fundamental theorem of calculus gives $\partial S/\partial \mathbf{x} = \mathbf{F}$, and in particular $\partial S/\partial \mathbf{q} = \mathbf{p}$ as required.

So S generates a canonical transformation $(\mathbf{q}, \mathbf{p}) \mapsto (\boldsymbol{\phi}, \mathbf{I})$. Since $\mathbf{I} = \mathbf{I}(\mathbf{c}) = \mathbf{I}(\mathbf{f}(\mathbf{x}))$ is a function of the first integrals alone, we have $\dot{\mathbf{I}} = 0$; and since $\dot{\mathbf{I}} = -\partial\tilde{H}/\partial\boldsymbol{\phi}$, the new Hamiltonian is independent of $\boldsymbol{\phi}$. Integrating up,

$$\boldsymbol{\phi}(t) = \boldsymbol{\phi}_0 + \boldsymbol{\Omega}t, \quad \mathbf{I}(t) = \mathbf{I}_0, \quad \boldsymbol{\Omega} = \frac{\partial\tilde{H}}{\partial\mathbf{I}}(\mathbf{I}_0). \quad \square$$

The picture that emerges is a very appealing one. Phase space is foliated by invariant tori $M_{\mathbf{c}}$, one for each value of the conserved quantities, and on each torus the motion is uniform straight-line motion in the angle variables – a winding line, going round the j th cycle at frequency Ω_j . Drawing the torus in the usual way as a square with opposite edges identified, the trajectory is simply a straight line of slope Ω_2/Ω_1 :

If the frequencies $\Omega_1, \dots, \Omega_n$ are rationally related the trajectory closes up and the motion is periodic; if they are rationally independent the trajectory winds around forever, densely filling the torus, and the motion is called **quasi-periodic**.

§32.1.6 Action–Angle Variables

The proof above is constructive, and gives us a recipe. To integrate up an integrable Hamiltonian system:

- (1) Identify the n cycles $\Gamma_1, \dots, \Gamma_n$ on the invariant torus $M_{\mathbf{c}}$, and solve $f_i(\mathbf{q}, \mathbf{p}) = c_i$ for $\mathbf{p} = \mathbf{p}(\mathbf{q}, \mathbf{c})$.
- (2) Compute the actions

$$I_j = \frac{1}{2\pi} \oint_{\Gamma_j} \mathbf{p} \cdot d\mathbf{q},$$

and invert to obtain $\mathbf{c} = \mathbf{c}(\mathbf{I})$.

- (3) Form the generating function

$$S(\mathbf{q}, \mathbf{I}) = \int^{\mathbf{q}} \mathbf{p}(\mathbf{q}', \mathbf{c}(\mathbf{I})) \cdot d\mathbf{q}'$$

and read off the angles $\boldsymbol{\phi} = \partial S / \partial \mathbf{I}$.

- (4) Write $\tilde{H} = \tilde{H}(\mathbf{I})$ and read off the frequencies $\boldsymbol{\Omega} = \partial\tilde{H}/\partial\mathbf{I}$.

In practice step (4) is often all one wants: the frequencies of an integrable system can be extracted without ever computing the angles, since $\tilde{H}(\mathbf{I})$ is determined by step (2) alone.

Let us run the recipe on the harmonic oscillator, and see the transformation appear without any divine intervention.

Example 32.1.28 (Harmonic oscillator, second pass)

With $H = \frac{1}{2}p^2 + \frac{1}{2}\omega^2 q^2$ we have

$$M_c = \{(q, p) : \frac{1}{2}p^2 + \frac{1}{2}\omega^2 q^2 = c\},$$

an ellipse, which is indeed diffeomorphic to $T^1 = S^1$ as the theorem promises. There is only one cycle, the ellipse itself. Solving for p ,

$$p = p(q, c) = \pm \sqrt{2c - \omega^2 q^2}.$$

The action is the enclosed area over 2π . The ellipse $\frac{1}{2}p^2 + \frac{1}{2}\omega^2 q^2 = c$ has semi-axes $\sqrt{2c}/\omega$ and $\sqrt{2c}$, so its area is $\pi \cdot \frac{\sqrt{2c}}{\omega} \cdot \sqrt{2c} = 2\pi c/\omega$ and

$$I = \frac{1}{2\pi} \oint p \, dq = \frac{c}{\omega}.$$

Inverting, $c = c(I) = \omega I$, so immediately

$$\tilde{H} = c = \omega I, \quad \Omega = \frac{d\tilde{H}}{dI} = \omega.$$

The frequency is ω , independent of amplitude – the defining feature of the harmonic oscillator.

For the angle, take the base point to be $q = 0$ with $p > 0$. Then

$$S(q, I) = \int_0^q \sqrt{2\omega I - \omega^2 q'^2} \, dq',$$

and differentiating under the integral sign,

$$\phi = \frac{\partial S}{\partial I} = \int_0^q \frac{\omega \, dq'}{\sqrt{2\omega I - \omega^2 q'^2}} = \int_0^q \frac{dq'}{\sqrt{2I/\omega - q'^2}} = \sin^{-1} \left(\sqrt{\frac{\omega}{2I}} q \right).$$

Sure enough, this is well defined only up to multiples of 2π . Inverting,

$$q = \sqrt{\frac{2I}{\omega}} \sin \phi, \quad p = \frac{\partial S}{\partial q} = \sqrt{2\omega I - \omega^2 q^2} = \sqrt{2I\omega} \cos \phi,$$

which is exactly the transformation we pulled out of thin air earlier.

The next example is the one to remember, because it is the simplest system in which the frequency actually depends on the action.

Example 32.1.29 (The simple pendulum)

A pendulum of unit mass and unit length in unit gravity has Hamiltonian

$$H(q, p) = \frac{1}{2}p^2 - \cos q,$$

where q is the angle from the downward vertical. The phase portrait is the following, with the equilibria marked: centres at $q = 0, \pm 2\pi, \dots$ (the pendulum hanging down) and saddles at $q = \pm \pi$ (the pendulum balanced upright).

There are three qualitatively different kinds of motion, separated by the thick red curve.

- (i) For $-1 < E < 1$ the level set $\{H = E\}$ is a closed curve encircling the origin. This is **libration**: the pendulum swings back and forth about the bottom, with q bounded by the turning points $\pm q_0$ where $\cos q_0 = -E$.
- (ii) For $E > 1$ the level set consists of two curves, one with $p > 0$ throughout and one with $p < 0$. This is **rotation**: the pendulum has enough energy to go over the top, and q increases (or decreases) without bound.
- (iii) At $E = 1$ we have the **separatrix**, $p = \pm 2 \cos(q/2)$, on which the pendulum takes infinite time to creep up to the inverted position $q = \pi$.

Note that the phase space here is really a cylinder rather than a plane, since q and $q + 2\pi$ describe the same configuration; on the cylinder the libration curves are circles, and so are the rotation curves, but the two families of circles are not homotopic to one another.

Consider the librating region. Solving for p ,

$$p = \pm \sqrt{2(E + \cos q)},$$

and the action is

$$I(E) = \frac{1}{2\pi} \oint p \, dq = \frac{1}{\pi} \int_{-q_0}^{q_0} \sqrt{2(E + \cos q)} \, dq,$$

where $q_0 = \cos^{-1}(-E)$ and the factor of two from the upper and lower halves of the curve has been absorbed. Using $\cos q = 1 - 2 \sin^2(q/2)$ and writing $k^2 = (1 + E)/2 \in (0, 1)$, this becomes

$$I(E) = \frac{4}{\pi} \int_0^{q_0} \sqrt{k^2 - \sin^2(q/2)} \, dq = \frac{8}{\pi} [\mathcal{E}(k) - (1 - k^2)\mathcal{K}(k)],$$

where $\mathcal{K}$ and $\mathcal{E}$ are the complete elliptic integrals of the first and second kind. This is not an elementary function, and that is the point: the pendulum is integrable, but its action-angle variables involve elliptic functions. The frequency is

$$\Omega(I) = \frac{dE}{dI} = \left(\frac{dI}{dE} \right)^{-1} = \frac{\pi}{2\mathcal{K}(k)},$$

using $dI/dE = \frac{2}{\pi}\mathcal{K}(k)$, which follows from differentiating the integral for I under the integral sign.

It is worth sanity-checking the two limits. As $E \rightarrow -1^+$ we have $k \rightarrow 0$, and $\mathcal{K}(0) = \pi/2$, so $\Omega \rightarrow 1$: small oscillations have unit frequency, in agreement with linearising $\ddot{q} = -\sin q \approx -q$. As $E \rightarrow 1^-$ we have $k \rightarrow 1$ and $\mathcal{K}(k) \rightarrow \infty$, so $\Omega \rightarrow 0$: the period diverges as we approach the separatrix, which is the statement that the pendulum takes forever to reach the top. The pendulum is thus the standard example of an integrable system whose frequency depends on its amplitude.

Our final example has two degrees of freedom, so that we get an honest two-torus and two genuinely different cycles.

Example 32.1.30 (A particle in a central potential)

Consider a particle of unit mass moving in a plane under a central potential $U(r)$. Using polar coordinates (r, θ) , the Hamiltonian is

$$H = \frac{1}{2} \left(p_r^2 + \frac{p_\theta^2}{r^2} \right) + U(r),$$

with the canonical pairs (r, p_r) and (θ, p_θ) . This is a four-dimensional phase space, so we need two first integrals in involution, and we have them: $f_1 = H$ and $f_2 = p_\theta$, the angular momentum. They are in involution because H does not depend on θ :

$$\{p_\theta, H\} = -\frac{\partial H}{\partial \theta} = 0.$$

So the system is integrable. Fix $\mathbf{c} = (E, L)$. The invariant surface $M_{\mathbf{c}}$ is described by

$$p_\theta = L, \quad p_r = \pm \sqrt{2(E - U(r)) - \frac{L^2}{r^2}},$$

and provided the effective potential $U_{\text{eff}}(r) = U(r) + L^2/2r^2$ has a well, so that r oscillates between turning points r_- and r_+ , this really is a torus: θ runs around a circle, and (r, p_r) traces a closed curve in its own plane.

The two cycles are then evident. Taking Γ_1 to be the loop on which θ increases by 2π at fixed r , and Γ_2 the loop on which (r, p_r) traverses its closed curve at fixed θ , we get

$$I_1 = \frac{1}{2\pi} \oint_{\Gamma_1} p_\theta \, d\theta = L, \quad I_2 = \frac{1}{2\pi} \oint_{\Gamma_2} p_r \, dr = \frac{1}{\pi} \int_{r_-}^{r_+} \sqrt{2(E - U(r)) - \frac{L^2}{r^2}} \, dr.$$

The first action is just the angular momentum, as one would hope. The second is the **radial action**, and computing it gives E as a function of (I_1, I_2) and hence both frequencies at once.

For the Kepler potential $U(r) = -1/r$ this integral can be done by contour methods, with the answer

$$I_2 = -I_1 + \frac{1}{\sqrt{-2E}}, \quad \text{i.e.} \quad \tilde{H} = E = -\frac{1}{2(I_1 + I_2)^2}.$$

The remarkable thing here is that $\tilde{H}$ depends on I_1 and I_2 only through the combination $I_1 + I_2$, so that

$$\Omega_1 = \frac{\partial \tilde{H}}{\partial I_1} = \frac{\partial \tilde{H}}{\partial I_2} = \Omega_2 = \frac{1}{(I_1 + I_2)^3}.$$

The two frequencies are equal, so the winding line on the torus closes up after one circuit: Kepler orbits are closed curves, which is the statement that planetary orbits are ellipses that do not precess. This **degeneracy** is special to the $1/r$ potential (and to the harmonic oscillator), and its breaking by relativistic corrections is what produces the precession of the perihelion of Mercury.

This is a good point to pause and take stock. We have a complete and satisfying theory: a Hamiltonian system with enough commuting conserved quantities lives on invariant tori, and on those tori the motion is trivial. For the rest of the course we ask whether anything like this survives when we pass to partial differential equations. The answer, remarkably, is yes – but almost every ingredient will have to be reinvented.

§32.2 Integrable PDEs and Solitons

For the rest of the course we turn to partial differential equations. It is helpful to think of a PDE as an infinite-dimensional dynamical system: instead of finitely many coordinates $x_i(t)$ we have a whole function $u(x, t)$, with the spatial variable x playing the role of the index i .

What should we expect of an integrable PDE? If a $2n$ -dimensional ODE is integrable when it has n first integrals, and our phase space is now infinite-dimensional, then – since half of infinity is still infinity – we should expect an integrable PDE to possess *infinitely many* conserved quantities. We should also expect some magic transformation, analogous to the passage to action–angle variables, which turns the equation into something trivial. Both of these expectations turn out to be correct. What is much less obvious is how to find the transformation, and we will spend the whole of Section 3 constructing it for one particular equation.

We will not attempt to define integrability for PDEs. Nobody has managed to do so in a way that is both precise and useful, and we will be content to work with examples.

§32.2.1 Dispersion and Nonlinearity

The equation at the centre of this course is the Korteweg–de Vries equation

$$u_t + u_{xxx} - 6uu_x = 0.$$

Before meeting it properly, it pays to understand the two terms u_{xxx} and $-6uu_x$ separately, because each on its own does something violent to a wave, and the whole point of KdV is that the two violences cancel.

Example 32.2.1 (Dispersion)

Consider the *linear* equation

$$u_t + u_{xxx} = 0.$$

Being linear and constant-coefficient, it is solved by Fourier methods (IB Methods). Plane wave modes $u = e^{i(kx - \omega t)}$ solve it provided ω satisfies the **dispersion relation**

$$\omega = \omega(k) = -k^3.$$

The general solution is then a superposition,

$$u(x, t) = \int_{-\infty}^{\infty} A(k) e^{i(kx - \omega(k)t)} dk,$$

with $A(k) = \hat{u}_0(k)/2\pi$ determined by the initial data.

Writing a single mode as

$$u(x, t) = \exp\left(ik\left(x - \frac{\omega(k)}{k}t\right)\right),$$

we see that it travels with phase speed $\omega/k = -k^2$. The crucial point is that this depends on k : modes of different wavelength travel at different speeds. So an initial profile, which is a superposition of many modes, does not translate rigidly – it spreads out, with the short wavelengths racing off in one direction and the long wavelengths lagging behind. This is **dispersion**, and it is the work of the u_{xxx} term. A localised initial bump decays into an oscillatory wave train:

Had we written $u_t + u_x = 0$ instead, the dispersion relation would be $\omega = k$, the phase speed would be 1 for every mode, and the initial profile would translate rigidly. It is the *third* derivative that does the damage.

Example 32.2.2 (Wave breaking)

Now consider the *nonlinear* equation

$$u_t - 6uu_x = 0.$$

This looks worse, being nonlinear, but in fact it can be solved exactly for any initial data $u(x, 0) = f(x)$ by the method of characteristics. The characteristics are the curves along which u is constant, and since the equation says u is transported at speed $-6u$, they are straight lines. The solution is given implicitly by

$$u(x, t) = f(\xi), \quad \xi = x - 6tf(\xi).$$

This is fine as long as the implicit relation can be solved for ξ . Let us see when it fails. Differentiating,

$$u_x = f'(\xi) \frac{\partial \xi}{\partial x}, \quad \frac{\partial \xi}{\partial x} = 1 - 6tf'(\xi) \frac{\partial \xi}{\partial x},$$

so

$$\frac{\partial \xi}{\partial x} = \frac{1}{1 + 6tf'(\xi)}, \quad u_x = \frac{f'(\xi)}{1 + 6tf'(\xi)}.$$

Whenever f' takes a negative value somewhere, this blows up at the finite time $t = -1/(6f'(\xi))$: the slope becomes infinite, and after that the implicit formula would give a multi-valued ‘solution’.

This is **wave breaking**, and it is what the nonlinear term $-6uu_x$ does on its own: taller parts of the wave move faster, overtake the parts in front of them, and the wave topples over.

So dispersion spreads a wave out and destroys it, and nonlinearity steepens a wave and destroys it. What happens if we include both?

§32.2.2 The Korteweg–de Vries Equation

Definition 32.2.3 (KdV equation)

The **Korteweg–de Vries equation**, or **KdV equation**, is

$$u_t + u_{xxx} - 6uu_x = 0.$$

The equation has a distinguished history. In 1834 the Scottish engineer John Scott Russell was watching a boat being drawn along a canal by a pair of horses. When the boat stopped suddenly, the water it had been pushing rolled forward as a single smooth heap, and Russell – to his eternal credit – got on his horse and chased it for a mile or two along the canal, watching it travel without change of shape or speed. He called it the ‘wave of translation’. It took until 1895 for Korteweg and de Vries to write down the equation governing it.

Let us see, at least at the level of scaling, where the equation comes from.

Example 32.2.4 (Shallow water waves)

Consider small-amplitude surface waves on a layer of water of undisturbed depth h , and let $u(x, t)$ denote the surface elevation. Linear water wave theory gives the exact dispersion relation

$$\omega^2 = gk \tanh(kh).$$

For long waves, $kh \ll 1$, we expand $\tanh z = z - z^3/3 + O(z^5)$ to get

$$\omega^2 = gk \left(kh - \frac{(kh)^3}{3} + \dots \right) = c^2 k^2 \left(1 - \frac{(kh)^2}{3} + \dots \right), \quad c = \sqrt{gh},$$

so that for right-moving waves

$$\omega = ck \left(1 - \frac{k^2 h^2}{6} + \dots \right) = ck - \frac{ch^2}{6} k^3 + \dots.$$

A wave packet whose modes obey $\omega = ck - \beta k^3$ satisfies the linear PDE

$$u_t + cu_x + \beta u_{xxx} = 0, \quad \beta = \frac{ch^2}{6},$$

since $\partial_t \rightarrow -i\omega$ and $\partial_x \rightarrow ik$.

Now put back the leading nonlinearity. A finite-amplitude long wave rides on water of local depth $h + u$, so it travels a little faster where it is taller; carrying out the expansion properly gives a correction to the propagation speed of $\frac{3}{2}cu/h$, and hence a term γuu_x with $\gamma = 3c/2h$. Putting both effects together,

$$u_t + cu_x + \gamma uu_x + \beta u_{xxx} = 0.$$

Finally we normalise. Passing to a frame moving at speed c kills the cu_x term, and setting $u = Av(y, s)$ with $y = x - ct$ and $s = t/\beta$ gives

$$v_s + \frac{\gamma A}{\beta} vv_y + v_{yyy} = 0.$$

Choosing $A = -6\beta/\gamma$ produces

$$v_s + v_{yyy} - 6vv_y = 0,$$

which is KdV. So the equation is not some arbitrary combination of terms: it is what one gets from *any* weakly nonlinear, weakly dispersive, unidirectional wave system at leading order. This universality is why KdV turns up in plasma physics, in nonlinear optics, in blood flow and in lattice dynamics as well as in canals.

Some structural remarks are worth making before we solve anything. The KdV equation is invariant under

- (i) translations $x \mapsto x + a$, $t \mapsto t + b$;
- (ii) the scaling $u \mapsto \lambda^2 u$, $x \mapsto \lambda^{-1} x$, $t \mapsto \lambda^{-3} t$;
- (iii) the Galilean boost $u(x, t) \mapsto u(x - 6ct, t) + c$ for constant c .

The third is easy to miss and will matter later: adding a constant to u is the same as moving to a uniformly translating frame. The scaling symmetry tells us that there is really only a one-parameter family of solitary waves, all obtainable from one another by rescaling.

§32.2.3 Travelling Waves and the One-Soliton Solution

We now look for travelling wave solutions of KdV, and we shall find Russell's wave of translation. Let

$$u(x, t) = f(\xi), \quad \xi = x - ct,$$

for some speed c , and impose the boundary conditions $f, f', f'' \rightarrow 0$ as $|\xi| \rightarrow \infty$ (we want a localised wave on still water). Substituting,

$$-cf' + f''' - 6ff' = 0.$$

Every term is a derivative, so we can integrate once:

$$-cf + f'' - 3f^2 = A$$

for a constant A , and letting $\xi \rightarrow \infty$ forces $A = 0$. Now multiply by the integrating factor f' :

$$-cf f' + f'' f' - 3f^2 f' = 0,$$

and integrate again, noting that $f'' f' = \frac{1}{2} \frac{d}{d\xi} (f')^2$:

$$-\frac{c}{2} f^2 + \frac{1}{2} (f')^2 - f^3 = B,$$

and again $B = 0$ by the boundary conditions. Rearranging,

$$(f')^2 = 2f^3 + cf^2 = f^2(2f + c). \quad (\dagger)$$

This is a first-order ODE which we could grind through by separation of variables. It is quicker to guess. Since $(f')^2 \geq 0$ we need $2f + c \geq 0$ wherever $f \neq 0$; if we look for a solution with $f < 0$ (which is the natural sign for KdV in this normalisation) this forces $c > 0$ and $-c/2 \leq f \leq 0$. A function which decays at both ends and has a minimum of $-c/2$ suggests sech^2 , so we try

$$f(\xi) = -\frac{c}{2} \text{sech}^2(\alpha \xi)$$

and see what α must be. Using $\frac{d}{d\theta} \text{sech } \theta = -\text{sech } \theta \tanh \theta$,

$$f'(\xi) = c\alpha \text{sech}^2(\alpha \xi) \tanh(\alpha \xi), \quad (f')^2 = c^2 \alpha^2 \text{sech}^4 \tanh^2.$$

On the other side of $(\dagger)$,

$$f^2(2f + c) = \frac{c^2}{4} \text{sech}^4 \cdot c(1 - \text{sech}^2) = \frac{c^3}{4} \text{sech}^4 \tanh^2,$$

using $1 - \text{sech}^2 = \tanh^2$. So $(\dagger)$ holds precisely when $c^2 \alpha^2 = c^3/4$, that is $\alpha = \frac{1}{2} \sqrt{c}$. We have found our solution.

Proposition 32.2.5 (One-soliton solution)

For any $c > 0$, the function

$$u(x, t) = -\frac{c}{2} \text{sech}^2 \left(\frac{\sqrt{c}}{2} (x - ct - x_0) \right)$$

solves the KdV equation. Writing $c = 4\chi^2$ with $\chi > 0$, this takes the standard form

$$u(x, t) = -2\chi^2 \text{sech}^2 (\chi(x - 4\chi^2 t - x_0)).$$

We call this a **soliton**. Look at what it says: the amplitude is $2\chi^2$, the speed is $4\chi^2$, and the width is $1/\chi$. So

taller solitons are faster and narrower.

This single fact is responsible for almost everything interesting that follows.

The balance is delicate. The dispersive term wants to spread the wave out; the nonlinear term wants to steepen its leading edge. For this particular profile, at this particular relation between height and speed, the two exactly cancel and the wave propagates unchanged forever.

Remark. The parameter χ is not a typographical accident. When we come to the inverse scattering transform we will find that $-\chi^2$ is precisely the eigenvalue of the Schrödinger operator $-\partial_x^2 + u$ associated with this potential. A one-soliton solution is the potential with exactly one bound state.

§32.2.4 Two Solitons, and Why Solitons Are Particles

Now for the interesting question. Suppose we start with two solitons, well separated, the taller one behind. Since the taller one is faster, it will catch up with the shorter one, and at some point they will overlap. The KdV equation is nonlinear, so we cannot simply add the two solutions; and we have every reason to expect that the collision will be messy, generating radiation and destroying both waves.

Here is what actually happens. (We will derive the exact formula in Section 3; for now we simply plot it, with $\chi_1 = 1$ and $\chi_2 = 1.6$. The window follows the interaction – both humps are in fact moving steadily to the right, and we plot $-u$ so that the solitons point upwards.)

The two solitons pass straight through one another and re-emerge with exactly their original shapes and speeds. Nothing is radiated away, nothing is lost. The only trace of the interaction is a **phase shift**: the taller soliton ends up slightly ahead of where it would have been, and the shorter one slightly behind. One can show that these shifts are

$$\Delta_2 = +\frac{1}{\chi_2} \log \frac{\chi_2 + \chi_1}{\chi_2 - \chi_1}, \quad \Delta_1 = -\frac{1}{\chi_1} \log \frac{\chi_2 + \chi_1}{\chi_2 - \chi_1},$$

for the taller and shorter solitons respectively, so the taller one gains and the shorter one loses.

This is extraordinary behaviour for a nonlinear PDE, and it is the reason for the name: a ‘soliton’ is a solitary wave which behaves like a *particle* in collisions. The phenomenon was discovered numerically by Zabusky and Kruskal in 1965, who were simulating KdV as a continuum model for the Fermi–Pasta–Ulam problem and were startled to find their

pulses surviving collisions intact. It was their work that started the modern theory of integrable systems.

Note also that in the middle panel, at the moment of collision, the combined profile is not the sum of the two solitons, nor even taller than the larger one – the interaction is genuinely nonlinear. Superposition is violated at every instant; it is only the asymptotics that are clean.

§32.2.5 Conservation Laws

If solitons survive collisions, something must be preventing energy from leaking into other modes. The something is an infinite family of conservation laws. Let us find the first few by hand.

We will always assume that u and its derivatives decay rapidly as $|x| \rightarrow \infty$, so that we may integrate by parts freely and discard boundary terms.

Definition 32.2.6 (Conservation law)

A **conservation law** for an evolution equation is a relation of the form

$$\frac{\partial T}{\partial t} + \frac{\partial X}{\partial x} = 0,$$

where the **density** T and the **flux** X are functions of x, t, u and the derivatives of u . If such a relation holds for all solutions, then

$$\frac{d}{dt} \int_{-\infty}^{\infty} T \, dx = -[X]_{-\infty}^{\infty} = 0,$$

so $\int T \, dx$ is a first integral.

Proposition 32.2.7

The KdV equation possesses the conservation laws

$$\begin{aligned} \partial_t(u) + \partial_x(u_{xx} - 3u^2) &= 0, \\ \partial_t(u^2) + \partial_x(2uu_{xx} - u_x^2 - 4u^3) &= 0, \\ \partial_t(u^3 + \tfrac{1}{2}u_x^2) + \partial_x(\cdots) &= 0. \end{aligned}$$

Hence

$$I_1 = \int u \, dx, \quad I_2 = \int u^2 \, dx, \quad I_3 = \int (u^3 + \tfrac{1}{2}u_x^2) \, dx$$

are first integrals of KdV.

Proof. The first is just KdV rewritten: $u_t = -u_{xxx} + 6uu_x = -\partial_x(u_{xx} - 3u^2)$.

For the second, multiply KdV by $2u$:

$$(u^2)_t = 2uu_t = 2u(-u_{xxx} + 6uu_x) = -2uu_{xxx} + 12u^2u_x.$$

We must write the right-hand side as $-\partial_x X$. Observe that

$$\partial_x(2uu_{xx} - u_x^2 - 4u^3) = 2u_x u_{xx} + 2u u_{xxx} - 2u_x u_{xx} - 12u^2 u_x = 2u u_{xxx} - 12u^2 u_x,$$

which is exactly $-(u^2)_t$, as required.

For the third we argue slightly differently, since guessing the flux is tedious. Set $I_3 = \int (u^3 + \frac{1}{2}u_x^2) dx$ and differentiate:

$$\begin{aligned} \frac{dI_3}{dt} &= \int (3u^2 u_t + u_x u_{xt}) dx \\ &= \int (3u^2 - u_{xx}) u_t dx, \end{aligned}$$

integrating the second term by parts. Now substitute $u_t = \partial_x(3u^2 - u_{xx})$ from the first conservation law, and write $w = 3u^2 - u_{xx}$. Then

$$\frac{dI_3}{dt} = \int w w_x dx = \frac{1}{2} \int \partial_x(w^2) dx = 0. \quad \square$$

Physically, I_1 is the mass, I_2 is the momentum, and I_3 will turn out to be the Hamiltonian for KdV, which we may reasonably call the energy. The pattern continues: there is a conserved density involving u^4 , another involving u^5 , and so on forever. Finding them one at a time by inspection quickly becomes hopeless, and in Section 3 we will produce the whole infinite family in one stroke using the scattering problem.

Remark. Not every conservation law is interesting. For instance $\partial_t(u_x) + \partial_x(u_{xx} - 3u^2)_x = 0$ gives the first integral $\int u_x dx = 0$, which is true but vacuous, since it holds for any decaying function whatsoever. We will meet a systematic supply of such trivial laws later, and we will have to learn to discard them.

§32.2.6 The Miura Transform

We finish this section with a piece of magic whose significance will only become clear in Section 3. Alongside KdV sits its close relative.

Definition 32.2.8 (mKdV)

The **modified KdV equation** is

$$v_t + v_{xxx} - 6v^2 v_x = 0.$$

The two equations look similar but are genuinely different (mKdV, for instance, is invariant under $v \mapsto -v$, which KdV is not). Nevertheless, they are related.

Proposition 32.2.9 (Miura transform)

Define the **Miura transform**

$$u = v^2 + v_x.$$

Then

$$u_t + u_{xxx} - 6uu_x = (2v + \partial_x)(v_t + v_{xxx} - 6v^2 v_x).$$

In particular, if v solves mKdV then $u = v^2 + v_x$ solves KdV.

Proof. This is a direct computation. From $u = v^2 + v_x$ we get

$$\begin{aligned} u_t &= 2vv_t + v_{xt}, \\ u_x &= 2vv_x + v_{xx}, \\ u_{xxx} &= 6v_xv_{xx} + 2vv_{xxx} + v_{xxxx}, \\ 6uu_x &= 6(v^2 + v_x)(2vv_x + v_{xx}) = 12v^3v_x + 6v^2v_{xx} + 12vv_x^2 + 6v_xv_{xx}. \end{aligned}$$

Adding up,

$$\begin{aligned} u_t + u_{xxx} - 6uu_x &= 2vv_t + v_{xt} + 6v_xv_{xx} + 2vv_{xxx} + v_{xxxx} \\ &\quad - 12v^3v_x - 6v^2v_{xx} - 12vv_x^2 - 6v_xv_{xx} \\ &= 2v(v_t + v_{xxx} - 6v^2v_x) + (v_{xt} + v_{xxxx} - 6v^2v_{xx} - 12vv_x^2). \end{aligned}$$

On the other hand, writing $M = v_t + v_{xxx} - 6v^2v_x$,

$$\partial_x M = v_{xt} + v_{xxxx} - 6(2vv_x \cdot v_x + v^2v_{xx}) = v_{xt} + v_{xxxx} - 12vv_x^2 - 6v^2v_{xx},$$

which is exactly the bracketed expression above. So the two sides agree. $\square$

This is already useful – it lets us manufacture solutions of KdV from solutions of mKdV. But the reason it is a landmark result is the following observation. The relation

$$u = v^2 + v_x$$

is a **Riccati equation** for v , and the standard trick for Riccati equations is to substitute

$$v = \frac{\psi_x}{\psi}.$$

Then

$$v_x = \frac{\psi_{xx}}{\psi} - \frac{\psi_x^2}{\psi^2}, \quad v^2 = \frac{\psi_x^2}{\psi^2},$$

so $u = \psi_{xx}/\psi$, that is

$$-\psi_{xx} + u\psi = 0.$$

Better still, KdV has the Galilean symmetry noted above, so if u solves KdV then so does $u + \lambda$ suitably translated; applying the Miura transform to the shifted equation gives

$$-\psi_{xx} + u\psi = \lambda\psi.$$

Out of nowhere, the time-independent Schrödinger equation has appeared, with the solution of KdV playing the role of the potential. Gardner, Greene, Kruskal and Miura took this hint seriously in 1967, and what came out of it is the subject of the next section.

§32.3 The Inverse Scattering Transform

We now come to the heart of the course. In IB Methods we learned to solve linear PDEs with the Fourier transform: to solve

$$u_t + u_{xxx} = 0,$$

we transform in x to get $\hat{u}_t - ik^3\hat{u} = 0$, which is a trivial ODE in t for each k ; we solve it, and transform back.

The whole scheme rests on the fact that the transform diagonalises ∂_x , converting a differential equation into an algebraic one.

The inverse scattering transform follows exactly the same three-step pattern, but with a much cleverer transform. Given $u(x, t)$, for each fixed t we regard u as the potential in a Schrödinger operator and compute its *scattering data*. The KdV equation then dictates how the scattering data evolves, and – astonishingly – the evolution is linear and explicit. Finally we invert the transform to recover u .

The remarkable thing is that every step of this process is linear, and yet the equation we are solving is not.

We build the machine in pieces: first the forward scattering problem (Section 3.1), then the inverse problem (Section 3.2), then the mechanism – Lax pairs – which links the evolution of u to the evolution of the scattering data (Sections 3.3–3.4), and finally the payoff (Sections 3.5–3.6).

§32.3.1 The Forward Scattering Problem

Throughout this section L denotes the Schrödinger operator

$$L = -\frac{\partial^2}{\partial x^2} + u(x),$$

where the potential u has compact support, so that $u = 0$ for $|x|$ sufficiently large. What we actually need is only that u decays fast enough at infinity, but assuming compact support saves us from having to be careful, and costs nothing.

For a given u , the **forward scattering problem** is to find the eigenvalues and eigenfunctions of L , that is, to solve

$$L\psi = \lambda\psi.$$

The *inverse* problem, which we address next, is to reconstruct u from that data.

There are two regimes to consider, corresponding to $\lambda > 0$ and $\lambda < 0$.

The Continuous Spectrum

Take $\lambda = k^2 > 0$ with k real. Since u vanishes for large $|x|$, any solution satisfies

$$\psi_{xx} + k^2\psi = 0$$

out there, so is asymptotically a combination of $e^{\pm ikx}$. We single out a particular solution $\varphi = \varphi(x, k)$ by the boundary condition

$$\varphi(x, k) = e^{-ikx} \quad \text{as } x \rightarrow -\infty,$$

and then there must exist coefficients $a(k)$ and $b(k)$ with

$$\varphi(x, k) = a(k)e^{-ikx} + b(k)e^{ikx} \quad \text{as } x \rightarrow +\infty.$$

Definition 32.3.1 (Reflection and transmission coefficients)

With φ as above, set

$$\Phi(x, k) = \frac{\varphi(x, k)}{a(k)}, \quad R(k) = \frac{b(k)}{a(k)}, \quad T(k) = \frac{1}{a(k)}.$$

We call R the **reflection coefficient** and T the **transmission coefficient**.

By construction,

$$\Phi(x, k) = \begin{cases} T(k)e^{-ikx} & x \rightarrow -\infty, \\ e^{-ikx} + R(k)e^{ikx} & x \rightarrow +\infty. \end{cases}$$

The physical reading is exactly the one from IB Quantum Mechanics. Thinking of e^{-ikx} as a leftward-moving wave and e^{ikx} as a rightward-moving one, we have a unit-amplitude wave incident from the right, of which a portion $R(k)e^{ikx}$ is reflected back to the right and a portion $T(k)e^{-ikx}$ is transmitted through to the left.

Conservation of probability flux (equivalently, constancy of the Wronskian) gives

$$|R(k)|^2 + |T(k)|^2 = 1,$$

which is on the first example sheet. One expects, and it is true, that $T(k) \rightarrow 1$ and $R(k) \rightarrow 0$ as $k \rightarrow \infty$: a sufficiently energetic wave barely notices the potential.

So far this is all hypothetical – we have described what a solution would look like if it existed. Let us check that it does.

The difficulty with existence questions for differential equations is that differentiation makes functions worse: it can destroy differentiability, or even continuity, so a differential operator may fling us out of whatever function space we started in. Integration, by contrast, makes functions better. So the standard move is to convert the differential equation into an integral equation, and work there.

Consider therefore the integral equation for $f = f(x, k)$,

$$f(x, k) = f_0(x, k) + \int_{-\infty}^{\infty} G(x - y, k)u(y)f(y, k) \, dy,$$

where f_0 is any solution of $(\partial_x^2 + k^2)f_0 = 0$ and G is a Green's function for $\partial_x^2 + k^2$, so that

$$(\partial_x^2 + k^2)G(x, k) = \delta(x).$$

Any solution of the integral equation solves the eigenvalue problem, since

$$(\partial_x^2 + k^2)f = (\partial_x^2 + k^2)f_0 + \int_{-\infty}^{\infty} (\partial_x^2 + k^2)G(x - y, k)u(y)f(y, k) \, dy$$

$$\begin{aligned}
&= 0 + \int_{-\infty}^{\infty} \delta(x-y)u(y)f(y,k) \, dy \\
&= u(x)f(x,k),
\end{aligned}$$

which rearranges to $Lf = k^2 f$.

To get the boundary condition we want, we choose $f_0 = e^{-ikx}$ and take the retarded Green's function

$$G(x,k) = \begin{cases} 0 & x < 0, \\ \frac{1}{k} \sin(kx) & x \geq 0. \end{cases}$$

Then the integrand vanishes unless $y \leq x$, so for x far to the left of the support of u the integral is zero and $f(x,k) = e^{-ikx}$ exactly, as required.

It remains to show that the integral equation has a solution. Write it abstractly as

$$(I - K)f = f_0, \quad (Kf)(x) = \int_{-\infty}^{\infty} G(x-y,k)u(y)f(y,k) \, dy,$$

so that formally

$$f = (I - K)^{-1} f_0 = (I + K + K^2 + \cdots) f_0.$$

This is a **Neumann series**, and one shows on the second example sheet that it converges (the point being that G is bounded and u has compact support, so K is a contraction after finitely many iterations). Given convergence, it visibly solves the equation:

$$(I - K)(f_0 + Kf_0 + K^2f_0 + \cdots) = f_0 + Kf_0 + \cdots - (Kf_0 + K^2f_0 + \cdots) = f_0.$$

We will use this series once more, for a completely different purpose, in Section 3.4; the key consequence to remember is that *the solution with $f_0 = 0$ is $f = 0$* .

Bound States

Now take $\lambda = -\kappa^2 < 0$, and look for solutions of

$$L\psi_\kappa = -\kappa^2 \psi_\kappa$$

which are normalisable,

$$\|\psi_\kappa\|^2 = \int_{-\infty}^{\infty} \psi_\kappa(x)^2 \, dx = 1.$$

These are the **bound states**, and we take them real without loss of generality.

Again, since u has compact support, any solution obeys $\varphi_{xx} - \kappa^2 \varphi = 0$ for large $|x|$, so is a combination of $e^{\pm \kappa x}$ out there. Fix φ_κ by

$$\varphi_\kappa(x) = e^{-\kappa x} \quad \text{as } x \rightarrow +\infty,$$

so that it decays to the right, and write

$$\varphi_\kappa(x) = \alpha(\kappa)e^{\kappa x} + \beta(\kappa)e^{-\kappa x} \quad \text{as } x \rightarrow -\infty.$$

For *any* κ we can solve the ODE and find such a φ_κ . What we cannot do for any κ is make it normalisable: the term $\beta(\kappa)e^{-\kappa x}$ blows up as $x \rightarrow -\infty$, so we need

$$\beta(\kappa) = 0.$$

This is a genuine constraint, and it is what quantises the spectrum. One can show that β has only finitely many zeros, which we label

$$\chi_1 > \chi_2 > \cdots > \chi_N > 0.$$

The corresponding normalised bound states are

$$\psi_n(x) = c_n \varphi_{\chi_n}(x),$$

with the constants c_n chosen so that $\|\psi_n\| = 1$. Equivalently, c_n is determined by the large- x behaviour

$$\psi_n(x) = c_n e^{-\chi_n x} \quad \text{as } x \rightarrow +\infty.$$

We call the c_n the **normalisation constants**.

The Scattering Data

Assembling everything, the outcome of the forward problem is the following package.

Definition 32.3.2 (Scattering data)

The **scattering data** of the operator $L = -\partial_x^2 + u$ is

$$S = \left\{ \{\chi_n, c_n\}_{n=1}^N, R(k), T(k) \right\}.$$

Let us compute it in an example where everything can be done by hand.

Example 32.3.3 (A delta-function potential)

Take $u(x) = -2\alpha\delta(x)$ with $\alpha > 0$. (This is not of compact support, but it decays even faster, so all is well.)

Continuous spectrum. Since u vanishes away from the origin, we have exactly

$$\Phi(x, k) = \begin{cases} T(k)e^{-ikx} & x < 0, \\ e^{-ikx} + R(k)e^{ikx} & x > 0. \end{cases}$$

Continuity at $x = 0$ gives

$$T = 1 + R.$$

For the second condition, integrate $L\Phi = k^2\Phi$ over $(-\varepsilon, \varepsilon)$ and let $\varepsilon \rightarrow 0$. The $k^2\Phi$ term contributes nothing in the limit, and we obtain the jump condition

$$\left[\Phi_x \right]_{0^-}^{0^+} = -2\alpha\Phi(0),$$

that is

$$(-ik + ikR) - (-ikT) = -2\alpha T.$$

Substituting $T = 1 + R$ and solving the two equations gives

$$R(k) = \frac{i\alpha}{k - i\alpha}, \quad T(k) = \frac{k}{k - i\alpha}.$$

As a check,

$$|R|^2 + |T|^2 = \frac{\alpha^2 + k^2}{k^2 + \alpha^2} = 1,$$

and as $k \rightarrow \infty$ we do indeed find $R \rightarrow 0$, $T \rightarrow 1$.

Bound states. Away from the origin $-\psi_{xx} + \chi^2\psi = 0$, and decay at both ends forces

$$\psi(x) = c e^{-\chi|x|}.$$

The same jump condition now reads

$$-c\chi - c\chi = -2\alpha c \implies \chi = \alpha.$$

So there is exactly one bound state, with $\chi_1 = \alpha$. Normalising,

$$1 = c_1^2 \int_{-\infty}^{\infty} e^{-2\alpha|x|} dx = \frac{c_1^2}{\alpha} \implies c_1 = \sqrt{\alpha}.$$

Hence the scattering data is

$$S = \left\{ \{\alpha, \sqrt{\alpha}\}, \frac{i\alpha}{k - i\alpha}, \frac{k}{k - i\alpha} \right\}.$$

The next example is the one that matters most, because it is a soliton.

Example 32.3.4 (The soliton potential)

Take $u(x) = -2\operatorname{sech}^2 x$, which is the one-soliton profile with $\chi = 1$ at time $t = 0$.

Continuous spectrum. We claim that

$$f(x, k) = e^{ikx} (\tanh x - ik)$$

satisfies $Lf = k^2 f$. Writing $T = \tanh x$, so that $T' = \operatorname{sech}^2 x = 1 - T^2$ and $T'' = -2TT'$,

$$\begin{aligned} f' &= e^{ikx} [ik(T - ik) + T'], \\ f'' &= e^{ikx} [-k^2(T - ik) + 2ikT' + T''], \end{aligned}$$

and hence

$$\begin{aligned} -f'' - 2T'f &= e^{ikx} [k^2(T - ik) - 2ikT' - T'' - 2T'(T - ik)] \\ &= e^{ikx} [k^2(T - ik) - 2ikT' - T'' - 2TT' + 2ikT'] \\ &= e^{ikx} k^2(T - ik), \end{aligned}$$

since $-T'' - 2TT' = 2TT' - 2TT' = 0$. So $Lf = k^2 f$ as claimed.

Replacing k by $-k$ gives another solution,

$$g(x, k) = e^{-ikx} (\tanh x + ik),$$

whose limits are

$$g \rightarrow e^{-ikx}(ik - 1) \text{ as } x \rightarrow -\infty, \quad g \rightarrow e^{-ikx}(ik + 1) \text{ as } x \rightarrow +\infty.$$

So the normalised Jost solution is $\varphi = g/(ik-1)$, and comparing with the definitions,

$$a(k) = \frac{ik+1}{ik-1}, \quad b(k) = 0.$$

Therefore

$$R(k) = 0, \quad T(k) = \frac{ik-1}{ik+1}.$$

The reflection coefficient vanishes identically! A soliton is completely transparent: waves of every frequency pass through it without any reflection at all. (Note $|T| = 1$, consistent with $|R|^2 + |T|^2 = 1$.)

Bound states. We look for a normalisable solution of $-\psi_{xx} - 2\operatorname{sech}^2 x \psi = -\chi^2 \psi$. Trying $\psi = \operatorname{sech} x$, and using $(\operatorname{sech} x)'' = \operatorname{sech} x - 2\operatorname{sech}^3 x$, we get

$$-\psi_{xx} - 2\operatorname{sech}^2 x \psi = -\operatorname{sech} x + 2\operatorname{sech}^3 x - 2\operatorname{sech}^3 x = -\operatorname{sech} x,$$

so $\psi = \operatorname{sech} x$ is a bound state with $\chi_1 = 1$. Normalising, $\int \operatorname{sech}^2 x \, dx = 2$, so the normalised state is $\psi_1 = \frac{1}{\sqrt{2}} \operatorname{sech} x$. Since $\operatorname{sech} x \sim 2e^{-x}$ as $x \rightarrow +\infty$,

$$\psi_1(x) \sim \sqrt{2} e^{-x}, \quad \text{so} \quad c_1 = \sqrt{2}.$$

One can check there are no others. So the scattering data is simply

$$S = \{ \{1, \sqrt{2}\}, R(k) = 0 \}.$$

Definition 32.3.5 (Reflectionless potential)

A potential u with $R(k) \equiv 0$ is called **reflectionless**.

We have just seen that the one-soliton potential is reflectionless. This is not a coincidence, and it is the key to everything: reflectionless potentials are exactly the potentials for which the inverse problem can be solved in closed form, and they will turn out to be exactly the N -soliton solutions.

§32.3.2 The Inverse Scattering Problem

Now we go backwards. Given scattering data S , can we reconstruct the potential u that produced it? The answer is yes, and remarkably the transmission coefficient is not even needed.

Theorem 32.3.6 (Gelfand–Levitan–Marchenko)

A potential $u = u(x)$ decaying rapidly as $|x| \rightarrow \infty$ is completely determined by the scattering data

$$S = \{ \{ \chi_n, c_n \}_{n=1}^N, R(k) \}.$$

Specifically, define

$$F(x) = \sum_{n=1}^N c_n^2 e^{-\chi_n x} + \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{ikx} R(k) \, dk,$$

and let $K(x, y)$ be the unique solution of the **GLM equation**

$$K(x, y) + F(x + y) + \int_x^\infty K(x, z)F(z + y) \, dz = 0, \quad y > x.$$

Then

$$u(x) = -2 \frac{d}{dx} K(x, x).$$

Proof. Beyond the scope of this course. □

The GLM equation looks forbidding but is not. For fixed x it is a linear integral equation in y , of the abstract form

$$\mathbf{K} + \mathbf{b} + \mathcal{A}\mathbf{K} = 0$$

for a known vector $\mathbf{b}$ and known linear operator $\mathcal{A}$. As with any linear equation, one can guess a solution and then verify it. In the reflectionless case, which is the one we shall care about, the integral equation degenerates into a finite-dimensional matrix equation and can be solved exactly.

Notice that the function F has a very transparent structure: the sum records the bound states, and the integral is the Fourier transform of the reflection coefficient. If there are no bound states and no reflection, $F = 0$, hence $K = 0$, hence $u = 0$ – reassuringly, the empty scattering data corresponds to the zero potential.

Example 32.3.7 (Reconstructing the soliton)

Let us check the theorem on the data we computed above,

$$S = \left\{ \{\chi_1, c_1\} = \{1, \sqrt{2}\}, R = 0 \right\},$$

and see whether we recover $u = -2 \operatorname{sech}^2 x$. Here

$$F(x) = c_1^2 e^{-\chi_1 x} = 2e^{-x}.$$

Since F is a single exponential in x , we look for a solution of the same shape,

$$K(x, y) = K_1(x)e^{-y}.$$

Substituting into the GLM equation,

$$K_1(x)e^{-y} + 2e^{-x}e^{-y} + \int_x^\infty K_1(x)e^{-z} \cdot 2e^{-z}e^{-y} \, dz = 0.$$

Every term carries a factor e^{-y} , which we cancel, and the remaining integral is

$$2K_1(x) \int_x^\infty e^{-2z} \, dz = K_1(x)e^{-2x}.$$

So

$$K_1(x) (1 + e^{-2x}) = -2e^{-x}, \quad K_1(x) = \frac{-2e^{-x}}{1 + e^{-2x}}.$$

Hence, writing $w = e^{-2x}$,

$$K(x, x) = K_1(x)e^{-x} = \frac{-2w}{1+w},$$

and since $dw/dx = -2w$,

$$\frac{d}{dx}K(x, x) = -2 \cdot \frac{w'(1+w) - ww'}{(1+w)^2} = \frac{-2w'}{(1+w)^2} = \frac{4w}{(1+w)^2}.$$

Therefore

$$u(x) = -2 \frac{d}{dx}K(x, x) = \frac{-8w}{(1+w)^2} = \frac{-8e^{-2x}}{(1+e^{-2x})^2} = \frac{-8}{(e^x + e^{-x})^2} = -2 \operatorname{sech}^2 x,$$

exactly as it should be.

We can now go in both directions between potentials and scattering data. That, on its own, is a piece of nineteenth-century-flavoured mathematical physics. What makes it explosive is the next ingredient.

§32.3.3 Lax Pairs

We need to connect the time evolution of u to the time evolution of the scattering data. The mechanism is due to Peter Lax.

Recall from Section 1 that under a Hamiltonian flow, functions evolve according to

$$\frac{df}{dt} = \{f, H\},$$

so H ‘generates’ the time evolution. In quantum mechanics the corresponding statement in the Heisenberg picture is

$$i\hbar \frac{dL}{dt} = [L, H],$$

for operators L . We want something of exactly this shape: an operator whose commutator with L generates the time evolution of L .

Definition 32.3.8 (Lax pair)

Let

$$L = a_m(x, t) \frac{\partial^m}{\partial x^m} + \cdots + a_1(x, t) \frac{\partial}{\partial x} + a_0(x, t)$$

be a time-dependent self-adjoint linear operator, and write

$$L_t = \dot{a}_m \frac{\partial^m}{\partial x^m} + \cdots + \dot{a}_0$$

for its derivative with respect to t (differentiating the coefficients only). If there is an operator A with

$$L_t = LA - AL = [L, A],$$

then (L, A) is called a **Lax pair**, and the equation $L_t = [L, A]$ is called **Lax’s equation**.

The reason to care is the following.

Theorem 32.3.9 (Isospectral flow)

Let (L, A) be a Lax pair, with A antisymmetric. Then the discrete eigenvalues of L are independent of time. Moreover if $L\psi = \lambda\psi$ then

$$L\tilde{\psi} = \lambda\tilde{\psi}, \quad \text{where } \tilde{\psi} = \psi_t + A\psi.$$

The word **isospectral** means precisely this: the operator changes with time, but its spectrum does not.

Proof. We assume that eigenvalues vary smoothly, so that an eigenvalue λ_0 with normalised eigenfunction ψ_0 at $t = 0$ extends to a family $\lambda(t)$, $\psi(x, t)$ with

$$L(t)\psi(x, t) = \lambda(t)\psi(x, t), \quad \|\psi\| = 1.$$

Differentiate with respect to t :

$$L_t\psi + L\psi_t = \lambda_t\psi + \lambda\psi_t,$$

so, substituting Lax's equation and using $L\psi = \lambda\psi$,

$$\begin{aligned} \lambda_t\psi &= L_t\psi + L\psi_t - \lambda\psi_t \\ &= LA\psi - AL\psi + L\psi_t - \lambda\psi_t \\ &= LA\psi - \lambda A\psi + L\psi_t - \lambda\psi_t \\ &= (L - \lambda)(\psi_t + A\psi). \end{aligned}$$

Now take the inner product with ψ and use self-adjointness of $L - \lambda$:

$$\lambda_t = \langle \psi, \lambda_t\psi \rangle = \langle \psi, (L - \lambda)(\psi_t + A\psi) \rangle = \langle (L - \lambda)\psi, \psi_t + A\psi \rangle = 0,$$

since $(L - \lambda)\psi = 0$. So λ is constant, and the displayed equation reduces to $(L - \lambda)\tilde{\psi} = 0$. $\square$

So far this is abstract. The whole thing turns on being able to find, for a given equation, an operator A making Lax's equation equivalent to it. For KdV such an A exists, and here it is.

Proposition 32.3.10 (Lax pair for KdV)

Let

$$L = -\partial_x^2 + u(x, t), \quad A = 4\partial_x^3 - 3(u\partial_x + \partial_x u).$$

Then A is antisymmetric, and

$$L_t = [L, A] \iff u_t + u_{xxx} - 6uu_x = 0.$$

Proof. Throughout, $\partial = \partial_x$, and we treat everything as operators acting on a test function; in particular ∂u means the operator $\psi \mapsto (u\psi)_x$, so that

$$\partial u = u\partial + u_x.$$

Hence

$$A = 4\partial^3 - 3u\partial - 3(u\partial + u_x) = 4\partial^3 - 6u\partial - 3u_x.$$

For antisymmetry, recall $\partial^\dagger = -\partial$ and $u^\dagger = u$, so

$$A^\dagger = -4\partial^3 - 3(u\partial)^\dagger - 3u_x = -4\partial^3 + 3\partial u - 3u_x = -4\partial^3 + 3u\partial + 3u_x - 3u_x,$$

giving $A^\dagger = -4\partial^3 + 6u\partial + 3u_x = -A$ once we recombine (the middle term arises twice, once from each half of $u\partial + \partial u$).

Now for the commutator. We will repeatedly use the operator identities

$$\partial^2 u \partial = u \partial^3 + 2u_x \partial^2 + u_{xx} \partial, \quad \partial^2 u_x = u_x \partial^2 + 2u_{xx} \partial + u_{xxx},$$

$$\partial^3 u = u \partial^3 + 3u_x \partial^2 + 3u_{xx} \partial + u_{xxx},$$

each of which is just the Leibniz rule. First,

$$\begin{aligned} LA &= (-\partial^2 + u)(4\partial^3 - 6u\partial - 3u_x) \\ &= -4\partial^5 + 6\partial^2 u \partial + 3\partial^2 u_x + 4u\partial^3 - 6u^2 \partial - 3uu_x \\ &= -4\partial^5 + 6(u\partial^3 + 2u_x \partial^2 + u_{xx} \partial) + 3(u_x \partial^2 + 2u_{xx} \partial + u_{xxx}) \\ &\quad + 4u\partial^3 - 6u^2 \partial - 3uu_x \\ &= -4\partial^5 + 10u\partial^3 + 15u_x \partial^2 + 12u_{xx} \partial - 6u^2 \partial + 3u_{xxx} - 3uu_x. \end{aligned}$$

Similarly,

$$\begin{aligned} AL &= (4\partial^3 - 6u\partial - 3u_x)(-\partial^2 + u) \\ &= -4\partial^5 + 4\partial^3 u + 6u\partial^3 - 6u\partial u + 3u_x \partial^2 - 3uu_x \\ &= -4\partial^5 + 4(u\partial^3 + 3u_x \partial^2 + 3u_{xx} \partial + u_{xxx}) + 6u\partial^3 \\ &\quad - 6(u^2 \partial + uu_x) + 3u_x \partial^2 - 3uu_x \\ &= -4\partial^5 + 10u\partial^3 + 15u_x \partial^2 + 12u_{xx} \partial - 6u^2 \partial + 4u_{xxx} - 9uu_x. \end{aligned}$$

Every differential term cancels in the difference, and we are left with the multiplication operator

$$[L, A] = LA - AL = (3u_{xxx} - 3uu_x) - (4u_{xxx} - 9uu_x) = -u_{xxx} + 6uu_x.$$

On the other hand $L_t = u_t$, since only the coefficient u depends on t . So Lax's equation $L_t = [L, A]$ says exactly

$$u_t = -u_{xxx} + 6uu_x,$$

which is KdV. □

This is the miracle on which everything rests. It deserves a moment's contemplation: a fifth-order operator equation collapses, after everything cancels, to a scalar equation – and that scalar equation happens to be KdV. Combined with the isospectral flow theorem, we already know something remarkable.

Corollary 32.3.11

If $u(x, t)$ evolves according to KdV, then the discrete eigenvalues $-\chi_n^2$ of the operator $L = -\partial_x^2 + u(x, t)$ are constant in time. In particular the number N of bound states never changes.

Since the χ_n are the soliton amplitudes and speeds, this already tells us that solitons cannot be created or destroyed by the evolution.

§32.3.4 Evolution of the Scattering Data

We now let $u = u(x, t)$ evolve by KdV and work out how the rest of the scattering data moves. Since u has compact support, note first that

$$A = 4\partial_x^3 \quad \text{as } |x| \rightarrow \infty.$$

Continuous Spectrum

For each fixed t construct, as in Section 3.1, the solution φ of $L\varphi = k^2\varphi$ with

$$\varphi(x, t) = \begin{cases} e^{-ikx} & x \rightarrow -\infty, \\ a(k, t)e^{-ikx} + b(k, t)e^{ikx} & x \rightarrow +\infty. \end{cases}$$

Here k is fixed: solutions exist for every real k regardless of u , so there is no question of k moving.

Exactly as in the proof of the isospectral flow theorem (but now with $\lambda = k^2$ constant by fiat rather than by conclusion), differentiating $L\varphi = k^2\varphi$ gives

$$0 = (L - k^2)(\varphi_t + A\varphi),$$

so $\tilde{\varphi} = \varphi_t + A\varphi$ is another solution of $L\tilde{\varphi} = k^2\tilde{\varphi}$. We now compute its asymptotics, using $A = 4\partial_x^3$ out there:

$$\tilde{\varphi}(x, t) = \begin{cases} 4ik^3e^{-ikx} & x \rightarrow -\infty, \\ (a_t + 4ik^3a)e^{-ikx} + (b_t - 4ik^3b)e^{ikx} & x \rightarrow +\infty, \end{cases}$$

since $\partial_x^3 e^{\mp ikx} = \pm ik^3 e^{\mp ikx}$.

Here is the clever step. Consider

$$\theta = 4ik^3\varphi - \tilde{\varphi}.$$

By linearity $L\theta = k^2\theta$, and by construction $\theta \rightarrow 0$ as $x \rightarrow -\infty$. But we showed in Section 3.1 that the solution of $Lf = k^2f$ with prescribed behaviour f_0 at $-\infty$ is $f = (I + K + K^2 + \cdots)f_0$; with $f_0 = 0$ this gives $f = 0$. Hence

$$\theta \equiv 0, \quad \text{that is} \quad \tilde{\varphi} = 4ik^3\varphi.$$

Comparing coefficients of e^{-ikx} and e^{ikx} as $x \rightarrow +\infty$,

$$\begin{aligned} a_t + 4ik^3a &= 4ik^3a, \\ b_t - 4ik^3b &= 4ik^3b, \end{aligned}$$

that is $a_t = 0$ and $b_t = 8ik^3b$. These we can solve:

$$a(k, t) = a(k, 0), \quad b(k, t) = b(k, 0)e^{8ik^3t},$$

and therefore

$$R(k, t) = R(k, 0)e^{8ik^3t}, \quad T(k, t) = T(k, 0).$$

Stop and appreciate this. We assumed that u evolves by a thoroughly nasty nonlinear PDE, and concluded that its reflection coefficient simply rotates in the complex plane at a constant rate, and that its transmission coefficient does not move at all.

Discrete Spectrum

By the isospectral flow theorem the χ_n are constant. For each t we have normalised bound states $\psi_n(x, t)$ with

$$L\psi_n = -\chi_n^2\psi_n, \quad \|\psi_n\| = 1, \quad \psi_n(x, t) = c_n(t)e^{-\chi_n x} \text{ as } x \rightarrow +\infty.$$

By the isospectral flow theorem again,

$$\tilde{\psi}_n = \partial_t \psi_n + A\psi_n$$

also satisfies $L\tilde{\psi}_n = -\chi_n^2\tilde{\psi}_n$. Since the eigenvalue $-\chi_n^2$ is simple (a standard Wronskian argument shows bound states of a one-dimensional Schrödinger operator are non-degenerate), $\tilde{\psi}_n$ must be proportional to ψ_n . But

$$\begin{aligned} \langle \psi_n, \tilde{\psi}_n \rangle &= \langle \psi_n, \partial_t \psi_n \rangle + \langle \psi_n, A\psi_n \rangle \\ &= \frac{1}{2} \frac{\partial}{\partial t} \langle \psi_n, \psi_n \rangle + \langle \psi_n, A\psi_n \rangle \\ &= 0, \end{aligned}$$

because $\|\psi_n\|$ is constant and A is antisymmetric (so $\langle \psi, A\psi \rangle = -\langle A\psi, \psi \rangle = -\langle \psi, A\psi \rangle$). A multiple of ψ_n orthogonal to ψ_n is zero, so

$$\tilde{\psi}_n \equiv 0.$$

Now look at the large- x behaviour. There $A = 4\partial_x^3$ and $\psi_n = c_n(t)e^{-\chi_n x}$, so

$$\tilde{\psi}_n(x, t) = (\dot{c}_n - 4\chi_n^3 c_n) e^{-\chi_n x} \text{ as } x \rightarrow +\infty.$$

Since $\tilde{\psi}_n \equiv 0$ we must have $\dot{c}_n = 4\chi_n^3 c_n$, and hence

$$c_n(t) = c_n(0)e^{4\chi_n^3 t}.$$

The Transform

We can now assemble the machine. Suppose u evolves by KdV with initial data $u_0(x) = u(x, 0)$.

That is: compute the scattering data of u_0 ; evolve it by the explicit formulae above; feed the result into the GLM equation; and read off $u(x, t)$. Compare this with the Fourier transform diagram at the start of this section – it is the same three steps, with a more sophisticated transform. All the nonlinearity of KdV has been absorbed into the (nonlinear, but classical) map $u \mapsto S$.

The one thing that makes it work is the equivalence

$$u_t + u_{xxx} - 6uu_x = 0 \iff L_t = [L, A],$$

so the whole method hinges on finding a Lax pair.

Remark. This is not special to KdV. Choosing different operators A in the Lax equation with the same L produces an infinite hierarchy of equations – the **KdV hierarchy** – all of which are solvable by the same transform and all of which share the same conserved quantities. Choosing a different L altogether produces different integrable equations; the choice

$$L = i \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \partial_x + \begin{pmatrix} 0 & q \\ \bar{q} & 0 \end{pmatrix}$$

leads, by the same route, to the nonlinear Schrödinger equation, which we meet in Section 5.

§32.3.5 Reflectionless Potentials and N -Solitons

Now we cash in. The GLM equation is hard in general, but there is one case in which it can be solved completely, and it is exactly the case that produces solitons.

Recall that a potential is reflectionless if $R(k, 0) = 0$. Since

$$R(k, t) = R(k, 0)e^{8ik^3t},$$

a potential which starts reflectionless stays reflectionless forever. So this is a class of initial data preserved by the KdV flow, and within it the machinery becomes elementary.

Suppose then that $R \equiv 0$, so that

$$F(x) = \sum_{n=1}^N c_n^2 e^{-\chi_n x}.$$

(We suppress the time dependence for the moment, restoring it at the very end.) Since F is a finite sum of exponentials, we look for K of the same shape,

$$K(x, y) = \sum_{m=1}^N K_m(x) e^{-\chi_m y};$$

one shows on the second example sheet that K *must* have this form. Substituting into the GLM equation,

$$\sum_{m=1}^N K_m(x) e^{-\chi_m y} + \sum_{n=1}^N c_n^2 e^{-\chi_n x} e^{-\chi_n y} + \sum_{n,m} c_n^2 K_m(x) \int_x^\infty e^{-\chi_m z} e^{-\chi_n(z+y)} dz = 0.$$

The integral evaluates to

$$\int_x^\infty e^{-(\chi_n + \chi_m)z} dz = \frac{e^{-(\chi_n + \chi_m)x}}{\chi_n + \chi_m},$$

so, collecting everything over the common index n ,

$$\sum_{n=1}^N \left[c_n^2 e^{-\chi_n x} + K_n(x) + \sum_{m=1}^N \frac{c_n^2 K_m(x)}{\chi_n + \chi_m} e^{-(\chi_n + \chi_m)x} \right] e^{-\chi_n y} = 0. \quad (*)$$

The functions $e^{-\chi_n y}$, $n = 1, \dots, N$, are linearly independent, so each bracket must vanish separately. Thus for each n ,

$$K_n(x) + \sum_{m=1}^N \frac{c_n^2 e^{-(\chi_n + \chi_m)x}}{\chi_n + \chi_m} K_m(x) = -c_n^2 e^{-\chi_n x}.$$

For each fixed x this is a linear system! Setting

$$\begin{aligned} \mathbf{c} &= (c_1^2 e^{-\chi_1 x}, \dots, c_N^2 e^{-\chi_N x})^T, \\ \mathbf{K} &= (K_1(x), \dots, K_N(x))^T, \\ A_{nm} &= \delta_{nm} + \frac{c_n^2 e^{-(\chi_n + \chi_m)x}}{\chi_n + \chi_m}, \end{aligned}$$

the system reads

$$A\mathbf{K} = -\mathbf{c}.$$

So we have reduced an integral equation to inverting an $N \times N$ matrix. Even better, we do not need $\mathbf{K}$ itself, only the diagonal value

$$K(x, x) = \sum_{m=1}^N K_m(x) e^{-\chi_m x} = \sum_{m,n} (A^{-1})_{mn} (-\mathbf{c})_n e^{-\chi_m x}.$$

Now observe that

$$A'_{nm}(x) = \frac{d}{dx} A_{nm}(x) = -c_n^2 e^{-\chi_n x} e^{-\chi_m x} = (-\mathbf{c})_n e^{-\chi_m x},$$

which is exactly the combination appearing above. Hence

$$K(x, x) = \sum_{m,n} (A^{-1})_{mn} A'_{nm} = \text{tr} (A^{-1} A').$$

Finally we use the identity (an exercise on the second example sheet, proved by expanding the determinant)

$$\text{tr} (A^{-1} A') = \frac{1}{\det A} \frac{d}{dx} (\det A) = \frac{d}{dx} \log (\det A),$$

which gives

$$u(x) = -2 \frac{d}{dx} K(x, x) = -2 \frac{d^2}{dx^2} \log (\det A).$$

Restoring the time dependence via $c_n(t)^2 = c_n(0)^2 e^{8\chi_n^3 t}$, we have proved the following.

Theorem 32.3.12 (N -soliton solution)

Let $\chi_1 > \dots > \chi_N > 0$ and $c_1(0), \dots, c_N(0)$ be given. Then

$$u(x, t) = -2 \frac{\partial^2}{\partial x^2} \log (\det A(x, t)),$$

where A is the $N \times N$ matrix

$$A_{nm}(x, t) = \delta_{nm} + \frac{c_n(0)^2 e^{8\chi_n^3 t} e^{-(\chi_n + \chi_m)x}}{\chi_n + \chi_m},$$

is a solution of the KdV equation. It is the N -soliton solution, and describes N solitary waves of amplitudes $2\chi_n^2$ and speeds $4\chi_n^2$.

We have obtained a closed-form solution to a nonlinear PDE, involving nothing worse than a determinant. Let us unpack it in the two simplest cases.

Example 32.3.13 ($N = 1$)

With a single bound state, A is a 1×1 matrix,

$$\det A = 1 + \frac{c_1(0)^2 e^{8\chi_1^3 t} e^{-2\chi_1 x}}{2\chi_1} = 1 + e^{-2\chi_1(x - 4\chi_1^2 t - \delta)},$$

where the constant δ absorbs $c_1(0)$ via $e^{2\chi_1 \delta} = c_1(0)^2 / 2\chi_1$. Writing $\xi = x - 4\chi_1^2 t - \delta$ and $w = e^{-2\chi_1 \xi}$,

$$\log \det A = \log(1 + w),$$

and differentiating twice (using $w' = -2\chi_1 w$),

$$\frac{\partial}{\partial x} \log(1 + w) = \frac{-2\chi_1 w}{1 + w}, \quad \frac{\partial^2}{\partial x^2} \log(1 + w) = \frac{4\chi_1^2 w}{(1 + w)^2}.$$

Hence

$$\begin{aligned} u &= -\frac{8\chi_1^2 w}{(1 + w)^2} = -\frac{8\chi_1^2}{(w^{1/2} + w^{-1/2})^2} = -\frac{8\chi_1^2}{4 \cosh^2(\chi_1 \xi)} \\ &= -2\chi_1^2 \operatorname{sech}^2(\chi_1(x - 4\chi_1^2 t - \delta)), \end{aligned}$$

which is precisely the one-soliton solution of Section 2.3. So a single bound state means a single soliton, with χ_1 determining both its height and its speed, and $c_1(0)$ determining only where it is.

Example 32.3.14 ($N = 2$)

With two bound states, write

$$E_n = E_n(x, t) = \frac{c_n(0)^2 e^{8\chi_n^3 t} e^{-2\chi_n x}}{2\chi_n},$$

so that $A_{nn} = 1 + E_n$ and

$$A_{12}A_{21} = \frac{c_1^2 c_2^2 e^{-2(\chi_1 + \chi_2)x}}{(\chi_1 + \chi_2)^2} = \frac{4\chi_1 \chi_2}{(\chi_1 + \chi_2)^2} E_1 E_2.$$

Therefore

$$\det A = (1 + E_1)(1 + E_2) - \frac{4\chi_1 \chi_2}{(\chi_1 + \chi_2)^2} E_1 E_2 = 1 + E_1 + E_2 + \left(\frac{\chi_2 - \chi_1}{\chi_2 + \chi_1} \right)^2 E_1 E_2,$$

using $1 - \frac{4\chi_1\chi_2}{(\chi_1+\chi_2)^2} = \frac{(\chi_2-\chi_1)^2}{(\chi_2+\chi_1)^2}$. Substituting into the theorem gives the two-soliton solution plotted in Section 2.4.

The interesting thing is what happens at large $|t|$, and this we can extract without any further computation. Write

$$\delta = \frac{\chi_2 - \chi_1}{\chi_2 + \chi_1} \in (0, 1),$$

and follow the taller soliton by fixing $\xi = x - 4\chi_2^2 t$. In this frame

$$E_2 \propto e^{8\chi_2^3 t - 2\chi_2(4\chi_2^2 t + \xi)} = e^{-2\chi_2 \xi},$$

which is constant in t , while

$$E_1 \propto e^{8\chi_1^3 t - 2\chi_1(4\chi_2^2 t + \xi)} = e^{8\chi_1(\chi_1^2 - \chi_2^2)t} e^{-2\chi_1 \xi} \longrightarrow \begin{cases} 0 & t \rightarrow +\infty, \\ \infty & t \rightarrow -\infty, \end{cases}$$

since $\chi_1 < \chi_2$. So:

- As $t \rightarrow +\infty$ we have $\det A \rightarrow 1 + E_2$, and by the $N = 1$ computation u tends to a soliton of parameter χ_2 sitting at $\xi = \delta_2$ for some fixed δ_2 .
- As $t \rightarrow -\infty$ the term E_1 dominates, and

$$\det A \approx E_1 (1 + \delta^2 E_2).$$

Now $\log E_1$ is a linear function of x , so it is killed by ∂_x^2 and contributes nothing. We are left with $u \rightarrow -2\partial_x^2 \log(1 + \delta^2 E_2)$, which is again a soliton of parameter χ_2 – but with E_2 replaced by $\delta^2 E_2$.

Since $E_2 \propto e^{-2\chi_2 \xi}$, multiplying E_2 by δ^2 is the same as translating ξ by

$$\Delta \quad \text{where} \quad e^{2\chi_2 \Delta} = \delta^2, \quad \text{i.e.} \quad \Delta = \frac{1}{\chi_2} \log \delta = -\frac{1}{\chi_2} \log \frac{\chi_2 + \chi_1}{\chi_2 - \chi_1} < 0.$$

So long before the collision the tall soliton is at $\xi = \delta_2 + \Delta$, and long afterwards it is at $\xi = \delta_2$: it has been pushed *forward* by

$$|\Delta| = \frac{1}{\chi_2} \log \frac{\chi_2 + \chi_1}{\chi_2 - \chi_1}.$$

Repeating the argument in the frame of the shorter soliton (where now E_2 is the one that blows up) gives a shift backwards by $\frac{1}{\chi_1} \log \frac{\chi_2 + \chi_1}{\chi_2 - \chi_1}$. These are the phase shifts we quoted in Section 2.4.

Two remarks are in order. First, the number of solitons is the number of bound states, so we can read off the eventual fate of *any* initial profile from a linear eigenvalue problem: count the bound states of $-\partial_x^2 + u_0$, and that is how many solitons will emerge. Everything else – the reflection coefficient – disperses away, and one can show that it contributes a decaying oscillatory tail travelling in the opposite direction. So the general picture is:

any decaying initial profile resolves into N solitons plus radiation.

Second, the total absence of any interaction term in the final answer – the shifts Δ

depend only on χ_1 and χ_2 , not on when or where the collision happened – is precisely the sense in which solitons behave like particles.

§32.3.6 Infinitely Many Conservation Laws

We promised at the start of Section 2 that an integrable PDE should have infinitely many conserved quantities, and in Section 2.5 we found three of them by inspection. Now we can produce them all at once.

The idea is that we have already found something conserved: the quantity $a(k, t) = a(k, 0)$ is independent of time, for every k . If we can expand $a(k)$ in powers of $1/k$, then every coefficient in that expansion must be conserved as well, and we will have infinitely many first integrals in a single stroke.

Recall the setup: $\varphi = \varphi(x, k, t)$ solves $L\varphi = k^2\varphi$ with

$$\varphi = \begin{cases} e^{-ikx} & x \rightarrow -\infty, \\ a(k, t)e^{-ikx} + b(k, t)e^{ikx} & x \rightarrow +\infty. \end{cases}$$

Multiplying by e^{ikx} ,

$$e^{ikx}\varphi(x, k, t) = a(k) + b(k, t)e^{2ikx} \quad \text{as } x \rightarrow +\infty.$$

To isolate a we average out the oscillating term. Over the window $[R, 2R]$,

$$\frac{1}{R} \int_R^{2R} a(k) \, dx = a(k), \quad \frac{1}{R} \int_R^{2R} b(k, t)e^{2ikx} \, dx = O\left(\frac{1}{R}\right),$$

so

$$a(k) = \lim_{R \rightarrow \infty} \frac{1}{R} \int_R^{2R} e^{ikx}\varphi(x, k, t) \, dx = \lim_{R \rightarrow \infty} \int_1^2 e^{ikRx}\varphi(Rx, k, t) \, dx,$$

substituting $x \mapsto Rx$.

Now we need a good representation of φ . Since $\varphi = e^{-ikx}$ as $x \rightarrow -\infty$, it is natural to write

$$\varphi(x, k, t) = \exp\left(-ikx + \int_{-\infty}^x S(y, k, t) \, dy\right)$$

for some function S . Feeding this into the formula above and passing to the limit,

$$a(k) = \lim_{R \rightarrow \infty} \int_1^2 \exp\left(\int_{-\infty}^{Rx} S(y, k, t) \, dy\right) \, dx = \exp\left(\int_{-\infty}^{\infty} S(y, k, t) \, dy\right). \quad (\dagger)$$

The left-hand side has no t in it; the right-hand side appears to. That is where our conserved quantities will come from.

It remains to find S . Substituting the exponential ansatz into $L\varphi = k^2\varphi$, and using

$$\varphi_x = (S - ik)\varphi, \quad \varphi_{xx} = S_x\varphi + (S - ik)^2\varphi,$$

we find, after dividing by φ ,

$$S_x - 2ikS + S^2 = -u.$$

The function φ has disappeared entirely, and we are left with a **Riccati equation** for S . (This is the Riccati equation of the Miura transform in disguise, which is no coincidence.)

We solve it as an asymptotic series in $1/k$:

$$S(x, k, t) = \sum_{n=1}^{\infty} \frac{S_n(x, t)}{(2ik)^n}.$$

Substituting and comparing coefficients of k^{-n} gives the recursion

$$S_1 = -u, \quad S_{n+1} = \frac{dS_n}{dx} + \sum_{m=1}^{n-1} S_m S_{n-m}.$$

This is entirely mechanical, and the first few terms are

$$S_1 = -u, \quad S_2 = -u_x, \quad S_3 = -u_{xx} + u^2, \quad S_4 = -u_{xxx} + 4uu_x, \dots$$

Now put this back into (†):

$$\log a(k) = \int_{-\infty}^{\infty} S(x, k, t) dx = \sum_{n=1}^{\infty} \frac{1}{(2ik)^n} \int_{-\infty}^{\infty} S_n(x, t) dx.$$

The left-hand side is independent of t , and this holds for all k , so every coefficient must be independent of t separately. We conclude:

Theorem 32.3.15

If u evolves by KdV then, for every $n \geq 1$,

$$\int_{-\infty}^{\infty} S_n(x, t) dx$$

is a first integral, where the S_n are given by the recursion above.

Let us look at the first few.

(i) $n = 1$ gives

$$\int_{-\infty}^{\infty} u dx,$$

conservation of mass – our I_1 .

(ii) $n = 2$ gives $\int u_x dx$, which vanishes identically because u decays. This is a *trivial* conservation law: true, but empty. In fact one can show that S_n is a total derivative for every even n , so the even members of the family give us nothing.

(iii) $n = 3$ gives

$$\int_{-\infty}^{\infty} (-u_{xx} + u^2) dx = \int_{-\infty}^{\infty} u^2 dx,$$

conservation of momentum – our I_2 .

(iv) $n = 5$ gives $S_5 = -u_{xxxx} + 5u_x^2 + 6uu_{xx} - 2u^3$. Integrating, the first term vanishes and $\int 6uu_{xx} dx = -\int 6u_x^2 dx$ by parts, leaving

$$\int_{-\infty}^{\infty} S_5 dx = -\int_{-\infty}^{\infty} (u_x^2 + 2u^3) dx = -2I_3,$$

so we recover the energy.

So half of the family is trivial. But half of infinity is still infinity, and we have produced infinitely many genuine first integrals of KdV, exactly as the finite-dimensional theory led us to expect.

Remark. It is worth noticing where the conserved quantities came from: they are the coefficients in an expansion of the transmission data. The scattering data $\{\chi_n\}$ and $R(k)$ are, in a real sense, the action variables of KdV; the phases of c_n and R are the angles, moving at constant rates $4\chi_n^3$ and $8k^3$. In the next section we make this analogy considerably more precise.

§32.4 The Hamiltonian Structure of Integrable PDEs

The integrable ODEs of Section 1 were not arbitrary ODEs – they were Hamiltonian systems, and their integrability was expressed in terms of Poisson-commuting first integrals. If we really want to think of PDEs as infinite-dimensional dynamical systems, we should ask whether they too are Hamiltonian, and whether the conserved quantities we found are in involution. They are, and putting the theory in this language explains where the infinite family of conservation laws comes from.

§32.4.1 Infinite-Dimensional Hamiltonian Systems

Recall the finite-dimensional set-up: a phase space $\mathbb{R}^{2n}$, a non-degenerate antisymmetric matrix J , a Hamiltonian $H : \mathbb{R}^{2n} \rightarrow \mathbb{R}$, and the equation of motion

$$\frac{d\mathbf{x}}{dt} = J \frac{\partial H}{\partial \mathbf{x}}.$$

We now promote each ingredient in turn. The rule of thumb is that the discrete index i becomes the continuous variable x , sums become integrals, and partial derivatives become functional derivatives.

First, the inner product. In finite dimensions we had $\mathbf{x} \cdot \mathbf{y} = \sum_i x_i y_i$; here we replace the sum by an integral.

Notation. For functions u, v on $\mathbb{R}$ we write

$$\langle u, v \rangle = \int_{\mathbb{R}} u(x)v(x) \, dx.$$

If u and v also depend on t , then so does the inner product.

Secondly, functions on phase space. In finite dimensions the Hamiltonian was a function $H(\mathbf{x})$; here the analogue is not a function of u at each point, but a *functional*.

Definition 32.4.1 (Functional)

A **functional** is a real-valued map on a space of functions of the form

$$F[u] = \int_{\mathbb{R}} f(x, u, u_x, u_{xx}, \dots) \, dx.$$

The function f is called the **density**.

Thirdly, differentiation with respect to phase-space coordinates. We met this in IB Variational Principles.

Definition 32.4.2 (Functional derivative)

The **functional derivative** (or Euler–Lagrange derivative) of F at u is the unique function δF with

$$\langle \delta F, \eta \rangle = \lim_{\varepsilon \rightarrow 0} \frac{F[u + \varepsilon \eta] - F[u]}{\varepsilon}$$

for all smooth η of compact support; equivalently

$$F[u + \varepsilon \eta] = F[u] + \varepsilon \langle \delta F, \eta \rangle + o(\varepsilon).$$

Note that δF is itself a function of x , depending on u . We often write $\delta F / \delta u$ for it.

Example 32.4.3

Let $F[u] = \frac{1}{2} \int u_x^2 dx$. Then

$$\begin{aligned} F[u + \varepsilon \eta] &= \frac{1}{2} \int (u_x + \varepsilon \eta_x)^2 dx \\ &= \frac{1}{2} \int u_x^2 dx + \varepsilon \int u_x \eta_x dx + o(\varepsilon) \\ &= F[u] + \varepsilon \langle u_x, \eta_x \rangle + o(\varepsilon). \end{aligned}$$

This is not yet of the required form, since we want η rather than η_x in the second slot. When in doubt, integrate by parts – and since η has compact support there are no boundary terms:

$$F[u + \varepsilon \eta] = F[u] + \varepsilon \langle -u_{xx}, \eta \rangle + o(\varepsilon).$$

So $\delta F = -u_{xx}$.

The general formula, from IB Variational Principles, is

$$\delta F = \frac{\partial f}{\partial u} - D_x \left(\frac{\partial f}{\partial u_x} \right) + D_x^2 \left(\frac{\partial f}{\partial u_{xx}} \right) - \cdots,$$

where D_x is the *total* derivative, not the partial one.

Definition 32.4.4 (Total derivative)

For a function $f(x, u, u_x, \dots)$ and a given $u = u(x)$, the **total derivative** is

$$D_x f = \frac{\partial f}{\partial x} + u_x \frac{\partial f}{\partial u} + u_{xx} \frac{\partial f}{\partial u_x} + \cdots.$$

Example 32.4.5

For $f = xu$ we have $\partial f / \partial x = u$ but $D_x f = u + xu_x$. The partial derivative treats u as an independent coordinate; the total derivative remembers that u is a function of x .

Finally we need an analogue of J . It is helpful first to notice that in finite dimensions we can think of J in two ways: as an antisymmetric bilinear form, or – since we also have a dot product – as an antisymmetric linear *map*, applied via $\mathbf{v} \cdot J\mathbf{w}$. It is the

second picture that generalises: we look for an antisymmetric linear operator $\mathcal{J}$ acting on functions, and define

$$\{F, G\} = \langle \delta F, \mathcal{J} \delta G \rangle = \int \delta F(x) \mathcal{J} \delta G(x) \, dx.$$

Bilinearity and antisymmetry are then automatic. The Jacobi identity, however, is *not*: it constrains the choice of $\mathcal{J}$.

Definition 32.4.6 (Hamiltonian operator)

A **Hamiltonian operator** is a linear, antisymmetric operator $\mathcal{J}$ on functions such that the induced bracket

$$\{F, G\} = \langle \delta F, \mathcal{J} \delta G \rangle$$

satisfies the Jacobi identity.

The simplest antisymmetric operator one can write down is $\mathcal{J} = \partial_x$ (antisymmetric because $\langle u_x, v \rangle = -\langle u, v_x \rangle$ after integrating by parts). One can check – the proof is straightforward but tedious – that it is Hamiltonian.

Definition 32.4.7 (Hamiltonian form)

An evolution equation for $u(x, t)$ is in **Hamiltonian form** if it can be written

$$u_t = \mathcal{J} \frac{\delta H}{\delta u}$$

for some functional $H[u]$ and some Hamiltonian operator $\mathcal{J}$.

Everything from Section 1 now goes through verbatim.

Proposition 32.4.8

If $u_t = \mathcal{J} \delta H$ and $I = I[u]$ is a functional, then

$$\frac{dI}{dt} = \{I, H\}.$$

In particular I is a first integral if and only if $\{I, H\} = 0$.

Proof. Directly from the definition of the functional derivative,

$$\frac{dI}{dt} = \lim_{\varepsilon \rightarrow 0} \frac{I[u + \varepsilon u_t] - I[u]}{\varepsilon} = \langle \delta I, u_t \rangle = \langle \delta I, \mathcal{J} \delta H \rangle = \{I, H\}. \quad \square$$

In summary, the dictionary is:

<i>2n-dimensional phase space</i>	<i>infinite-dimensional phase space</i>
$x_i(t), i = 1, \dots, 2n$	$u(x, t), x \in \mathbb{R}$
$\mathbf{x} \cdot \mathbf{y} = \sum_i x_i y_i$	$\langle u, v \rangle = \int uv \, dx$
d/dt	$\partial/\partial t$
$\partial/\partial \mathbf{x}$	$\delta/\delta u$
antisymmetric matrix J	antisymmetric operator $\mathcal{J}$
functions $f(\mathbf{x})$	functionals $F[u]$

§32.4.2 Bi-Hamiltonian Systems

So far this is only a change of language. The interesting phenomenon is that the *same* equation may be Hamiltonian in more than one way.

Definition 32.4.9 (Bi-Hamiltonian)

An evolution equation is **bi-Hamiltonian** if it can be written in Hamiltonian form for two different Hamiltonian operators,

$$u_t = \mathcal{J}_0 \delta H_0 = \mathcal{J}_1 \delta H_1.$$

Example 32.4.10 (KdV is bi-Hamiltonian)

Take

$$\mathcal{J}_1 = \partial_x, \quad H_1[u] = \int \left(\frac{1}{2} u_x^2 + u^3 \right) dx.$$

Then the density is $f = \frac{1}{2} u_x^2 + u^3$, and

$$\delta H_1 = \frac{\partial f}{\partial u} - D_x \left(\frac{\partial f}{\partial u_x} \right) = 3u^2 - u_{xx},$$

so

$$\mathcal{J}_1 \delta H_1 = \partial_x (3u^2 - u_{xx}) = 6uu_x - u_{xxx} = u_t,$$

which is KdV. So H_1 – which is precisely the first integral I_3 from Section 2.5 – is the Hamiltonian for KdV.

But KdV is also Hamiltonian with respect to a completely different structure. Take

$$\mathcal{J}_0 = -\partial_x^3 + 4u\partial_x + 2u_x, \quad H_0[u] = \int \frac{1}{2} u^2 dx.$$

Now $\delta H_0 = u$, and

$$\mathcal{J}_0 \delta H_0 = -u_{xxx} + 4uu_x + 2u_x u = -u_{xxx} + 6uu_x = u_t,$$

which is KdV again. Here $H_0 = \frac{1}{2} I_2$ is the momentum. One checks that $\mathcal{J}_0$ is antisymmetric (the operators ∂_x^3 and $u\partial_x + \partial_x u$ both are) and that it satisfies the Jacobi identity, which is less obvious.

Why does this matter? Because two compatible Hamiltonian structures generate an infinite hierarchy of conserved quantities, all in involution, for free. Given the two structures, define a sequence of functionals $H_0, H_1, H_2, \dots$ recursively by

$$\mathcal{J}_1 \delta H_{n+1} = \mathcal{J}_0 \delta H_n.$$

(One has to show that this can always be solved for H_{n+1} ; we take this on faith.) Then:

Theorem 32.4.11 (Magri)

Suppose $u_t = \mathcal{J}_0 \delta H_0 = \mathcal{J}_1 \delta H_1$ is bi-Hamiltonian, and let $\{H_n\}_{n \geq 0}$ be defined by the recursion above. Then all the H_n are first integrals, and they are in involution:

$$\{H_n, H_m\} = 0 \quad \text{for all } n, m \geq 0,$$

where the bracket is taken with respect to $\mathcal{J}_1$.

Proof. The whole proof rests on one observation. For $m \geq 1$,

$$\begin{aligned}
 \{H_n, H_m\} &= \langle \delta H_n, \mathcal{J}_1 \delta H_m \rangle \\
 &= \langle \delta H_n, \mathcal{J}_0 \delta H_{m-1} \rangle && (\text{recursion}) \\
 &= -\langle \mathcal{J}_0 \delta H_n, \delta H_{m-1} \rangle && (\mathcal{J}_0 \text{ antisymmetric}) \\
 &= -\langle \mathcal{J}_1 \delta H_{n+1}, \delta H_{m-1} \rangle && (\text{recursion}) \\
 &= \langle \delta H_{n+1}, \mathcal{J}_1 \delta H_{m-1} \rangle && (\mathcal{J}_1 \text{ antisymmetric}) \\
 &= \{H_{n+1}, H_{m-1}\}.
 \end{aligned}$$

So we may shift an index from one slot to the other. Iterating m times gives

$$\{H_n, H_m\} = \{H_{n+m}, H_0\},$$

and iterating n times in the other direction gives $\{H_n, H_m\} = \{H_0, H_{n+m}\}$. Hence $\{H_n, H_m\} = \{H_m, H_n\}$; but the bracket is antisymmetric, so both sides vanish.

Finally, taking $m = 1$ shows $\{H_n, H_1\} = 0$ for all n , and H_1 is the Hamiltonian, so every H_n is a first integral. $\square$

This is a genuinely miraculous piece of bookkeeping: the mere existence of a second Hamiltonian structure forces infinitely many commuting conservation laws into existence. For KdV the resulting H_n are (up to normalisation) the integrals $\int S_{2n+1} dx$ we constructed from the scattering problem in Section 3.6. And the flows they generate,

$$u_{t_n} = \mathcal{J}_1 \delta H_n,$$

are the members of the KdV hierarchy: $n = 0$ gives $u_t = u_x$ (translation), $n = 1$ gives KdV, $n = 2$ gives a fifth-order equation, and so on. Since the Hamiltonians are in involution, all these flows commute, exactly as the Hamiltonian flows on a Liouville torus did in Section 1.

§32.4.3 Zero-Curvature Representation

There is a second, more geometric way to package integrability, which is often more flexible than the Lax formulation.

Given a function $u(x, t)$, suppose we can construct $N \times N$ matrices $U = U(\lambda)$ and $V = V(\lambda)$ depending on λ , on u and on its derivatives. Here λ is a **spectral parameter**, playing the same role as the λ in $L\varphi = \lambda\varphi$. Consider the linear system

$$\frac{\partial}{\partial x} \mathbf{v} = U(\lambda) \mathbf{v}, \quad \frac{\partial}{\partial t} \mathbf{v} = V(\lambda) \mathbf{v}, \quad (\dagger)$$

for an N -component vector $\mathbf{v} = \mathbf{v}(x, t; \lambda)$.

This is an overdetermined system – we have twice as many equations as unknowns – so there is a compatibility condition, obtained from $\mathbf{v}_{xt} = \mathbf{v}_{tx}$:

$$\begin{aligned}
 0 &= \frac{\partial}{\partial t} (U \mathbf{v}) - \frac{\partial}{\partial x} (V \mathbf{v}) \\
 &= U_t \mathbf{v} + U \mathbf{v}_t - V_x \mathbf{v} - V \mathbf{v}_x
 \end{aligned}$$

$$\begin{aligned}
&= U_t \mathbf{v} + UV \mathbf{v} - V_x \mathbf{v} - VU \mathbf{v} \\
&= (U_t - V_x + [U, V]) \mathbf{v}.
\end{aligned}$$

So if (†) is to have a solution for every initial $\mathbf{v}_0$, we need

Definition 32.4.12 (Zero-curvature equation)

The **zero-curvature equation** is

$$\frac{\partial U}{\partial t} - \frac{\partial V}{\partial x} + [U, V] = 0.$$

A theorem of Frobenius says the converse also holds: if the zero-curvature equation is satisfied, then solutions of (†) exist. So we have a correspondence between the solvability of a linear system and a nonlinear equation for U, V .

The name comes from differential geometry. The curvature of a connection A has components

$$F_{ij} = \frac{\partial A_j}{\partial x_i} - \frac{\partial A_i}{\partial x_j} + [A_i, A_j],$$

which is exactly the shape of our equation with $(A_1, A_2) = (U, V)$ and $(x_1, x_2) = (x, t)$. So the equation says that the connection built from U and V is flat.

Example 32.4.13 (Sine–Gordon)

Take

$$U(\lambda) = \frac{i}{2} \begin{pmatrix} 2\lambda & u_x \\ u_x & -2\lambda \end{pmatrix}, \quad V(\lambda) = \frac{1}{4i\lambda} \begin{pmatrix} \cos u & -i \sin u \\ i \sin u & -\cos u \end{pmatrix}.$$

A computation shows that the zero-curvature equation is equivalent to

$$u_{xt} = \sin u,$$

the sine–Gordon equation in light-cone coordinates (Section 5.1).

The geometric picture pays off immediately. Curvature is an intrinsic object: if it vanishes in one gauge it vanishes in all of them. So given one pair (U, V) solving the zero-curvature equation, a gauge transformation

$$U \mapsto \tilde{U} = gUg^{-1} + g_x g^{-1}, \quad V \mapsto \tilde{V} = gVg^{-1} + g_t g^{-1}$$

produces a new pair solving the same equation, and hence potentially a new integrable equation, or new solutions of the same one. This is explored on the last example sheet.

Zero curvature also supports its own version of inverse scattering. In the sine–Gordon example above, if $u_x \rightarrow 0$ as $|x| \rightarrow \infty$ then writing $\mathbf{v} = (\psi_1, \psi_2)^T$ the first equation of (†) becomes

$$\frac{\partial}{\partial x} \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix} = i\lambda \begin{pmatrix} \psi_1 \\ -\psi_2 \end{pmatrix},$$

so that

$$\begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix} \rightarrow A \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{i\lambda x} + B \begin{pmatrix} 0 \\ 1 \end{pmatrix} e^{-i\lambda x}$$

as $|x| \rightarrow \infty$. The coefficients A and B are the scattering data, and the second equation of (†) tells us how they evolve in t . This is the AKNS scheme, and it is how one solves sine–Gordon and the nonlinear Schrödinger equation.

§32.4.4 From Lax Pairs to Zero Curvature

The two formulations are closely related, and in fact every Lax pair gives rise to a zero-curvature representation.

Recall that in the isospectral flow theorem we found two equations holding simultaneously:

$$L\psi = \lambda\psi, \quad \psi_t + A\psi = 0,$$

the second because $\tilde{\psi}$ vanished. Conversely, suppose we *impose* these two equations and demand $\lambda_t = 0$. Differentiating the first and substituting the second gives

$$L_t\psi + L\psi_t = \lambda\psi_t \implies L_t\psi = (L - \lambda)(-\psi_t) = (L - \lambda)A\psi = LA\psi - AL\psi,$$

that is $L_t = [L, A]$. So Lax's equation is exactly the compatibility condition for the pair of linear equations above – the same logical role played by the zero-curvature equation for (†).

To make the correspondence explicit, suppose

$$L = \partial_x^n + \sum_{j=0}^{n-1} u_j(x, t) \partial_x^j, \quad A = \partial_x^m + \sum_{j=0}^{m-1} v_j(x, t) \partial_x^j.$$

The equation $L\psi = \lambda\psi$ lets us express every derivative of order $\geq n$ in terms of the lower ones:

$$\partial_x^n \psi = \lambda\psi - \sum_{j=0}^{n-1} u_j \partial_x^j \psi,$$

and differentiating this repeatedly handles the higher derivatives. So introducing the vector

$$\Psi = (\psi, \partial_x \psi, \dots, \partial_x^{n-1} \psi)^T,$$

the equation $L\psi = \lambda\psi$ becomes a first-order system $\Psi_x = U(\lambda)\Psi$ with companion matrix

$$U(\lambda) = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ \lambda - u_0 & -u_1 & -u_2 & \cdots & -u_{n-1} \end{pmatrix}.$$

Similarly, differentiating $\psi_t + A\psi = 0$ a total of $i - 1$ times with respect to x and using the above to eliminate high derivatives, we get

$$(\partial_x^{i-1} \psi)_t + \sum_{j=1}^n V_{ij}(x, t) \partial_x^{j-1} \psi = 0$$

for suitable V_{ij} built from the u_j, v_j and their derivatives, that is $\Psi_t = -V\Psi$ (after an overall sign). So

$$L_t = [L, A] \iff \begin{cases} L\psi = \lambda\psi \\ \psi_t + A\psi = 0 \end{cases} \iff \begin{cases} \Psi_x = U(\lambda)\Psi \\ \Psi_t = V(\lambda)\Psi \end{cases} \iff U_t - V_x + [U, V] = 0.$$

The zero-curvature formulation is strictly more general – there are integrable equations with a zero-curvature representation but no scalar Lax pair – and it is the one that generalises most readily to other settings.

§32.5 Further Integrable Equations

KdV is not alone. In this section we meet two more equations which are integrable in the same sense – they have Lax pairs, infinitely many conservation laws and soliton solutions – and which are at least as important in applications.

§32.5.1 The Sine–Gordon Equation

Definition 32.5.1 (Sine–Gordon equation)

The **sine–Gordon equation** is

$$u_{tt} - u_{xx} + \sin u = 0.$$

The name is a joke. The **Klein–Gordon equation** of relativistic quantum mechanics is

$$u_{tt} - u_{xx} + u = 0,$$

and replacing the u by $\sin u$ turns Klein into sine.

Example 32.5.2 (A chain of pendulums)

Here is a mechanical system governed by the equation. Take a horizontal rod, and hang from it a row of pendulums of length ℓ and mass m , spaced Δx apart, each free to rotate in the vertical plane perpendicular to the rod. Let $\theta_i(t)$ be the angle of the i th pendulum from the downward vertical, and connect neighbouring masses by torsional springs.

Gravity exerts a torque $-m\ell g \sin \theta_i$ on the i th pendulum, and the springs exert torques

$$\frac{K(\theta_{i+1} - \theta_i)}{\Delta x}, \quad \frac{K(\theta_{i-1} - \theta_i)}{\Delta x}$$

from its two neighbours. Newton's second law for rotation, with moment of inertia $m\ell^2$, gives

$$m\ell^2 \frac{d^2 \theta_i}{dt^2} = -m\ell g \sin \theta_i + \frac{K(\theta_{i+1} - 2\theta_i + \theta_{i-1}))}{\Delta x}.$$

Now divide by Δx and take the continuum limit $\Delta x \rightarrow 0$, holding $M = m/\Delta x$ fixed and writing $\theta_i(t) = \theta(i\Delta x, t)$. The second difference over Δx^2 tends to θ_{xx} , so

$$M\ell^2 \frac{\partial^2 \theta}{\partial t^2} = -M\ell g \sin \theta + K \frac{\partial^2 \theta}{\partial x^2}.$$

Rescaling x and t to remove the constants gives $u_{tt} - u_{xx} + \sin u = 0$.

There is also a differential-geometric origin: solutions of the sine–Gordon equation correspond to *pseudospherical* surfaces in $\mathbb{R}^3$, that is surfaces of constant negative Gaussian curvature. This is the historical source of the equation, and of the Bäcklund transformations of Section 6.

It is often convenient to pass to **light-cone coordinates**

$$\xi = \frac{1}{2}(x - t), \quad \tau = \frac{1}{2}(x + t),$$

in which $\partial_x = \frac{1}{2}(\partial_\xi + \partial_\tau)$ and $\partial_t = \frac{1}{2}(\partial_\tau - \partial_\xi)$, so that $\partial_t^2 - \partial_x^2 = -\partial_\xi \partial_\tau$. The equation becomes

$$\frac{\partial^2 u}{\partial \xi \partial \tau} = \sin u,$$

which is the form we will mostly use.

Kinks and Antikinks

Let us find the travelling waves. Put $u(x, t) = f(\gamma(x - vt))$ with $|v| < 1$ and $\gamma = (1 - v^2)^{-1/2}$, and write $\theta = \gamma(x - vt)$. Then $u_{tt} = v^2 \gamma^2 f''$ and $u_{xx} = \gamma^2 f''$, so

$$\gamma^2(v^2 - 1)f'' + \sin f = 0, \quad \text{i.e.} \quad f'' = \sin f,$$

since $\gamma^2(v^2 - 1) = -1$. This is the equation of a pendulum with the sign of gravity reversed – which is no coincidence, given where the equation came from. Multiplying by f' and integrating,

$$\frac{1}{2}(f')^2 = -\cos f + C,$$

and imposing $f \rightarrow 0, f' \rightarrow 0$ as $\theta \rightarrow -\infty$ gives $C = 1$. Hence

$$(f')^2 = 2(1 - \cos f) = 4 \sin^2(f/2), \quad f' = 2 \sin(f/2),$$

taking the positive root. Separating variables and substituting $g = f/2$,

$$\int \frac{dg}{\sin g} = \int d\theta \implies \log \tan \frac{g}{2} = \theta + \text{const},$$

so $\tan(f/4) = Ae^\theta$. Absorbing A into a translation we obtain the following.

Proposition 32.5.3 (Kink solution)

For any $|v| < 1$,

$$u(x, t) = 4 \tan^{-1} \left(\exp \left(\frac{x - vt}{\sqrt{1 - v^2}} \right) \right)$$

solves the sine–Gordon equation. It is called a **kink**. Replacing $x - vt$ by $-(x - vt)$ gives the **antikink**.

The kink interpolates between $u = 0$ at $x = -\infty$ and $u = 2\pi$ at $x = +\infty$; the antikink runs the other way.

Note the Lorentz factor γ : a fast kink is narrower than a slow one, exactly as a moving rod is contracted in special relativity. This is not an accident, since the sine–Gordon equation is Lorentz invariant.

In the pendulum picture, a kink is a single full twist of the chain, propagating along it. Now remember that u is an *angle*: the values 0 and 2π describe the same physical configuration. So both the kink and the trivial solution $u = 0$ satisfy the same boundary conditions in the physical sense. Nevertheless the kink can never evolve into the trivial solution, and here is why.

Definition 32.5.4 (Topological charge)

For a solution with $u \rightarrow 2\pi n_{\pm}$ as $x \rightarrow \pm\infty$, the **topological charge** is

$$Q = \frac{1}{2\pi} [u]_{x=-\infty}^{x=+\infty} = n_+ - n_- \in \mathbb{Z}.$$

Since u evolves continuously and Q takes values in $\mathbb{Z}$, the charge cannot change: it is conserved for purely topological reasons, with no differential equation required. The kink has $Q = 1$, the antikink $Q = -1$, and the vacuum $Q = 0$. So a kink is stable, not because it sits at a minimum of some energy, but because there is no continuous path from it to anything else.

If we think of u as taking values on the circle S^1 , the picture is that the solution is a path in the cylinder $\mathbb{R} \times S^1$ which winds Q times around:

No amount of continuous deformation, subject to the boundary conditions, can unwind it.

Remark. Sine–Gordon has multi-soliton solutions too, obtained (as we shall see in Section 6) by Bäcklund transformations. Besides kink–kink and kink–antikink scattering solutions there is a genuinely new object, the **breather**

$$u(x, t) = 4 \tan^{-1} \left(\frac{\sqrt{1 - \omega^2}}{\omega} \frac{\sin(\omega t)}{\cosh(\sqrt{1 - \omega^2} x)} \right),$$

a kink and antikink bound together, oscillating in place with frequency ω . It has $Q = 0$, and yet it is perfectly stable – a periodic, localised, nonlinear excitation with no linear analogue.

§32.5.2 The Nonlinear Schrödinger Equation

Our final example is the equation governing envelope waves: pulses in optical fibres, wave packets on deep water, and Bose–Einstein condensates.

Definition 32.5.5 (Nonlinear Schrödinger equation)

The **nonlinear Schrödinger equation** (NLS) for a complex-valued $q(x, t)$ is

$$iq_t + q_{xx} + 2|q|^2q = 0.$$

The sign of the nonlinear term matters. With $+2|q|^2q$ the equation is **focusing**, and supports *bright* solitons – localised pulses on a zero background. With $-2|q|^2q$ it is **defocusing**, and supports *dark* solitons – localised dips in a non-zero background. We treat the focusing case.

The equation looks like the linear Schrödinger equation of IB Quantum Mechanics with a potential $-2|q|^2$ generated by the wavefunction itself, which is exactly the physical situation in a nonlinear optical medium whose refractive index depends on the intensity of the light passing through it.

Let us find the soliton. Look first for a standing solution

$$q(x, t) = f(x)e^{i\theta t}$$

with f real. Then $iq_t = -\theta f e^{i\theta t}$, and the equation becomes

$$f'' = \theta f - 2f^3.$$

Multiplying by f' and integrating, with $f, f' \rightarrow 0$ at infinity,

$$(f')^2 = \theta f^2 - f^4 = f^2(\theta - f^2).$$

This has exactly the shape of the KdV travelling-wave equation, and the same guess works. Trying $f = a \operatorname{sech}(ax)$ we get

$$(f')^2 = a^4 \operatorname{sech}^2(ax) \tanh^2(ax) = a^4 \operatorname{sech}^2 - a^4 \operatorname{sech}^4,$$

while

$$f^2(\theta - f^2) = a^2 \theta \operatorname{sech}^2 - a^4 \operatorname{sech}^4,$$

so the two agree precisely when $\theta = a^2$.

Finally we set the soliton moving. NLS is Galilean invariant: if $q(x, t)$ is a solution then so is

$$\tilde{q}(x, t) = e^{i\left(\frac{v}{2}x - \frac{v^2}{4}t\right)} q(x - vt, t),$$

as one checks by direct substitution. Applying this to the standing solution gives the following.

Proposition 32.5.6 (Bright soliton)

For any $a > 0$ and $v \in \mathbb{R}$,

$$q(x, t) = a \operatorname{sech}(a(x - vt)) \exp\left(i\left[\frac{v}{2}x + \left(a^2 - \frac{v^2}{4}\right)t\right]\right)$$

solves the focusing NLS equation.

So the modulus $|q| = a \operatorname{sech}(a(x - vt))$ is a solitary wave of amplitude a and width $1/a$, travelling at speed v , while the phase oscillates underneath it:

Note the crucial difference from KdV: here the amplitude and the speed are *independent* parameters. A tall NLS soliton is narrow, but it need not be fast.

Like KdV, the NLS equation has a Lax pair and is solvable by inverse scattering; the relevant linear problem is the 2×2 Zakharov–Shabat system,

$$\frac{\partial}{\partial x} \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix} = \begin{pmatrix} -i\lambda & q \\ -\bar{q} & i\lambda \end{pmatrix} \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix},$$

which is exactly of the zero-curvature type $\Psi_x = U(\lambda)\Psi$ discussed in Section 4.3. Each discrete eigenvalue of this system corresponds to a soliton, with the real and imaginary parts of the eigenvalue giving the soliton’s amplitude and velocity respectively. NLS solitons, like KdV solitons, pass through one another with nothing but a phase shift to show for it.

Finally, NLS is a Hamiltonian system in the sense of Section 4.1, with

$$iq_t = \frac{\delta H}{\delta \bar{q}}, \quad H[q] = \int (|q_x|^2 - |q|^4) \, dx,$$

and it has the conserved quantities

$$\int |q|^2 \, dx, \quad \frac{i}{2} \int (q\bar{q}_x - \bar{q}q_x) \, dx, \quad H[q]$$

– the number of photons, the momentum, and the energy – together with infinitely many more.

§32.6 Bäcklund Transformations

For a linear PDE we have the principle of superposition: add two solutions and get a third. For a nonlinear PDE this fails completely, and it is precisely this failure that makes nonlinear equations hard. Bäcklund transformations are a partial substitute – a way of manufacturing new solutions from old, not by adding them, but by solving an auxiliary system of first-order equations.

The idea originated in differential geometry, where Bäcklund studied transformations taking one pseudospherical surface to another. We will only look at what it does to PDEs. The general definition is a little slippery, so we start with an example that will be familiar.

Example 32.6.1 (Cauchy–Riemann)

Consider the Cauchy–Riemann equations

$$u_x = v_y, \quad u_y = -v_x.$$

From IB Complex Analysis we know that a pair (u, v) satisfies these if and only if both u and v are harmonic, that is

$$u_{xx} + u_{yy} = 0, \quad v_{xx} + v_{yy} = 0.$$

(One direction is immediate: $u_{xx} + u_{yy} = (v_y)_x + (-v_x)_y = 0$.)

So suppose we have found some harmonic function v . We may then try to *solve* the Cauchy–Riemann equations for u , and whatever we get is guaranteed to be harmonic as well.

For instance take $v = 2xy$, which is harmonic. The Cauchy–Riemann equations become

$$u_x = 2x, \quad u_y = -2y,$$

which we integrate to get

$$u(x, y) = x^2 - y^2 + C$$

for an arbitrary constant C . And indeed $x^2 - y^2$ is harmonic.

So the Cauchy–Riemann equations act as a machine for turning solutions of Laplace’s equation into other solutions of Laplace’s equation, at the cost of solving a first-order system. This is exactly what a Bäcklund transformation does.

Definition 32.6.2 (Bäcklund transformation)

A **Bäcklund transformation** is a system of equations relating solutions of one PDE to

- (i) solutions of a *different* PDE; or
- (ii) other solutions of the *same* PDE.

In the second case we call it an **auto-Bäcklund transformation**.

Transformations of the first kind are useful when one of the two equations is easier than the other.

Example 32.6.3 (The Liouville equation)

The equation $u_{xt} = e^u$ is related to the trivial equation $v_{xt} = 0$ by the Bäcklund transformation

$$u_x + v_x = \sqrt{2} \exp\left(\frac{u - v}{2}\right), \quad u_t - v_t = \sqrt{2} \exp\left(\frac{u + v}{2}\right).$$

Verifying this is an exercise on the first example sheet. Since $v_{xt} = 0$ has the general solution $v = f(x) + g(t)$, this reduces the nonlinear Liouville equation to a pair of first-order ODEs.

§32.6.1 An Auto-Bäcklund Transformation for Sine–Gordon

The most important example, and the one we will use, is for the sine–Gordon equation in light-cone coordinates,

$$\varphi_{\xi\tau} = \sin \varphi.$$

Proposition 32.6.4

Fix a non-zero constant ε , and suppose φ and ψ are related by

$$\frac{\partial}{\partial \xi} (\varphi - \psi) = 2\varepsilon \sin \left(\frac{\varphi + \psi}{2} \right), \quad (\text{B1})$$

$$\frac{\partial}{\partial \tau} (\varphi + \psi) = \frac{2}{\varepsilon} \sin \left(\frac{\varphi - \psi}{2} \right). \quad (\text{B2})$$

Then φ solves the sine-Gordon equation if and only if ψ does.

Proof. Differentiate (B1) with respect to τ and use (B2):

$$\begin{aligned} (\varphi - \psi)_{\xi\tau} &= 2\varepsilon \cos \left(\frac{\varphi + \psi}{2} \right) \cdot \frac{1}{2} (\varphi + \psi)_\tau \\ &= \varepsilon \cos \left(\frac{\varphi + \psi}{2} \right) \cdot \frac{2}{\varepsilon} \sin \left(\frac{\varphi - \psi}{2} \right) \\ &= 2 \cos \left(\frac{\varphi + \psi}{2} \right) \sin \left(\frac{\varphi - \psi}{2} \right) \\ &= \sin \varphi - \sin \psi, \end{aligned}$$

using the identity $2 \cos A \sin B = \sin(A + B) - \sin(A - B)$.

Similarly, differentiating (B2) with respect to ξ and using (B1),

$$\begin{aligned} (\varphi + \psi)_{\xi\tau} &= \frac{2}{\varepsilon} \cos \left(\frac{\varphi - \psi}{2} \right) \cdot \frac{1}{2} (\varphi - \psi)_\xi \\ &= \frac{1}{\varepsilon} \cos \left(\frac{\varphi - \psi}{2} \right) \cdot 2\varepsilon \sin \left(\frac{\varphi + \psi}{2} \right) \\ &= \sin \varphi + \sin \psi. \end{aligned}$$

Adding the two displayed results gives $2\varphi_{\xi\tau} = 2 \sin \varphi$, and subtracting them gives $2\psi_{\xi\tau} = 2 \sin \psi$. So in fact both equations hold, and in particular each implies the other. $\square$

Note that we have a whole *family* of auto-Bäcklund transformations, one for each $\varepsilon \neq 0$. This parameter will be essential.

§32.6.2 Generating Solitons from Nothing

Let us put the transformation to work. We start with the most boring solution imaginable, $\psi \equiv 0$, and see what comes out. The equations (B1), (B2) become

$$\varphi_\xi = 2\varepsilon \sin \frac{\varphi}{2}, \quad \varphi_\tau = \frac{2}{\varepsilon} \sin \frac{\varphi}{2}.$$

There is an evident symmetry between ξ and τ here, which suggests the ansatz

$$\varphi(\xi, \tau) = 2\chi(z), \quad z = \varepsilon\xi + \frac{\tau}{\varepsilon}.$$

Then $\varphi_\xi = 2\varepsilon\chi'$ and $\varphi_\tau = (2/\varepsilon)\chi'$, and *both* equations reduce to the same ODE,

$$\frac{d\chi}{dz} = \sin \chi.$$

This we can separate:

$$\int \frac{d\chi}{\sin \chi} = \int dz \implies \log \tan \frac{\chi}{2} = z + \text{const},$$

so $\tan(\chi/2) = Ae^z$ and $\chi = 2 \tan^{-1}(Ae^z)$. Therefore

$$\varphi(\xi, \tau) = 4 \tan^{-1} \left(A \exp \left(\varepsilon \xi + \frac{\tau}{\varepsilon} \right) \right).$$

Let us see what this is. Substituting $\xi = \frac{1}{2}(x - t)$ and $\tau = \frac{1}{2}(x + t)$,

$$\varepsilon \xi + \frac{\tau}{\varepsilon} = \frac{\varepsilon^2 + 1}{2\varepsilon} x + \frac{1 - \varepsilon^2}{2\varepsilon} t = \gamma(x - vt),$$

where

$$\gamma = \frac{\varepsilon^2 + 1}{2\varepsilon}, \quad v = \frac{\varepsilon^2 - 1}{\varepsilon^2 + 1}.$$

A quick check confirms these are consistent with $\gamma = (1 - v^2)^{-1/2}$:

$$1 - v^2 = \frac{(\varepsilon^2 + 1)^2 - (\varepsilon^2 - 1)^2}{(\varepsilon^2 + 1)^2} = \frac{4\varepsilon^2}{(\varepsilon^2 + 1)^2}.$$

So φ is exactly the kink of Section 5.1, and the Bäcklund parameter ε is nothing but a relabelling of the kink's velocity. We have generated a soliton out of the vacuum, by solving two first-order ODEs.

The obvious next move is to apply the transformation again, to the kink instead of the vacuum, and get a two-soliton solution. This works, but it requires solving another pair of PDEs, and the algebra gets unpleasant. Remarkably, there is a way to avoid it entirely.

§32.6.3 Bianchi Permutability

Suppose we start from a solution φ_0 and apply the Bäcklund transformation twice, with two different parameters ε_1 and ε_2 , in the two possible orders. Write $\varphi_1 = B_{\varepsilon_1}(\varphi_0)$ and $\varphi_2 = B_{\varepsilon_2}(\varphi_0)$. The claim is that we may then choose $B_{\varepsilon_2}(\varphi_1)$ and $B_{\varepsilon_1}(\varphi_2)$ to be the *same* solution φ_{12} – the transformations commute:

This is the **Bianchi permutability theorem**, and its real content is that φ_{12} can be written down *algebraically*, with no integration at all.

Theorem 32.6.5 (Bianchi permutability)

With notation as above,

$$\tan\left(\frac{\varphi_{12} - \varphi_0}{4}\right) = \frac{\varepsilon_1 + \varepsilon_2}{\varepsilon_1 - \varepsilon_2} \tan\left(\frac{\varphi_1 - \varphi_2}{4}\right).$$

Proof. We use only (B1), applied along each of the four edges of the diagram:

$$\begin{aligned} (\varphi_1 - \varphi_0)_\xi &= 2\varepsilon_1 \sin\left(\frac{\varphi_1 + \varphi_0}{2}\right), & (\varphi_2 - \varphi_0)_\xi &= 2\varepsilon_2 \sin\left(\frac{\varphi_2 + \varphi_0}{2}\right), \\ (\varphi_{12} - \varphi_1)_\xi &= 2\varepsilon_2 \sin\left(\frac{\varphi_{12} + \varphi_1}{2}\right), & (\varphi_{12} - \varphi_2)_\xi &= 2\varepsilon_1 \sin\left(\frac{\varphi_{12} + \varphi_2}{2}\right). \end{aligned}$$

Adding the first and third gives an expression for $(\varphi_{12} - \varphi_0)_\xi$; adding the second and fourth gives another. Equating them,

$$\varepsilon_1 \sin\left(\frac{\varphi_1 + \varphi_0}{2}\right) + \varepsilon_2 \sin\left(\frac{\varphi_{12} + \varphi_1}{2}\right) = \varepsilon_2 \sin\left(\frac{\varphi_2 + \varphi_0}{2}\right) + \varepsilon_1 \sin\left(\frac{\varphi_{12} + \varphi_2}{2}\right),$$

that is

$$\varepsilon_1 \left[\sin\left(\frac{\varphi_1 + \varphi_0}{2}\right) - \sin\left(\frac{\varphi_{12} + \varphi_2}{2}\right) \right] = \varepsilon_2 \left[\sin\left(\frac{\varphi_2 + \varphi_0}{2}\right) - \sin\left(\frac{\varphi_{12} + \varphi_1}{2}\right) \right].$$

Now apply $\sin A - \sin B = 2 \cos \frac{A+B}{2} \sin \frac{A-B}{2}$ to each side. The crucial point is that the *same* quantity

$$\frac{A+B}{2} = \frac{\varphi_0 + \varphi_1 + \varphi_2 + \varphi_{12}}{4}$$

appears on both sides, so the cosine factor cancels (generically it is non-zero). We are left with

$$\varepsilon_1 \sin\left(\frac{\varphi_0 + \varphi_1 - \varphi_2 - \varphi_{12}}{4}\right) = \varepsilon_2 \sin\left(\frac{\varphi_0 - \varphi_1 + \varphi_2 - \varphi_{12}}{4}\right).$$

Write

$$P = \frac{\varphi_0 - \varphi_{12}}{4}, \quad Q = \frac{\varphi_1 - \varphi_2}{4},$$

so this reads $\varepsilon_1 \sin(P+Q) = \varepsilon_2 \sin(P-Q)$. Expanding both sides,

$$\varepsilon_1 (\sin P \cos Q + \cos P \sin Q) = \varepsilon_2 (\sin P \cos Q - \cos P \sin Q),$$

so

$$(\varepsilon_1 - \varepsilon_2) \sin P \cos Q = -(\varepsilon_1 + \varepsilon_2) \cos P \sin Q,$$

and dividing,

$$\tan P = -\frac{\varepsilon_1 + \varepsilon_2}{\varepsilon_1 - \varepsilon_2} \tan Q.$$

Since $P = -(\varphi_{12} - \varphi_0)/4$, this is the stated formula. $\square$

This is a genuine **nonlinear superposition principle**. Given the vacuum $\varphi_0 = 0$ and two one-soliton solutions φ_1, φ_2 , it delivers the two-soliton solution

$$\varphi_{12} = 4 \tan^{-1} \left(\frac{\varepsilon_1 + \varepsilon_2}{\varepsilon_1 - \varepsilon_2} \tan \left(\frac{\varphi_1 - \varphi_2}{4} \right) \right)$$

by pure algebra. Iterating produces the whole soliton hierarchy of sine–Gordon: from

φ_{12} and φ_{13} we get φ_{123} , and so on. Every multi-soliton solution of the sine–Gordon equation can be reached this way, starting from nothing.

Example 32.6.6

Take $\varphi_0 = 0$ and two kinks

$$\varphi_j = 4 \tan^{-1}(\exp(\gamma_j(x - v_j t))), \quad j = 1, 2,$$

with parameters $\varepsilon_1, \varepsilon_2$ as above. Writing $E_j = \exp(\gamma_j(x - v_j t))$ and using

$$\tan\left(\frac{\varphi_1 - \varphi_2}{4}\right) = \frac{\tan(\varphi_1/4) - \tan(\varphi_2/4)}{1 + \tan(\varphi_1/4)\tan(\varphi_2/4)} = \frac{E_1 - E_2}{1 + E_1 E_2},$$

the theorem gives the closed form

$$\varphi_{12}(x, t) = 4 \tan^{-1}\left(\frac{\varepsilon_1 + \varepsilon_2}{\varepsilon_1 - \varepsilon_2} \cdot \frac{E_1 - E_2}{1 + E_1 E_2}\right).$$

Depending on the signs and magnitudes of the parameters this describes kink–kink scattering, kink–antikink scattering, or – for complex conjugate ε ’s – the breather of Section 5.1. As with KdV, the only lasting effect of the collision is a phase shift.

Remark. It is no coincidence that we found a nonlinear superposition principle here and a determinant formula for KdV in Section 3.5. Both are shadows of the same underlying structure, and for KdV there is a Bäcklund transformation too, namely

$$w_{1,x} + w_{2,x} = \lambda - \frac{1}{2}(w_1 - w_2)^2$$

relating potentials $u_j = w_{j,x}$. Its Bianchi permutability formula reproduces exactly the N -soliton solutions we obtained from the GLM equation.

§32.7 Symmetry Methods

We finish with a topic which is both older and more general than everything else in this course: the systematic use of symmetry to solve differential equations. This is Lie’s programme, and it was the original reason Sophus Lie invented what we now call Lie groups.

Since differential equations are continuous objects, the symmetries we care about come in continuous families, and to handle these we need groups equipped with a smooth structure.

At this point a reader of applied inclination may be tempted to skip anything with the word ‘group’ in it. It is worth resisting the temptation, and here is a cautionary tale (whose historical accuracy I will not vouch for). In the 1960s Gell-Mann was trying to make sense of the bewildering zoo of apparently fundamental particles. He plotted them according to two quantum numbers, isospin and hypercharge, and obtained the following picture:

Clearly there is a pattern, but it is not at all clear where it comes from or how to extend it. The story goes that a pure mathematician wandered into the physics department, saw the diagram, and asked ‘so you’re interested in the eight-dimensional adjoint representation of $\mathfrak{su}(3)$ too?’. He was not. But the weight diagram of that representation looks exactly like the picture, and once the correspondence between representations of $\mathfrak{su}(3)$ and quantum numbers was understood, the whole subject fell into place.

§32.7.1 Lie Groups and Lie Algebras

We begin by recalling, from IA Groups, what a group is.

Definition 32.7.1 (Group)

A **group** is a set G with a binary operation $(g_1, g_2) \mapsto g_1 g_2$ which is associative, has an identity e , and in which every element has an inverse.

Definition 32.7.2 (Group action)

A group G **acts** on a set X if there is a map $G \times X \rightarrow X$, $(g, x) \mapsto g(x)$, with

$$g(h(x)) = (gh)(x), \quad e(x) = x$$

for all $g, h \in G$ and $x \in X$.

We now want groups whose elements depend smoothly on parameters. The honest definition involves manifolds; we adopt a working version which is really the definition of a *local* Lie group, and which is all we shall need.

Definition 32.7.3 (Lie group)

An **m -dimensional Lie group** is a group whose elements depend continuously on m real parameters, in such a way that the maps $(g_1, g_2) \mapsto g_1 g_2$ and $g \mapsto g^{-1}$ are smooth functions of those parameters.

In practice it is enough to check that $(g_1, g_2) \mapsto g_1 g_2^{-1}$ is smooth. We write elements as $g(\mathbf{t})$ with $\mathbf{t} \in \mathbb{R}^m$, normalised so that $g(\mathbf{0}) = e$.

Example 32.7.4

Every element of $G = \text{SO}(2)$ can be written as

$$g(t) = \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix}, \quad t \in \mathbb{R}.$$

Since $g(t)^{-1} = g(-t)$, we have $g(t_1)g(t_2)^{-1} = g(t_1 - t_2)$, so in terms of parameters the map is $(t_1, t_2) \mapsto t_1 - t_2$, which is smooth. So $\text{SO}(2)$ is a one-dimensional Lie group.

Example 32.7.5 (The Heisenberg group)

Consider the matrices

$$g(\mathbf{t}) = \begin{pmatrix} 1 & t_1 & t_3 \\ 0 & 1 & t_2 \\ 0 & 0 & 1 \end{pmatrix}, \quad \mathbf{t} \in \mathbb{R}^3.$$

Multiplying,

$$g(\mathbf{a})g(\mathbf{b}) = \begin{pmatrix} 1 & a_1 + b_1 & a_3 + b_3 + a_1b_2 \\ 0 & 1 & a_2 + b_2 \\ 0 & 0 & 1 \end{pmatrix},$$

so this is closed under multiplication, and

$$g(\mathbf{b})^{-1} = \begin{pmatrix} 1 & -b_1 & b_1b_2 - b_3 \\ 0 & 1 & -b_2 \\ 0 & 0 & 1 \end{pmatrix}.$$

Combining,

$$(\mathbf{a}, \mathbf{b}) \mapsto (a_1 - b_1, a_2 - b_2, a_3 - b_3 + b_1b_2 - a_1b_2),$$

which is a polynomial, hence smooth. So the **Heisenberg group** is a three-dimensional Lie group.

Lie groups are still complicated. As with flows in Section 1.1, the trick is to look at the infinitesimal picture instead, which is linear and therefore easy. We do this informally, and only for matrix groups, so that we may freely add and differentiate group elements.

Let $A(\varepsilon)$ be a smooth curve in G with $A(0) = I$, and set $a = A'(0)$, so that

$$A(\varepsilon) = I + \varepsilon a + o(\varepsilon).$$

Define $\mathfrak{g}$ to be the set of all such ‘leading order terms’ a . We claim $\mathfrak{g}$ is a vector space, and more.

If $B(\varepsilon) = I + \varepsilon b + o(\varepsilon)$ is another such curve, then $\varepsilon \mapsto A(\varepsilon)B(\varepsilon)$ is a curve in G with

$$A(\varepsilon)B(\varepsilon) = (I + \varepsilon a + o(\varepsilon))(I + \varepsilon b + o(\varepsilon)) = I + \varepsilon(a + b) + o(\varepsilon),$$

so $a + b \in \mathfrak{g}$. And $\varepsilon \mapsto A(\lambda\varepsilon)$ gives $\lambda a \in \mathfrak{g}$ for any $\lambda \in \mathbb{R}$. So $\mathfrak{g}$ is a vector space, which is already interesting: out of a group, with its awkward non-commutative multiplication, we have extracted a vector space.

But there is more. Note first that $A(\varepsilon)^{-1} = I - \varepsilon a + o(\varepsilon)$, since if $A(\varepsilon)^{-1} = I + \varepsilon \tilde{a} + o(\varepsilon)$ then

$$I = A(\varepsilon)A(\varepsilon)^{-1} = I + \varepsilon(a + \tilde{a}) + o(\varepsilon),$$

forcing $\tilde{a} = -a$. Now consider the curve

$$C(\varepsilon) = A(\sqrt{\varepsilon})B(\sqrt{\varepsilon})A(\sqrt{\varepsilon})^{-1}B(\sqrt{\varepsilon})^{-1}.$$

Expanding and keeping track of the second-order terms (which is a slightly fiddly exercise), the first-order terms cancel and one finds

$$C(\varepsilon) = I + \varepsilon(ab - ba) + o(\varepsilon).$$

So $\mathfrak{g}$ is closed under the commutator. The moral is that although the product of two elements infinitesimally close to the identity need not be infinitesimally close in the same sense, the group-theoretic commutator always is.

Definition 32.7.6 (Lie algebra)

A **Lie algebra** is a vector space $\mathfrak{g}$ equipped with a bilinear, antisymmetric bracket $[\cdot, \cdot] : \mathfrak{g} \times \mathfrak{g} \rightarrow \mathfrak{g}$ satisfying the **Jacobi identity**

$$[a, [b, c]] + [b, [c, a]] + [c, [a, b]] = 0.$$

Example 32.7.7

$\mathfrak{g} = \mathbb{R}^3$ with $[\mathbf{a}, \mathbf{b}] = \mathbf{a} \wedge \mathbf{b}$ is a Lie algebra.

Example 32.7.8

Let M be a phase space and $\mathfrak{g}$ the space of smooth functions $M \rightarrow \mathbb{R}$. Then

$$[f, g] = \{f, g\}$$

is a Lie algebra, by the properties of the Poisson bracket in Section 1.2. So Section 1 was secretly about Lie algebras all along.

Example 32.7.9

Let $G = \mathrm{SO}(n) = \{A \in \mathrm{Mat}_n(\mathbb{R}) : AA^T = I, \det A = 1\}$, and let $A(\varepsilon)$ be a curve with $A(0) = I$. Then

$$I = A(\varepsilon)A(\varepsilon)^T = (I + \varepsilon a + o(\varepsilon))(I + \varepsilon a^T + o(\varepsilon)) = I + \varepsilon(a + a^T) + o(\varepsilon),$$

so a must be antisymmetric. The determinant condition gives

$$1 = \det(I + \varepsilon a + o(\varepsilon)) = 1 + \varepsilon \operatorname{tr} a + o(\varepsilon),$$

so $\operatorname{tr} a = 0$, which antisymmetry already guarantees. Conversely every antisymmetric a arises, from the curve $A(t) = \exp(at)$. So

$$\mathfrak{so}(n) = \{a \in \mathrm{Mat}_n(\mathbb{R}) : a + a^T = 0\},$$

and one checks directly that it is closed under the commutator:

$$[a, b]^T = (ab - ba)^T = b^T a^T - a^T b^T = ba - ab = -[a, b].$$

The convention is that a group written in capitals has a Lie algebra written with the same letters in lower-case fraktur: $\mathrm{SO}(n)$ has $\mathfrak{so}(n)$, $\mathrm{SL}(n)$ has $\mathfrak{sl}(n)$, and so on. Choosing a basis $\{a_i\}$ of a finite-dimensional $\mathfrak{g}$, the bracket is determined by the **structure constants** c_{ij}^k in

$$[a_i, a_j] = \sum_k c_{ij}^k a_k.$$

§32.7.2 One-Parameter Groups of Transformations

Ultimately we want groups acting on the space in which our differential equation lives, giving new coordinates $\tilde{\mathbf{x}} = g(\mathbf{x})$. Happily, the action of a whole Lie group can be reduced to the study of one-parameter families, which we already understand from Section 1.1.

Definition 32.7.10 (One-parameter group of transformations)

A smooth family of maps $g^\varepsilon : \mathbb{R}^n \rightarrow \mathbb{R}^n$ is a **one-parameter group of transformations** (1.p.g.t.) if

$$g^0 = \mathrm{id}, \quad g^{\varepsilon_1} g^{\varepsilon_2} = g^{\varepsilon_1 + \varepsilon_2}.$$

It is **generated by** the vector field

$$\mathbf{V}(\mathbf{x}) = \left. \frac{d}{d\varepsilon} (g^\varepsilon \mathbf{x}) \right|_{\varepsilon=0},$$

so that $g^\varepsilon \mathbf{x} = \mathbf{x} + \varepsilon \mathbf{V}(\mathbf{x}) + o(\varepsilon)$. Conversely every vector field generates a 1.p.g.t. by solving

$$\frac{d\tilde{\mathbf{x}}}{d\varepsilon} = \mathbf{V}(\tilde{\mathbf{x}}), \quad \tilde{\mathbf{x}}(0) = \mathbf{x}.$$

This is exactly the flow-map picture of Section 1.1, with ε in place of t . Differential geometers write vector fields in a way that looks odd at first but is extremely convenient.

Notation. A vector field $\mathbf{V} = (V_1, \dots, V_n)^T$ is identified with the differential operator

$$V = V_1 \frac{\partial}{\partial x_1} + \dots + V_n \frac{\partial}{\partial x_n},$$

and we think of the $\partial/\partial x_i$ as a basis. We will freely confuse the two.

Example 32.7.11

The vector field $\mathbf{V} = (x^2 + y, yx)$ is written $V = (x^2 + y)\partial_x + yx\partial_y$.

The reason for the notation is that the commutator becomes literally the commutator of operators. Indeed, computing $(VW - WV)f$ for a test function f ,

$$\begin{aligned} (VW - WV)(f) &= V_j \frac{\partial}{\partial x_j} \left(W_i \frac{\partial f}{\partial x_i} \right) - W_j \frac{\partial}{\partial x_j} \left(V_i \frac{\partial f}{\partial x_i} \right) \\ &= \left(V_j \frac{\partial W_i}{\partial x_j} - W_j \frac{\partial V_i}{\partial x_j} \right) \frac{\partial f}{\partial x_i} + (V_j W_i - W_j V_i) \frac{\partial^2 f}{\partial x_i \partial x_j}, \end{aligned}$$

and the second-derivative terms cancel by symmetry, leaving exactly the commutator of vector fields from Section 1.1. So in this notation

$$[V, W] = VW - WV.$$

Let us see some examples of the correspondence between vector fields and transformations.

Example 32.7.12

Let $V = x\partial_x + \partial_y$. The 1.p.g.t. it generates solves

$$\frac{d\tilde{x}}{d\varepsilon} = \tilde{x}, \quad \frac{d\tilde{y}}{d\varepsilon} = 1, \quad (\tilde{x}(0), \tilde{y}(0)) = (x, y),$$

so

$$g^\varepsilon(x, y) = (xe^\varepsilon, y + \varepsilon).$$

Example 32.7.13

The natural action of $SO(2)$ on $\mathbb{R}^2$ is

$$g^\varepsilon(x, y) = (x \cos \varepsilon - y \sin \varepsilon, x \sin \varepsilon + y \cos \varepsilon),$$

which satisfies $g^0 = \text{id}$ and $g^{\varepsilon_1}g^{\varepsilon_2} = g^{\varepsilon_1+\varepsilon_2}$. Its generator is

$$V = \left. \frac{d\tilde{x}}{d\varepsilon} \right|_0 \partial_x + \left. \frac{d\tilde{y}}{d\varepsilon} \right|_0 \partial_y = -y\partial_x + x\partial_y,$$

which we can draw:

The arrows are tangent to circles about the origin, and grow with the radius, as they should for a rotation.

Example 32.7.14

$V = \alpha\partial_x$ generates $g^\varepsilon x = x + \alpha\varepsilon$, a translation at constant speed; while $V = \beta x\partial_x$ generates $g^\varepsilon x = e^{\beta\varepsilon}x$, an exponential dilation.

The relevance of all this to Lie groups is the following. If a Lie group G acts on $\mathbb{R}^n$, it typically contains many one-parameter subgroups, and any $g(\mathbf{t}) \in G$ sufficiently close to the identity can be written as a product

$$g(\mathbf{t}) = g_{i_1}^{\varepsilon_1} g_{i_2}^{\varepsilon_2} \cdots g_{i_N}^{\varepsilon_N}$$

of elements of such subgroups. So to understand the action of G it suffices to understand its one-parameter subgroups, and to understand those it suffices to understand the vector

fields generating them – that is, the Lie algebra. Once more, the infinitesimal picture is enough.

§32.7.3 Symmetries of Differential Equations

We write a general differential equation as

$$\Delta[\mathbf{x}, u, u_{\mathbf{x}}, u_{\mathbf{x}\mathbf{x}}, \dots] = 0,$$

where Δ may be vector-valued (so that we can handle systems), and a solution is a function $u = u(\mathbf{x})$ satisfying it.

Definition 32.7.15 (Lie point symmetry)

Let g^ε be a 1.p.g.t. generated by a vector field V , acting on both the independent and dependent variables:

$$(\tilde{\mathbf{x}}, \tilde{u}) = g^\varepsilon(\mathbf{x}, u).$$

We call g^ε a **Lie point symmetry** of Δ if

$$\Delta[\mathbf{x}, u, u_{\mathbf{x}}, \dots] = 0 \implies \Delta[\tilde{\mathbf{x}}, \tilde{u}, \tilde{u}_{\tilde{\mathbf{x}}}, \dots] = 0,$$

that is, if it takes solutions to solutions. We say the symmetry is *generated by* V .

Note that we are allowed to mix up the domain and the codomain – the new independent variable may depend on u , and vice versa. This freedom is what makes the theory powerful.

Example 32.7.16

Consider KdV, $\Delta = u_t + u_{xxx} - 6uu_x$. Translation in time,

$$g^\varepsilon(x, t, u) = (x, t + \varepsilon, u),$$

is a Lie point symmetry generated by $V = \partial_t$. Indeed, by the chain rule

$$\frac{\partial \tilde{u}}{\partial \tilde{t}} = \frac{\partial t}{\partial \tilde{t}} \frac{\partial u}{\partial t} + \frac{\partial x}{\partial \tilde{t}} \frac{\partial u}{\partial x} = \frac{\partial u}{\partial t},$$

and similarly $\tilde{u}_{\tilde{x}} = u_x$ and $\tilde{u}_{\tilde{x}\tilde{x}\tilde{x}} = u_{xxx}$, so $\Delta[\tilde{x}, \tilde{t}, \tilde{u}] = \Delta[x, t, u]$.

Symmetries obviously give us new solutions from old ones. Much more importantly, they let us *solve* equations.

Example 32.7.17 (Reduction of a first-order ODE)

Consider the homogeneous ODE

$$\frac{du}{dx} = F\left(\frac{u}{x}\right).$$

Both sides only see the combination u/x , so we should expect

$$g^\varepsilon(x, u) = (e^\varepsilon x, e^\varepsilon u)$$

to be a symmetry, generated by

$$V = x \frac{\partial}{\partial x} + u \frac{\partial}{\partial u}.$$

Now the trick: find coordinates (s, t) in which

$$V(s) = 0, \quad V(t) = 1,$$

so that in the new coordinates $V = \partial_t$. Since the equation is invariant under the flow of V , and the flow is now just translation in t , we expect the variable t not to appear explicitly.

Such coordinates are easy to find here:

$$s = \frac{u}{x}, \quad t = \log |x|,$$

for which $V(s) = x \cdot (-u/x^2) + u \cdot (1/x) = 0$ and $V(t) = x \cdot (1/x) = 1$. Inverting, $x = e^t$ and $u = se^t$. Then

$$du = e^t ds + se^t dt, \quad dx = e^t dt,$$

so

$$\frac{du}{dx} = \frac{ds}{dt} + s.$$

The equation therefore becomes

$$\frac{ds}{dt} = F(s) - s, \quad \text{i.e.} \quad \frac{dt}{ds} = \frac{1}{F(s) - s},$$

which – as promised – contains no t . So we can integrate it up:

$$t = C + \int^s \frac{ds'}{F(s') - s'},$$

and returning to the original variables,

$$\log |x| = C + \int^{u/x} \frac{ds}{F(s) - s}.$$

Knowing a single Lie point symmetry has reduced the ODE to a quadrature.

The same works in general. For an n th order ODE

$$\Delta [x, u, u', \dots, u^{(n)}] = 0$$

admitting a Lie point symmetry generated by

$$V = \xi(x, u) \frac{\partial}{\partial x} + \eta(x, u) \frac{\partial}{\partial u},$$

we introduce invariant coordinates $s = s(x, u)$, $t = t(x, u)$ with $V = \partial_t$. The equation becomes

$$\Delta [s, t', \dots, t^{(n)}] = 0$$

with no explicit t , and setting $r = t'$ reduces the order by one:

$$\Delta [s, r, r', \dots, r^{(n-1)}] = 0.$$

Now rinse and repeat, if we have more symmetries.

§32.7.4 Jets and Prolongations

This is all very well, but so far we have found our symmetries by inspection. We need a systematic method.

Start with the trivial case, a ‘zeroth order equation’ $\Delta[x, u] = 0$. Then g^ε is a symmetry if $\Delta = 0$ implies $\Delta \circ g^\varepsilon = 0$. Provided Δ is of **maximal rank** – meaning the matrix $\partial\Delta_j/\partial y_i$ has maximal rank, where y_i ranges over all the coordinates – one can show (example sheet) that this is equivalent to the infinitesimal condition

$$\Delta = 0 \implies V(\Delta) = 0,$$

where V acts as a differential operator. The maximal rank hypothesis rules out degenerate cases like $\Delta = x^2$, which vanishes only where its derivative does. The implication is only required to hold *on* the solution set, a restriction we call an **on-shell** condition.

This is a wonderful reduction, because the condition $V(\Delta) = 0$ is purely *algebraic* in the coefficients of V . The problem is that a genuine differential equation involves u_x , u_{xx} and so on, and V only knows what to do to x and u . The remedy is to extend its action to the derivatives, which is called *prolongation*.

Example 32.7.18

Take $g^\varepsilon : (x, u) \mapsto (e^\varepsilon x, e^{-\varepsilon} u)$, generated by $V = x\partial_x - u\partial_u$. Then by the chain rule

$$\frac{d\tilde{u}}{d\tilde{x}} = \frac{d\tilde{u}/dx}{d\tilde{x}/dx} = \frac{e^{-\varepsilon}u_x}{e^\varepsilon} = e^{-2\varepsilon}u_x,$$

so the induced transformation on the triple (x, u, u_x) is

$$(\tilde{x}, \tilde{u}, \tilde{u}_{\tilde{x}}) = (e^\varepsilon x, e^{-\varepsilon} u, e^{-2\varepsilon} u_x),$$

which is again a 1.p.g.t., now on a three-dimensional space, generated by

$$\text{pr}^{(1)} V = x \frac{\partial}{\partial x} - u \frac{\partial}{\partial u} - 2u_x \frac{\partial}{\partial u_x}.$$

Repeating for the second derivative gives $\tilde{u}_{\tilde{x}\tilde{x}} = e^{-3\varepsilon}u_{xx}$ and

$$\text{pr}^{(2)} V = x \frac{\partial}{\partial x} - u \frac{\partial}{\partial u} - 2u_x \frac{\partial}{\partial u_x} - 3u_{xx} \frac{\partial}{\partial u_{xx}}.$$

The space with coordinates (x, u, u_x) is called the **first jet space**, and $(x, u, u_x, \dots, u^{(n)})$ the **n th jet space**. Any function $u = u(x)$ determines a curve in it. The operator $\text{pr}^{(n)} V$ above is the **n th prolongation** of V .

If it feels strange to treat u_x as an independent coordinate, one may relabel it p_1 , and $u^{(n)}$ as p_n ; nothing changes. An n th order ODE is then an algebraic equation on the n th jet space, and we are back to the situation we could handle:

$$g^\varepsilon \text{ is a Lie point symmetry } \iff \text{pr}^{(n)} V(\Delta) = 0 \text{ whenever } \Delta = 0.$$

The catch, of course, is that we must restrict attention to points of the jet space which come from actual functions, and to transformations which are prolongations of transformations of the base space.

So we need a formula for the prolongation of an arbitrary vector field. Note how much easier this is at the level of the Lie *algebra*: prolonging the group action would be a horrible mess, whereas prolonging the vector field is a one-line recursion.

Write

$$g^\varepsilon(x, u) = (x + \varepsilon \xi(x, u), u + \varepsilon \eta(x, u)) + o(\varepsilon),$$

and seek the prolongation in the form

$$\text{pr}^{(n)} V = V + \sum_{k=1}^n \eta_k \frac{\partial}{\partial u^{(k)}},$$

so that $\tilde{u}^{(k)} = u^{(k)} + \varepsilon \eta_k + o(\varepsilon)$. To find η_1 we use the **contact condition**

$$d\tilde{u} = \tilde{u}_{\tilde{x}} d\tilde{x},$$

which is nothing but the statement that $\tilde{u}_{\tilde{x}}$ really is the derivative of $\tilde{u}$ with respect to $\tilde{x}$. Substituting the expansions,

$$du + \varepsilon d\eta = \tilde{u}_{\tilde{x}} (dx + \varepsilon d\xi) + o(\varepsilon).$$

We express everything in terms of dx . Since $du = u_x dx$ and

$$d\eta = \frac{\partial \eta}{\partial x} dx + \frac{\partial \eta}{\partial u} du = \left(\frac{\partial \eta}{\partial x} + u_x \frac{\partial \eta}{\partial u} \right) dx = (D_x \eta) dx,$$

with D_x the total derivative of Section 4.1, and similarly $d\xi = (D_x \xi) dx$, we get

$$(u_x + \varepsilon D_x \eta) dx = \tilde{u}_{\tilde{x}} (1 + \varepsilon D_x \xi) dx + o(\varepsilon).$$

Hence

$$\tilde{u}_{\tilde{x}} = \frac{u_x + \varepsilon D_x \eta}{1 + \varepsilon D_x \xi} + o(\varepsilon) = u_x + \varepsilon (D_x \eta - u_x D_x \xi) + o(\varepsilon),$$

so

$$\eta_1 = D_x \eta - u_x D_x \xi.$$

Exactly the same argument applied to the contact condition $d\tilde{u}^{(k)} = \tilde{u}^{(k+1)} d\tilde{x}$ gives the recursion in general.

Proposition 32.7.19 (Prolongation formula)

Let

$$V = \xi(x, u) \frac{\partial}{\partial x} + \eta(x, u) \frac{\partial}{\partial u}.$$

Then

$$\text{pr}^{(n)} V = V + \sum_{k=1}^n \eta_k \frac{\partial}{\partial u^{(k)}},$$

where

$$\eta_0 = \eta, \quad \eta_{k+1} = D_x \eta_k - u^{(k+1)} D_x \xi.$$

Example 32.7.20

For $g^\varepsilon : (x, u) \mapsto (e^\varepsilon x, e^{-\varepsilon} u)$ we have $\xi = x$ and $\eta = -u$, so

$$\eta_1 = D_x(-u) - u_x D_x(x) = -u_x - u_x = -2u_x,$$

in agreement with the direct computation above.

Example 32.7.21 (Checking a symmetry)

Let us verify by this method that $V = x\partial_x + u\partial_u$ is a symmetry of $\Delta = u_x - F(u/x)$. Here $\xi = x$, $\eta = u$, so

$$\eta_1 = D_x(u) - u_x D_x(x) = u_x - u_x = 0,$$

and $\text{pr}^{(1)} V = x\partial_x + u\partial_u$. Applying it,

$$\text{pr}^{(1)} V(\Delta) = x \cdot \left(\frac{u}{x^2} F' \left(\frac{u}{x} \right) \right) + u \cdot \left(-\frac{1}{x} F' \left(\frac{u}{x} \right) \right) + 0 = \frac{u}{x} F' - \frac{u}{x} F' = 0,$$

identically, so it is a symmetry – and not merely on shell.

In general, imposing $\text{pr}^{(n)} V(\Delta) = 0$ on shell produces an over-determined linear system of PDEs for the two unknown functions $\xi(x, u)$ and $\eta(x, u)$, the **determining equations**. These are usually easy to solve, and their solution space is exactly the Lie algebra of symmetries. An analogous formula for PDEs, with several independent variables, appears on the last example sheet.

§32.7.5 Group-Invariant Solutions and ODE Reductions

Symmetries do more than generate new solutions: they let us look for solutions which are themselves invariant.

Suppose a PDE admits a Lie point symmetry generated by V . A solution is **group-invariant** if it is unchanged by the symmetry. To find such solutions we introduce coordinates invariant under V , and look for solutions depending only on those. Since the number of invariant coordinates is one fewer than the number of variables, this reduces the PDE to an equation in one fewer variable – typically an ODE.

Example 32.7.22 (Travelling waves)

The most familiar case. Any translation-invariant equation admits $V = \partial_x + c\partial_t$, whose invariants are $z = x - ct$ and u . Looking for solutions $u = f(z)$ is exactly the travelling-wave ansatz we used for KdV, sine-Gordon and NLS. So all our soliton computations were symmetry reductions.

Example 32.7.23 (Sine-Gordon)

Take sine-Gordon in light-cone coordinates, $u_{xt} = \sin u$. This admits the scaling symmetry

$$g^\varepsilon(x, t, u) = (e^\varepsilon x, e^{-\varepsilon} t, u), \quad V = x\partial_x - t\partial_t.$$

An invariant coordinate is $z = xt$, since $V(z) = xt - tx = 0$; and u itself is invariant. So we look for

$$u(x, t) = F(z), \quad z = xt.$$

Then $u_x = tF'(z)$ and $u_{xt} = F'(z) + xtF''(z) = F' + zF''$, so the PDE becomes the ODE

$$zF'' + F' = \sin F.$$

This does not look like anything standard, but substituting $w = e^{iF}$ transforms it. Writing $F = -i \log w$, we have $F' = -iw'/w$ and $F'' = -i(w''/w - (w')^2/w^2)$, while $\sin F = (w - w^{-1})/2i$. Substituting and simplifying gives

$$\frac{d^2w}{dz^2} = \frac{1}{w} \left(\frac{dw}{dz} \right)^2 - \frac{1}{z} \frac{dw}{dz} + \frac{1}{z} \left(\frac{w^2}{2} - \frac{1}{2} \right),$$

which is the third Painlevé equation with $\alpha = \frac{1}{2}$, $\beta = -\frac{1}{2}$, $\gamma = \delta = 0$.

Example 32.7.24 (KdV)

The KdV equation admits a rather less obvious Lie point symmetry,

$$g^\varepsilon(x, t, u) = \left(x + \varepsilon t + \frac{1}{2}\varepsilon^2, \quad t + \varepsilon, \quad u - \frac{1}{6}\varepsilon \right),$$

generated by

$$V = t \frac{\partial}{\partial x} + \frac{\partial}{\partial t} - \frac{1}{6} \frac{\partial}{\partial u}.$$

(It is a combination of a Galilean boost and a time translation.) Invariant coordinates are

$$z = x - \frac{1}{2}t^2, \quad w = u + \frac{1}{6}t,$$

since $V(z) = t - t = 0$ and $V(w) = -\frac{1}{6} + \frac{1}{6} = 0$. So we seek a solution

$$u(x, t) = -\frac{1}{6}t + w(z).$$

Then

$$u_t = -\frac{1}{6} - tw'(z), \quad u_x = w'(z), \quad u_{xxx} = w'''(z),$$

and substituting into KdV,

$$0 = u_t + u_{xxx} - 6uu_x = -\frac{1}{6} - tw' + w''' - 6\left(-\frac{1}{6}t + w\right)w' = -\frac{1}{6} + w''' - 6ww'.$$

The t 's have cancelled, as they had to: our coordinates were built to be invariant, so nothing non-invariant can survive. Integrating once,

$$w'' - 3w^2 = \frac{1}{6}z + \text{const},$$

and after rescaling w and z and translating z to absorb the constant, this is the first Painlevé equation

$$\frac{d^2W}{dZ^2} = 6W^2 + Z.$$

Both reductions have landed us on a Painlevé equation, and this is not a coincidence.

§32.7.6 The Painlevé Test

Suppose someone hands us a PDE and asks whether it is integrable. We have no definition of integrability to appeal to, but we do have a *necessary condition* which can be checked.

Definition 32.7.25 (Singularity)

A **singularity** of a complex-valued function $w = w(z)$ is a point at which it fails to be analytic.

For a *linear* ODE

$$\frac{d^2w}{dz^2} + p(z)\frac{dw}{dz} + q(z)w = 0,$$

a theorem of complex analysis says that any singularity of a solution must already be a singularity of p or q . In particular the *locations* of the singularities do not depend on the initial conditions.

For nonlinear equations this fails spectacularly. Consider

$$\frac{dw}{dz} + w^2 = 0,$$

whose solution is

$$w(z) = \frac{1}{z - z_0},$$

with z_0 determined by the initial data. The singularity has moved: we call it a **movable** singularity.

Movable singularities are unavoidable in nonlinear problems, but their *type* turns out to be a very sensitive indicator.

Definition 32.7.26 (Painlevé property)

An ODE of the form

$$\frac{d^n w}{dz^n} = F\left(\frac{d^{n-1}w}{dz^{n-1}}, \dots, w, z\right)$$

has the **Painlevé property** if all of its movable singularities are at worst poles.

Example 32.7.27

The equation $w' + w^2 = 0$ has solution $w = (z - z_0)^{-1}$, whose movable singularity is a simple pole. So it has the Painlevé property.

Example 32.7.28

The equation $w' + w^3 = 0$ has solution

$$w(z) = \frac{1}{\sqrt{2(z - z_0)}},$$

whose movable singularity is a branch point, not a pole. So it does not have the Painlevé property.

Painlevé set out to classify all equations of the form

$$\frac{d^2w}{dz^2} = F\left(\frac{dw}{dz}, w, z\right),$$

with F rational, possessing this property. He found fifty of them, up to simple changes of coordinates. Of these, forty-four can be solved in terms of functions already known – elementary functions, elliptic functions, Bessel functions and the like. The remaining six define genuinely new functions, the **Painlevé transcendents**. The first two are

$$\begin{aligned} \text{(PI)} \quad & \frac{d^2w}{dz^2} = 6w^2 + z, \\ \text{(PII)} \quad & \frac{d^2w}{dz^2} = 2w^3 + zw + \alpha, \end{aligned}$$

and the remaining four (PIII)–(PVI) are increasingly baroque rational expressions; PIII is the one that appeared in the sine–Gordon reduction above,

$$\frac{d^2w}{dz^2} = \frac{1}{w} \left(\frac{dw}{dz} \right)^2 + \frac{1}{z} \left(-\frac{dw}{dz} + \alpha w^2 + \beta \right) + \gamma w^3 + \frac{\delta}{w}.$$

Remark. Painlevé was also twice prime minister of France, for nine weeks in 1917 and seven months in 1925. It is not recorded whether this affected his classification.

The connection with our subject is the following.

Conjecture 32.7.29 (Ablowitz–Ramani–Segur, 1980). Every ODE reduction of an integrable PDE has the Painlevé property.

This remains a conjecture, since (as we have said) integrability has no agreed definition; but it has been proved in every setting where a precise definition has been pinned down, and it is overwhelmingly supported by examples. Two of those examples are the reductions we performed in the previous subsection, both of which landed on Painlevé equations.

This gives us a practical test.

The Painlevé test.

- (1) Find all Lie point symmetries of the PDE, using the prolongation formula.
- (2) Compute the corresponding ODE reductions.
- (3) Test each reduction for the Painlevé property.

If any reduction fails, the equation is not integrable. If all of them pass, we have learned nothing definitive – but we have found strong evidence, and in practice a good reason to start hunting for a Lax pair.

That is a fitting place to stop. We began with ODEs, where integrability is completely understood: enough commuting conserved quantities, and the motion is uniform winding on a torus. We end with PDEs, where the corresponding picture is only visible in outline. The KdV equation has its infinitely many conserved quantities, its action–angle variables in the guise of scattering data, and its solitons; but what integrability *is*, in general, remains a question with no satisfactory answer. That there should be so much beautiful and useful mathematics hanging on an undefined term is perhaps the most remarkable feature of the whole subject.

33 Linear Analysis

Linear analysis is what happens when you take the linear algebra you know and let the dimension become infinite. Almost nothing survives unscathed. A linear map need not be continuous. A subspace need not be closed. A bounded sequence need not have a convergent subsequence, and the closed unit ball – that most innocuous of objects – is never compact. The whole edifice of ‘pick a basis and write down a matrix’ collapses, and we need genuinely new tools to replace it.

The tools we get are marvellous. The Hahn–Banach theorem manufactures linear functionals out of thin air, so that a normed space always has a rich supply of them. The Baire category theorem, an almost embarrassingly soft statement about complete metric spaces, yields three of the great theorems of the subject in a single stroke. And in Hilbert space – where we have not just a length but an angle – geometry comes flooding back, and we recover a spectral theorem that would make any linear algebraist feel at home.

This article constitutes my notes for the ‘Linear Analysis’ course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§33.1 Normed Spaces

Throughout this course, $\mathbb{F}$ will denote either $\mathbb{R}$ or $\mathbb{C}$, and all vector spaces will be over $\mathbb{F}$ unless we say otherwise. When a result works for both fields without change we will just write $\mathbb{F}$; when the distinction matters – and it does matter, for instance in the Hahn–Banach theorem – we will be careful to say so.

In IB Linear Algebra we studied vector spaces armed with nothing but their algebraic structure, and for finite-dimensional spaces this was enough: choose a basis, and everything becomes a matrix. In IB Analysis and Topology we studied metric spaces, where we could speak of convergence and continuity but had no algebra to play with. Linear analysis is what you get when you insist on having both at once, in a way that makes them compatible.

§33.1.1 Norms

The compatibility is achieved by the following definition, which is really just an abstraction of ‘length of a vector’ in $\mathbb{R}^n$.

Definition 33.1.1 (Norm)

Let V be a vector space over $\mathbb{F}$. A **norm** on V is a function $\|\cdot\| : V \rightarrow \mathbb{R}$ such that

- (i) (*Positivity*) $\|v\| \geq 0$ for all $v \in V$, with $\|v\| = 0$ if and only if $v = 0$;
- (ii) (*Homogeneity*) $\|\lambda v\| = |\lambda| \|v\|$ for all $\lambda \in \mathbb{F}$ and $v \in V$;
- (iii) (*Triangle inequality*) $\|v + w\| \leq \|v\| + \|w\|$ for all $v, w \in V$.

The pair $(V, \|\cdot\|)$ is called a **normed space**.

If we drop the ‘only if’ in (i), so that non-zero vectors are allowed to have zero length, we get what is called a **seminorm**. Seminorms turn up naturally – for instance $p(f) = |\int_0^1 f|$ on $C[0, 1]$ – and we will meet a very important one in the guise of the Minkowski functional later on.

The first thing to notice is that a norm gives us a metric for free.

Proposition 33.1.2

Let $(V, \|\cdot\|)$ be a normed space. Then $d(v, w) = \|v - w\|$ defines a metric on V .

Proof. Symmetry is homogeneity applied with $\lambda = -1$, and $d(v, w) = 0$ if and only if $v - w = 0$ by positivity. The triangle inequality for d reads $\|v - w\| \leq \|v - u\| + \|u - w\|$, which is the triangle inequality for the norm applied to $(v - u) + (u - w)$. $\square$

So all of the language of IB Analysis and Topology is available to us: open balls

$$B(v, r) = \{w \in V : \|v - w\| < r\}, \quad \bar{B}(v, r) = \{w \in V : \|v - w\| \leq r\},$$

open and closed sets, convergence, continuity, completeness, compactness. We will write B_V for the open unit ball $B(0, 1)$ and $\bar{B}_V$ for the closed unit ball when the space needs emphasising.

This metric is not just any old metric: it interacts well with the vector space structure. It is *translation invariant*, $d(v + u, w + u) = d(v, w)$, and it *scales*, $d(\lambda v, \lambda w) = |\lambda|d(v, w)$. In particular every ball is a translated dilate of the unit ball,

$$B(v, r) = v + rB_V,$$

so that the geometry of a normed space is completely determined by the shape of its unit ball. This is a genuinely useful principle, and worth keeping in mind.

Proposition 33.1.3

In a normed space V , the maps $+: V \times V \rightarrow V$ and $\cdot: \mathbb{F} \times V \rightarrow V$ are continuous, and so is $\|\cdot\|: V \rightarrow \mathbb{R}$.

Proof. If $\|v - v'\|, \|w - w'\| < \varepsilon/2$ then $\|(v + w) - (v' + w')\| < \varepsilon$, giving continuity of addition. For scalar multiplication, we compute

$$\|\lambda v - \mu w\| \leq |\lambda| \|v - w\| + |\lambda - \mu| \|w\|,$$

which is small when λ is close to μ and v close to w . Finally the reverse triangle inequality

$$|\|v\| - \|w\|| \leq \|v - w\|$$

shows that the norm is 1-Lipschitz, hence continuous. $\square$

The reverse triangle inequality above is worth recording separately – we will use it constantly. It follows from $\|v\| \leq \|v - w\| + \|w\|$ and the same with v, w swapped.

§33.1.2 Examples of Normed Spaces

Let’s look at some examples. The whole subject would be rather empty without a good stock of these, and most of the theorems we prove will be tested against this list.

Example 33.1.4 (Finite-dimensional ℓ^p norms)

On $\mathbb{F}^n$, for $1 \leq p < \infty$, define

$$\|x\|_p = \left(\sum_{i=1}^n |x_i|^p \right)^{1/p}, \quad \|x\|_\infty = \max_{1 \leq i \leq n} |x_i|.$$

The case $p = 2$ is the usual Euclidean norm. We write ℓ_p^n for $\mathbb{F}^n$ equipped with $\|\cdot\|_p$.

Positivity and homogeneity are clear. The triangle inequality for $p = 1$ and $p = \infty$ is immediate, and for general p it is Minkowski's inequality, which we prove below.

Since the geometry of a normed space is the geometry of its unit ball, it is worth seeing what these unit balls actually look like. In $\mathbb{R}^2$ we get a diamond, a disc and a square.

As p increases from 1 to ∞ the unit ball swells continuously from the diamond out to the square, always staying convex and always containing the same four points $(\pm 1, 0)$, $(0, \pm 1)$. (Convexity of the ball is exactly the triangle inequality: if $\|v\|, \|w\| \leq 1$ and $t \in [0, 1]$ then $\|tv + (1-t)w\| \leq t + (1-t) = 1$. This is why $\|\cdot\|_p$ is *not* a norm for $p < 1$ – the ‘ball’ becomes a four-pointed star, and it is not convex.)

The curves drawn are $p = 1, \frac{3}{2}, 2, 4, \infty$, and they nest outwards as p increases.

Before we can prove Minkowski's inequality we need Hölder's, which is one of the workhorses of the subject. We say that $p, q \in [1, \infty]$ are **conjugate exponents** if

$$\frac{1}{p} + \frac{1}{q} = 1,$$

with the convention $1/\infty = 0$, so that 1 and ∞ are conjugate to each other and 2 is conjugate to itself.

Lemma 33.1.5 (Young's Inequality)

Let $p, q \in (1, \infty)$ be conjugate. Then for all $a, b \geq 0$,

$$ab \leq \frac{a^p}{p} + \frac{b^q}{q}.$$

Proof. If a or b is zero this is clear, so assume both are positive. The logarithm is concave, so

$$\log\left(\frac{a^p}{p} + \frac{b^q}{q}\right) \geq \frac{1}{p} \log(a^p) + \frac{1}{q} \log(b^q) = \log a + \log b = \log(ab),$$

and we exponentiate. $\square$

Proposition 33.1.6 (Hölder's Inequality)

Let $p, q \in [1, \infty]$ be conjugate exponents. Then for $x, y \in \mathbb{F}^n$,

$$\sum_{i=1}^n |x_i y_i| \leq \|x\|_p \|y\|_q.$$

Proof. The cases $p = 1, q = \infty$ (and vice versa) are immediate, since $\sum |x_i y_i| \leq (\max_i |y_i|) \sum_i |x_i|$. So suppose $1 < p < \infty$. If either x or y is zero there is nothing to prove; otherwise, by homogeneity we may rescale and assume $\|x\|_p = \|y\|_q = 1$. Then Young's inequality gives

$$\sum_{i=1}^n |x_i y_i| \leq \sum_{i=1}^n \left(\frac{|x_i|^p}{p} + \frac{|y_i|^q}{q} \right) = \frac{1}{p} + \frac{1}{q} = 1 = \|x\|_p \|y\|_q,$$

as required. $\square$

Proposition 33.1.7 (Minkowski's Inequality)

Let $1 \leq p \leq \infty$. Then for $x, y \in \mathbb{F}^n$,

$$\|x + y\|_p \leq \|x\|_p + \|y\|_p.$$

Proof. Again $p = 1, \infty$ are clear, so take $1 < p < \infty$ and let q be conjugate to p . We may assume $\|x + y\|_p \neq 0$. Then

$$\begin{aligned} \|x + y\|_p^p &= \sum_{i=1}^n |x_i + y_i| \cdot |x_i + y_i|^{p-1} \\ &\leq \sum_{i=1}^n |x_i| \cdot |x_i + y_i|^{p-1} + \sum_{i=1}^n |y_i| \cdot |x_i + y_i|^{p-1} \\ &\leq (\|x\|_p + \|y\|_p) \left(\sum_{i=1}^n |x_i + y_i|^{(p-1)q} \right)^{1/q}, \end{aligned}$$

using Hölder on each sum. Since $(p-1)q = p$, the last bracket is $\|x + y\|_p^{p/q}$. Dividing through by $\|x + y\|_p^{p/q}$ and noting $p - p/q = 1$ gives the result. $\square$

Exactly the same arguments work for infinite sums and for integrals, and we will use them in those settings without further comment.

Example 33.1.8 (Sequence spaces)

For $1 \leq p < \infty$ let

$$\ell^p = \left\{ x = (x_1, x_2, \dots) : x_i \in \mathbb{F}, \sum_{i=1}^{\infty} |x_i|^p < \infty \right\}, \quad \|x\|_p = \left(\sum_{i=1}^{\infty} |x_i|^p \right)^{1/p},$$

and let

$$\ell^\infty = \left\{ x : \sup_i |x_i| < \infty \right\}, \quad \|x\|_\infty = \sup_i |x_i|.$$

Minkowski's inequality (applied to partial sums and passing to the limit) shows both that ℓ^p is a vector space and that $\|\cdot\|_p$ is a norm on it.

Inside ℓ^∞ sit two further spaces which will be useful for producing counterexamples:

$$c_0 = \{x : x_i \rightarrow 0\}, \quad c_{00} = \{x : x_i = 0 \text{ for all but finitely many } i\}.$$

We give both the $\|\cdot\|_\infty$ norm. Note $c_{00} \subseteq c_0 \subseteq \ell^\infty$, and in fact c_{00} is dense in c_0 but not in ℓ^∞ .

Example 33.1.9 (Spaces of continuous functions)

Let K be a compact topological space (usually for us a closed bounded subset of $\mathbb{R}^n$, or a compact metric space). Write

$$C(K) = \{f : K \rightarrow \mathbb{F} \text{ continuous}\}, \quad \|f\|_\infty = \sup_{x \in K} |f(x)|.$$

The supremum is finite because a continuous function on a compact space is bounded, and it is attained. This is called the **uniform** or **supremum norm**, and convergence in it is exactly uniform convergence, as studied in IB Analysis and Topology.

More generally, for any set S we may take $B(S)$, the space of all bounded functions $S \rightarrow \mathbb{F}$, with the same norm.

Example 33.1.10 (L^p spaces)

For $1 \leq p < \infty$ define on $C[0, 1]$ the norm

$$\|f\|_{L^p} = \left(\int_0^1 |f(x)|^p dx \right)^{1/p}.$$

The integral version of Minkowski's inequality gives the triangle inequality, and $\|f\|_{L^p} = 0$ forces $f = 0$ because a non-zero continuous function is bounded away from zero on some interval. So this is a norm.

It is, however, a rather badly behaved one: as we will see, $(C[0, 1], \|\cdot\|_{L^p})$ is not complete. One writes $L^p[0, 1]$ for its completion. In IID Probability and Measure you will see that this completion can be described concretely as the space of p -integrable measurable functions modulo equality almost everywhere, but we will not need that here – for us L^p is simply ‘the completion of the continuous functions’.

Example 33.1.11 (Subspaces and products)

Any linear subspace W of a normed space V is a normed space with the restricted norm. If V, W are normed spaces then $V \oplus W$ becomes one via, say, $\|(v, w)\| = \|v\|_V + \|w\|_W$, and the topology this induces is the product topology.

There is one more construction we will want, and it is a little less obvious.

Proposition 33.1.12 (Quotient norm)

Let V be a normed space and $W \subseteq V$ a *closed* subspace. Then

$$\|v + W\|_{V/W} = \inf_{w \in W} \|v + w\| = \text{dist}(v, W)$$

defines a norm on the quotient vector space V/W .

Proof. Homogeneity and the triangle inequality are straightforward: for the latter, given $\varepsilon > 0$ pick $w_1, w_2 \in W$ with $\|v_i + w_i\| \leq \|v_i + W\| + \varepsilon$, and then $\|(v_1 + v_2) + (w_1 + w_2)\| \leq \|v_1 + W\| + \|v_2 + W\| + 2\varepsilon$.

For positivity, suppose $\|v + W\| = 0$. Then there are $w_n \in W$ with $\|v + w_n\| \rightarrow 0$, so $-w_n \rightarrow v$, and since W is closed we get $v \in W$, i.e. $v + W = 0$ in V/W . This is exactly where closedness is needed: without it we would only get a seminorm. $\square$

§33.1.3 Completeness and Banach Spaces

The single most important extra hypothesis in this course is completeness. Recall from IB Analysis and Topology that a metric space is complete if every Cauchy sequence converges.

Definition 33.1.13 (Banach space)

A normed space which is complete in the induced metric is called a **Banach space**.

Completeness is what lets us construct things: we build a candidate solution as a limit of approximations, and completeness guarantees that the limit exists. Almost every theorem in this course that produces something out of nothing uses completeness somewhere.

Let’s check our examples.

Proposition 33.1.14

For any set S , the space $B(S)$ of bounded functions $S \rightarrow \mathbb{F}$ with the supremum norm is a Banach space. Consequently so is $C(K)$ for K compact, and so is ℓ^∞ .

Proof. Let (f_n) be Cauchy in $B(S)$. For each fixed $x \in S$ we have $|f_n(x) - f_m(x)| \leq \|f_n - f_m\|_\infty$, so $(f_n(x))$ is Cauchy in $\mathbb{F}$ and therefore converges; call the limit $f(x)$.

Given $\varepsilon > 0$, choose N with $\|f_n - f_m\|_\infty < \varepsilon$ for $n, m \geq N$. Fixing $n \geq N$ and $x \in S$ and letting $m \rightarrow \infty$ in $|f_n(x) - f_m(x)| < \varepsilon$ gives $|f_n(x) - f(x)| \leq \varepsilon$. As x was arbitrary, $\|f_n - f\|_\infty \leq \varepsilon$ for all $n \geq N$. In particular f is bounded (being within ε of the bounded function f_N) and $f_n \rightarrow f$ in $B(S)$.

For $C(K)$: it is a subspace of $B(K)$, and a closed one, because a uniform limit of continuous functions is continuous. A closed subspace of a complete space is complete. Finally $\ell^\infty = B(\mathbb{N})$. $\square$

Proposition 33.1.15

For $1 \leq p < \infty$, ℓ^p is a Banach space. So are c_0 and c (the space of convergent sequences), with the supremum norm.

Proof. Let $(x^{(n)})$ be Cauchy in ℓ^p . For each coordinate i we have $|x_i^{(n)} - x_i^{(m)}| \leq \|x^{(n)} - x^{(m)}\|_p$, so each coordinate sequence is Cauchy in $\mathbb{F}$; let $x_i = \lim_n x_i^{(n)}$ and $x = (x_1, x_2, \dots)$.

Let $\varepsilon > 0$ and pick N with $\|x^{(n)} - x^{(m)}\|_p < \varepsilon$ for $n, m \geq N$. For any fixed $K \in \mathbb{N}$ and $n, m \geq N$,

$$\sum_{i=1}^K |x_i^{(n)} - x_i^{(m)}|^p < \varepsilon^p.$$

Letting $m \rightarrow \infty$ (a finite sum, so no issue) gives $\sum_{i=1}^K |x_i^{(n)} - x_i|^p \leq \varepsilon^p$, and now letting $K \rightarrow \infty$ gives $\|x^{(n)} - x\|_p \leq \varepsilon$. In particular $x^{(n)} - x \in \ell^p$, so $x = x^{(n)} - (x^{(n)} - x) \in \ell^p$, and $x^{(n)} \rightarrow x$.

For c_0 and c : both are subspaces of ℓ^∞ , and both are closed, since a uniform limit of sequences tending to 0 tends to 0, and a uniform limit of convergent sequences is convergent (this is the same interchange-of-limits argument as for continuity). $\square$

Example 33.1.16 (An incomplete normed space)

The space c_{00} of finitely supported sequences with $\|\cdot\|_\infty$ is *not* complete. Indeed take

$$x^{(n)} = (1, \frac{1}{2}, \frac{1}{3}, \dots, \frac{1}{n}, 0, 0, \dots).$$

Then $\|x^{(n)} - x^{(m)}\|_\infty = 1/(\min(n, m) + 1) \rightarrow 0$, so the sequence is Cauchy, but the only possible limit is $(1, \frac{1}{2}, \frac{1}{3}, \dots)$, which is not in c_{00} . The point is that c_{00} is a dense but proper subspace of c_0 .

Example 33.1.17 ($C[0, 1]$ with the L^1 norm is incomplete)

Consider the continuous functions

$$f_n(x) = \begin{cases} 0 & 0 \leq x \leq \frac{1}{2}, \\ n(x - \frac{1}{2}) & \frac{1}{2} \leq x \leq \frac{1}{2} + \frac{1}{n}, \\ 1 & \frac{1}{2} + \frac{1}{n} \leq x \leq 1. \end{cases}$$

For $m > n$ we have $\|f_n - f_m\|_{L^1} \leq 1/n \rightarrow 0$, so (f_n) is Cauchy. If $f_n \rightarrow f$ in L^1 with f continuous, then on $[0, \frac{1}{2}]$ we would need $\int_0^{1/2} |f| = 0$, so $f \equiv 0$ there, and on $[\frac{1}{2} + \delta, 1]$ we would need $f \equiv 1$ for every $\delta > 0$. No continuous function does both. So $(C[0, 1], \|\cdot\|_{L^1})$ is not complete.

§33.1.4 Series in Normed Spaces

In a normed space we can add up infinitely many vectors, provided the partial sums converge. It turns out that the interaction between two natural notions of convergence for series characterises completeness exactly, which is a pleasant surprise and often the most convenient way to check that a space is Banach.

Definition 33.1.18 (Convergence of series)

Let V be a normed space and (v_n) a sequence in V . We say $\sum_{n=1}^{\infty} v_n$ **converges** to $v \in V$ if the partial sums $s_N = \sum_{n=1}^N v_n$ satisfy $s_N \rightarrow v$. We say the series is **absolutely convergent** if $\sum_{n=1}^{\infty} \|v_n\| < \infty$.

In $\mathbb{R}$, absolute convergence implies convergence, and the proof uses the completeness of $\mathbb{R}$ in an essential way. The same is true in any Banach space, and conversely.

Theorem 33.1.19 (Series criterion for completeness)

A normed space V is a Banach space if and only if every absolutely convergent series in V converges.

Proof. ($\Rightarrow$) Suppose V is complete and $\sum \|v_n\| < \infty$. For $M > N$,

$$\|s_M - s_N\| = \left\| \sum_{n=N+1}^M v_n \right\| \leq \sum_{n=N+1}^M \|v_n\| \leq \sum_{n>N} \|v_n\|,$$

which tends to 0 as $N \rightarrow \infty$ since the tail of a convergent series of reals tends to zero. So (s_N) is Cauchy, hence convergent.

($\Leftarrow$) Suppose every absolutely convergent series converges, and let (x_n) be a Cauchy sequence in V . Choose a subsequence as follows: pick $n_1 < n_2 < \dots$ such that

$$\|x_n - x_m\| < 2^{-k} \quad \text{for all } n, m \geq n_k.$$

Set $v_1 = x_{n_1}$ and $v_k = x_{n_k} - x_{n_{k-1}}$ for $k \geq 2$, so that $\sum_{k=1}^K v_k = x_{n_K}$. Then $\|v_k\| < 2^{-(k-1)}$ for $k \geq 2$, so $\sum \|v_k\| < \infty$ and by hypothesis $\sum v_k$ converges, i.e. $x_{n_K} \rightarrow x$ for some $x \in V$.

Finally, a Cauchy sequence with a convergent subsequence converges: given $\varepsilon > 0$, take N with $\|x_n - x_m\| < \varepsilon/2$ for $n, m \geq N$ and K with $n_K \geq N$ and $\|x_{n_K} - x\| < \varepsilon/2$; then $\|x_n - x\| < \varepsilon$ for $n \geq N$. $\square$

Remark. The subsequence trick in the second half is worth remembering in its own right: *every Cauchy sequence has a rapidly Cauchy subsequence*, one where the successive differences are summable. It reappears in measure theory and in the proof of the open mapping theorem.

Here is a typical application, which also gives us a supply of Banach spaces we did not have before.

Proposition 33.1.20

Let V be a Banach space and $W \subseteq V$ a closed subspace. Then W and V/W are both Banach spaces.

Proof. That W is complete is standard (a closed subset of a complete metric space is complete). For V/W we use the series criterion. Let $\sum_n \|v_n + W\| < \infty$. For each n pick $w_n \in W$ with

$$\|v_n + w_n\| \leq \|v_n + W\| + 2^{-n}.$$

Then $\sum_n \|v_n + w_n\| < \infty$, so by completeness of V the series $\sum_n (v_n + w_n)$ converges to some $v \in V$. Since the quotient map $q : V \rightarrow V/W$ satisfies $\|q(u)\| \leq \|u\|$, it is continuous, and hence

$$\sum_{n=1}^N (v_n + W) = q \left(\sum_{n=1}^N (v_n + w_n) \right) \rightarrow q(v)$$

as $N \rightarrow \infty$. So the series converges in V/W . $\square$

§33.1.5 Completions

We remarked above that $L^p[0, 1]$ is ‘the completion’ of $C[0, 1]$. Let us make sure that makes sense.

Theorem 33.1.21 (Completion)

Let V be a normed space. Then there is a Banach space $\bar{V}$ and a linear isometry $\iota : V \rightarrow \bar{V}$ with $\iota(V)$ dense in $\bar{V}$. Moreover $\bar{V}$ is unique up to isometric isomorphism.

Proof sketch. One route is the standard metric space completion from IB Analysis and Topology: take Cauchy sequences in V modulo the equivalence $(x_n) \sim (y_n)$ iff $\|x_n - y_n\| \rightarrow 0$. The vector space operations and the norm $\|[(x_n)]\| = \lim_n \|x_n\|$ descend to this set, and one checks the axioms.

A slicker route, available once we have the Hahn–Banach theorem, is to embed V isometrically into the Banach space $\ell^\infty(\bar{B}_{V^*})$ and take the closure of the image; we will see this idea again when we discuss the double dual.

Uniqueness: if $\iota_1 : V \rightarrow X_1$ and $\iota_2 : V \rightarrow X_2$ are two such, then $\iota_2 \circ \iota_1^{-1}$ is an isometry defined on the dense subspace $\iota_1(V)$ of X_1 , and a uniformly continuous map into a complete space extends uniquely to the closure. $\square$

We will use completions sparingly, but it is comforting to know they exist: it means that when we prove a theorem about Banach spaces, we have not narrowed our attention as much as it might appear.

§33.1.6 Finite-Dimensional Spaces

Finite-dimensional normed spaces are, from the point of view of this course, thoroughly boring – and it is worth understanding exactly *how* boring, because that tells us what to expect (or rather, what not to expect) in infinite dimensions. The headline is that a finite-dimensional space has essentially only one norm.

Definition 33.1.22 (Equivalent norms)

Two norms $\|\cdot\|_a$ and $\|\cdot\|_b$ on a vector space V are **equivalent** if there is a constant $C \geq 1$ with

$$C^{-1} \|v\|_b \leq \|v\|_a \leq C \|v\|_b \quad \text{for all } v \in V.$$

This is an equivalence relation, and equivalent norms have the same open sets, the same convergent sequences, the same Cauchy sequences and the same compact sets – essentially, everything we care about is unaffected.

Theorem 33.1.23 (Equivalence of norms in finite dimensions)

Let V be a finite-dimensional vector space over $\mathbb{F}$. Then any two norms on V are equivalent.

Proof. Fix a basis $e_1, \dots, e_n$ of V and let $\|\cdot\|_1$ denote the associated ℓ^1 norm, $\|\sum_i \lambda_i e_i\|_1 = \sum_i |\lambda_i|$. Since equivalence is transitive, it suffices to show that an arbitrary norm $\|\cdot\|$ is equivalent to $\|\cdot\|_1$.

One direction is easy: writing $v = \sum_i \lambda_i e_i$,

$$\|v\| \leq \sum_{i=1}^n |\lambda_i| \|e_i\| \leq C \|v\|_1, \quad C := \max_i \|e_i\|,$$

which is finite as it is a maximum over a finite set.

For the other direction, let $S = \{v \in V : \|v\|_1 = 1\}$. The inequality just proved shows that $\|\cdot\| : (V, \|\cdot\|_1) \rightarrow \mathbb{R}$ is continuous, since

$$|\|v\| - \|w\|| \leq \|v - w\| \leq C \|v - w\|_1.$$

Also S is compact in $(V, \|\cdot\|_1)$: identifying V with $\mathbb{F}^n$ via the basis, S is the unit

sphere of ℓ_1^n , which is closed and bounded, hence compact by Bolzano–Weierstrass (applied coordinate by coordinate, extracting subsequences n times).

Therefore $\|\cdot\|$ attains its infimum on S , say at v_* . Since $v_* \in S$ we have $v_* \neq 0$, so $c := \|v_*\| > 0$, and $\|v\| \geq c$ for all $v \in S$. For general $v \neq 0$, applying this to $v/\|v\|_1 \in S$ gives $\|v\| \geq c\|v\|_1$. Taking $\max(C, c^{-1})$ finishes the proof. $\square$

Several pleasant consequences follow immediately.

Corollary 33.1.24

Let V be a finite-dimensional normed space. Then:

- (i) V is a Banach space;
- (ii) the closed unit ball $\bar{B}_V$ is compact;
- (iii) any linear map from V to a normed space W is continuous;
- (iv) any finite-dimensional subspace of a normed space is closed.

Proof. By the theorem we may compute in ℓ_1^n , which is complete and in which closed bounded sets are compact; this gives (i) and (ii). For (iii), if $T : V \rightarrow W$ is linear then $\|v\|' := \|v\|_V + \|Tv\|_W$ is a norm on V , hence equivalent to $\|\cdot\|_V$, so $\|Tv\|_W \leq \|v\|' \leq C\|v\|_V$; and a linear map satisfying such a bound is continuous, as we check in the next section. For (iv), a complete subspace of a metric space is closed. $\square$

Part (ii) is the interesting one, because it turns out to *characterise* finite dimensionality. The key is the following geometric lemma, which says that from any proper closed subspace we can always step almost perpendicularly away.

Lemma 33.1.25 (Riesz's Lemma)

Let X be a normed space and $Y \subsetneq X$ a closed proper subspace. Then for every $\theta \in (0, 1)$ there exists $x \in X$ with $\|x\| = 1$ and

$$\text{dist}(x, Y) = \inf_{y \in Y} \|x - y\| \geq \theta.$$

Proof. Pick any $z \in X \setminus Y$. Since Y is closed, $d := \text{dist}(z, Y) > 0$. As $\theta < 1$ we have $d < d/\theta$, so by definition of the infimum there is some $y_0 \in Y$ with

$$d \leq \|z - y_0\| \leq \frac{d}{\theta}.$$

Set

$$x = \frac{z - y_0}{\|z - y_0\|},$$

so $\|x\| = 1$. For any $y \in Y$,

$$\|x - y\| = \frac{1}{\|z - y_0\|} \|z - y_0 - \|z - y_0\| y\| = \frac{\|z - y'\|}{\|z - y_0\|}$$

where $y' = y_0 + \|z - y_0\| y \in Y$. Hence $\|z - y'\| \geq d$, and so

$$\|x - y\| \geq \frac{d}{\|z - y_0\|} \geq \frac{d}{d/\theta} = \theta,$$

as required. $\square$

Geometrically, we take a point z off the subspace, find a point $y_0 \in Y$ that very nearly realises the distance from z to Y , and then rescale the difference to have length one. The resulting unit vector sticks out of Y by almost its full length.

Theorem 33.1.26 (Riesz)

Let X be a normed space. Then the closed unit ball $\bar{B}_X$ is compact if and only if X is finite-dimensional.

Proof. We have already seen $(\Leftarrow)$. For $(\Rightarrow)$, suppose X is infinite-dimensional. We build a sequence (x_n) of unit vectors with $\|x_n - x_m\| \geq \frac{1}{2}$ for $n \neq m$; such a sequence has no convergent subsequence, so $\bar{B}_X$ is not (sequentially, hence not) compact.

Take any unit vector x_1 . Having chosen $x_1, \dots, x_n$, let $Y_n = \text{span}\{x_1, \dots, x_n\}$. This is finite-dimensional, hence closed, and it is proper because X is infinite-dimensional. By Riesz's lemma with $\theta = \frac{1}{2}$ there is a unit vector x_{n+1} with $\text{dist}(x_{n+1}, Y_n) \geq \frac{1}{2}$, and in particular $\|x_{n+1} - x_j\| \geq \frac{1}{2}$ for all $j \leq n$. $\square$

Example 33.1.27

In ℓ^p (any $1 \leq p \leq \infty$) the standard unit vectors $e_n = (0, \dots, 0, 1, 0, \dots)$ satisfy $\|e_n\|_p = 1$ and $\|e_n - e_m\|_p = 2^{1/p}$ for $n \neq m$ (interpreted as 1 when $p = \infty$). So we can see the failure of compactness with our bare hands, without invoking Riesz's lemma.

This is the first genuinely infinite-dimensional phenomenon we have met, and it is a serious one. In $\mathbb{R}^n$, 'closed and bounded' is the same as 'compact', and compactness is what makes extremal problems solvable – continuous functions attain their bounds, sequences have convergent subsequences. In infinite dimensions all of that is gone. A great deal of this course consists of finding substitutes.

§33.2 Bounded Linear Operators

Having set up our objects, we now turn to the maps between them. In linear algebra the maps of interest were the linear ones; here we want them to be linear *and* continuous. The pleasant surprise is that for linear maps, continuity has a very concrete reformulation.

33.2.1 Boundedness and the Operator Norm

Definition 33.2.1 (Bounded linear map)

Let X, Y be normed spaces. A linear map $T : X \rightarrow Y$ is **bounded** if there is a constant $C \geq 0$ with

$$\|Tx\|_Y \leq C \|x\|_X \quad \text{for all } x \in X.$$

We write $\mathcal{B}(X, Y)$ for the set of bounded linear maps $X \rightarrow Y$, and $\mathcal{B}(X) = \mathcal{B}(X, X)$.

Note that ‘bounded’ here does *not* mean ‘has bounded image’ – no non-zero linear map has bounded image. It means ‘bounded on the unit ball’, which by linearity is the same as the displayed condition.

Proposition 33.2.2

Let $T : X \rightarrow Y$ be linear. The following are equivalent:

- (i) T is continuous;
- (ii) T is continuous at 0;
- (iii) T is bounded;
- (iv) T is Lipschitz.

Proof. (i) $\Rightarrow$ (ii) is trivial and (iv) $\Rightarrow$ (i) is standard.

(ii) $\Rightarrow$ (iii). By continuity at 0 there is $\delta > 0$ such that $\|x\| \leq \delta$ implies $\|Tx\| \leq 1$. For general $x \neq 0$, apply this to $\delta x / \|x\|$ to get $\|Tx\| \leq \delta^{-1} \|x\|$.

(iii) $\Rightarrow$ (iv). If $\|Tx\| \leq C \|x\|$ then $\|Tx - Tx'\| = \|T(x - x')\| \leq C \|x - x'\|$. $\square$

So continuity is a purely quantitative matter, and we may as well keep track of the best constant.

Definition 33.2.3 (Operator norm)

For $T \in \mathcal{B}(X, Y)$, the **operator norm** of T is

$$\|T\| = \sup_{x \neq 0} \frac{\|Tx\|_Y}{\|x\|_X} = \sup_{\|x\| \leq 1} \|Tx\|_Y = \sup_{\|x\|=1} \|Tx\|_Y.$$

The three expressions agree by homogeneity (the last requires $X \neq \{0\}$). By construction $\|Tx\| \leq \|T\| \|x\|$, and $\|T\|$ is the least constant with this property.

Proposition 33.2.4

$\mathcal{B}(X, Y)$ is a vector space and $\|\cdot\|$ is a norm on it. Moreover if $T \in \mathcal{B}(X, Y)$ and $S \in \mathcal{B}(Y, Z)$ then $ST \in \mathcal{B}(X, Z)$ with

$$\|ST\| \leq \|S\| \|T\|.$$

Proof. If $\|T\| = 0$ then $Tx = 0$ for all x , so $T = 0$. Homogeneity is clear, and for the triangle inequality,

$$\|(S + T)x\| \leq \|Sx\| + \|Tx\| \leq (\|S\| + \|T\|) \|x\|,$$

so $\|S + T\| \leq \|S\| + \|T\|$. Finally $\|STx\| \leq \|S\| \|Tx\| \leq \|S\| \|T\| \|x\|$. $\square$

The last inequality says that $\mathcal{B}(X)$ is a **normed algebra**: it is an algebra under composition, and the norm is submultiplicative. If X is a Banach space it is a **Banach algebra**, by the next result.

Theorem 33.2.5

If Y is a Banach space then $\mathcal{B}(X, Y)$ is a Banach space, for any normed space X .

Proof. Let (T_n) be Cauchy in $\mathcal{B}(X, Y)$. For each $x \in X$,

$$\|T_n x - T_m x\| \leq \|T_n - T_m\| \|x\|,$$

so $(T_n x)$ is Cauchy in Y , hence converges; define $Tx = \lim_n T_n x$. The map T is linear, being a pointwise limit of linear maps.

Cauchy sequences are bounded, say $\|T_n\| \leq M$; then $\|Tx\| = \lim_n \|T_n x\| \leq M \|x\|$, so T is bounded.

Finally, given $\varepsilon > 0$ take N with $\|T_n - T_m\| < \varepsilon$ for $n, m \geq N$. For $\|x\| \leq 1$ and $n \geq N$,

$$\|T_n x - Tx\| = \lim_{m \rightarrow \infty} \|T_n x - T_m x\| \leq \varepsilon,$$

and taking the supremum over such x gives $\|T_n - T\| \leq \varepsilon$. So $T_n \rightarrow T$ in operator norm. $\square$

Note carefully that completeness of X played no role. This is a recurring theme: it is the *target* that needs to be complete.

Example 33.2.6 (i) Let $X = \ell^p$ and let $\lambda = (\lambda_n)$ be a bounded sequence. The **diagonal operator** $M_\lambda x = (\lambda_n x_n)$ is bounded with $\|M_\lambda\| = \|\lambda\|_\infty$. Indeed $\|M_\lambda x\|_p \leq \|\lambda\|_\infty \|x\|_p$, and testing on e_n gives $\|M_\lambda\| \geq |\lambda_n|$ for each n .

(ii) The **right shift** $R : \ell^p \rightarrow \ell^p$, $R(x_1, x_2, \dots) = (0, x_1, x_2, \dots)$, is an isometry, so $\|R\| = 1$. It is injective but not surjective. The **left shift** $L(x_1, x_2, \dots) = (x_2, x_3, \dots)$ has $\|L\| = 1$, and is surjective but not injective. In finite dimensions no linear map can behave like either of these; this is the rank-nullity theorem failing to have an infinite-dimensional analogue.

(iii) Let $k \in C([0, 1]^2)$ and define $T : C[0, 1] \rightarrow C[0, 1]$ by

$$(Tf)(x) = \int_0^1 k(x, y) f(y) \, dy.$$

This is the **integral operator** with kernel k . It is bounded, with $\|T\| \leq \sup_x \int_0^1 |k(x, y)| \, dy \leq \|k\|_\infty$. These operators will be our main source of ex-

amples of compact operators.

- (iv) Differentiation $\frac{d}{dx} : C^1[0, 1] \rightarrow C[0, 1]$ is *unbounded* when $C^1[0, 1]$ is given the sup norm: take $f_n(x) = \sin(n^2x)/n$, so $\|f_n\|_\infty \leq 1/n \rightarrow 0$ but $\|f'_n\|_\infty = n \rightarrow \infty$. Unboundedness of differentiation is the reason a great deal of analysis is hard.

Proposition 33.2.7

Let X be a normed space, Y a Banach space and $Z \subseteq X$ a dense subspace. Then every $T \in \mathcal{B}(Z, Y)$ extends uniquely to $\tilde{T} \in \mathcal{B}(X, Y)$, and $\|\tilde{T}\| = \|T\|$.

Proof. Given $x \in X$ pick $z_n \in Z$ with $z_n \rightarrow x$. Then (z_n) is Cauchy, so $\|Tz_n - Tz_m\| \leq \|T\| \|z_n - z_m\|$ shows (Tz_n) is Cauchy in Y , and we set $\tilde{T}x = \lim_n Tz_n$. This is independent of the choice of sequence (interleave two such sequences), and linearity passes to the limit. Also $\|\tilde{T}x\| = \lim \|Tz_n\| \leq \|T\| \lim \|z_n\| = \|T\| \|x\|$, so $\|\tilde{T}\| \leq \|T\|$; the reverse is clear as $\tilde{T}$ extends T . Uniqueness holds because two continuous maps agreeing on a dense set agree everywhere. $\square$

§33.2.2 Isomorphisms

Definition 33.2.8 (Isomorphism)

A linear map $T : X \rightarrow Y$ between normed spaces is an **isomorphism** if it is a bijection and both T and T^{-1} are bounded. If in addition $\|Tx\| = \|x\|$ for all x , we call T an **isometric isomorphism** and say X and Y are **isometrically isomorphic**, written $X \cong Y$.

Being an isomorphism is equivalent to there existing $c, C > 0$ with $c\|x\| \leq \|Tx\| \leq C\|x\|$ and T surjective. The lower bound alone says T is **bounded below**, which is equivalent to T being injective with closed range.

Proposition 33.2.9

Let X be a Banach space and $T \in \mathcal{B}(X)$ with $\|T\| < 1$. Then $I - T$ is invertible in $\mathcal{B}(X)$, with

$$(I - T)^{-1} = \sum_{n=0}^{\infty} T^n,$$

the series converging in operator norm. Moreover $\|(I - T)^{-1}\| \leq (1 - \|T\|)^{-1}$.

Proof. Since $\|T^n\| \leq \|T\|^n$ and $\|T\| < 1$, the series $\sum_n T^n$ is absolutely convergent in $\mathcal{B}(X)$, which is a Banach space; so it converges, to S say, and $\|S\| \leq \sum_n \|T\|^n = (1 - \|T\|)^{-1}$. Writing $S_N = \sum_{n=0}^N T^n$ we have

$$(I - T)S_N = S_N(I - T) = I - T^{N+1} \longrightarrow I,$$

since $\|T^{N+1}\| \rightarrow 0$. As multiplication in $\mathcal{B}(X)$ is continuous, letting $N \rightarrow \infty$ gives $(I - T)S = S(I - T) = I$. $\square$

This is the **Neumann series**, and it is the workhorse of spectral theory. An immediate consequence is that the invertible elements of $\mathcal{B}(X)$ form an open set: if T is invertible and $\|S - T\| < \|T^{-1}\|^{-1}$ then $S = T(I - T^{-1}(T - S))$ is invertible.

§33.2.3 Dual Spaces

Among all bounded operators, those with target $\mathbb{F}$ deserve a special name.

Definition 33.2.10 (Dual space)

Let X be a normed space. Its **dual space** is

$$X^* = \mathcal{B}(X, \mathbb{F}),$$

whose elements are called **bounded linear functionals** on X .

Since $\mathbb{F}$ is complete, X^* is *always* a Banach space, whether or not X is. This is a very useful piece of leverage: even for a horrible normed space X , the dual is a nice object.

In IB Linear Algebra we studied the dual V' of a finite-dimensional space and found $\dim V' = \dim V$. In infinite dimensions the *algebraic* dual (all linear functionals) is enormous and useless; it is the topological dual X^* that carries information. It is not even obvious at this stage that $X^* \neq \{0\}$ for a general normed space X – that will be a consequence of the Hahn–Banach theorem.

Let's compute some duals.

Proposition 33.2.11

For $1 < p < \infty$ with conjugate exponent q , we have $(\ell^p)^* \cong \ell^q$. Also $(\ell^1)^* \cong \ell^\infty$ and $(c_0)^* \cong \ell^1$.

Proof. We do the case $1 \leq p < \infty$, the argument for c_0 being similar. Define $\Phi : \ell^q \rightarrow (\ell^p)^*$ by

$$(\Phi y)(x) = \sum_{n=1}^{\infty} x_n y_n.$$

By Hölder this converges with $|(\Phi y)(x)| \leq \|x\|_p \|y\|_q$, so $\Phi y \in (\ell^p)^*$ with $\|\Phi y\| \leq \|y\|_q$. It is clearly linear in y .

Φ is *isometric*. Suppose first $1 < p < \infty$. Given $y \in \ell^q$ non-zero, set $x_n = |y_n|^{q-1} \overline{\text{sgn}(y_n)}$ where $\text{sgn}(y) = y/|y|$ (and $x_n = 0$ if $y_n = 0$). Then $|x_n|^p = |y_n|^{(q-1)p} = |y_n|^q$, so $x \in \ell^p$ with $\|x\|_p = \|y\|_q^{q/p}$, while

$$(\Phi y)(x) = \sum_n |y_n|^q = \|y\|_q^q.$$

Hence $\|\Phi y\| \geq \|y\|_q^{q-q/p} = \|y\|_q$. For $p = 1, q = \infty$, test instead on $x = e_n$ to get $\|\Phi y\| \geq |y_n|$ for each n .

Φ is *surjective*. Let $f \in (\ell^p)^*$ and put $y_n = f(e_n)$. For any N , applying f to

$x = \sum_{n \leq N} |y_n|^{q-1} \overline{\text{sgn}(y_n)} e_n$ and using $|f(x)| \leq \|f\| \|x\|_p$ exactly as above gives

$$\left(\sum_{n \leq N} |y_n|^q \right)^{1/q} \leq \|f\|.$$

Letting $N \rightarrow \infty$ shows $y \in \ell^q$ with $\|y\|_q \leq \|f\|$. Finally, f and Φy are bounded functionals agreeing on each e_n , hence on c_{00} , which is dense in ℓ^p for $p < \infty$; so $f = \Phi y$. $\square$

Remark. The density of c_{00} is what fails for $p = \infty$, and indeed $(\ell^\infty)^* \neq \ell^1$: the dual of ℓ^∞ is strictly bigger, containing exotic objects called *Banach limits* which one constructs with Hahn–Banach. So duality is not symmetric: we have $(\ell^1)^* = \ell^\infty$ but $(\ell^\infty)^* \not\cong \ell^1$.

Example 33.2.12

If X is finite-dimensional with basis $e_1, \dots, e_n$, then every linear functional is bounded, and X^* is spanned by the dual basis $e_1^*, \dots, e_n^*$. In particular $(\ell_p^n)^* \cong \ell_q^n$ isometrically, by the same computation as above.

The dual of $C(K)$ is also computable, but the answer – the space of regular Borel measures on K , by the Riesz–Markov theorem – needs measure theory, so we will leave it aside. The one dual we will compute completely, and rather beautifully, is that of a Hilbert space.

§33.2.4 Adjoints

Every bounded operator induces one on the duals, going the other way.

Definition 33.2.13 (Adjoint)

Let $T \in \mathcal{B}(X, Y)$. The **adjoint** (or **dual map**) $T^* : Y^* \rightarrow X^*$ is defined by

$$T^*f = f \circ T, \quad \text{i.e. } (T^*f)(x) = f(Tx).$$

This is the same construction as the dual of a linear map in IB Linear Algebra, where it corresponded to transposing the matrix. Note that the Hilbert space adjoint we meet later is a slightly different (though closely related) object: it maps $H \rightarrow H$ rather than $H^* \rightarrow H^*$, and it is conjugate-linear in T .

Proposition 33.2.14

For $T \in \mathcal{B}(X, Y)$ we have $T^* \in \mathcal{B}(Y^*, X^*)$ with $\|T^*\| \leq \|T\|$. Moreover $(ST)^* = T^*S^*$ and $(S + T)^* = S^* + T^*$.

Proof. Linearity of T^* is immediate, and

$$\|T^*f\| = \sup_{\|x\| \leq 1} |f(Tx)| \leq \|f\| \sup_{\|x\| \leq 1} \|Tx\| = \|f\| \|T\|.$$

The algebraic identities are direct computations. $\square$

In fact $\|T^*\| = \|T\|$, but proving this requires us to know that Y^* has enough functionals to detect the norm of a vector in Y – and that is precisely what Hahn–Banach provides. So we turn to that now.

§33.2.5 The Double Dual

Since X^* is a normed space, it too has a dual, $X^{**} = (X^*)^*$, called the **double dual** or **bidual**. There is a completely canonical map from X into it.

Definition 33.2.15 (Canonical embedding)

Define $\iota : X \rightarrow X^{**}$ by

$$\iota(x)(f) = f(x) \quad (x \in X, f \in X^*).$$

That is, we let a vector act on functionals by evaluation. This is manifestly linear in x , and

$$|\iota(x)(f)| = |f(x)| \leq \|f\| \|x\|,$$

so $\iota(x) \in X^{**}$ with $\|\iota(x)\| \leq \|x\|$; hence $\iota \in \mathcal{B}(X, X^{**})$ with $\|\iota\| \leq 1$. Whether ι is *isometric* – equivalently, whether there are enough functionals to see the norm of every vector – is again a question for Hahn–Banach. We will see that it is, and this leads to the following notion.

Definition 33.2.16 (Reflexive)

A normed space X is **reflexive** if $\iota : X \rightarrow X^{**}$ is surjective (hence an isometric isomorphism).

Reflexivity is a strong condition. We will see that ℓ^p is reflexive for $1 < p < \infty$, that ℓ^1 and c_0 are not, and that every Hilbert space is. Note that a reflexive space must be a Banach space, since X^{**} always is.

Remark. It is essential that reflexivity is defined via the *canonical* map ι , and not merely by the existence of *some* isomorphism $X \cong X^{**}$. R. C. James constructed a Banach space which is isometrically isomorphic to its double dual but for which ι is not surjective; so the distinction is real, if rather subtle.

§33.3 The Hahn–Banach Theorem

We have repeatedly deferred questions to ‘Hahn–Banach’: does X^* separate points? Is ι isometric? Is $\|T^*\| = \|T\|$? All of these ask whether a normed space has *enough* bounded linear functionals, and all are answered by one theorem, which is really a theorem about extending functionals from a subspace to the whole space without increasing their size.

§33.3.1 Zorn’s Lemma

The extension will be carried out one dimension at a time, and to get from ‘one dimension at a time’ to ‘all at once’ we need a transfinite tool. Recall a **partial order** on a set P is a reflexive, antisymmetric, transitive relation $\leq$; a **chain** is a subset on which $\leq$ is a

total order; an **upper bound** for $S \subseteq P$ is $u \in P$ with $s \leq u$ for all $s \in S$; and $m \in P$ is **maximal** if $m \leq p$ implies $p = m$.

Theorem 33.3.1 (Zorn's Lemma)

Let $(P, \leq)$ be a non-empty partially ordered set in which every chain has an upper bound. Then P has a maximal element.

Zorn's lemma is equivalent to the axiom of choice (and to the well-ordering principle), as you will see in II Logic and Set Theory. We will simply use it.

Proposition 33.3.2

Every vector space has a basis, and every linearly independent set extends to a basis.

Proof. Let S be linearly independent in V and let P be the set of linearly independent subsets of V containing S , ordered by inclusion. It is non-empty ($S \in P$). Given a chain $\mathcal{C} \subseteq P$, the union $\bigcup \mathcal{C}$ is linearly independent – any linear dependence involves finitely many vectors, which all lie in a single member of the chain – so it is an upper bound. By Zorn there is a maximal linearly independent $B \supseteq S$. If $\text{span } B \neq V$, pick $v \notin \text{span } B$; then $B \cup \{v\}$ is linearly independent, contradicting maximality. So B is a basis. $\square$

Such a basis is called a **Hamel basis**, to distinguish it from the orthonormal bases we will meet in Hilbert space (where infinite sums are permitted). Hamel bases of infinite-dimensional Banach spaces are always uncountable and always useless – we will prove the first assertion with the Baire category theorem.

§33.3.2 The Analytic Form

The theorem is about domination by a sublinear functional.

Definition 33.3.3 (Sublinear functional)

Let V be a real vector space. A map $p : V \rightarrow \mathbb{R}$ is **sublinear** if

$$p(v + w) \leq p(v) + p(w) \quad \text{and} \quad p(\lambda v) = \lambda p(v)$$

for all $v, w \in V$ and $\lambda > 0$.

A norm is sublinear, but so is (say) $p(x) = \max_i x_i$ on $\mathbb{R}^n$, and so is the Minkowski functional of a convex set containing the origin. The extra generality is what makes the geometric forms of the theorem available.

Lemma 33.3.4 (One-step extension)

Let V be a real vector space, p sublinear on V , $W \subseteq V$ a subspace and $f : W \rightarrow \mathbb{R}$ linear with $f \leq p$ on W . Let $v_0 \in V \setminus W$. Then f extends to a linear $g : W \oplus \mathbb{R}v_0 \rightarrow \mathbb{R}$ with $g \leq p$.

Proof. Any linear extension is determined by the value $c = g(v_0)$, via $g(w + tv_0) = f(w) + tc$. We must choose c so that

$$f(w) + tc \leq p(w + tv_0) \quad \text{for all } w \in W, t \in \mathbb{R}.$$

For $t = 0$ this is the hypothesis. For $t > 0$, dividing by t and replacing w/t by w , the condition becomes

$$c \leq p(w + v_0) - f(w) \quad \text{for all } w \in W.$$

For $t < 0$, writing $t = -s$ with $s > 0$ and dividing by s , it becomes

$$c \geq f(w') - p(w' - v_0) \quad \text{for all } w' \in W.$$

So a suitable c exists precisely when

$$\sup_{w' \in W} (f(w') - p(w' - v_0)) \leq \inf_{w \in W} (p(w + v_0) - f(w)).$$

But for any $w, w' \in W$,

$$f(w') + f(w) = f(w' + w) \leq p(w' + w) \leq p(w' - v_0) + p(w + v_0),$$

and rearranging gives exactly $f(w') - p(w' - v_0) \leq p(w + v_0) - f(w)$. So the supremum is at most the infimum, and any c in between will do. $\square$

The heart of the matter is the last display. The positive values of t produce an upper bound for c and the negative values produce a lower bound, and sublinearity of p is exactly what guarantees that the lower bounds all sit below all of the upper bounds – so that there is a non-empty window of legal choices.

Theorem 33.3.5 (Hahn–Banach, analytic form)

Let V be a real vector space, $p : V \rightarrow \mathbb{R}$ sublinear, $W \subseteq V$ a subspace and $f : W \rightarrow \mathbb{R}$ linear with $f(w) \leq p(w)$ for all $w \in W$. Then there is a linear $\tilde{f} : V \rightarrow \mathbb{R}$ with $\tilde{f}|_W = f$ and $\tilde{f}(v) \leq p(v)$ for all $v \in V$.

Proof. Let P be the set of pairs (U, g) where $W \subseteq U \subseteq V$ is a subspace, $g : U \rightarrow \mathbb{R}$ is linear, $g|_W = f$ and $g \leq p$ on U . Order P by

$$(U_1, g_1) \leq (U_2, g_2) \iff U_1 \subseteq U_2 \text{ and } g_2|_{U_1} = g_1.$$

This is a partial order, and $P \neq \emptyset$ as $(W, f) \in P$.

Let $\mathcal{C} = \{(U_i, g_i)\}_{i \in I}$ be a chain in P . Put $U = \bigcup_i U_i$ and define g on U by $g(u) = g_i(u)$ whenever $u \in U_i$; this is well defined by the compatibility built into the order. Since $\mathcal{C}$ is a chain, any two elements of U lie in a common U_i , so U is a subspace and g is linear; and $g \leq p$ since each $g_i \leq p$. So $(U, g) \in P$ is an upper

bound for $\mathcal{C}$.

By Zorn's lemma, P has a maximal element $(U_{\max}, \tilde{f})$. If $U_{\max} \neq V$, pick $v_0 \in V \setminus U_{\max}$ and apply the one-step extension lemma to obtain a strictly larger element of P , contradicting maximality. Hence $U_{\max} = V$. $\square$

Notice that the picture of the extension is exactly a growing domain: we start on W , and repeatedly (transfinitely) enlarge the domain by one dimension, always keeping underneath the ceiling p .

For the complex case, and for the applications we actually want, the following symmetric version is more convenient. Recall that a **seminorm** is a map $p : V \rightarrow [0, \infty)$ with $p(v + w) \leq p(v) + p(w)$ and $p(\lambda v) = |\lambda|p(v)$ for all scalars λ .

Theorem 33.3.6 (Hahn–Banach, seminorm form)

Let V be a vector space over $\mathbb{F} = \mathbb{R}$ or $\mathbb{C}$, let p be a seminorm on V , let $W \subseteq V$ be a subspace and let $f : W \rightarrow \mathbb{F}$ be linear with $|f(w)| \leq p(w)$ on W . Then there is a linear $\tilde{f} : V \rightarrow \mathbb{F}$ with $\tilde{f}|_W = f$ and $|\tilde{f}(v)| \leq p(v)$ for all $v \in V$.

Proof. Real case. A seminorm is sublinear, so the analytic form gives an extension with $\tilde{f} \leq p$. Then also $-\tilde{f}(v) = \tilde{f}(-v) \leq p(-v) = p(v)$, so $|\tilde{f}| \leq p$.

Complex case. Let $g = \operatorname{Re} f : W \rightarrow \mathbb{R}$, which is $\mathbb{R}$ -linear, and note that

$$f(w) = g(w) - ig(iw),$$

since writing $f(w) = g(w) + ih(w)$ and using $f(iw) = if(w)$ gives $h(w) = -g(iw)$. Now $|g| \leq |f| \leq p$, and regarding V as a real vector space, the real case gives an $\mathbb{R}$ -linear extension $\tilde{g} : V \rightarrow \mathbb{R}$ with $|\tilde{g}| \leq p$. Define

$$\tilde{f}(v) = \tilde{g}(v) - i\tilde{g}(iv).$$

This is $\mathbb{R}$ -linear, and $\tilde{f}(iv) = \tilde{g}(iv) - i\tilde{g}(-v) = i(\tilde{g}(v) - i\tilde{g}(iv)) = i\tilde{f}(v)$, so it is $\mathbb{C}$ -linear. It restricts to f on W by the identity above.

Finally, fix v and choose $\theta \in \mathbb{R}$ with $e^{i\theta}\tilde{f}(v) = |\tilde{f}(v)|$. Then

$$|\tilde{f}(v)| = \tilde{f}(e^{i\theta}v) = \operatorname{Re} \tilde{f}(e^{i\theta}v) = \tilde{g}(e^{i\theta}v) \leq p(e^{i\theta}v) = p(v),$$

using that $|\tilde{f}(v)|$ is real so equals its own real part. $\square$

§33.3.3 Consequences

Now we harvest. Everything in this subsection follows by applying Hahn–Banach with $p = \|\cdot\|$ or a scaled version of it.

Corollary 33.3.7 (Norm-preserving extension)

Let X be a normed space, $W \subseteq X$ a subspace and $f \in W^*$. Then there is $\tilde{f} \in X^*$ with $\tilde{f}|_W = f$ and $\|\tilde{f}\|_{X^*} = \|f\|_{W^*}$.

Proof. Apply the seminorm form with $p(x) = \|f\|_{W^*} \|x\|$, which is a seminorm (indeed a norm if $f \neq 0$) and dominates $|f|$ on W . We obtain $\tilde{f}$ with $|\tilde{f}(x)| \leq \|f\| \|x\|$, so $\|\tilde{f}\| \leq \|f\|$; and $\|\tilde{f}\| \geq \|f\|$ since $\tilde{f}$ extends f . $\square$

Corollary 33.3.8 (Support functionals)

Let X be a normed space and $x_0 \in X$ with $x_0 \neq 0$. Then there is $f \in X^*$ with $\|f\| = 1$ and $f(x_0) = \|x_0\|$.

Proof. Let $W = \mathbb{F}x_0$ and define $f_0(\lambda x_0) = \lambda \|x_0\|$. Then $|f_0(\lambda x_0)| = \|\lambda x_0\|$, so $\|f_0\|_{W^*} = 1$. Extend by the previous corollary. $\square$

Such an f is called a **support functional** at x_0 . It is the abstract version of ‘the tangent hyperplane to the unit ball at $x_0/\|x_0\|$ ’.

Corollary 33.3.9

Let X be a normed space. Then:

- (i) if $X \neq \{0\}$ then $X^* \neq \{0\}$;
- (ii) X^* separates points: if $x \neq y$ there is $f \in X^*$ with $f(x) \neq f(y)$;
- (iii) for every $x \in X$,

$$\|x\| = \sup\{|f(x)| : f \in X^*, \|f\| \leq 1\},$$

and the supremum is attained;

- (iv) the canonical embedding $\iota : X \rightarrow X^{**}$ is an isometry.

Proof. (i) and (ii) follow from the existence of support functionals (for (ii) apply it to $x - y$). For (iii), the inequality $\leq$ is the support functional and $\geq$ is $|f(x)| \leq \|f\| \|x\|$. Finally (iv) is a restatement of (iii), since $\|\iota(x)\| = \sup_{\|f\| \leq 1} |\iota(x)(f)| = \sup_{\|f\| \leq 1} |f(x)|$. $\square$

Part (iv) is worth pausing on. It says that *every normed space embeds isometrically into a Banach space*, namely the closure of $\iota(X)$ in X^{**} . This gives the slick construction of the completion promised earlier.

Corollary 33.3.10

For $T \in \mathcal{B}(X, Y)$ we have $\|T^*\| = \|T\|$.

Proof. We know $\|T^*\| \leq \|T\|$. Conversely, given $\varepsilon > 0$ pick x with $\|x\| \leq 1$ and $\|Tx\| \geq \|T\| - \varepsilon$, and let $f \in Y^*$ be a support functional at Tx , so $\|f\| = 1$ and $f(Tx) = \|Tx\|$. Then

$$\|T^*\| \geq \|T^*f\| \geq |(T^*f)(x)| = |f(Tx)| = \|Tx\| \geq \|T\| - \varepsilon. \quad \square$$

Corollary 33.3.11 (Separating a point from a subspace)

Let $W \subseteq X$ be a closed subspace and $x_0 \in X \setminus W$. Then there is $f \in X^*$ with $\|f\| = 1$, $f|_W = 0$ and $f(x_0) = \text{dist}(x_0, W) > 0$.

Proof. Work in the quotient X/W , which is a normed space since W is closed, and let $q : X \rightarrow X/W$ be the quotient map, which satisfies $\|q\| \leq 1$. As $x_0 \notin W$ we have $q(x_0) \neq 0$, so there is a support functional $g \in (X/W)^*$ with $\|g\| = 1$ and $g(q(x_0)) = \|q(x_0)\| = \text{dist}(x_0, W)$. Put $f = g \circ q$. Then $\|f\| \leq 1$, f kills W , and $f(x_0) = \text{dist}(x_0, W)$. For $\|f\| = 1$, note $\|f\| \geq \text{dist}(x_0, W)/\|x_0 - w\|$ for every $w \in W$, and take the infimum over w . $\square$

Corollary 33.3.12

A subspace $W \subseteq X$ is dense if and only if the only $f \in X^*$ vanishing on W is $f = 0$.

Proof. If W is dense and $f|_W = 0$ then $f = 0$ by continuity. Conversely if $\bar{W} \neq X$ pick $x_0 \notin \bar{W}$ and apply the previous corollary to the closed subspace $\bar{W}$. $\square$

This last statement is one we will use again and again: to prove something lies in the closure of a subspace, it suffices to show every functional killing the subspace kills it too. It converts an approximation problem into a duality problem.

Example 33.3.13 (Reflexivity of ℓ^p)

Let $1 < p < \infty$ and q its conjugate. We computed $(\ell^p)^* \cong \ell^q$ and $(\ell^q)^* \cong \ell^p$, so $(\ell^p)^{**} \cong \ell^p$. Chasing the identifications shows the composite is exactly ι , so ℓ^p is reflexive.

On the other hand c_0 is not reflexive: $(c_0)^* \cong \ell^1$ and $(\ell^1)^* \cong \ell^\infty$, so $c_0^{**} \cong \ell^\infty \supsetneq c_0$. Nor is ℓ^1 reflexive, since $(\ell^1)^{**} = (\ell^\infty)^*$ is strictly larger than ℓ^1 .

Hahn–Banach is not merely a device for extending functionals we already have; it can conjure up functionals with prescribed and rather magical properties. Here is the standard example.

Example 33.3.14 (Banach limits)

We construct a linear functional Λ on the real space ℓ^∞ such that

- (i) $\liminf_n x_n \leq \Lambda(x) \leq \limsup_n x_n$ for every $x \in \ell^\infty$;
- (ii) $\Lambda(Lx) = \Lambda(x)$, where L is the left shift.

In particular Λ agrees with $\lim$ on the convergent sequences, but is defined on *all*

bounded sequences, and is shift-invariant. So it assigns a ‘limit’ to $(1, 0, 1, 0, \dots)$ – necessarily $\frac{1}{2}$, by (i) and (ii) applied to $x + Lx = (1, 1, 1, \dots)$.

For the construction, define

$$p(x) = \lim_{n \rightarrow \infty} \sup_{k \geq 1} \frac{x_k + x_{k+1} + \dots + x_{k+n-1}}{n}.$$

The limit exists because the quantity $a_n = \sup_k (x_k + \dots + x_{k+n-1})$ is subadditive in n , so a_n/n converges by Fekete’s lemma. One checks that p is sublinear and that $p(x) \leq \limsup_n x_n$, with $p(Lx - x) \leq 0$ and $p(x - Lx) \leq 0$.

Apply Hahn–Banach to the zero functional on the zero subspace, dominated by p : we get a linear $\Lambda \leq p$ on ℓ^∞ . Then $\Lambda(x) \leq p(x) \leq \limsup x_n$, and $-\Lambda(x) = \Lambda(-x) \leq p(-x) \leq -\liminf x_n$, giving (i). And $\Lambda(Lx - x) \leq p(Lx - x) \leq 0$ together with the same for $x - Lx$ gives (ii).

Such a Λ is called a **Banach limit**. It is an element of $(\ell^\infty)^*$ which does not come from ℓ^1 : it vanishes on c_{00} but not on ℓ^∞ . This is the promised proof that $(\ell^\infty)^* \supsetneq \ell^1$, and hence that ℓ^1 is not reflexive.

§33.3.4 The Geometric Forms

The analytic form is about functionals dominated by a sublinear p ; the geometric form is about hyperplanes separating convex sets. The bridge between them is the following construction, which turns a convex set into a sublinear functional.

Definition 33.3.15 (Minkowski functional)

Let V be a vector space and $C \subseteq V$ a convex set with $0 \in C$. The **Minkowski functional** (or **gauge**) of C is

$$\mu_C(v) = \inf\{t > 0 : v \in tC\} \in [0, \infty].$$

Lemma 33.3.16

Let X be a normed space and C an open convex set with $0 \in C$. Then μ_C is sublinear, $C = \{v : \mu_C(v) < 1\}$, and there is $M > 0$ with $\mu_C(v) \leq M \|v\|$.

Proof. Positive homogeneity is immediate from the definition. For subadditivity, suppose $v \in sC$ and $w \in tC$, say $v = sc_1$, $w = tc_2$ with $c_i \in C$. Then

$$\frac{v+w}{s+t} = \frac{s}{s+t}c_1 + \frac{t}{s+t}c_2 \in C$$

by convexity, so $\mu_C(v+w) \leq s+t$; taking infima gives $\mu_C(v+w) \leq \mu_C(v) + \mu_C(w)$.

Since C is open and $0 \in C$, there is $r > 0$ with $B(0, r) \subseteq C$, whence $\mu_C(v) \leq \|v\|/r$; take $M = 1/r$. If $v \in C$ then by openness $(1+\varepsilon)v \in C$ for small ε , so $\mu_C(v) \leq (1+\varepsilon)^{-1} < 1$; conversely $\mu_C(v) < 1$ gives $v \in tC \subseteq C$ for some $t < 1$ (using $0 \in C$ and convexity). $\square$

Theorem 33.3.17 (Hahn–Banach, separation form)

Let X be a real normed space and let $A, B \subseteq X$ be non-empty disjoint convex sets.

- (i) If A is open, there exist $f \in X^* \setminus \{0\}$ and $\alpha \in \mathbb{R}$ with

$$f(a) < \alpha \leq f(b) \quad \text{for all } a \in A, b \in B.$$

- (ii) If A is closed and B is compact, there exist $f \in X^* \setminus \{0\}$ and $\alpha_1 < \alpha_2$ with

$$f(a) \leq \alpha_1 < \alpha_2 \leq f(b) \quad \text{for all } a \in A, b \in B.$$

Proof. (i) Fix $a_0 \in A$, $b_0 \in B$ and set $v_0 = b_0 - a_0$ and

$$C = A - B + v_0 = \{a - b + v_0 : a \in A, b \in B\}.$$

Then C is convex (a sum of convex sets), open (a union of translates of the open set A), and contains 0 (take $a = a_0, b = b_0$). Also $v_0 \notin C$: otherwise $v_0 = a - b + v_0$ for some $a \in A, b \in B$, forcing $a = b$, contradicting disjointness.

Let $\mu = \mu_C$, which is sublinear and bounded by $M \|\cdot\|$. On the line $W = \mathbb{R}v_0$ define $g(tv_0) = t$. For $t > 0$ we have $g(tv_0) = t \leq t\mu(v_0) = \mu(tv_0)$, since $\mu(v_0) \geq 1$ as $v_0 \notin C$; for $t \leq 0$, $g(tv_0) \leq 0 \leq \mu(tv_0)$. So $g \leq \mu$ on W , and Hahn–Banach gives a linear $f : X \rightarrow \mathbb{R}$ with $f \leq \mu$ and $f(v_0) = 1$. Since $f(x) \leq \mu(x) \leq M \|x\|$ and $-f(x) = f(-x) \leq M \|x\|$, we get $f \in X^*$, and $f \neq 0$.

Now for $a \in A, b \in B$, the point $a - b + v_0 \in C$ so $\mu(a - b + v_0) < 1$, giving

$$f(a) - f(b) + 1 = f(a - b + v_0) \leq \mu(a - b + v_0) < 1,$$

i.e. $f(a) < f(b)$. Hence $\alpha := \inf_{b \in B} f(b)$ satisfies $f(a) \leq \alpha \leq f(b)$ for all a, b . Finally $f(a) < \alpha$ strictly: A is open and $f \neq 0$, so $f(A)$ is an open subset of $\mathbb{R}$ (pick u with $f(u) = 1$; then $f(a + su) = f(a) + s$ covers a neighbourhood of $f(a)$), and an open set cannot contain its own supremum.

(ii) Since A is closed, B compact and $A \cap B = \emptyset$, the distance $\delta = \text{dist}(A, B)$ is strictly positive. (If $\text{dist}(a_n, b_n) \rightarrow 0$, pass to a convergent subsequence $b_n \rightarrow b \in B$; then $a_n \rightarrow b$, so $b \in \bar{A} = A$, a contradiction.) Let

$$A_\delta = A + B(0, \delta/2),$$

which is open and convex, and disjoint from B by the choice of δ . By (i) there is $f \neq 0$ with $f(a') < f(b)$ for $a' \in A_\delta, b \in B$. For $a \in A$ and $\|u\| < \delta/2$ we get $f(a) + f(u) < f(b)$, and taking the supremum over such u gives

$$f(a) + \frac{\delta}{2} \|f\| \leq f(b)$$

for all $a \in A, b \in B$. As $\|f\| > 0$ we may take $\alpha_1 = \sup_A f$ and $\alpha_2 = \alpha_1 + \frac{\delta}{2} \|f\| > \alpha_1$. $\square$

Geometrically, a functional f and a level α determine an affine **hyperplane** $H = f^{-1}(\alpha)$, which is closed exactly when f is continuous, and which divides X into two half-spaces $\{f < \alpha\}$ and $\{f > \alpha\}$. The theorem says that two disjoint convex sets can be put on

opposite sides of a hyperplane, strictly so if one is closed and the other compact.

Corollary 33.3.18

Let X be a real normed space, $C \subseteq X$ a closed convex set and $x_0 \notin C$. Then there is $f \in X^*$ with $\sup_{c \in C} f(c) < f(x_0)$. In particular, a closed convex set is the intersection of the closed half-spaces containing it.

Proof. Apply part (ii) with $A = C$ and $B = \{x_0\}$, which is compact. The final statement follows since any $x_0 \notin C$ is excluded by one of these half-spaces. $\square$

Remark. Convexity is essential. In $\mathbb{R}^2$ we cannot separate a point at the centre of an annulus from the annulus itself. The theorem is a genuinely convex-geometric statement, and it is the starting point of convex analysis and of the theory of weak topologies.

§33.4 The Baire Category Theorem

The Hahn–Banach theorem was a statement about the algebraic and convex structure of a normed space, and its proof used no completeness at all. We now turn to the other pillar of the subject, which is entirely about completeness, and which is in some ways even more remarkable: a very soft topological statement whose consequences include three of the fundamental theorems of functional analysis.

§33.4.1 Category

Recall that a subset A of a topological space X is **dense** if $\bar{A} = X$, equivalently if A meets every non-empty open set.

Definition 33.4.1 (Nowhere dense)

A subset A of a topological space X is **nowhere dense** (or **rare**) if $\bar{A}$ has empty interior, i.e. $\bar{A}$ contains no non-empty open set.

Equivalently, A is nowhere dense if and only if $X \setminus \bar{A}$ is dense: every open set contains an open subset missing A entirely. Think of it as being ‘full of holes at every scale’.

Example 33.4.2 (i) A single point in $\mathbb{R}$ is nowhere dense, as is any finite set, as is $\{1/n : n \in \mathbb{N}\} \cup \{0\}$.

- (ii) $\mathbb{Z}$ is nowhere dense in $\mathbb{R}$, but $\mathbb{Q}$ is *not* – its closure is all of $\mathbb{R}$.
- (iii) The Cantor set is nowhere dense in $[0, 1]$: it is closed, and contains no interval since it has empty interior by construction.
- (iv) In $C[0, 1]$, the set of polynomials of degree at most d is nowhere dense (it is a finite-dimensional, hence closed, proper subspace, and a proper subspace has empty interior – if it contained a ball it would contain a translate of a ball about 0, hence everything).

Definition 33.4.3 (Meagre)

A subset of a topological space is **meagre** (or **of first category**) if it is a countable union of nowhere dense sets, and **of second category** otherwise. A set whose complement is meagre is called **residual** or **comeagre**.

‘Meagre’ is a topological notion of smallness. It behaves as one would hope: a countable union of meagre sets is meagre, and a subset of a meagre set is meagre. The content of the Baire category theorem is that in a complete space, ‘meagre’ really does mean small – in particular, the whole space is not meagre in itself.

Theorem 33.4.4 (Baire Category Theorem)

Let (X, d) be a complete non-empty metric space. Then:

- (i) if $(U_n)_{n \geq 1}$ are open and dense in X , then $\bigcap_{n \geq 1} U_n$ is dense in X ;
- (ii) X is not meagre in itself. Equivalently, if $X = \bigcup_{n \geq 1} F_n$ with each F_n closed, then some F_n has non-empty interior.

Proof. (i) Let $W \subseteq X$ be non-empty and open; we must show $W \cap \bigcap_n U_n \neq \emptyset$. We construct a nested sequence of closed balls.

Since U_1 is dense and open, $W \cap U_1$ is non-empty and open, so it contains a closed ball $\bar{B}(x_1, r_1)$ with $0 < r_1 < 1$. Inductively, given $\bar{B}(x_n, r_n)$, the set $B(x_n, r_n) \cap U_{n+1}$ is non-empty (density of U_{n+1}) and open, so it contains a closed ball $\bar{B}(x_{n+1}, r_{n+1})$ with $0 < r_{n+1} < 2^{-n}$.

By construction $\bar{B}(x_1, r_1) \supseteq \bar{B}(x_2, r_2) \supseteq \dots$ and $r_n \rightarrow 0$. For $m > n$ we have $x_m \in \bar{B}(x_n, r_n)$, so $d(x_n, x_m) \leq r_n \rightarrow 0$ and (x_n) is Cauchy. By completeness $x_n \rightarrow x$ for some $x \in X$, and since $x_m \in \bar{B}(x_n, r_n)$ for all $m \geq n$ and this ball is closed, $x \in \bar{B}(x_n, r_n)$ for every n . Hence

$$x \in \bar{B}(x_1, r_1) \subseteq W \cap U_1 \quad \text{and} \quad x \in \bar{B}(x_{n+1}, r_{n+1}) \subseteq U_{n+1}$$

for every n , so $x \in W \cap \bigcap_n U_n$ as required.

(ii) Suppose $X = \bigcup_n A_n$ with each A_n nowhere dense. Then $U_n = X \setminus \bar{A}_n$ is open and dense, and $\bigcap_n U_n = X \setminus \bigcup_n \bar{A}_n = \emptyset$, contradicting (i) (as $X \neq \emptyset$). The reformulation follows by taking F_n closed with empty interior, i.e. nowhere dense. $\square$

Before the big applications, here are two quick ones that show the flavour.

Proposition 33.4.5

$\mathbb{Q}$ is not the intersection of countably many open subsets of $\mathbb{R}$.

Proof. Suppose $\mathbb{Q} = \bigcap_n U_n$ with U_n open. Each $U_n \supseteq \mathbb{Q}$ is dense. Enumerate $\mathbb{Q} = \{q_1, q_2, \dots\}$; then each $V_n = \mathbb{R} \setminus \{q_n\}$ is open and dense. So

$$\bigcap_n U_n \cap \bigcap_n V_n = \mathbb{Q} \setminus \mathbb{Q} = \emptyset,$$

contradicting Baire applied to the complete space $\mathbb{R}$. $\square$

Proposition 33.4.6

An infinite-dimensional Banach space cannot have a countable Hamel basis.

Proof. Suppose X has Hamel basis $\{e_1, e_2, \dots\}$, and let $X_n = \text{span}\{e_1, \dots, e_n\}$. Each X_n is finite-dimensional, hence closed, and proper (as X is infinite-dimensional), hence has empty interior. But $X = \bigcup_n X_n$, contradicting Baire. $\square$

Remark. Hence, for instance, c_{00} (which *does* have the countable Hamel basis $\{e_n\}$) admits no norm making it complete. That is a strong statement, and it would be painful to prove directly.

Theorem 33.4.7 (Osgood)

Let X be a complete metric space and $f_n : X \rightarrow \mathbb{R}$ continuous with $f_n \rightarrow f$ pointwise. Then the set of points at which f is continuous is residual, in particular dense.

Proof. For $\varepsilon > 0$ and $N \in \mathbb{N}$ put

$$F_{N,\varepsilon} = \{x \in X : |f_n(x) - f_m(x)| \leq \varepsilon \text{ for all } n, m \geq N\},$$

which is closed by continuity of the f_n . Pointwise convergence gives $X = \bigcup_N F_{N,\varepsilon}$,

so

$$U_\varepsilon = \bigcup_N \text{int } F_{N,\varepsilon}$$

is open, and it is dense: for any open ball B , applying Baire inside the complete space $\bar{B}$ to the sets $F_{N,\varepsilon} \cap \bar{B}$ produces some N for which $F_{N,\varepsilon} \cap \bar{B}$ has interior, so U_ε meets B .

Now let $D = \bigcap_{k \geq 1} U_{1/k}$, a residual set. We claim f is continuous at each $x \in D$. Given $\varepsilon > 0$ choose k with $3/k < \varepsilon$. As $x \in U_{1/k}$, there is N and an open $V \ni x$ with $V \subseteq F_{N,1/k}$. Letting $m \rightarrow \infty$ in the defining inequality gives $|f_N(y) - f(y)| \leq 1/k$ for all $y \in V$. Shrinking V so that $|f_N(y) - f_N(x)| < 1/k$ on it, we get

$$|f(y) - f(x)| \leq |f(y) - f_N(y)| + |f_N(y) - f_N(x)| + |f_N(x) - f(x)| \leq \frac{3}{k} < \varepsilon. \quad \square$$

So a pointwise limit of continuous functions, while not continuous in general, cannot be discontinuous everywhere – which incidentally shows that the indicator of $\mathbb{Q}$ is not a pointwise limit of continuous functions, though it is a pointwise limit of pointwise limits.

§33.4.2 A Continuous Nowhere Differentiable Function

Here is the classical showpiece application. Weierstrass constructed such a function explicitly in 1872, to general consternation; Banach observed in 1931 that Baire category makes the existence almost obvious – and in fact shows that such functions are the *typical* continuous function, the differentiable ones forming a meagre set.

Theorem 33.4.8

There is a continuous function $f : [0, 1] \rightarrow \mathbb{R}$ which is differentiable at no point of $[0, 1]$. Indeed, the set of such f is residual in $C[0, 1]$.

Proof. Work in the Banach space $X = C[0, 1]$ with the sup norm. For $n \in \mathbb{N}$ let

$$A_n = \{f \in X : \exists x \in [0, 1] \text{ with } |f(x) - f(y)| \leq n|x - y| \text{ for all } y \in [0, 1]\}.$$

If f is differentiable at some point x , then f is Lipschitz at x in this sense with some constant, so $f \in A_n$ for some n . Thus it suffices to show each A_n is closed with empty interior; then $\bigcup_n A_n$ is meagre and any f in its (non-empty, by Baire) complement works.

A_n is closed. Let $f_k \in A_n$ with $f_k \rightarrow f$ uniformly, and let x_k witness $f_k \in A_n$. By compactness of $[0, 1]$, pass to a subsequence with $x_k \rightarrow x$. For any $y \in [0, 1]$,

$$|f(x) - f(y)| \leq |f(x) - f(x_k)| + |f(x_k) - f_k(x_k)| + |f_k(x_k) - f_k(y)| + |f_k(y) - f(y)|.$$

The second and fourth terms are at most $\|f - f_k\|_\infty \rightarrow 0$; the first tends to 0 by continuity of f and $x_k \rightarrow x$; and the third is at most $n|x_k - y| \rightarrow n|x - y|$. Hence $|f(x) - f(y)| \leq n|x - y|$, so $f \in A_n$.

A_n has empty interior. Let $f \in X$ and $\varepsilon > 0$; we find g with $\|f - g\|_\infty < \varepsilon$ and $g \notin A_n$. By the Weierstrass approximation theorem (or just uniform continuity and piecewise-linear interpolation), choose a piecewise linear h with $\|f - h\|_\infty < \varepsilon/2$.

Let M be the maximum absolute slope of h . Let s be a ‘sawtooth’ function of amplitude $\varepsilon/2$ whose slopes all have absolute value Λ , where $\Lambda > M + n$; explicitly, s is the $\varepsilon/2$ -scaled zigzag of period ε/Λ . Put $g = h + s$.

Then $\|f - g\|_\infty \leq \|f - h\|_\infty + \|s\|_\infty < \varepsilon$. At every point x , and for y close enough to x on a suitable side, the difference quotient of g has absolute value at least $\Lambda - M > n$, since s contributes slope $\pm\Lambda$ and h at most M . Hence $g \notin A_n$. $\square$

The picture is the point of the proof: adding a tiny but very steep sawtooth changes the function hardly at all in the uniform norm, while destroying any chance of a bounded difference quotient. Uniform closeness is simply blind to derivatives.

§33.4.3 The Principle of Uniform Boundedness

The second application is the one that gets used most often in practice.

Theorem 33.4.9 (Banach–Steinhaus / Uniform Boundedness Principle)

Let X be a Banach space, Y a normed space, and $\{T_i\}_{i \in I} \subseteq \mathcal{B}(X, Y)$ a family of bounded operators which is *pointwise bounded*:

$$\sup_{i \in I} \|T_i x\| < \infty \quad \text{for every } x \in X.$$

Then it is *uniformly bounded*: $\sup_{i \in I} \|T_i\| < \infty$.

Proof. For $n \in \mathbb{N}$ let

$$F_n = \{x \in X : \|T_i x\| \leq n \text{ for all } i \in I\} = \bigcap_{i \in I} \{x : \|T_i x\| \leq n\}.$$

Each set in the intersection is closed (preimage of a closed set under the continuous map $x \mapsto \|T_i x\|$), so F_n is closed. By pointwise boundedness $X = \bigcup_n F_n$.

Since X is complete, Baire gives some N with F_N having non-empty interior, say $\bar{B}(x_0, r) \subseteq F_N$ with $r > 0$. Now for any x with $\|x\| \leq 1$ and any i ,

$$\|T_i x\| = \frac{1}{r} \|T_i(x_0 + rx) - T_i x_0\| \leq \frac{1}{r} (\|T_i(x_0 + rx)\| + \|T_i x_0\|) \leq \frac{2N}{r},$$

since both $x_0 + rx$ and x_0 lie in $\bar{B}(x_0, r) \subseteq F_N$. Hence $\|T_i\| \leq 2N/r$ for all i . $\square$

The theorem is genuinely surprising: pointwise information about a family of operators upgrades, for free, to uniform information. Completeness of X is essential – on c_{00} , the functionals $f_n(x) = nx_n$ are pointwise bounded but have $\|f_n\| = n$.

Corollary 33.4.10

Let X be a Banach space, Y a normed space and $T_n \in \mathcal{B}(X, Y)$ with $T_n x \rightarrow Tx$ for every $x \in X$. Then T is linear and bounded, with

$$\|T\| \leq \liminf_n \|T_n\| < \infty.$$

Proof. Linearity is clear. Each convergent sequence $(T_n x)$ is bounded, so $\{T_n\}$ is pointwise bounded, hence $\sup_n \|T_n\| = M < \infty$ by uniform boundedness. Then $\|Tx\| = \lim \|T_n x\| \leq M \|x\|$. The sharper bound follows by taking a subsequence realising the $\liminf$. $\square$

Corollary 33.4.11 (Weak boundedness implies boundedness)

Let X be a normed space and $S \subseteq X$. If $f(S)$ is bounded in $\mathbb{F}$ for every $f \in X^*$, then S is bounded in norm.

Proof. Apply uniform boundedness in the Banach space X^* to the family $\{\iota(x) : x \in S\} \subseteq X^{**}$. The hypothesis says exactly that this family is pointwise bounded on X^* , so $\sup_{x \in S} \|\iota(x)\| < \infty$; and $\|\iota(x)\| = \|x\|$ by Hahn–Banach. $\square$

Note the slight sleight of hand: X itself need not be complete, but X^* always is, so we may apply Baire there. This trick – move the problem into a dual space to gain completeness – is worth remembering.

Example 33.4.12 (Divergence of Fourier series)

Here is a striking application. For $f \in C(\mathbb{T})$, the continuous 2π -periodic functions with the sup norm, write

$$S_N f(x) = \sum_{|k| \leq N} \hat{f}(k) e^{ikx}, \quad \hat{f}(k) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(t) e^{-ikt} dt.$$

We claim that there is a continuous function whose Fourier series diverges at 0; indeed the set of such functions is residual.

Consider the functionals $\Lambda_N : C(\mathbb{T}) \rightarrow \mathbb{C}$, $\Lambda_N f = S_N f(0)$. A computation with the geometric series gives

$$\Lambda_N f = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(t) D_N(t) dt, \quad D_N(t) = \sum_{|k| \leq N} e^{-ikt} = \frac{\sin((N + \frac{1}{2})t)}{\sin(t/2)},$$

where D_N is the **Dirichlet kernel**. One checks that

$$\|\Lambda_N\| = \frac{1}{2\pi} \int_{-\pi}^{\pi} |D_N(t)| dt =: L_N,$$

the **Lebesgue constant**: the bound $\leq$ is clear, and it is attained in the limit by

taking f to approximate $\operatorname{sgn} D_N$ continuously. Now

$$L_N \geq \frac{1}{\pi} \int_0^\pi \frac{|\sin((N + \frac{1}{2})t)|}{t} dt \geq \frac{1}{\pi} \sum_{k=1}^N \frac{1}{k} \int_0^\pi |\sin u| \frac{du}{\pi} \cdot c \longrightarrow \infty$$

for a suitable constant $c > 0$; the essential point is the divergence of the harmonic series, giving $L_N \sim \frac{4}{\pi^2} \log N$.

So $\|\Lambda_N\| \rightarrow \infty$. Since $C(\mathbb{T})$ is a Banach space, uniform boundedness says the family $\{\Lambda_N\}$ cannot be pointwise bounded: there is $f \in C(\mathbb{T})$ with $\sup_N |S_N f(0)| = \infty$, so the Fourier series of f diverges at 0.

Remark. This example is worth contrasting with what happens in L^2 , where we will prove that the Fourier series of *every* function converges (in the L^2 norm). Pointwise convergence is a much more delicate matter; Carleson proved in 1966 that the Fourier series of an L^2 function converges almost everywhere, which is a very deep theorem.

§33.4.4 The Open Mapping Theorem

Recall that a map $T : X \rightarrow Y$ is **open** if $T(U)$ is open in Y whenever U is open in X . This is a strong requirement, but for surjective bounded operators between Banach spaces it comes for free.

Theorem 33.4.13 (Open Mapping Theorem)

Let X, Y be Banach spaces and $T \in \mathcal{B}(X, Y)$ surjective. Then T is an open map. Equivalently, there is $c > 0$ with

$$T(B_X) \supseteq cB_Y,$$

where B_X, B_Y are the open unit balls.

Proof. First, the equivalence. If $T(B_X) \supseteq cB_Y$ then for $U \subseteq X$ open and $x \in U$, choose r with $x + rB_X \subseteq U$; then

$$T(U) \supseteq Tx + rT(B_X) \supseteq Tx + rcB_Y,$$

so $T(U)$ is open. Conversely if T is open then $T(B_X)$ is an open set containing 0.

Step 1: $\overline{T(B_X)}$ contains a ball about 0. Since T is surjective and $X = \bigcup_n nB_X$,

$$Y = \bigcup_{n=1}^{\infty} T(nB_X) = \bigcup_{n=1}^{\infty} nT(B_X) \subseteq \bigcup_{n=1}^{\infty} n\overline{T(B_X)}.$$

As Y is complete, Baire gives an n for which $n\overline{T(B_X)}$ has non-empty interior, hence so does $K := \overline{T(B_X)}$: say $B(y_0, r) \subseteq K$. Now K is convex and symmetric ($-K = K$), being the closure of the convex symmetric set $T(B_X)$. So $B(-y_0, r) = -B(y_0, r) \subseteq K$, and for $\|y\| < r$,

$$y = \frac{1}{2}((y_0 + y) + (-y_0 + y)) \in \frac{1}{2}(K + K) = K$$

by convexity. Hence $rB_Y \subseteq \overline{T(B_X)}$.

Step 2: removing the closure. We claim $\frac{r}{2}B_Y \subseteq T(B_X)$. By scaling, Step 1 gives

$$2^{-k}rB_Y \subseteq \overline{T(2^{-k}B_X)} \quad \text{for all } k \geq 0.$$

Let $y \in Y$ with $\|y\| < r/2$. Since $y \in \overline{T(\frac{1}{2}B_X)}$, there is x_1 with $\|x_1\| < \frac{1}{2}$ and $\|y - Tx_1\| < r/4$. Since $y - Tx_1 \in \overline{T(\frac{1}{4}B_X)}$, there is x_2 with $\|x_2\| < \frac{1}{4}$ and $\|y - Tx_1 - Tx_2\| < r/8$. Continuing, we obtain x_k with $\|x_k\| < 2^{-k}$ and

$$\left\| y - T \left(\sum_{k=1}^n x_k \right) \right\| < 2^{-(n+1)}r.$$

Now $\sum_k \|x_k\| < 1$, so by completeness of X the series $\sum_k x_k$ converges to some x with $\|x\| < 1$, and by continuity of T we get $Tx = y$. Hence $y \in T(B_X)$. $\square$

Both completeness hypotheses are used, and both are needed: completeness of Y for Baire in Step 1, completeness of X for the series in Step 2.

Theorem 33.4.14 (Inverse Mapping Theorem)

Let X, Y be Banach spaces and $T \in \mathcal{B}(X, Y)$ a bijection. Then $T^{-1} \in \mathcal{B}(Y, X)$; that is, T is an isomorphism.

Proof. T is open by the open mapping theorem, and an open bijection has continuous inverse: $(T^{-1})^{-1}(U) = T(U)$ is open for every open U . $\square$

This is a genuinely useful tool. It says that for operators between Banach spaces, algebraic invertibility automatically gives topological invertibility – so to check that an equation $Tx = y$ has a solution depending continuously on the data, we need only check existence and uniqueness.

Corollary 33.4.15

Let $\|\cdot\|_1$ and $\|\cdot\|_2$ be two norms on a vector space X , each making X complete. If there is C with $\|x\|_2 \leq C\|x\|_1$ for all x , then the norms are equivalent.

Proof. The identity map $(X, \|\cdot\|_1) \rightarrow (X, \|\cdot\|_2)$ is a bounded bijection between Banach spaces, hence has bounded inverse. $\square$

Corollary 33.4.16

Let X be a Banach space and $X = Y \oplus Z$ an algebraic direct sum with Y, Z closed subspaces. Then the projection $P : X \rightarrow Y$ along Z is bounded.

Proof. $Y \oplus Z$ with the norm $\|(y, z)\| = \|y\| + \|z\|$ is a Banach space (as Y, Z are closed in the complete X), and the addition map $(y, z) \mapsto y + z$ is a bounded bijection onto X . Its inverse $x \mapsto (Px, x - Px)$ is bounded by the inverse mapping theorem, so P is bounded. $\square$

§33.4.5 The Closed Graph Theorem

To prove an operator is bounded we must show $x_n \rightarrow x$ implies $Tx_n \rightarrow Tx$. The closed graph theorem says that – between Banach spaces – we may *assume* that Tx_n converges, and only check that its limit is right. In practice this halves the work.

Definition 33.4.17 (Graph)

Let $T : X \rightarrow Y$ be linear. Its **graph** is

$$\Gamma(T) = \{(x, Tx) : x \in X\} \subseteq X \oplus Y.$$

We say T is **closed** if $\Gamma(T)$ is a closed subspace of $X \oplus Y$ (with the norm $\|(x, y)\| = \|x\| + \|y\|$).

Unwinding the definition, T is closed precisely when: whenever $x_n \rightarrow x$ in X and $Tx_n \rightarrow y$ in Y , we have $y = Tx$.

Theorem 33.4.18 (Closed Graph Theorem)

Let X, Y be Banach spaces and $T : X \rightarrow Y$ linear. Then T is bounded if and only if it is closed.

Proof. ($\Rightarrow$) If T is bounded and $(x_n, Tx_n) \rightarrow (x, y)$ then $Tx_n \rightarrow Tx$ by continuity, so $y = Tx$.

($\Leftarrow$) Suppose $\Gamma = \Gamma(T)$ is closed. Then Γ is a closed subspace of the Banach space $X \oplus Y$, hence itself a Banach space. Consider the two coordinate projections restricted to Γ :

$$\pi_X : \Gamma \rightarrow X, (x, Tx) \mapsto x, \quad \pi_Y : \Gamma \rightarrow Y, (x, Tx) \mapsto Tx.$$

Both are bounded, with norm at most 1. Moreover π_X is a bijection. By the inverse mapping theorem, $\pi_X^{-1} : X \rightarrow \Gamma$ is bounded. But then

$$T = \pi_Y \circ \pi_X^{-1}$$

is bounded, being a composite of bounded maps. □

Example 33.4.19

Let X be a Banach space and $T : X \rightarrow X$ linear with the property that $f \circ T \in X^*$ for every $f \in X^*$. Then T is bounded. Indeed, suppose $x_n \rightarrow x$ and $Tx_n \rightarrow y$. For any $f \in X^*$,

$$f(y) = \lim_n f(Tx_n) = \lim_n (f \circ T)(x_n) = (f \circ T)(x) = f(Tx),$$

using continuity of $f \circ T$. Since X^* separates points, $y = Tx$, so T is closed, hence bounded.

Example 33.4.20 (Where it fails)

Differentiation $D : C^1[0, 1] \rightarrow C[0, 1]$, with $C^1[0, 1]$ given the sup norm, *is* closed: if $f_n \rightarrow f$ uniformly and $f'_n \rightarrow g$ uniformly then f is differentiable with $f' = g$, by the theorem on differentiating uniform limits from IB Analysis and Topology. But we saw that D is unbounded. There is no contradiction: $(C^1[0, 1], \|\cdot\|_\infty)$ is not complete. This shows that completeness of the *domain* really is needed.

§33.5 The Topology of $C(K)$

Of all our examples, the space $C(K)$ of continuous functions on a compact space is the most important, and it deserves a section of its own. We ask three questions. Are there enough continuous functions on K to be interesting? Which subsets of $C(K)$ are compact? And which subalgebras are dense?

Throughout, K is a compact Hausdorff space, and $C(K)$ carries the sup norm.

§33.5.1 Normality and Urysohn's Lemma

Definition 33.5.1 (Normal space)

A topological space X is **normal** if for any two disjoint closed sets $C_1, C_2 \subseteq X$ there are disjoint open sets $U_1 \supseteq C_1$ and $U_2 \supseteq C_2$.

Proposition 33.5.2

Every compact Hausdorff space is normal. So is every metric space.

Proof. Let X be compact Hausdorff and C_1, C_2 disjoint closed sets, hence compact.

First suppose $C_2 = \{y\}$ is a point. For each $x \in C_1$ use the Hausdorff property to find disjoint open $U_x \ni x$ and $V_x \ni y$. The U_x cover C_1 , so finitely many suffice, say $U_{x_1}, \dots, U_{x_n}$; then $U = \bigcup_i U_{x_i}$ and $V = \bigcap_i V_{x_i}$ are disjoint open sets separating C_1 from y .

In general, for each $y \in C_2$ we obtain from the above disjoint open $U_y \supseteq C_1$ and $V_y \ni y$. The V_y cover C_2 , so finitely many suffice, and $\bigcap_i U_{y_i} \supseteq C_1$ and $\bigcup_i V_{y_i} \supseteq C_2$ are disjoint and open.

For a metric space, take $U_i = \{x : \text{dist}(x, C_i) < \text{dist}(x, C_{3-i})\}$; these are open by continuity of the distance functions, disjoint, and contain C_1, C_2 respectively. $\square$

Normality is precisely the hypothesis under which $C(X)$ is rich.

Lemma 33.5.3 (Urysohn's Lemma)

Let X be normal and $C_0, C_1 \subseteq X$ disjoint non-empty closed sets. Then there is a continuous $f : X \rightarrow [0, 1]$ with $f|_{C_0} = 0$ and $f|_{C_1} = 1$.

Proof. First note a reformulation of normality: if $C \subseteq U$ with C closed and U open, then there is an open V with

$$C \subseteq V \subseteq \bar{V} \subseteq U.$$

(Apply normality to C and $X \setminus U$ to get disjoint open $V \supseteq C$ and $W \supseteq X \setminus U$; then $\bar{V} \subseteq X \setminus W \subseteq U$.)

Let $D = \{k/2^n : n \geq 0, 0 \leq k \leq 2^n\}$ be the dyadic rationals in $[0, 1]$. We construct open sets U_r for $r \in D$ with

$$C_0 \subseteq U_0, \quad U_1 = X \setminus C_1, \quad \text{and} \quad \bar{U}_r \subseteq U_s \quad \text{whenever} \quad r < s.$$

Start by setting $U_1 = X \setminus C_1$ and using the reformulation to pick U_0 with $C_0 \subseteq U_0 \subseteq \bar{U}_0 \subseteq U_1$. Inductively, having defined U_r for all $r \in D$ with denominator 2^n , and given a new dyadic $r = (2k+1)/2^{n+1}$ lying between the old neighbours $a = k/2^n$ and $b = (k+1)/2^n$, we have $\bar{U}_a \subseteq U_b$ and use the reformulation to choose U_r with

$$\bar{U}_a \subseteq U_r \subseteq \bar{U}_r \subseteq U_b.$$

This maintains the nesting property.

Now define

$$f(x) = \inf\{r \in D : x \in U_r\},$$

with $f(x) = 1$ if x lies in no U_r . Then $f = 0$ on C_0 and $f = 1$ on C_1 , and $0 \leq f \leq 1$.

It remains to check continuity. The sets $[0, a)$ and $(a, 1]$ generate the topology of $[0, 1]$, so it is enough to see that $f^{-1}([0, a))$ and $f^{-1}((a, 1])$ are open. For the first,

$$f(x) < a \iff \exists r \in D, r < a, x \in U_r,$$

so $f^{-1}([0, a)) = \bigcup_{r < a} U_r$ is open. For the second, we claim

$$f(x) > a \iff \exists r \in D, r > a, x \notin \bar{U}_r,$$

giving $f^{-1}((a, 1]) = \bigcup_{r > a} (X \setminus \bar{U}_r)$, which is open. Indeed if $x \notin \bar{U}_r$ with $r > a$ then $x \notin U_s$ for all $s \leq r$ (as $U_s \subseteq \bar{U}_s \subseteq U_r$ for $s < r$), so $f(x) \geq r > a$. Conversely if $f(x) > a$, pick dyadics $a < r < s < f(x)$; then $x \notin U_s \supseteq \bar{U}_r$. $\square$

Corollary 33.5.4

If K is compact Hausdorff then $C(K)$ separates the points of K .

Proof. Points are closed in a Hausdorff space, so apply Urysohn to $\{x\}$ and $\{y\}$ for $x \neq y$. $\square$

Theorem 33.5.5 (Tietze Extension Theorem)

Let X be normal, $C \subseteq X$ closed and $f : C \rightarrow \mathbb{R}$ continuous and bounded. Then there is a continuous $\tilde{f} : X \rightarrow \mathbb{R}$ with $\tilde{f}|_C = f$ and $\|\tilde{f}\|_\infty = \|f\|_\infty$.

Proof. By rescaling assume $\|f\|_\infty \leq 1$. We claim: given continuous $g : C \rightarrow \mathbb{R}$ with $\|g\|_\infty \leq M$, there is a continuous $h : X \rightarrow \mathbb{R}$ with $\|h\|_\infty \leq M/3$ and $\|g - h|_C\|_\infty \leq 2M/3$.

To see this, let $A = g^{-1}([-M, -M/3])$ and $B = g^{-1}([M/3, M])$, which are disjoint closed subsets of C , hence closed in X . If both are non-empty, Urysohn gives a continuous $u : X \rightarrow [0, 1]$ with $u|_A = 0$, $u|_B = 1$, and we set $h = \frac{M}{3}(2u - 1)$, which takes values in $[-M/3, M/3]$. On A , $h = -M/3$ and $g \in [-M, -M/3]$, so $|g - h| \leq 2M/3$; similarly on B ; and on the rest of C both g and h lie in $[-M/3, M/3]$. (If A or B is empty, take h constant appropriately.)

Now iterate. Put $g_0 = f$ and $M_0 = 1$. Given g_n with $\|g_n\|_\infty \leq (2/3)^n$, obtain h_n on X with $\|h_n\|_\infty \leq \frac{1}{3}(2/3)^n$ and set $g_{n+1} = g_n - h_n|_C$, so $\|g_{n+1}\|_\infty \leq (2/3)^{n+1}$. Since

$$\sum_{n=0}^{\infty} \|h_n\|_\infty \leq \frac{1}{3} \sum_{n=0}^{\infty} \left(\frac{2}{3}\right)^n = 1 < \infty,$$

the series $\tilde{f} = \sum_n h_n$ converges uniformly on X (as $C(X)$ with the sup norm, or rather $B(X)$, is complete), so $\tilde{f}$ is continuous with $\|\tilde{f}\|_\infty \leq 1$. On C we have $\sum_{n \leq N} h_n = f - g_{N+1} \rightarrow f$, so $\tilde{f}|_C = f$. Finally $\|\tilde{f}\|_\infty \geq \|f\|_\infty$ trivially, giving equality. $\square$

§33.5.2 The Arzelà–Ascoli Theorem

We know that closed bounded subsets of $C(K)$ are never compact (the space is infinite-dimensional). So what is the right extra condition? The answer is a uniformity in the modulus of continuity.

Definition 33.5.6 (Totally bounded)

A subset S of a metric space is **totally bounded** if for every $\varepsilon > 0$ there are finitely many points $x_1, \dots, x_n$ with $S \subseteq \bigcup_i B(x_i, \varepsilon)$. Such a set $\{x_i\}$ is called an **ε -net**.

Proposition 33.5.7

Let (X, d) be a complete metric space and $S \subseteq X$. Then $\bar{S}$ is compact if and only if S is totally bounded.

Proof. ($\Rightarrow$) If $\bar{S}$ is compact, cover it by the balls $B(x, \varepsilon)$, $x \in \bar{S}$, and extract a finite subcover.

($\Leftarrow$) In a metric space, compactness is equivalent to sequential compactness, so let $(y_n) \subseteq \bar{S}$; we find a Cauchy subsequence, which converges by completeness (and its limit is in $\bar{S}$, which is closed). By total boundedness of S , hence of $\bar{S}$, cover $\bar{S}$ by finitely many balls of radius 1; one of them, B_1 say, contains y_n for infinitely many n . Cover $\bar{S}$ by finitely many balls of radius $\frac{1}{2}$; one of them, B_2 , contains y_n for infinitely many of those n . Continuing and taking a diagonal subsequence gives (y_{n_k}) with $y_{n_k} \in B_1 \cap \dots \cap B_k$ for each k , so $d(y_{n_k}, y_{n_l}) \leq 2/k$ for $l \geq k$. This subsequence is Cauchy. $\square$

Definition 33.5.8 (Equicontinuity)

Let K be a compact Hausdorff space. A family $\mathcal{F} \subseteq C(K)$ is

- (i) **equibounded** if $\sup_{f \in \mathcal{F}} \|f\|_\infty < \infty$;
- (ii) **equicontinuous at $x \in K$** if for every $\varepsilon > 0$ there is an open $U \ni x$ with $|f(y) - f(x)| < \varepsilon$ for all $y \in U$ and all $f \in \mathcal{F}$;
- (iii) **equicontinuous** if it is equicontinuous at every point.

The point is the order of quantifiers: one neighbourhood works for the whole family at once. For $K \subseteq \mathbb{R}$ a typical sufficient condition is a uniform Lipschitz bound, $|f(x) - f(y)| \leq L|x - y|$ for all $f \in \mathcal{F}$.

Theorem 33.5.9 (Arzelà–Ascoli)

Let K be a compact Hausdorff space and $\mathcal{F} \subseteq C(K)$. Then $\mathcal{F}$ is relatively compact (i.e. $\bar{\mathcal{F}}$ is compact) if and only if $\mathcal{F}$ is equibounded and equicontinuous.

Proof. ($\Rightarrow$) Suppose $\bar{\mathcal{F}}$ is compact, so $\mathcal{F}$ is totally bounded. Equiboundedness is immediate. For equicontinuity at x , let $\varepsilon > 0$ and take an $\varepsilon/3$ -net $f_1, \dots, f_n$ for $\mathcal{F}$. Each f_i is continuous, so there is an open $U \ni x$ with $|f_i(y) - f_i(x)| < \varepsilon/3$ for $y \in U$ and all i (intersect the finitely many neighbourhoods). Given $f \in \mathcal{F}$, pick i with $\|f - f_i\|_\infty < \varepsilon/3$; then for $y \in U$,

$$|f(y) - f(x)| \leq |f(y) - f_i(y)| + |f_i(y) - f_i(x)| + |f_i(x) - f(x)| < \varepsilon.$$

($\Leftarrow$) Since $C(K)$ is complete, it suffices to show $\mathcal{F}$ is totally bounded. Let $\varepsilon > 0$. By equicontinuity, each $x \in K$ has an open $U_x \ni x$ with $|f(y) - f(x)| < \varepsilon/4$ for all $y \in U_x$, $f \in \mathcal{F}$. By compactness, $K = U_{x_1} \cup \dots \cup U_{x_m}$.

Consider the map $\Phi : \mathcal{F} \rightarrow \mathbb{R}^m$, $\Phi(f) = (f(x_1), \dots, f(x_m))$. By equiboundedness the image lies in a bounded subset of $\mathbb{R}^m$, which is totally bounded, so there are $f_1, \dots, f_n \in \mathcal{F}$ such that every $f \in \mathcal{F}$ has some j with $|f(x_i) - f_j(x_i)| < \varepsilon/4$ for all i .

We claim $\{f_j\}$ is an ε -net. Given f , choose j as above, and let $y \in K$, say $y \in U_{x_i}$. Then

$$|f(y) - f_j(y)| \leq |f(y) - f(x_i)| + |f(x_i) - f_j(x_i)| + |f_j(x_i) - f_j(y)| < \frac{\varepsilon}{4} + \frac{\varepsilon}{4} + \frac{\varepsilon}{4} < \varepsilon.$$

So $\|f - f_j\|_\infty \leq \varepsilon$, as needed. $\square$

Example 33.5.10

Let $k \in C([0, 1]^2)$ and let $T : C[0, 1] \rightarrow C[0, 1]$ be the integral operator with kernel k . Then $T(\bar{B})$ is relatively compact. Indeed for $\|f\|_\infty \leq 1$ we have $\|Tf\|_\infty \leq \|k\|_\infty$, giving equiboundedness, and

$$|Tf(x) - Tf(x')| \leq \int_0^1 |k(x, y) - k(x', y)| dy \leq \sup_y |k(x, y) - k(x', y)|,$$

which is small when $|x - x'|$ is small, uniformly in f , since k is uniformly continuous

on the compact set $[0, 1]^2$. So T is a *compact operator* in the sense of the last section of these notes.

Theorem 33.5.11 (Cauchy–Peano)

Let $\varphi : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$ be continuous. Then the initial value problem $y' = \varphi(t, y)$, $y(t_0) = y_0$ has a solution on some interval around t_0 .

Proof sketch. On a suitable rectangle, $|\varphi| \leq M$. Build approximate solutions y_n by Euler’s method with step $1/n$, or by delaying the argument. Each y_n is M -Lipschitz and uniformly bounded, so the family is equibounded and equicontinuous; by Arzelà–Ascoli a subsequence converges uniformly to some y , and passing to the limit in the integral equation $y_n(t) = y_0 + \int_{t_0}^t \varphi(s, y_n(s)) \, ds + o(1)$ shows y solves the problem. $\square$

Note the contrast with the Picard–Lindelöf theorem from IB Analysis and Topology, which assumed φ Lipschitz in y and gave existence *and uniqueness* via the contraction mapping theorem. Continuity alone buys existence only: $y' = \sqrt{|y|}$, $y(0) = 0$ has both $y \equiv 0$ and $y = t^2/4$ as solutions.

§33.5.3 The Stone–Weierstrass Theorem

Finally, density. Weierstrass proved that polynomials are dense in $C[0, 1]$; Stone found the right generality.

Definition 33.5.12 (Subalgebra)

A **subalgebra** $\mathcal{A} \subseteq C(K)$ is a linear subspace closed under pointwise multiplication. It **separates points** if for all $x \neq y$ in K there is $f \in \mathcal{A}$ with $f(x) \neq f(y)$.

Theorem 33.5.13 (Stone–Weierstrass, real case)

Let K be compact Hausdorff and $\mathcal{A} \subseteq C_{\mathbb{R}}(K)$ a subalgebra which separates points and contains the constant functions. Then $\mathcal{A}$ is dense in $C_{\mathbb{R}}(K)$.

Proof. Replacing $\mathcal{A}$ by $\bar{\mathcal{A}}$ (still a subalgebra, since multiplication is continuous on bounded sets), we may assume $\mathcal{A}$ is closed, and must show $\mathcal{A} = C_{\mathbb{R}}(K)$.

Step 1: $\mathcal{A}$ is a lattice. We claim $f \in \mathcal{A} \Rightarrow |f| \in \mathcal{A}$. By scaling assume $\|f\|_{\infty} \leq 1$. The function $t \mapsto |t|$ is a uniform limit on $[-1, 1]$ of polynomials p_n with $p_n(0) = 0$: for instance take the binomial series for $\sqrt{s}$ about $s = 1$, evaluated at $s = t^2$, which converges uniformly on $[-1, 1]$; alternatively use $\sqrt{t^2 + \varepsilon^2}$ and expand. Then $p_n(f) \in \mathcal{A}$ (as $\mathcal{A}$ is an algebra containing constants) and $p_n(f) \rightarrow |f|$ uniformly, so $|f| \in \mathcal{A}$ as $\mathcal{A}$ is closed. Consequently

$$\max(f, g) = \frac{1}{2}(f + g + |f - g|), \quad \min(f, g) = \frac{1}{2}(f + g - |f - g|)$$

lie in $\mathcal{A}$ whenever f, g do.

Step 2: two-point interpolation. Given $x \neq y$ in K and $\alpha, \beta \in \mathbb{R}$, there is $h \in \mathcal{A}$

with $h(x) = \alpha$, $h(y) = \beta$: take $g \in \mathcal{A}$ with $g(x) \neq g(y)$ and set

$$h = \alpha + (\beta - \alpha) \frac{g - g(x)}{g(y) - g(x)},$$

which is in $\mathcal{A}$ since $\mathcal{A}$ contains the constants.

Step 3: approximation. Let $f \in C_{\mathbb{R}}(K)$ and $\varepsilon > 0$. Fix $x \in K$. For each $y \in K$ choose $h_{x,y} \in \mathcal{A}$ with $h_{x,y}(x) = f(x)$ and $h_{x,y}(y) = f(y)$. The set $V_y = \{z : h_{x,y}(z) < f(z) + \varepsilon\}$ is open and contains y , so finitely many $V_{y_1}, \dots, V_{y_n}$ cover K . Put

$$h_x = \min(h_{x,y_1}, \dots, h_{x,y_n}) \in \mathcal{A}.$$

Then $h_x < f + \varepsilon$ everywhere and $h_x(x) = f(x)$.

Now the set $W_x = \{z : h_x(z) > f(z) - \varepsilon\}$ is open and contains x , so finitely many $W_{x_1}, \dots, W_{x_m}$ cover K . Put $h = \max(h_{x_1}, \dots, h_{x_m}) \in \mathcal{A}$. Then $f - \varepsilon < h < f + \varepsilon$ everywhere, i.e. $\|f - h\|_{\infty} \leq \varepsilon$. As $\mathcal{A}$ is closed, $f \in \mathcal{A}$. $\square$

Theorem 33.5.14 (Stone–Weierstrass, complex case)

Let K be compact Hausdorff and $\mathcal{A} \subseteq C_{\mathbb{C}}(K)$ a subalgebra which separates points, contains the constants, and is closed under complex conjugation. Then $\mathcal{A}$ is dense.

Proof. Let $\mathcal{A}_{\mathbb{R}} = \{f \in \mathcal{A} : f \text{ real-valued}\}$. Since $\mathcal{A}$ is conjugation-closed, $\operatorname{Re} f = \frac{1}{2}(f + \bar{f})$ and $\operatorname{Im} f = \frac{1}{2i}(f - \bar{f})$ lie in $\mathcal{A}_{\mathbb{R}}$ for every $f \in \mathcal{A}$. Then $\mathcal{A}_{\mathbb{R}}$ is a real subalgebra containing the real constants, and it separates points: if $f(x) \neq f(y)$ then $\operatorname{Re} f$ or $\operatorname{Im} f$ separates them. By the real case, $\mathcal{A}_{\mathbb{R}}$ is dense in $C_{\mathbb{R}}(K)$, and hence $\mathcal{A} \supseteq \mathcal{A}_{\mathbb{R}} + i\mathcal{A}_{\mathbb{R}}$ is dense in $C_{\mathbb{C}}(K)$. $\square$

Conjugation-closedness cannot be dropped: on the closed unit disc $\bar{D} \subseteq \mathbb{C}$, the polynomials in z form a separating subalgebra containing the constants, but their closure consists of functions holomorphic on the interior – nothing like all of $C(\bar{D})$.

Example 33.5.15 (i) Polynomials are dense in $C[a, b]$: they form a subalgebra containing the constants, and $x \mapsto x$ separates points. This is the Weierstrass approximation theorem.

(ii) Trigonometric polynomials $\operatorname{span}\{e^{ikx} : k \in \mathbb{Z}\}$ are dense in $C(\mathbb{T})$: this is a conjugation-closed subalgebra ($\overline{e^{ikx}} = e^{-ikx}$) containing the constants, and e^{ix} separates points of the circle. We will use this to prove completeness of the Fourier basis in L^2 .

(iii) Functions of the form $\sum_j f_j(x)g_j(y)$ are dense in $C([0, 1]^2)$, which gives Fubini's theorem for continuous functions almost for free.

Remark. If $\mathcal{A}$ separates points but does *not* contain the constants, the conclusion becomes: $\bar{\mathcal{A}}$ is either all of $C(K)$ or the set $\{f : f(x_0) = 0\}$ for some $x_0 \in K$. Applying the theorem to $\mathcal{A} + \mathbb{C}$ and chasing through gives this refinement.

§33.6 Hilbert Spaces

So far we have had a notion of length but not of angle. If we add one – that is, if the norm comes from an inner product – an enormous amount of Euclidean geometry survives into infinite dimensions, and the theory becomes vastly more powerful. These are the Hilbert spaces, and they are the setting in which quantum mechanics, Fourier analysis and the spectral theorem all live.

§33.6.1 Inner Products

Definition 33.6.1 (Inner product)

Let V be a vector space over $\mathbb{F}$. An **inner product** on V is a map $\langle \cdot, \cdot \rangle : V \times V \rightarrow \mathbb{F}$ such that for all $u, v, w \in V$ and $\lambda \in \mathbb{F}$:

- (i) (*Linearity in the first slot*) $\langle \lambda u + v, w \rangle = \lambda \langle u, w \rangle + \langle v, w \rangle$;
- (ii) (*Conjugate symmetry*) $\langle v, w \rangle = \overline{\langle w, v \rangle}$;
- (iii) (*Positive definiteness*) $\langle v, v \rangle \geq 0$, with equality if and only if $v = 0$.

The pair $(V, \langle \cdot, \cdot \rangle)$ is an **inner product space**.

Note that (i) and (ii) together force conjugate-linearity in the second slot: $\langle u, \lambda v \rangle = \bar{\lambda} \langle u, v \rangle$. (This is the convention of the physicists' second slot; some books put the conjugate-linearity in the first slot instead. Nothing of substance depends on the choice, but one must be consistent.) Over $\mathbb{R}$ the inner product is just a symmetric positive definite bilinear form, as in IB Linear Algebra.

Example 33.6.2 (i) $\mathbb{F}^n$ with $\langle x, y \rangle = \sum_i x_i \bar{y}_i$, giving $\|\cdot\|_2$.

(ii) ℓ^2 with $\langle x, y \rangle = \sum_{i=1}^{\infty} x_i \bar{y}_i$, which converges absolutely by Cauchy–Schwarz.

(iii) $C[0, 1]$ with $\langle f, g \rangle = \int_0^1 f \bar{g} \, dx$, giving $\|\cdot\|_{L^2}$.

(iv) $C(\mathbb{T})$ with $\langle f, g \rangle = \frac{1}{2\pi} \int_{-\pi}^{\pi} f \bar{g} \, dx$.

Proposition 33.6.3 (Cauchy–Schwarz)

Let V be an inner product space. Then for all $v, w \in V$,

$$|\langle v, w \rangle| \leq \langle v, v \rangle^{1/2} \langle w, w \rangle^{1/2},$$

with equality if and only if v, w are linearly dependent.

Proof. If $w = 0$ both sides vanish. Otherwise, for $\lambda \in \mathbb{F}$,

$$0 \leq \langle v - \lambda w, v - \lambda w \rangle = \langle v, v \rangle - \bar{\lambda} \langle v, w \rangle - \lambda \overline{\langle v, w \rangle} + |\lambda|^2 \langle w, w \rangle.$$

Choosing $\lambda = \langle v, w \rangle / \langle w, w \rangle$ gives

$$0 \leq \langle v, v \rangle - \frac{|\langle v, w \rangle|^2}{\langle w, w \rangle},$$

which rearranges to the result. Equality forces $v = \lambda w$. $\square$

Corollary 33.6.4

$\|v\| = \langle v, v \rangle^{1/2}$ defines a norm on V .

Proof. Positivity and homogeneity are clear. For the triangle inequality,

$$\|v + w\|^2 = \|v\|^2 + 2 \operatorname{Re} \langle v, w \rangle + \|w\|^2 \leq \|v\|^2 + 2 \|v\| \|w\| + \|w\|^2 = (\|v\| + \|w\|)^2. \quad \square$$

Definition 33.6.5 (Hilbert space)

A **Hilbert space** is an inner product space which is complete in the induced norm.

So $\mathbb{F}^n$, ℓ^2 and $L^2[0, 1]$ are Hilbert spaces; $C[0, 1]$ with the L^2 inner product is an inner product space which is not complete.

Which norms come from an inner product? There is a clean answer.

Proposition 33.6.6 (Parallelogram law)

In an inner product space,

$$\|v + w\|^2 + \|v - w\|^2 = 2\|v\|^2 + 2\|w\|^2.$$

Conversely (Jordan–von Neumann), if a norm on V satisfies this identity for all v, w , then it comes from an inner product.

Proof. Expanding both left-hand terms, the cross terms $\pm 2 \operatorname{Re} \langle v, w \rangle$ cancel.

For the converse, the inner product must be given by the **polarisation identity**

$$\langle v, w \rangle = \frac{1}{4} (\|v + w\|^2 - \|v - w\|^2)$$

in the real case, and

$$\langle v, w \rangle = \frac{1}{4} \sum_{k=0}^3 i^k \|v + i^k w\|^2$$

in the complex case. One then verifies the inner product axioms directly, using the parallelogram law repeatedly; additivity in the first slot is a short computation, homogeneity over $\mathbb{Q}$ follows by induction, and over $\mathbb{R}$ by continuity. We omit the (unenlightening) details. $\square$

Example 33.6.7

The parallelogram law gives a quick way to see which of our spaces are not inner product spaces. In ℓ^p take $v = e_1$, $w = e_2$; then $\|v \pm w\|_p = 2^{1/p}$ and $\|v\|_p = \|w\|_p = 1$, so the law demands $2 \cdot 2^{2/p} = 4$, i.e. $p = 2$. Similarly $C[0, 1]$ with the sup norm is not an inner product space: take $f(x) = 1$ and $g(x) = x$, so $\|f\|_\infty = \|g\|_\infty = 1$, $\|f + g\|_\infty = 2$ and $\|f - g\|_\infty = 1$, and $4 + 1 \neq 2 + 2$.

Definition 33.6.8 (Orthogonality)

Vectors v, w in an inner product space are **orthogonal**, written $v \perp w$, if $\langle v, w \rangle = 0$. For $S \subseteq V$ the **orthogonal complement** is

$$S^\perp = \{v \in V : \langle v, s \rangle = 0 \text{ for all } s \in S\}.$$

A set is **orthonormal** if its elements are pairwise orthogonal and each has norm 1.

Proposition 33.6.9

$S^\perp$ is a closed subspace of V , and $S^\perp = (\overline{\text{span } S})^\perp$.

Proof. It is the intersection over $s \in S$ of the kernels of the continuous linear functionals $v \mapsto \langle v, s \rangle$, hence a closed subspace. The second claim holds since $\langle v, \cdot \rangle$ is continuous and conjugate-linear, so vanishing on S forces vanishing on $\overline{\text{span } S}$. $\square$

Proposition 33.6.10 (Pythagoras)

If $v \perp w$ then $\|v + w\|^2 = \|v\|^2 + \|w\|^2$. More generally, if $e_1, \dots, e_n$ are orthonormal and $v \in V$, then

$$\|v\|^2 = \left\| v - \sum_{i=1}^n \langle v, e_i \rangle e_i \right\|^2 + \sum_{i=1}^n |\langle v, e_i \rangle|^2.$$

Proof. The first claim is immediate on expanding. For the second, let $u = \sum_i \langle v, e_i \rangle e_i$. Then for each j ,

$$\langle v - u, e_j \rangle = \langle v, e_j \rangle - \langle v, e_j \rangle = 0,$$

so $v - u \perp u$, and Pythagoras with $\|u\|^2 = \sum_i |\langle v, e_i \rangle|^2$ gives the identity. $\square$

Corollary 33.6.11 (Bessel's Inequality)

If $(e_i)_{i \in I}$ is an orthonormal family in V and $v \in V$, then

$$\sum_{i \in I} |\langle v, e_i \rangle|^2 \leq \|v\|^2,$$

where the sum is the supremum over finite subfamilies. In particular only countably many terms are non-zero.

Proof. Each finite partial sum is at most $\|v\|^2$ by the previous proposition. For the last claim, the set of i with $|\langle v, e_i \rangle| > 1/n$ has at most $n^2 \|v\|^2$ elements. $\square$

The geometry here is exactly what you would draw in $\mathbb{R}^3$: the vector $\sum_i \langle v, e_i \rangle e_i$ is the orthogonal projection of v onto the span of the e_i , and Bessel says a projection cannot be longer than the original.

Now the fundamental construction. In a general normed space, a closed convex set need not contain a point closest to a given point; in a Hilbert space it always does, and uniquely.

Theorem 33.6.12 (Projection onto a closed convex set)

Let H be a Hilbert space and $C \subseteq H$ a non-empty closed convex set. Then for every $v \in H$ there is a unique $P_C v \in C$ with

$$\|v - P_C v\| = \text{dist}(v, C) = \inf_{c \in C} \|v - c\|.$$

Moreover $P_C v$ is characterised among points of C by

$$\text{Re}\langle c - P_C v, v - P_C v \rangle \leq 0 \quad \text{for all } c \in C,$$

and P_C is 1-Lipschitz.

Proof. Existence. Let $d = \text{dist}(v, C)$ and pick $c_n \in C$ with $\|v - c_n\| \rightarrow d$. Apply the parallelogram law to $v - c_n$ and $v - c_m$:

$$\|c_m - c_n\|^2 = 2\|v - c_n\|^2 + 2\|v - c_m\|^2 - 4\left\|v - \frac{c_n + c_m}{2}\right\|^2.$$

By convexity $\frac{c_n + c_m}{2} \in C$, so the last term is at least $4d^2$, giving

$$\|c_m - c_n\|^2 \leq 2\|v - c_n\|^2 + 2\|v - c_m\|^2 - 4d^2 \rightarrow 0.$$

So (c_n) is Cauchy; by completeness it converges to some $c \in C$ (C is closed), and $\|v - c\| = d$.

Uniqueness. If c, c' both realise the distance, the same computation gives $\|c - c'\|^2 \leq 2d^2 + 2d^2 - 4d^2 = 0$.

Variational characterisation. Write $u = P_C v$. For $c \in C$ and $t \in (0, 1]$, convexity gives $u + t(c - u) \in C$, so

$$\|v - u\|^2 \leq \|v - u - t(c - u)\|^2 = \|v - u\|^2 - 2t \text{Re}\langle c - u, v - u \rangle + t^2 \|c - u\|^2.$$

Hence $2 \text{Re}\langle c - u, v - u \rangle \leq t \|c - u\|^2$ for all $t \in (0, 1]$; letting $t \rightarrow 0$ gives $\text{Re}\langle c - u, v - u \rangle \leq 0$. Conversely, if $u \in C$ satisfies this then for any $c \in C$,

$$\|v - c\|^2 = \|(v - u) - (c - u)\|^2 = \|v - u\|^2 - 2 \text{Re}\langle c - u, v - u \rangle + \|c - u\|^2 \geq \|v - u\|^2,$$

so u minimises.

Lipschitz. Let $u = P_C v$, $u' = P_C v'$. Adding the variational inequalities with $c = u'$ and $c = u$ respectively gives

$$\operatorname{Re}\langle u' - u, v - u \rangle \leq 0, \quad \operatorname{Re}\langle u - u', v' - u' \rangle \leq 0,$$

and adding, $\operatorname{Re}\langle u' - u, (v - v') - (u - u') \rangle \leq 0$, i.e. $\|u - u'\|^2 \leq \operatorname{Re}\langle u - u', v - v' \rangle \leq \|u - u'\| \|v - v'\|$. $\square$

The variational condition says that the vector from the closest point to v makes an obtuse (or right) angle with every direction into C . If you draw it, the reason is obvious: if the angle were acute, we could move a little way into C and get closer.

Applying this to a closed subspace gives the decomposition that makes Hilbert space theory work.

Theorem 33.6.13 (Orthogonal decomposition)

Let H be a Hilbert space and $M \subseteq H$ a closed subspace. Then

$$H = M \oplus M^\perp,$$

and the projection P_M onto M is linear, bounded with $\|P_M\| \leq 1$, satisfies $P_M^2 = P_M$, and has $\ker P_M = M^\perp$, $\operatorname{img} P_M = M$. Moreover $(M^\perp)^\perp = M$.

Proof. A subspace is convex and, being closed, the projection theorem applies. Let $v \in H$ and $u = P_M v$. The variational inequality reads $\operatorname{Re}\langle m - u, v - u \rangle \leq 0$ for all $m \in M$; as M is a subspace, $m - u$ ranges over all of M , and replacing $m - u$ by $\lambda(m - u)$ for arbitrary $\lambda \in \mathbb{F}$ we conclude

$$\langle m, v - u \rangle = 0 \quad \text{for all } m \in M,$$

i.e. $v - u \in M^\perp$. Hence $v = u + (v - u) \in M + M^\perp$. The sum is direct since $M \cap M^\perp = \{0\}$ (a vector orthogonal to itself is zero).

Uniqueness of the decomposition gives linearity of P_M , and Pythagoras gives $\|v\|^2 = \|P_M v\|^2 + \|v - P_M v\|^2 \geq \|P_M v\|^2$, so $\|P_M\| \leq 1$ (with equality unless $M = \{0\}$). Clearly $P_M^2 = P_M$, $\operatorname{img} P_M = M$ and $\ker P_M = M^\perp$.

Finally $M \subseteq (M^\perp)^\perp$ is clear. Conversely if $v \in (M^\perp)^\perp$, write $v = u + w$ with $u \in M$, $w \in M^\perp$; then $w = v - u \in (M^\perp)^\perp$ too, and $w \in M^\perp \cap (M^\perp)^\perp = \{0\}$, so $v = u \in M$. $\square$

**Corollary 33.6.14**

Let $M \subseteq H$ be a subspace of a Hilbert space. Then M is dense if and only if $M^\perp = \{0\}$.

Proof. Apply the theorem to $\bar{M}$: we have $\bar{M} = (\bar{M}^\perp)^\perp = (M^\perp)^\perp$, which is H exactly when $M^\perp = \{0\}$. $\square$

§33.6.3 The Riesz Representation Theorem

We can now compute the dual of a Hilbert space completely, and the answer is as beautiful as could be hoped: a Hilbert space is its own dual.

Theorem 33.6.15 (Riesz–Fréchet Representation Theorem)

Let H be a Hilbert space and $f \in H^*$. Then there is a unique $w \in H$ with

$$f(v) = \langle v, w \rangle \quad \text{for all } v \in H,$$

and $\|f\| = \|w\|$. The map $w \mapsto \langle \cdot, w \rangle$ is a conjugate-linear isometric bijection $H \rightarrow H^*$.

Proof. Uniqueness. If $\langle v, w \rangle = \langle v, w' \rangle$ for all v then $w - w' \perp H$, so $w = w'$.

Existence. If $f = 0$ take $w = 0$. Otherwise $M = \ker f$ is a proper closed subspace, so by orthogonal decomposition $M^\perp \neq \{0\}$; pick $u \in M^\perp$ with $\|u\| = 1$, and note $f(u) \neq 0$ (else $u \in M \cap M^\perp$).

For any $v \in H$, the vector

$$v - \frac{f(v)}{f(u)}u$$

lies in $\ker f = M$, hence is orthogonal to u . Taking the inner product with u gives

$$\langle v, u \rangle - \frac{f(v)}{f(u)} = 0, \quad \text{i.e.} \quad f(v) = f(u)\langle v, u \rangle = \langle v, \overline{f(u)}u \rangle.$$

So $w = \overline{f(u)}u$ works.

Isometry. $|f(v)| = |\langle v, w \rangle| \leq \|v\| \|w\|$ by Cauchy–Schwarz, so $\|f\| \leq \|w\|$; and $f(w) = \|w\|^2$ gives $\|f\| \geq \|w\|$. Conjugate-linearity of $w \mapsto \langle \cdot, w \rangle$ is immediate. $\square$

Corollary 33.6.16

Every Hilbert space is reflexive.

Proof. Write $\Phi : H \rightarrow H^*$ for the conjugate-linear bijection above. Then H^* is itself a Hilbert space with $\langle \Phi v, \Phi w \rangle_{H^*} = \langle w, v \rangle_H$ (one checks the axioms; conjugating swaps the slots). Applying Riesz again gives a conjugate-linear bijection $\Psi : H^* \rightarrow H^{**}$, and $\Psi \circ \Phi : H \rightarrow H^{**}$ is a linear isometric bijection. A short computation shows $\Psi \circ \Phi = \iota$, the canonical embedding: for $v \in H$ and $f = \Phi w \in H^*$,

$$(\Psi \Phi v)(f) = \langle f, \Phi v \rangle_{H^*} = \langle v, w \rangle_H = f(v) = \iota(v)(f).$$

So ι is surjective. $\square$

§33.6.4 Orthonormal Bases

We now build coordinates. In a Hilbert space we want to allow infinite linear combinations, which changes the notion of ‘basis’ completely from the Hamel bases of the previous sections.

Proposition 33.6.17 (Gram–Schmidt)

Let $(v_n)_{n \geq 1}$ be a linearly independent sequence in an inner product space. Then there is an orthonormal sequence (e_n) with $\text{span}\{e_1, \dots, e_n\} = \text{span}\{v_1, \dots, v_n\}$ for every n .

Proof. Inductively set $e_1 = v_1 / \|v_1\|$ and

$$u_n = v_n - \sum_{i=1}^{n-1} \langle v_n, e_i \rangle e_i, \quad e_n = \frac{u_n}{\|u_n\|}.$$

Then $u_n \neq 0$ by linear independence, $u_n \perp e_i$ for $i < n$ by the computation in Pythagoras’ theorem, and the spans agree by construction. $\square$

Example 33.6.18 (Legendre polynomials)

Take $H = L^2[-1, 1]$ with $\langle f, g \rangle = \int_{-1}^1 f \bar{g} \, dx$, and apply Gram–Schmidt to the monomials $1, x, x^2, \dots$, which are linearly independent. We get $e_0 = 1/\sqrt{2}$, and then

$$u_1 = x - \langle x, e_0 \rangle e_0 = x, \quad e_1 = \sqrt{\frac{3}{2}} x,$$

since $\int_{-1}^1 x \, dx = 0$ and $\int_{-1}^1 x^2 \, dx = \frac{2}{3}$. Next,

$$u_2 = x^2 - \langle x^2, e_0 \rangle e_0 - \langle x^2, e_1 \rangle e_1 = x^2 - \frac{1}{3},$$

using $\int_{-1}^1 x^2 \, dx = \frac{2}{3}$ and $\int_{-1}^1 x^3 \, dx = 0$; normalising, $e_2 = \sqrt{\frac{45}{8}}(x^2 - \frac{1}{3})$.

Up to normalisation these are the **Legendre polynomials** P_n of IB Methods, with the standard normalisation $P_n(1) = 1$ giving $P_0 = 1$, $P_1 = x$, $P_2 = \frac{1}{2}(3x^2 - 1)$ and $e_n = \sqrt{\frac{2n+1}{2}}P_n$. That they form an orthonormal *basis* of $L^2[-1, 1]$ follows from Stone–Weierstrass: the polynomials are dense in $C[-1, 1]$ for the sup norm, hence in L^2 , and their closed span is the closed span of the e_n .

So the Legendre expansion of a function – which in Methods appeared as a somewhat mysterious consequence of Sturm–Liouville theory – is just the expansion in an orthonormal basis, and Parseval gives

$$\int_{-1}^1 |f|^2 dx = \sum_{n \geq 0} \frac{2n+1}{2} \left| \int_{-1}^1 f P_n dx \right|^2.$$

Definition 33.6.19 (Orthonormal basis)

An orthonormal family $(e_i)_{i \in I}$ in a Hilbert space H is an **orthonormal basis** (or **complete orthonormal system**, or **Hilbert basis**) if $\overline{\text{span}\{e_i\}} = H$.

Proposition 33.6.20

For an orthonormal family $(e_i)_{i \in I}$ in a Hilbert space H , the following are equivalent:

- (i) (e_i) is an orthonormal basis;
- (ii) (e_i) is maximal among orthonormal families;
- (iii) $\{e_i\}^\perp = \{0\}$;
- (iv) $v = \sum_{i \in I} \langle v, e_i \rangle e_i$ for every $v \in H$;
- (v) (*Parseval*) $\|v\|^2 = \sum_{i \in I} |\langle v, e_i \rangle|^2$ for every $v \in H$.

Proof. (i) $\iff$ (iii) is the density criterion proved above. (ii) $\iff$ (iii): a unit vector orthogonal to all e_i would enlarge the family, and conversely.

(i) $\Rightarrow$ (iv). By Bessel, only countably many coefficients are non-zero, so list them as $i_1, i_2, \dots$ and set $s_n = \sum_{k \leq n} \langle v, e_{i_k} \rangle e_{i_k}$. For $m < n$, Pythagoras gives $\|s_n - s_m\|^2 = \sum_{m < k \leq n} |\langle v, e_{i_k} \rangle|^2$, which tends to 0 by Bessel; so (s_n) is Cauchy and converges to some $s \in H$. Now $v - s$ is orthogonal to every e_i (for $i = i_k$ this is a limit of the finite computation, and for other i the coefficient is zero), so $v = s$ by (iii). The value of the sum does not depend on the ordering, since any rearrangement converges to a vector with the same inner products against all e_i .

(iv) $\Rightarrow$ (v) is Pythagoras applied to the partial sums and passing to the limit, and (v) $\Rightarrow$ (iii) is immediate: if $v \perp$ all e_i then $\|v\| = 0$.

(iv) $\Rightarrow$ (i) is clear. □

Proposition 33.6.21

Every Hilbert space has an orthonormal basis, and H is separable if and only if it has a countable orthonormal basis.

Proof. Existence: Zorn's lemma applied to the set of orthonormal families ordered by inclusion; the union of a chain of orthonormal families is orthonormal, and a maximal element is an orthonormal basis by (ii) above.

If H is separable with dense countable set $\{v_n\}$, discard those v_n lying in the span of the earlier ones and apply Gram–Schmidt; the resulting orthonormal sequence has the same closed span, namely H . Conversely, given a countable orthonormal basis, the rational (or rational-complex) linear combinations of the e_n form a countable dense set. $\square$

Theorem 33.6.22 (Classification of separable Hilbert spaces)

Every infinite-dimensional separable Hilbert space is isometrically isomorphic to ℓ^2 .

Proof. Let $(e_n)_{n \geq 1}$ be a countable orthonormal basis of H and define

$$U : H \rightarrow \ell^2, \quad Uv = (\langle v, e_n \rangle)_{n \geq 1}.$$

By Bessel this lands in ℓ^2 , and by Parseval $\|Uv\|_2 = \|v\|$, so U is a linear isometry, in particular injective.

For surjectivity, let $a = (a_n) \in \ell^2$. The partial sums $s_N = \sum_{n \leq N} a_n e_n$ satisfy $\|s_N - s_M\|^2 = \sum_{M < n \leq N} |a_n|^2 \rightarrow 0$, so by completeness of H they converge to some v , and $\langle v, e_n \rangle = a_n$ by continuity of the inner product. So $Uv = a$. $\square$

This is a striking statement: up to isometric isomorphism there is only *one* infinite-dimensional separable Hilbert space. Compare the situation for Banach spaces, where the spaces ℓ^1 , ℓ^2 , c_0 , $C[0, 1]$ and $L^1[0, 1]$ are all separable and pairwise non-isomorphic. Hilbert space is a very rigid object.

Example 33.6.23 (Fourier series)

Take $H = L^2(\mathbb{T})$, the completion of $C(\mathbb{T})$ under $\langle f, g \rangle = \frac{1}{2\pi} \int_{-\pi}^{\pi} f \bar{g}$. The family $e_k(x) = e^{ikx}$, $k \in \mathbb{Z}$, is orthonormal:

$$\langle e_k, e_l \rangle = \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{i(k-l)x} dx = \delta_{kl}.$$

It is an orthonormal basis: by Stone–Weierstrass the trigonometric polynomials are dense in $C(\mathbb{T})$ for the sup norm, hence for the L^2 norm (as $\|\cdot\|_{L^2} \leq \|\cdot\|_{\infty}$ here), and $C(\mathbb{T})$ is dense in $L^2(\mathbb{T})$ by construction.

So for every $f \in L^2(\mathbb{T})$ the Fourier series converges in L^2 ,

$$\left\| f - \sum_{|k| \leq N} \hat{f}(k) e_k \right\|_{L^2} \rightarrow 0,$$

and Parseval reads

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} |f|^2 dx = \sum_{k \in \mathbb{Z}} |\hat{f}(k)|^2.$$

This is the theorem that was quoted without proof in IB Methods, and here it is at last, as a special case of a general principle: $L^2(\mathbb{T}) \cong \ell^2(\mathbb{Z})$ via the Fourier coefficients.

§33.6.5 Adjoints on Hilbert Space

Riesz representation lets us define an adjoint that lives on H itself rather than on H^* , and this is the version that generalises the conjugate transpose from IB Linear Algebra.

Proposition 33.6.24

Let H be a Hilbert space and $T \in \mathcal{B}(H)$. Then there is a unique $T^* \in \mathcal{B}(H)$ with

$$\langle Tv, w \rangle = \langle v, T^*w \rangle \quad \text{for all } v, w \in H,$$

and $\|T^*\| = \|T\|$.

Proof. Fix w . The map $v \mapsto \langle Tv, w \rangle$ is a bounded linear functional of norm at most $\|T\| \|w\|$, so by Riesz there is a unique vector, call it T^*w , with $\langle Tv, w \rangle = \langle v, T^*w \rangle$ for all v . Uniqueness of the Riesz vector makes T^* well defined, and gives linearity: $T^*(\lambda w_1 + w_2)$ and $\lambda T^*w_1 + T^*w_2$ represent the same functional. Also $\|T^*w\| \leq \|T\| \|w\|$, so $\|T^*\| \leq \|T\|$; applying the same to T^* and noting $T^{**} = T$ gives equality. $\square$

Proposition 33.6.25

For $S, T \in \mathcal{B}(H)$ and $\lambda \in \mathbb{F}$:

- (i) $(S + T)^* = S^* + T^*$, $(\lambda T)^* = \bar{\lambda}T^*$, $(ST)^* = T^*S^*$, $T^{**} = T$;
- (ii) $\|T^*T\| = \|T\|^2$;
- (iii) $\ker T = (\text{img } T^*)^\perp$ and $\overline{\text{img } T} = (\ker T^*)^\perp$.

Proof. (i) All are routine verifications from the defining identity.

(ii) $\|T^*T\| \leq \|T^*\| \|T\| = \|T\|^2$, and conversely

$$\|Tv\|^2 = \langle Tv, Tv \rangle = \langle T^*Tv, v \rangle \leq \|T^*T\| \|v\|^2,$$

so $\|T\|^2 \leq \|T^*T\|$. (This identity is the C^* -identity, and it is the reason $\mathcal{B}(H)$ is such a rigid algebra.)

(iii) $v \in \ker T$ iff $Tv = 0$ iff $\langle Tv, w \rangle = 0$ for all w iff $\langle v, T^*w \rangle = 0$ for all w iff $v \perp \text{img } T^*$. Taking orthogonal complements and using $(M^\perp)^\perp = \bar{M}$ for a subspace gives the second identity applied to T^* . $\square$

Definition 33.6.26

Let $T \in \mathcal{B}(H)$. We say T is

- (i) **self-adjoint** (or Hermitian) if $T = T^*$;

- (ii) **unitary** if $T^*T = TT^* = I$;
- (iii) **normal** if $T^*T = TT^*$.

Self-adjoint and unitary operators are normal. Unitaries are exactly the surjective isometries of H : $\|Uv\|^2 = \langle U^*Uv, v \rangle = \|v\|^2$.

Example 33.6.27 (i) On $\mathbb{F}^n$, the adjoint of a matrix A is the conjugate transpose $\bar{A}^T$, and self-adjoint means Hermitian.

- (ii) On ℓ^2 , the left and right shifts satisfy $L = R^*$: indeed $\langle Rx, y \rangle = \sum_{n \geq 2} x_{n-1} \bar{y}_n = \sum_{n \geq 1} x_n \bar{y}_{n+1} = \langle x, Ly \rangle$. Neither is normal.
- (iii) The diagonal operator M_λ on ℓ^2 has $M_\lambda^* = M_{\bar{\lambda}}$, so it is normal, and self-adjoint exactly when all λ_n are real.
- (iv) The integral operator on $L^2[0, 1]$ with kernel k has adjoint the integral operator with kernel $k^*(x, y) = \overline{k(y, x)}$. It is self-adjoint when k is Hermitian, $k(y, x) = \overline{k(x, y)}$; this is the Hilbert space form of the symmetric Sturm–Liouville kernels from IB Methods.

Proposition 33.6.28

Let $T \in \mathcal{B}(H)$ with H complex.

- (i) T is self-adjoint if and only if $\langle Tv, v \rangle \in \mathbb{R}$ for all v .
- (ii) If T is self-adjoint then $\|T\| = \sup_{\|v\| \leq 1} |\langle Tv, v \rangle|$.
- (iii) If T is normal then $\ker T = \ker T^*$, and eigenvectors for distinct eigenvalues are orthogonal.

Proof. (i) If $T = T^*$ then $\langle Tv, v \rangle = \langle v, Tv \rangle = \overline{\langle Tv, v \rangle}$. Conversely, suppose $\langle Tv, v \rangle \in \mathbb{R}$ for all v . Then $\langle (T - T^*)v, v \rangle = 0$ for all v , and over $\mathbb{C}$ this forces $T = T^*$: expanding $\langle S(v + w), v + w \rangle = 0$ and $\langle S(v + iw), v + iw \rangle = 0$ for $S = T - T^*$ gives $\langle Sv, w \rangle = 0$ for all v, w .

(ii) Write M for the supremum. Clearly $M \leq \|T\|$. For the converse, note that for self-adjoint T ,

$$\langle T(v + w), v + w \rangle - \langle T(v - w), v - w \rangle = 4 \operatorname{Re} \langle Tv, w \rangle.$$

The left-hand side is at most $M(\|v + w\|^2 + \|v - w\|^2) = 2M(\|v\|^2 + \|w\|^2)$ in absolute value. Taking $\|v\| = \|w\| = 1$ gives $\operatorname{Re} \langle Tv, w \rangle \leq M$, and choosing a phase, $|\langle Tv, w \rangle| \leq M$; taking $w = Tv / \|Tv\|$ gives $\|Tv\| \leq M$.

(iii) If T is normal then $\|Tv\|^2 = \langle T^*Tv, v \rangle = \langle TT^*v, v \rangle = \|T^*v\|^2$, so the kernels agree. If $Tv = \lambda v$ and $Tw = \mu w$ with $\lambda \neq \mu$, note $T - \lambda I$ is normal so $T^*v = \bar{\lambda}v$, and then

$$\lambda \langle v, w \rangle = \langle Tv, w \rangle = \langle v, T^*w \rangle = \langle v, \bar{\mu}w \rangle = \bar{\mu} \langle v, w \rangle,$$

forcing $\langle v, w \rangle = 0$. □

§33.7 Spectral Theory

In IB Linear Algebra, the key to understanding a linear map on a finite-dimensional space was its eigenvalues. In infinite dimensions eigenvalues are not enough – an operator can fail to be invertible without having any eigenvalues at all – and the right generalisation is the *spectrum*.

Throughout this section X is a complex Banach space (complex is essential: over $\mathbb{R}$ even a rotation of the plane has empty spectrum) and $T \in \mathcal{B}(X)$. We abbreviate $T - \lambda I$ to $T - \lambda$.

§33.7.1 The Spectrum and the Resolvent

Definition 33.7.1 (Spectrum and resolvent)

Let $T \in \mathcal{B}(X)$. The **resolvent set** of T is

$$\rho(T) = \{\lambda \in \mathbb{C} : T - \lambda \text{ is a bijection } X \rightarrow X\},$$

and the **spectrum** is $\sigma(T) = \mathbb{C} \setminus \rho(T)$. For $\lambda \in \rho(T)$ the **resolvent** is

$$R_\lambda = R_T(\lambda) = (T - \lambda)^{-1} \in \mathcal{B}(X).$$

Two remarks on the definition. First, we only demanded that $T - \lambda$ be a bijection; by the inverse mapping theorem the inverse is then automatically bounded, so we get $R_\lambda \in \mathcal{B}(X)$ for free. This is a nice payoff from the Baire category theorem. Second, λ is an eigenvalue exactly when $T - \lambda$ fails to be *injective*; but it can also fail to be *surjective*, and that also puts λ in the spectrum. So eigenvalues form only part of the spectrum.

Definition 33.7.2 (Parts of the spectrum)

Let $\lambda \in \sigma(T)$. We say λ lies in

- (i) the **point spectrum** $\sigma_p(T)$ if $T - \lambda$ is not injective; the elements of $\ker(T - \lambda) \setminus \{0\}$ are **eigenvectors** and λ an **eigenvalue**;
- (ii) the **continuous spectrum** $\sigma_c(T)$ if $T - \lambda$ is injective with dense but proper range;
- (iii) the **residual spectrum** $\sigma_r(T)$ if $T - \lambda$ is injective with non-dense range.

We also define the **approximate point spectrum**

$$\sigma_{\text{ap}}(T) = \{\lambda : \exists v_n \text{ with } \|v_n\| = 1 \text{ and } \|(T - \lambda)v_n\| \rightarrow 0\}.$$

These three parts are disjoint and cover $\sigma(T)$. Note $\sigma_p \subseteq \sigma_{\text{ap}}$, and $\lambda \in \sigma_{\text{ap}}$ exactly when $T - \lambda$ is not bounded below.

Theorem 33.7.3

Let $T \in \mathcal{B}(X)$ with X a complex Banach space. Then:

- (i) $\rho(T)$ is open and $\lambda \mapsto R_\lambda$ is analytic on it;
- (ii) $\sigma(T) \subseteq \{\lambda : |\lambda| \leq \|T\|\}$, so $\sigma(T)$ is compact;

(iii) $\sigma(T) \neq \emptyset$.

Proof. (ii) If $|\lambda| > \|T\|$ then $\|T/\lambda\| < 1$, so by the Neumann series $I - T/\lambda$ is invertible, hence so is $T - \lambda = -\lambda(I - T/\lambda)$. Moreover

$$R_\lambda = -\frac{1}{\lambda} \sum_{n=0}^{\infty} \left(\frac{T}{\lambda}\right)^n, \quad \|R_\lambda\| \leq \frac{1}{|\lambda| - \|T\|}. \quad (*)$$

So $\sigma(T)$ is contained in the closed disc of radius $\|T\|$, and it is closed by (i).

(i) Let $\lambda_0 \in \rho(T)$. For λ near λ_0 write

$$T - \lambda = (T - \lambda_0) - (\lambda - \lambda_0) = (T - \lambda_0)(I - (\lambda - \lambda_0)R_{\lambda_0}).$$

If $|\lambda - \lambda_0| < \|R_{\lambda_0}\|^{-1}$ the bracket is invertible by the Neumann series, so $\lambda \in \rho(T)$ and

$$R_\lambda = \left(\sum_{n=0}^{\infty} (\lambda - \lambda_0)^n R_{\lambda_0}^n \right) R_{\lambda_0} = \sum_{n=0}^{\infty} R_{\lambda_0}^{n+1} (\lambda - \lambda_0)^n.$$

Thus $\rho(T)$ is open and R_λ is given locally by a convergent power series in λ with coefficients in $\mathcal{B}(X)$: it is analytic, with $\frac{d}{d\lambda} R_\lambda = R_\lambda^2$.

(iii) Suppose for contradiction $\sigma(T) = \emptyset$, so R_λ is defined and analytic on all of $\mathbb{C}$. Fix $\varphi \in \mathcal{B}(X)^*$ and let $g(\lambda) = \varphi(R_\lambda)$. Composing an analytic $\mathcal{B}(X)$ -valued function with a bounded functional gives an analytic function $\mathbb{C} \rightarrow \mathbb{C}$, so g is entire. By (*), $\|R_\lambda\| \rightarrow 0$ as $|\lambda| \rightarrow \infty$, hence $g(\lambda) \rightarrow 0$; in particular g is bounded. By Liouville's theorem from IB Complex Analysis, g is constant, and the constant is 0.

This holds for every $\varphi \in \mathcal{B}(X)^*$, so by Hahn–Banach (which says the dual separates points) $R_\lambda = 0$ for every λ . But R_λ is a bijection and $X \neq \{0\}$, so this is absurd. $\square$

Remark. The proof of (iii) is where complex scalars are indispensable. Over $\mathbb{R}$, the rotation by 90° on $\mathbb{R}^2$ has $T - \lambda$ invertible for every real λ .

Example 33.7.4 (Multiplication operators)

Let $\lambda = (\lambda_n) \in \ell^\infty$ and M_λ the diagonal operator on ℓ^2 . Then $M_\lambda - \mu$ is the diagonal operator with entries $\lambda_n - \mu$, which is invertible precisely when $\inf_n |\lambda_n - \mu| > 0$. Hence

$$\sigma(M_\lambda) = \overline{\{\lambda_n : n \in \mathbb{N}\}},$$

with $\sigma_p = \{\lambda_n\}$ and the remaining limit points forming the continuous spectrum. In particular every non-empty compact subset of $\mathbb{C}$ arises as a spectrum: take $\{\lambda_n\}$ to be a countable dense subset of it.

Example 33.7.5 (Shift operators)

Consider L, R on ℓ^2 , with $L = R^*$.

For R : it is an isometry, so $\|Rx - \mu x\| \geq (1 - |\mu|)\|x\|$ shows $R - \mu$ is bounded below for $|\mu| < 1$; but its range is not dense, since $\text{img}(R - \mu)^\perp = \ker(L - \bar{\mu})$ and $Ly = \bar{\mu}y$ is solved by $y = (1, \bar{\mu}, \bar{\mu}^2, \dots) \in \ell^2$. So $\{|\mu| < 1\} \subseteq \sigma_r(R)$. Also R has no eigenvalues: $Rx = \mu x$ forces $x = 0$ by comparing coordinates. Since $\sigma(R)$ is closed and contained in the closed unit disc, $\sigma(R) = \bar{D}$, with the open disc residual and the unit circle continuous spectrum.

For L : for $|\mu| < 1$ the vector $x = (1, \mu, \mu^2, \dots)$ lies in ℓ^2 and satisfies $Lx = \mu x$. So the open disc is point spectrum, and again $\sigma(L) = \bar{D}$, with the circle as continuous spectrum.

These are worth internalising. R is injective but not surjective, L is surjective but not injective, and their spectra are nonetheless the same closed disc.

Proposition 33.7.6

Let $T \in \mathcal{B}(X)$. Then $\partial\sigma(T) \subseteq \sigma_{\text{ap}}(T)$; in particular $\sigma_{\text{ap}}(T) \neq \emptyset$.

Proof. Let $\lambda \in \partial\sigma(T)$ and take $\lambda_n \in \rho(T)$ with $\lambda_n \rightarrow \lambda$. We claim $\|R_{\lambda_n}\| \rightarrow \infty$. If not, pass to a subsequence with $\|R_{\lambda_n}\| \leq M$; then for n large, $|\lambda - \lambda_n| < M^{-1}$, and the Neumann series argument used to prove openness of $\rho(T)$ shows $\lambda \in \rho(T)$, a contradiction.

So choose unit vectors w_n with $\|R_{\lambda_n} w_n\| \geq \frac{1}{2} \|R_{\lambda_n}\|$ and set $v_n = R_{\lambda_n} w_n / \|R_{\lambda_n} w_n\|$. Then $\|v_n\| = 1$ and

$$\|(T - \lambda_n)v_n\| = \frac{\|w_n\|}{\|R_{\lambda_n} w_n\|} \leq \frac{2}{\|R_{\lambda_n}\|} \rightarrow 0,$$

so $\|(T - \lambda)v_n\| \leq \|(T - \lambda_n)v_n\| + |\lambda_n - \lambda| \rightarrow 0$. Hence $\lambda \in \sigma_{\text{ap}}(T)$. The last claim holds since $\sigma(T)$ is a non-empty compact set, so has non-empty boundary. $\square$

Remark (Spectral radius). Define the **spectral radius** $r(T) = \sup_{\lambda \in \sigma(T)} |\lambda|$, which we have shown satisfies $r(T) \leq \|T\|$. In fact Gelfand's formula holds:

$$r(T) = \lim_{n \rightarrow \infty} \|T^n\|^{1/n},$$

the limit existing by subadditivity of $n \mapsto \log \|T^n\|$. The proof runs by considering the Laurent expansion $R_\lambda = -\sum_{n \geq 0} T^n \lambda^{-n-1}$, valid for $|\lambda| > \|T\|$ and, by analyticity of the resolvent, for $|\lambda| > r(T)$; comparing radii of convergence gives the formula. For a self-adjoint operator on Hilbert space, $\|T^2\| = \|T\|^2$ by the C^* -identity, so $\|T^{2^k}\| = \|T\|^{2^k}$ and hence $r(T) = \|T\|$ – recovering a fact we proved by hand above.

Proposition 33.7.7

Let $T \in \mathcal{B}(X)$. Then $\sigma(T^*) = \sigma(T)$, where T^* is the Banach space adjoint. If H is a complex Hilbert space and $T \in \mathcal{B}(H)$, then $\sigma(T^*) = \overline{\sigma(T)} = \{\bar{\lambda} : \lambda \in \sigma(T)\}$.

Proof. $T - \lambda$ is invertible if and only if $(T - \lambda)^* = T^* - \lambda$ is, since taking adjoints is multiplicative and $I^* = I$; and if S is a two-sided inverse of $T - \lambda$ then S^* is one for $T^* - \lambda$. Conversely if $T^* - \lambda$ is invertible then so is $T^{**} - \lambda$, and $T - \lambda$ is invertible by restricting to the image of the canonical embedding. On Hilbert space the adjoint is conjugate-linear in the scalar, whence the conjugation. $\square$

§33.7.2 The Spectrum of a Self-Adjoint Operator

For self-adjoint operators on a Hilbert space the spectrum is far better behaved, and the picture becomes much closer to the finite-dimensional one: the spectrum is real, there is no residual part, and the extreme points of the spectrum are exactly the extreme values of the quadratic form $v \mapsto \langle Tv, v \rangle$.

Proposition 33.7.8

Let H be a complex Hilbert space and $T \in \mathcal{B}(H)$ self-adjoint. Then

- (i) $\sigma(T) \subseteq \mathbb{R}$;
- (ii) $\sigma_r(T) = \emptyset$;
- (iii) writing $m = \inf_{\|v\|=1} \langle Tv, v \rangle$ and $M = \sup_{\|v\|=1} \langle Tv, v \rangle$, we have $\sigma(T) \subseteq [m, M]$ and $m, M \in \sigma(T)$.

Proof. (i) Let $\lambda = a + ib$ with $b \neq 0$. For any v ,

$$\|(T - \lambda)v\| \|v\| \geq |\langle (T - \lambda)v, v \rangle| \geq |\operatorname{Im} \langle (T - \lambda)v, v \rangle| = |b| \|v\|^2,$$

using that $\langle Tv, v \rangle$ is real. So $T - \lambda$ is bounded below, hence injective with closed range. The same estimate applies to $T - \bar{\lambda} = (T - \lambda)^*$, so $\ker(T - \lambda)^* = \{0\}$, and therefore $\operatorname{img}(\overline{T - \lambda}) = (\ker(T - \lambda)^*)^\perp = H$. A closed dense range is everything, so $T - \lambda$ is a bijection.

(ii) If $T - \lambda$ has non-dense range then $\ker(T - \bar{\lambda}) = \ker(T - \lambda)^* \neq \{0\}$; by (i) λ is real, so λ is an eigenvalue and lies in σ_p , not σ_r .

(iii) Let $\lambda > M$ be real and set $\delta = \lambda - M > 0$. Then

$$\langle (\lambda - T)v, v \rangle = \lambda \|v\|^2 - \langle Tv, v \rangle \geq \delta \|v\|^2,$$

so $\|(T - \lambda)v\| \geq \delta \|v\|$ by Cauchy–Schwarz, and as in (i) we conclude $T - \lambda$ is invertible. Similarly for $\lambda < m$. For the last claim, suppose $M \in \rho(T)$; then $S = M - T$ is a positive self-adjoint operator ($\langle Sv, v \rangle \geq 0$) which is invertible and bounded below by some $\delta > 0$. But $\inf_{\|v\|=1} \langle Sv, v \rangle = 0$ by definition of M , and for a positive operator the Cauchy–Schwarz inequality for the semi-inner product

$(v, w) \mapsto \langle Sv, w \rangle$ gives

$$\|Sv\|^2 = \langle Sv, Sv \rangle \leq \langle Sv, v \rangle^{1/2} \langle S(Sv), Sv \rangle^{1/2} \leq \langle Sv, v \rangle^{1/2} \|S\|^{3/2} \|v\|,$$

so $\langle Sv, v \rangle$ small forces $\|Sv\|$ small – contradicting boundedness below. Hence $M \in \sigma(T)$, and similarly m . $\square$

Corollary 33.7.9

If T is self-adjoint then $\|T\| = \max(|m|, |M|) = \sup_{\lambda \in \sigma(T)} |\lambda|$.

Proof. We proved $\|T\| = \sup_{\|v\| \leq 1} |\langle Tv, v \rangle| = \max(|m|, |M|)$ earlier, and $m, M \in \sigma(T) \subseteq [m, M]$. $\square$

§33.8 Compact Operators

The failure of compactness of the unit ball was the first infinite-dimensional pathology we met. Compact operators are those that repair it: they are the operators which do send the unit ball into something with compact closure. They behave, in many respects, like matrices, and they have a genuinely satisfactory spectral theory.

§33.8.1 Definition and Examples

Definition 33.8.1 (Compact operator)

Let X, Y be normed spaces. A linear map $T : X \rightarrow Y$ is **compact** if $\overline{T(\bar{B}_X)}$ is compact in Y . We write $\mathcal{K}(X, Y)$ for the set of compact operators, and $\mathcal{K}(X) = \mathcal{K}(X, X)$.

Equivalently (when Y is complete, and using that compactness and sequential compactness agree in metric spaces), T is compact if and only if every bounded sequence (x_n) in X has a subsequence with (Tx_{n_k}) convergent. A compact operator is automatically bounded, since a compact set is bounded.

Example 33.8.2 (i) Any bounded operator with finite-dimensional range is compact: $T(\bar{B}_X)$ is a bounded subset of a finite-dimensional space, whose closure is compact by Riesz. We call such T a **finite rank** operator.

(ii) The identity on X is compact if and only if $\dim X < \infty$, by Riesz's theorem.

(iii) The diagonal operator M_λ on ℓ^2 is compact if and only if $\lambda_n \rightarrow 0$. If $\lambda_n \rightarrow 0$,

then M_λ is the operator-norm limit of the finite rank truncations $M_{\lambda^{(N)}}$, where $\lambda^{(N)}$ agrees with λ up to N and vanishes after; indeed $\|M_\lambda - M_{\lambda^{(N)}}\| = \sup_{n>N} |\lambda_n| \rightarrow 0$. Compactness then follows from the closedness theorem below. Conversely, if $|\lambda_{n_k}| \geq \delta > 0$ then $(M_\lambda e_{n_k})$ has no convergent subsequence, as $\|M_\lambda e_{n_k} - M_\lambda e_{n_l}\| \geq \delta\sqrt{2}$.

- (iv) The integral operator with continuous kernel k on $C[0, 1]$ is compact – this is exactly what we proved with Arzelà–Ascoli. The same operator on $L^2[0, 1]$ is compact too.

Theorem 33.8.3

Let X be a normed space and Y a Banach space. Then $\mathcal{K}(X, Y)$ is a closed linear subspace of $\mathcal{B}(X, Y)$. Moreover $\mathcal{K}(X)$ is a two-sided ideal in $\mathcal{B}(X)$: if T is compact and S bounded, then ST and TS are compact.

Proof. Subspace. If S, T are compact and (x_n) is bounded, extract a subsequence along which Sx_n converges, then a further subsequence along which Tx_n converges; then $(S + \lambda T)x_n$ converges along it.

Closed. Let $T_n \in \mathcal{K}(X, Y)$ with $T_n \rightarrow T$ in operator norm. We show $T(\bar{B}_X)$ is totally bounded; since Y is complete, this gives compact closure. Let $\varepsilon > 0$ and choose n with $\|T - T_n\| < \varepsilon/2$. As $T_n(\bar{B}_X)$ is totally bounded, there are $y_1, \dots, y_m$ forming an $\varepsilon/2$ -net for it. Then for $\|x\| \leq 1$ pick j with $\|T_n x - y_j\| < \varepsilon/2$, and

$$\|Tx - y_j\| \leq \|Tx - T_n x\| + \|T_n x - y_j\| < \varepsilon.$$

So $\{y_j\}$ is an ε -net for $T(\bar{B}_X)$.

Ideal. If T is compact and S bounded: $ST(\bar{B}_X) \subseteq \overline{S(T(\bar{B}_X))}$, the continuous image of a compact set, hence has compact closure. And $TS(\bar{B}_X) \subseteq \|S\| T(\bar{B}_X)$, which has compact closure. $\square$

Corollary 33.8.4

An operator-norm limit of finite rank operators is compact.

In a Hilbert space, the converse holds too, and this is a very useful way to think about compact operators.

Theorem 33.8.5 (Finite rank approximation)

Let H be a Hilbert space and $T \in \mathcal{B}(H)$. Then T is compact if and only if T is the operator-norm limit of finite rank operators.

Proof. $(\Leftarrow)$ is the corollary above.

$(\Rightarrow)$ Let T be compact and $\varepsilon > 0$. By total boundedness there are $v_1, \dots, v_n$ with $T(\bar{B}_H) \subseteq \bigcup_j B(Tv_j, \varepsilon)$ – we may take the net to consist of points of the image. Let $M = \text{span}\{Tv_1, \dots, Tv_n\}$, a finite-dimensional (hence closed) subspace, and let P be the orthogonal projection onto M . Set $T_\varepsilon = PT$, which has finite rank.

For $\|v\| \leq 1$, choose j with $\|Tv - Tv_j\| < \varepsilon$. Since $Tv_j \in M$ and P is the nearest-point projection onto M ,

$$\|Tv - PTv\| = \text{dist}(Tv, M) \leq \|Tv - Tv_j\| < \varepsilon.$$

Hence $\|T - T_\varepsilon\| \leq \varepsilon$. $\square$

Remark. This is false in general Banach spaces. Per Enflo constructed in 1973 a Banach space with a compact operator that is not a limit of finite rank operators – resolving the ‘approximation problem’ negatively, and famously earning him a live goose from Mazur.

Proposition 33.8.6

Let H be a Hilbert space and $T \in \mathcal{B}(H)$. Then T is compact if and only if T^* is.

Proof. If T is compact, write $T = \lim T_n$ with T_n finite rank. Then T_n^* has finite rank (its range is contained in $\text{img } T_n^*$, and $\text{rank } T_n^* = \text{rank } T_n$ since $\ker T_n^* = (\text{img } T_n)^\perp$), and $\|T^* - T_n^*\| = \|T - T_n\| \rightarrow 0$. So T^* is compact. The converse follows as $T^{**} = T$. $\square$

Definition 33.8.7 (Hilbert–Schmidt operator)

Let H be a separable Hilbert space with orthonormal basis (e_n) . An operator $T \in \mathcal{B}(H)$ is **Hilbert–Schmidt** if

$$\|T\|_{\text{HS}} = \left(\sum_n \|Te_n\|^2 \right)^{1/2} < \infty.$$

Proposition 33.8.8

The quantity $\|T\|_{\text{HS}}$ is independent of the choice of orthonormal basis, $\|T\| \leq \|T\|_{\text{HS}}$, and every Hilbert–Schmidt operator is compact.

Proof. If (f_m) is another orthonormal basis then by Parseval, applied twice,

$$\sum_n \|Te_n\|^2 = \sum_n \sum_m |\langle Te_n, f_m \rangle|^2 = \sum_m \sum_n |\langle e_n, T^* f_m \rangle|^2 = \sum_m \|T^* f_m\|^2,$$

and the right-hand side does not involve (e_n) ; applying the same argument to T^* shows it equals $\sum_m \|T f_m\|^2$. For the norm bound, write $v = \sum_n \langle v, e_n \rangle e_n$ with $\|v\| \leq 1$; then by Cauchy–Schwarz $\|Tv\| \leq \sum_n |\langle v, e_n \rangle| \|Te_n\| \leq \|v\| \|T\|_{\text{HS}}$.

For compactness, let P_N be the projection onto $\text{span}\{e_1, \dots, e_N\}$. Then TP_N has finite rank and $\|T - TP_N\| \leq \|T - TP_N\|_{\text{HS}} = (\sum_{n>N} \|Te_n\|^2)^{1/2} \rightarrow 0$, so T is a limit of finite rank operators. $\square$

Example 33.8.9

The diagonal operator M_λ on ℓ^2 is Hilbert–Schmidt exactly when $\lambda \in \ell^2$, compact exactly when $\lambda \in c_0$, and bounded exactly when $\lambda \in \ell^\infty$. So the Hilbert–Schmidt

operators form a proper subclass of the compact operators; taking $\lambda_n = 1/\log(n+1)$ gives a compact operator that is not Hilbert–Schmidt. The integral operator on $L^2[0, 1]$ with kernel $k \in L^2([0, 1]^2)$ is always Hilbert–Schmidt, with $\|T\|_{\text{HS}} = \|k\|_{L^2}$.

§33.8.2 Spectral Theory of Compact Operators

Compact operators have spectra that look very much like those of matrices.

Theorem 33.8.10

Let X be a complex Banach space, $T \in \mathcal{K}(X)$ and $\lambda \neq 0$. Then:

- (i) $\ker(T - \lambda)$ is finite-dimensional;
- (ii) $\text{img}(T - \lambda)$ is closed;
- (iii) $T - \lambda$ is injective if and only if it is surjective.

Consequently $\sigma(T) \setminus \{0\}$ consists of eigenvalues of finite multiplicity.

Proof. (i) Let $N = \ker(T - \lambda)$. On N we have $T = \lambda I$, so the restriction of T to N is λ times the identity, which is compact (a restriction of a compact operator to a closed invariant subspace is compact). As $\lambda \neq 0$, the identity on N is compact, so $\dim N < \infty$ by Riesz.

(ii) By (i), N is finite-dimensional, hence complemented: $X = N \oplus Z$ for some closed subspace Z (choose a basis $x_1, \dots, x_k$ of N , extend the coordinate functionals to X^* by Hahn–Banach, and let Z be the intersection of their kernels). Then $T - \lambda$ restricted to Z is injective with the same range.

We claim $S := (T - \lambda)|_Z$ is bounded below. If not, there are $z_n \in Z$ with $\|z_n\| = 1$ and $Sz_n \rightarrow 0$. By compactness pass to a subsequence with $Tz_n \rightarrow y$. Then $\lambda z_n = Tz_n - Sz_n \rightarrow y$, so $z_n \rightarrow y/\lambda =: z \in Z$ with $\|z\| = 1$, and by continuity $Sz = 0$ – contradicting injectivity on Z . So S is bounded below, and a bounded-below operator has closed range: if $Sz_n \rightarrow w$ then (z_n) is Cauchy, so $z_n \rightarrow z$ and $w = Sz$.

(iii) Suppose $T - \lambda$ is injective but not surjective. Set $X_n = \text{img}(T - \lambda)^n$. Each X_n is closed (by (ii) and induction, since $(T - \lambda)^n = (-\lambda)^n + (\text{compact})$, using that $\mathcal{K}$ is an ideal), and

$$X \supsetneq X_1 \supsetneq X_2 \supsetneq \cdots,$$

the inclusions being strict because $T - \lambda$ is injective (if $X_{n+1} = X_n$ then applying injectivity n times gives $X_1 = X$).

By Riesz’s lemma choose $x_n \in X_n$ with $\|x_n\| = 1$ and $\text{dist}(x_n, X_{n+1}) \geq \frac{1}{2}$. For $m > n$,

$$Tx_n - Tx_m = \lambda x_n - ((T - \lambda)x_n - (T - \lambda)x_m + \lambda x_m),$$

and the bracketed term lies in X_{n+1} (as $(T - \lambda)x_n \in X_{n+1}$, and $x_m, (T - \lambda)x_m \in X_m \subseteq X_{n+1}$). Hence $\|Tx_n - Tx_m\| \geq |\lambda| \text{dist}(x_n, X_{n+1}) \geq |\lambda|/2$, so (Tx_n) has no convergent subsequence, contradicting compactness.

Conversely suppose $T - \lambda$ is surjective but not injective. Now set $Y_n = \ker(T - \lambda)^n$, an increasing chain of finite-dimensional (hence closed) subspaces, strictly increasing

by surjectivity, and run the same Riesz's lemma argument with $\text{dist}(y_{n+1}, Y_n) \geq \frac{1}{2}$.
 The final statement: if $\lambda \in \sigma(T)$ and $\lambda \neq 0$, then $T - \lambda$ is not bijective, so by (iii) it is not injective, i.e. λ is an eigenvalue, with finite-dimensional eigenspace by (i). $\square$

Theorem 33.8.11 (Fredholm Alternative)

Let X be a complex Banach space, $T \in \mathcal{K}(X)$ and $\lambda \neq 0$. Then exactly one of the following holds:

- (a) the homogeneous equation $Tx = \lambda x$ has a non-zero solution;
- (b) for every $y \in X$ the equation $Tx - \lambda x = y$ has a unique solution, depending continuously on y .

Proof. This is a restatement of part (iii) above: either $T - \lambda$ fails to be injective, which is (a), or it is injective, hence surjective, hence a bijection, and its inverse is bounded by the inverse mapping theorem, which is (b). $\square$

This is exactly the dichotomy familiar from linear algebra – for a square matrix A , either $Ax = 0$ has a non-trivial solution or $Ax = y$ is always uniquely soluble – and it is remarkable that it survives into infinite dimensions for compact perturbations of λI . It fails badly without compactness: for the right shift R and λ with $|\lambda| < 1$, the equation $Rx - \lambda x = 0$ has only the zero solution, yet $R - \lambda$ is not surjective.

Theorem 33.8.12

Let $T \in \mathcal{K}(X)$ with X an infinite-dimensional complex Banach space. Then $0 \in \sigma(T)$, and $\sigma(T)$ is either finite or a sequence of eigenvalues tending to 0 (together with 0).

Proof. If $0 \notin \sigma(T)$ then T is invertible, so $I = T^{-1}T$ is compact, forcing $\dim X < \infty$.

For the second claim, it suffices to show that for each $\delta > 0$ there are only finitely many $\lambda \in \sigma(T)$ with $|\lambda| \geq \delta$. Suppose not, and let $\lambda_1, \lambda_2, \dots$ be distinct eigenvalues with $|\lambda_n| \geq \delta$, with eigenvectors v_n . Eigenvectors for distinct eigenvalues are linearly independent (the usual Vandermonde argument from IB Linear Algebra), so setting $V_n = \text{span}\{v_1, \dots, v_n\}$ we get a strictly increasing chain of finite-dimensional subspaces.

By Riesz's lemma pick $w_n \in V_n$ with $\|w_n\| = 1$ and $\text{dist}(w_n, V_{n-1}) \geq \frac{1}{2}$. For $m < n$,

$$Tw_n - Tw_m = \lambda_n w_n - ((\lambda_n - T)w_n + Tw_m).$$

Now $(\lambda_n - T)V_n \subseteq V_{n-1}$: writing $w_n = \sum_{k \leq n} a_k v_k$, the coefficient of v_n in $(\lambda_n - T)w_n$ is $a_n(\lambda_n - \lambda_n) = 0$. And $Tw_m \in V_m \subseteq V_{n-1}$. So the bracket lies in V_{n-1} , giving

$$\|Tw_n - Tw_m\| \geq |\lambda_n| \text{dist}(w_n, V_{n-1}) \geq \frac{\delta}{2}.$$

So (Tw_n) has no convergent subsequence, contradicting compactness. $\square$

§33.8.3 The Spectral Theorem

We can now prove the theorem that this whole course has been building towards: compact self-adjoint operators on a Hilbert space can be diagonalised, exactly as Hermitian matrices can.

Lemma 33.8.13

Let H be a complex Hilbert space and $T \in \mathcal{K}(H)$ self-adjoint and non-zero. Then $\|T\|$ or $-\|T\|$ is an eigenvalue of T .

Proof. Recall $\|T\| = \sup_{\|v\|=1} |\langle Tv, v \rangle|$, and that $\langle Tv, v \rangle$ is real. So there is a sequence (v_n) of unit vectors with $\langle Tv_n, v_n \rangle \rightarrow \lambda$, where $\lambda = \pm \|T\|$. Then

$$\begin{aligned} \|Tv_n - \lambda v_n\|^2 &= \|Tv_n\|^2 - 2\lambda \langle Tv_n, v_n \rangle + \lambda^2 \\ &\leq \|T\|^2 - 2\lambda \langle Tv_n, v_n \rangle + \lambda^2 \longrightarrow 2\lambda^2 - 2\lambda^2 = 0. \end{aligned}$$

By compactness, pass to a subsequence with $Tv_n \rightarrow w$. Then $\lambda v_n = Tv_n - (Tv_n - \lambda v_n) \rightarrow w$, so $v_n \rightarrow w/\lambda$ (using $\lambda \neq 0$, which holds as $T \neq 0$), and $\|w/\lambda\| = 1$. By continuity $T(w/\lambda) = \lambda(w/\lambda)$, so λ is an eigenvalue. $\square$

Theorem 33.8.14 (Spectral theorem for compact self-adjoint operators)

Let H be a complex Hilbert space and $T \in \mathcal{K}(H)$ self-adjoint. Then there is a finite or countable orthonormal system (e_n) in H and real numbers (λ_n) with $|\lambda_1| \geq |\lambda_2| \geq \dots$ and $\lambda_n \rightarrow 0$ (if the system is infinite), such that

$$Tv = \sum_n \lambda_n \langle v, e_n \rangle e_n \quad \text{for all } v \in H.$$

Equivalently, H has an orthonormal basis consisting of eigenvectors of T , and

$$H = \ker T \oplus \bigoplus_n \ker(T - \lambda_n)$$

as an orthogonal direct sum, each $\ker(T - \lambda_n)$ being finite-dimensional.

Proof. We construct the e_n inductively. Let $H_1 = H$ and $T_1 = T$. Given a closed T -invariant subspace H_n with $T_n = T|_{H_n}$, note that T_n is again compact and self-adjoint on H_n . If $T_n = 0$ we stop. Otherwise, by the lemma there is a unit vector $e_n \in H_n$ and $\lambda_n = \pm \|T_n\|$ with $Te_n = \lambda_n e_n$. Set

$$H_{n+1} = H_n \cap \{e_n\}^\perp,$$

which is closed, and T -invariant: if $v \perp e_n$ then $\langle Tv, e_n \rangle = \langle v, Te_n \rangle = \bar{\lambda}_n \langle v, e_n \rangle = 0$,

using self-adjointness and $\lambda_n \in \mathbb{R}$.

By construction the e_n are orthonormal, and $|\lambda_n| = \|T_n\|$ is non-increasing since $H_{n+1} \subseteq H_n$.

The λ_n tend to 0. If not, then $|\lambda_n| \geq \delta > 0$ for all n , and for $m \neq n$, orthogonality gives

$$\|Te_n - Te_m\|^2 = \|\lambda_n e_n - \lambda_m e_m\|^2 = \lambda_n^2 + \lambda_m^2 \geq 2\delta^2,$$

so (Te_n) has no convergent subsequence, contradicting compactness.

The formula. Let P_n be the orthogonal projection onto $\text{span}\{e_1, \dots, e_n\}$, so $P_n v = \sum_{k \leq n} \langle v, e_k \rangle e_k$ and $v - P_n v \in H_{n+1}$. Then

$$\left\| Tv - \sum_{k \leq n} \lambda_k \langle v, e_k \rangle e_k \right\| = \|T(v - P_n v)\| = \|T_{n+1}(v - P_n v)\| \leq |\lambda_{n+1}| \|v\|,$$

using $\|T_{n+1}\| = |\lambda_{n+1}|$ and $\|v - P_n v\| \leq \|v\|$. As $\lambda_{n+1} \rightarrow 0$ the left-hand side tends to 0, which is the required formula. (If the process terminates at stage n then $T_n = 0$ and the formula is exact.)

The decomposition. Grouping the e_n by their eigenvalue gives the eigenspaces $\ker(T - \lambda)$ for the distinct non-zero eigenvalues λ ; these are finite-dimensional as T is compact and $\lambda \neq 0$, and mutually orthogonal as T is self-adjoint. The formula shows that $Tv = 0$ whenever $v \perp$ all e_n , so the orthogonal complement of $\overline{\text{span}\{e_n\}}$ is exactly $\ker T$. Adjoining an orthonormal basis of $\ker T$ gives an orthonormal basis of H of eigenvectors. $\square$

Remark. The estimate in the proof gives more: writing $T_{(n)}v = \sum_{k \leq n} \lambda_k \langle v, e_k \rangle e_k$ for the truncation, we showed $\|T - T_{(n)}\| \leq |\lambda_{n+1}|$. So the eigenvalue expansion converges in operator norm, and exhibits T explicitly as a limit of finite rank operators.

Corollary 33.8.15 (Singular value decomposition)

Let $T \in \mathcal{K}(H_1, H_2)$ between Hilbert spaces. Then there are orthonormal systems (e_n) in H_1 , (f_n) in H_2 and $\mu_n \geq 0$ with $\mu_n \rightarrow 0$ such that $Tv = \sum_n \mu_n \langle v, e_n \rangle f_n$.

Proof. T^*T is compact, self-adjoint and positive, so by the spectral theorem $T^*Tv = \sum_n \mu_n^2 \langle v, e_n \rangle e_n$ with $\mu_n^2 \geq 0$ its eigenvalues and (e_n) orthonormal. Set $f_n = Te_n / \mu_n$ for $\mu_n \neq 0$; these are orthonormal since $\langle Te_n, Te_m \rangle = \langle T^*Te_n, e_m \rangle = \mu_n^2 \delta_{nm}$. $\square$

§33.8.4 Applications to Integral Equations

The theory was invented for a purpose, so let us see it applied. Consider the integral equation

$$f(x) - \mu \int_0^1 k(x, y) f(y) dy = g(x),$$

where k is a continuous Hermitian kernel, g is given, and f is to be found. Writing K for the integral operator, this is $(I - \mu K)f = g$, i.e. $(K - \mu^{-1})f = -\mu^{-1}g$.

Since K is compact and self-adjoint, the Fredholm alternative applies immediately.

Proposition 33.8.16

Let k be a continuous Hermitian kernel and $\mu \neq 0$. Exactly one of the following holds:

- (a) μ^{-1} is an eigenvalue of K , in which case the homogeneous equation $f = \mu K f$ has a non-trivial (finite-dimensional) space of solutions, and the inhomogeneous equation is soluble precisely when $g \perp \ker(K - \mu^{-1})$;
- (b) μ^{-1} is not an eigenvalue, in which case the equation has a unique solution for every g , and $\|f\| \leq C \|g\|$ for a constant depending only on k and μ .

Proof. The dichotomy is the Fredholm alternative. In case (a), the solubility criterion follows from $\overline{\text{img}(K - \mu^{-1})} = \ker(K - \mu^{-1})^\perp$ together with the fact (proved above) that the range is closed. $\square$

Moreover, the spectral theorem gives the solution explicitly. Let (e_n) be an orthonormal basis of eigenvectors with $Ke_n = \lambda_n e_n$. Expanding $f = \sum_n \hat{f}_n e_n$ and $g = \sum_n \hat{g}_n e_n$, the equation $(I - \mu K)f = g$ becomes

$$(1 - \mu\lambda_n)\hat{f}_n = \hat{g}_n \quad \text{for every } n,$$

so that, provided $\mu\lambda_n \neq 1$ for all n ,

$$f = \sum_n \frac{\hat{g}_n}{1 - \mu\lambda_n} e_n.$$

This converges because $\lambda_n \rightarrow 0$, so the denominators are eventually close to 1 and in particular bounded away from 0.

Example 33.8.17 (Sturm–Liouville theory)

In IB Methods we studied the eigenvalue problem

$$\mathcal{L}y = -(py')' + qy = \lambda wy \quad \text{on } [a, b], \quad y(a) = y(b) = 0,$$

and asserted – without proof – that the eigenvalues are real and discrete, the eigenfunctions are orthogonal with respect to the weight w , and the eigenfunctions form a complete system, so that any reasonable function can be expanded in them. We can now see where these facts come from.

Assume $p > 0$ and $q \geq 0$ on $[a, b]$, and $w > 0$. The operator $\mathcal{L}$ is unbounded, so we cannot apply our theory to it directly – this is the usual difficulty with differential operators. Instead we invert it. Using the Green's function $G(x, y)$ for $\mathcal{L}$ with the given boundary conditions (constructed in IB Methods from two solutions of the homogeneous equation and a jump condition), the map

$$(Kf)(x) = \int_a^b G(x, y)f(y) \, dy$$

is a two-sided inverse to $\mathcal{L}$ on the relevant space. The Green's function is continuous and symmetric, $G(x, y) = G(y, x)$, so K is a compact self-adjoint operator on $L^2([a, b], w \, dx)$.

Now apply the spectral theorem to K . It gives an orthonormal basis (y_n) of eigenfunctions, $Ky_n = \kappa_n y_n$ with κ_n real and $\kappa_n \rightarrow 0$. Since K is injective (as $\mathcal{L}Kf = f$), we have $\kappa_n \neq 0$, and applying $\mathcal{L}$ gives

$$\mathcal{L}y_n = \lambda_n w y_n, \quad \lambda_n = \kappa_n^{-1}.$$

Thus: the eigenvalues λ_n are real, they form a discrete sequence with $|\lambda_n| \rightarrow \infty$ (since $\kappa_n \rightarrow 0$), the eigenfunctions are orthogonal in the w -weighted inner product, and – this is the part that was simply asserted in Methods – they are *complete*, so that every $f \in L^2$ has a convergent eigenfunction expansion

$$f = \sum_n \langle f, y_n \rangle_w y_n.$$

The eigenfunction expansions of IB Methods, and the Fourier series that are their prototype, are all instances of the spectral theorem for compact self-adjoint operators.

Remark. This is a good place to stop and look back. We began by observing that the closed unit ball of an infinite-dimensional space is never compact, and that consequently the finite-dimensional theory breaks down. We then spent the course building substitutes: Hahn–Banach to supply functionals, Baire category to supply boundedness and openness for free, orthogonal projection to supply geometry, and finally compactness – reintroduced not as a property of the space but of the *operator* – to recover the spectral theorem. That last step is the pattern of much of modern analysis: when the space will not be compact, ask the operator to be.

34 Logic and Set Theory

Mathematics is done by writing down statements and proving them. In this course we take that activity itself as our object of study: we write down what a ‘statement’ is as a finite string of symbols, we write down what a ‘proof’ is as a finite list of such strings obeying some rules, and then we prove theorems about the resulting system. The most striking of these – the completeness theorem – says that the two ways we have of saying that something follows from something else, the semantic one (‘it is true in every situation where the hypotheses hold’) and the syntactic one (‘there is a proof of it’), give exactly the same answer.

Alongside this we develop set theory, which serves as the arena in which all of the above takes place. We will meet the ordinals, which extend counting past infinity and which give us induction and recursion of unlimited length; Zorn’s lemma, which is the form in which the axiom of choice is usually applied; and finally the axioms of Zermelo–Fraenkel set theory, together with a picture of the universe of sets that they describe. The two halves of the course meet at the very end, when we use a set-theoretic construction to write down a sentence of arithmetic that is true but unprovable.

This article constitutes my notes for the ‘Logic and Set Theory’ course, held in Lent 2023 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§34.1 Propositional Logic

We begin our study of logic by looking at *propositional logic*, which is the logic of statements built up out of atomic statements using connectives like ‘and’, ‘or’ and ‘implies’. It is a small enough system that we can prove everything we would want to about it, and it will act as a template for the more elaborate predicate logic that we meet in Section 34.4.

§34.1.1 Languages

The first thing to do is to say precisely what a statement *is*. It will be a finite string of symbols, built up according to some grammar from a supply of atoms.

Definition 34.1.1 (Language)

Let P be a set of **primitive propositions**. Unless otherwise stated we take $P = \{p_1, p_2, \dots\}$. The **language** L , or $L(P)$, is defined inductively by

- (i) If $p \in P$, then $p \in L$;
- (ii) $\perp \in L$ (where we read $\perp$ as ‘false’);
- (iii) If $p, q \in L$ then $(p \Rightarrow q) \in L$.

Every **proposition** (that is, member of L) is a finite string of symbols from the alphabet $\{(\,, \Rightarrow, \perp, p_1, p_2, \dots\}$, satisfying some grammar. It is worth being clear about what the

words ‘defined inductively’ mean above, since we will use the same device repeatedly.

We let $L_1 = P \cup \{\perp\}$, and define $L_{n+1} = L_n \cup \{(p \Rightarrow q) \mid p, q \in L_n\}$. Then $L = \bigcup_{n=1}^{\infty} L_n$. The rules building up the language are injective and have disjoint ranges, and so there is exactly *one* way in which any element of the language can be constructed from the rules above – a fact we will lean on constantly, since it is what lets us define things on L by recursion.

This unique readability is best seen by drawing a proposition as a tree, with the primitives and $\perp$ at the leaves and each internal node an application of $\Rightarrow$.

The proposition drawn above is $\neg p_3$ implied by $p_1 \Rightarrow p_2$, once we introduce the standard abbreviations $\neg$ (not), $\wedge$ (and) and $\vee$ (or), defined by

$$\neg p = (p \Rightarrow \perp); \quad p \wedge q = \neg(p \Rightarrow \neg q); \quad p \vee q = (\neg p) \Rightarrow q.$$

These are abbreviations only – our language really does have just the two constructors $\perp$ and $\Rightarrow$. This is purely for convenience: every proof below would go through with more connectives, at the cost of more cases.

§34.1.2 Semantic Implication

We now assign ‘true’ or ‘false’ values to propositions. Since a proposition is just a string of symbols, this has to be done by hand.

Definition 34.1.2 (Valuation)

A **valuation** is a function $v : L \rightarrow \{0, 1\}$ (where we think of 0 as false and 1 as true) such that

- (i) $v(\perp) = 0$;
- (ii) $v(p \Rightarrow q) = 0$ if $v(p) = 1$ and $v(q) = 0$, and 1 otherwise.

One would imagine that it is enough to know how a valuation acts on the primitives, since they are what our language is built out of – in the same way that a linear map is pinned down by its action on a basis. This is indeed the case.

Proposition 34.1.3 (Valuations are Determined on the Primitives)

- (i) Let $v, v' : L \rightarrow \{0, 1\}$ be valuations that agree on the primitives p_i . Then $v = v'$.
- (ii) Any function $w : P \rightarrow \{0, 1\}$ extends to a valuation.

Proof. (i) Clearly v, v' agree on L_1 . Then if they agree on p and q , they agree on $(p \Rightarrow q)$. So by induction they agree on L_n for all n , and hence on L .

(ii) Let $v(p) = w(p)$ for all $p \in P$ and $v(\perp) = 0$, to obtain v on the set L_1 . Assuming v is defined on p, q we can define it at $(p \Rightarrow q)$ in the obvious way. Since each element of L is built up in exactly one way, this consistently defines v on all of L . $\square$

In other words, valuations on L correspond exactly to functions $P \rightarrow \{0, 1\}$, which is what makes truth tables work.

Definition 34.1.4 (Tautology)

A **tautology** is an element $t \in L$ such that $v(t) = 1$ for every valuation v . We write $\models t$.

Example 34.1.5 (Some Tautologies)

Each of the following is a tautology, as one checks by running through the (at most eight) possibilities for the values of the primitives involved.

- (i) $p \Rightarrow (q \Rightarrow p)$. If $v(p) = 0$ then the whole thing is 1 immediately, and if $v(p) = 1$ then $v(q \Rightarrow p) = 1$.
- (ii) $\neg\neg p \Rightarrow p$, that is, $((p \Rightarrow \perp) \Rightarrow \perp) \Rightarrow p$. If $v(p) = 1$ this is 1, and if $v(p) = 0$ then $v(p \Rightarrow \perp) = 1$ so $v(\neg\neg p) = 0$.
- (iii) $[p \Rightarrow (q \Rightarrow r)] \Rightarrow [(p \Rightarrow q) \Rightarrow (p \Rightarrow r)]$. The only way for this to fail is $v(p) = v(q) = 1$ and $v(r) = 0$, and then the antecedent is already 0.

On the other hand $p \Rightarrow q$ is not a tautology, since we may take $v(p) = 1$ and $v(q) = 0$.

In practice one checks a tautology by drawing a truth table, listing the values of the primitives down the side and computing the value of each subformula.

Example 34.1.6 (A Truth Table)

We verify that $(\neg p \Rightarrow \neg q) \Rightarrow (q \Rightarrow p)$ is a tautology. Writing $v(p)$ and $v(q)$ in the first two columns:

$v(p)$	$v(q)$	$v(\neg p)$	$v(\neg q)$	$v(\neg p \Rightarrow \neg q)$	$v(q \Rightarrow p)$
0	0	1	1	1	1
0	1	1	0	0	0
1	0	0	1	1	1
1	1	0	0	1	1

In every row the last two columns agree, so the implication between them takes the value 1 throughout.

Remark. Since a valuation is determined by its values on the primitives, a formula in n primitives determines a function $\{0, 1\}^n \rightarrow \{0, 1\}$. Conversely every such function arises from a formula: one may write down a disjunction of conjunctions, one for each row of the truth table taking the value 1. So our two connectives $\perp$ and $\Rightarrow$ are already *adequate*, in the sense that every truth function is expressible.

Usually we are not interested in statements that hold outright, but in statements that

hold given some hypotheses.

Definition 34.1.7 (Semantic Implication)

Let $S \subseteq L$ and $t \in L$. We say S **entails** or **semantically implies** t , written $S \models t$, if $v(t) = 1$ whenever $v(s) = 1$ for all $s \in S$.

Definition 34.1.8 (Model)

We say that v is a **model** of S in L if $v(s) = 1$ for all $s \in S$.

So the statement $S \models t$ is precisely the statement that every model of S is also a model of t , and the notation $\models t$ is consistent with what we had before, being the same as $\emptyset \models t$.

Example 34.1.9

We have $\{p \vee q, \neg p\} \models q$: if $v(\neg p) = 1$ then $v(p) = 0$, and $p \vee q$ abbreviates $\neg p \Rightarrow q$, so $v(q) = 1$. On the other hand $\{p \Rightarrow q\} \not\models p$, as witnessed by the valuation sending every primitive to 0.

§34.1.3 Syntactic Implication

Semantic implication asks us to check every valuation, of which there are infinitely many. What we do in practice instead is give a *proof*. To make that notion precise we need a system of axioms and deduction rules.

Axiom 34.1.10 (Axiom Scheme for Propositional Logic)

- (1) $p \Rightarrow (q \Rightarrow p)$ for all $p, q \in L$;
- (2) $[p \Rightarrow (q \Rightarrow r)] \Rightarrow [(p \Rightarrow q) \Rightarrow (p \Rightarrow r)]$ for all $p, q, r \in L$;
- (3) $(\neg\neg p) \Rightarrow p$ for all $p \in L$.

Each of these is really an axiom *scheme*, since each line above is a whole set of axioms, one for each choice of the propositions involved. Notice also that each of them is a tautology – as one would hope, and as we will need for soundness.

For our deduction rules we take only **modus ponens**: from p and $p \Rightarrow q$ we may deduce q .

Definition 34.1.11 (Syntactic Implication)

For $S \subseteq L$ and $t \in L$, we say S **proves** or **syntactically implies** t , written $S \vdash t$, if there is a finite sequence $t_1, \dots, t_n = t$ of elements of L such that each t_i is either an axiom, or a member of S , or is obtained as q where $t_j = p$ and $t_k = (p \Rightarrow q)$ for some $j, k < i$.

We call S the set of **premises** or **hypotheses**, and t the **conclusion**.

Example 34.1.12

We will prove $\{p \Rightarrow q, q \Rightarrow r\} \vdash p \Rightarrow r$.

1. $q \Rightarrow r$ (hypothesis)
2. $(q \Rightarrow r) \Rightarrow (p \Rightarrow (q \Rightarrow r))$ (axiom 1)
3. $p \Rightarrow (q \Rightarrow r)$ (modus ponens on 1, 2)
4. $[p \Rightarrow (q \Rightarrow r)] \Rightarrow [(p \Rightarrow q) \Rightarrow (p \Rightarrow r)]$ (axiom 2)
5. $(p \Rightarrow q) \Rightarrow (p \Rightarrow r)$ (modus ponens on 3, 4)
6. $p \Rightarrow q$ (hypothesis)
7. $p \Rightarrow r$ (modus ponens on 5, 6)

Definition 34.1.13 (Theorem)

If $\emptyset \vdash t$, we say that t is a **theorem**, and write $\vdash t$.

Example 34.1.14

We will prove the theorem $\vdash (p \Rightarrow p)$. This looks like it should be trivial, and the fact that it is not is a good illustration of how weak our axiom system looks from the inside.

1. $(p \Rightarrow ((p \Rightarrow p) \Rightarrow p)) \Rightarrow ((p \Rightarrow (p \Rightarrow p)) \Rightarrow (p \Rightarrow p))$ (axiom 2)
2. $p \Rightarrow ((p \Rightarrow p) \Rightarrow p)$ (axiom 1)
3. $(p \Rightarrow (p \Rightarrow p)) \Rightarrow (p \Rightarrow p)$ (modus ponens on 1, 2)
4. $p \Rightarrow (p \Rightarrow p)$ (axiom 1)
5. $p \Rightarrow p$ (modus ponens on 3, 4)

Two easy remarks that we will use without comment. First, proofs are *finite*, so if $S \vdash t$ then $S' \vdash t$ for some finite $S' \subseteq S$. Second, if $S \subseteq S'$ and $S \vdash t$ then $S' \vdash t$, since a proof from S is already a proof from S' .

Example 34.1.15 (A Theorem Needing Axiom 3)

Not everything provable is provable from axioms 1 and 2 alone; axiom 3 is what makes our system *classical* rather than intuitionistic. For instance $\vdash (\perp \Rightarrow p)$ for every p : by the deduction theorem below it suffices to show $\{\perp\} \vdash p$, and from $\perp$ we get $(\neg p) \Rightarrow \perp$ by axiom 1, which is $\neg\neg p$, and then p by axiom 3. Without axiom 3 there is no proof of this.

§34.1.4 The Deduction Theorem

Writing out proofs like the one above by hand is unpleasant, and we would rather not have to. The following theorem is the tool that makes syntactic implication usable: it says that the connective ' $\Rightarrow$ ' inside the language really does correspond to implication in the metalanguage.

Theorem 34.1.16 (Deduction Theorem)

Let $S \subseteq L$ and $p, q \in L$. Then $S \vdash (p \Rightarrow q)$ if and only if $S \cup \{p\} \vdash q$.

Proof. Given a proof of $p \Rightarrow q$ from S , we add the line p (as a hypothesis) and deduce q by modus ponens, obtaining a proof of q from $S \cup \{p\}$.

Conversely, suppose we have a proof of q from $S \cup \{p\}$, with lines $t_1, \dots, t_n$. We show that $S \vdash (p \Rightarrow t_i)$ for all i , by induction on i . There are four cases.

- If t_i is an axiom, we write t_i (axiom); $t_i \Rightarrow (p \Rightarrow t_i)$ (axiom 1); $p \Rightarrow t_i$ (modus ponens).
- If $t_i \in S$, we write t_i (hypothesis); $t_i \Rightarrow (p \Rightarrow t_i)$ (axiom 1); $p \Rightarrow t_i$ (modus ponens).
- If $t_i = p$, we write out the proof of $\vdash p \Rightarrow p$ given above.
- If t_i is obtained by modus ponens from t_j and $t_k = (t_j \Rightarrow t_i)$, then by induction we have $S \vdash p \Rightarrow t_j$ and $S \vdash p \Rightarrow (t_j \Rightarrow t_i)$. We then write $(p \Rightarrow (t_j \Rightarrow t_i)) \Rightarrow ((p \Rightarrow t_j) \Rightarrow (p \Rightarrow t_i))$ (axiom 2); $(p \Rightarrow t_j) \Rightarrow (p \Rightarrow t_i)$ (modus ponens); $p \Rightarrow t_i$ (modus ponens).

Taking $i = n$ gives $S \vdash (p \Rightarrow q)$. □

Notice that axioms 1 and 2 were exactly what was needed to run this argument – and, conversely, that this is really the only thing we ever want to do with them.

Example 34.1.17 (Using the Deduction Theorem)

To show $\{p \Rightarrow q, q \Rightarrow r\} \vdash p \Rightarrow r$, the deduction theorem says it is enough to show that $\{p, p \Rightarrow q, q \Rightarrow r\} \vdash r$, which is just modus ponens twice. Compare this with the seven-line proof above.

§34.1.5 Soundness and Adequacy

We now have two relations between a set of hypotheses and a conclusion, $\models$ and $\vdash$, defined in completely different ways. The **completeness theorem** says that they agree: $S \models t$ if and only if $S \vdash t$.

This splits into two halves. The **soundness** statement, $S \vdash t \Rightarrow S \models t$, informally says ‘our axioms and deduction rule are not silly’. The **adequacy** statement, $S \models t \Rightarrow S \vdash t$, says ‘our axioms are strong enough to deduce from S every semantic consequence of S ’. Soundness is easy.

Proposition 34.1.18 (Soundness)

Let $S \subseteq L$ and $t \in L$. Then $S \vdash t$ implies $S \models t$.

Proof. Let v be a model of S , and let $t_1, \dots, t_n = t$ be a proof of t from S . We show $v(t_i) = 1$ for all i by induction. If t_i is an axiom then $v(t_i) = 1$ as each axiom is a tautology; if $t_i \in S$ then $v(t_i) = 1$ as v is a model of S ; and if t_i follows by modus ponens from earlier lines p and $p \Rightarrow q$, then $v(p) = v(p \Rightarrow q) = 1$ forces $v(q) = 1$ by

the definition of a valuation. Hence $v(t) = 1$. $\square$

Adequacy is the substantial half. The key is to notice that a special case of it implies the whole thing. Let us say that S is **consistent** if $S \not\vdash \perp$.

Definition 34.1.19 (Consistent)

A set $S \subseteq L$ is **consistent** if $S \not\vdash \perp$.

The case $t = \perp$ of adequacy says: $S \models \perp$ implies $S \vdash \perp$. Taking the contrapositive, and noting that $S \models \perp$ says exactly that S has no model, this reads:

$$S \text{ consistent} \implies S \text{ has a model.}$$

This special case implies adequacy in general. Indeed, suppose $S \models t$. Then $S \cup \{\neg t\}$ has no model, so by the above it is inconsistent, i.e. $S \cup \{\neg t\} \vdash \perp$. By the deduction theorem $S \vdash ((\neg t) \Rightarrow \perp)$, that is, $S \vdash \neg\neg t$. Axiom 3 gives $S \vdash ((\neg\neg t) \Rightarrow t)$, so $S \vdash t$ by modus ponens.

So we must build a model of S knowing only that S is consistent. The naive attempt is to set $v(t) = 1$ exactly when $t \in S$. This fails for $S = \{p_1, p_1 \Rightarrow p_2\}$, which would make p_2 false while p_1 and $p_1 \Rightarrow p_2$ are true. The problem is that S need not contain everything it proves.

Definition 34.1.20 (Deductive Closure)

A set $S \subseteq L$ is **deductively closed** if $p \in S$ whenever $S \vdash p$. The **deductive closure** of S is the set $\{t \in L \mid S \vdash t\}$, which is deductively closed, and consistent if S is.

Passing to the deductive closure fixes the example above, but not everything: if neither p nor $\neg p$ is provable from S , our recipe makes both false, which no valuation does. Remarkably, that is the only remaining obstruction, and we can remove it by ‘swallowing up’ one of $p, \neg p$ for each p .

Theorem 34.1.21 (Model Existence Lemma)

Every consistent $S \subseteq L$ has a model.

Proof. First we note that for any consistent $S \subseteq L$ and any $p \in L$, at least one of $S \cup \{p\}$ and $S \cup \{\neg p\}$ is consistent^a.

Since L is countable (each proposition is a finite string from a countable alphabet), we may list it as $t_1, t_2, \dots$. Let $S_0 = S$, and having chosen S_n consistent, let S_{n+1} be whichever of $S_n \cup \{t_{n+1}\}$ and $S_n \cup \{\neg t_{n+1}\}$ is consistent. Set $\bar{S} = \bigcup_{n \geq 0} S_n$. Then for all $t \in L$ we have $t \in \bar{S}$ or $(\neg t) \in \bar{S}$.

The set $\bar{S}$ is consistent: a proof of $\perp$ from $\bar{S}$ is finite, so it is a proof of $\perp$ from some S_n , contradicting consistency of S_n . It is also deductively closed: if $\bar{S} \vdash t$ but $t \notin \bar{S}$, then $\neg t \in \bar{S}$ and so $\bar{S} \vdash \perp$.

So we define $v : L \rightarrow \{0, 1\}$ by

$$v(t) = \begin{cases} 1 & t \in \bar{S}, \\ 0 & \text{otherwise,} \end{cases}$$

and check that v is a valuation. Certainly $v(\perp) = 0$, since $\bar{S}$ is consistent and so $\perp \notin \bar{S}$. Now let $p, q \in L$.

Suppose $v(p) = 1$ and $v(q) = 0$, so $p \in \bar{S}$ and $q \notin \bar{S}$; we want $(p \Rightarrow q) \notin \bar{S}$. If not, then $(p \Rightarrow q) \in \bar{S}$ and $p \in \bar{S}$ give $\bar{S} \vdash q$, so $q \in \bar{S}$ as $\bar{S}$ is deductively closed, a contradiction.

Now suppose $v(q) = 1$, so $q \in \bar{S}$; we want $(p \Rightarrow q) \in \bar{S}$. Indeed $\bar{S} \vdash q$, and by axiom 1 $\bar{S} \vdash q \Rightarrow (p \Rightarrow q)$, so $\bar{S} \vdash (p \Rightarrow q)$ and hence $(p \Rightarrow q) \in \bar{S}$ by deductive closure.

Finally suppose $v(p) = 0$, so $p \notin \bar{S}$ and hence $\neg p \in \bar{S}$; we want $(p \Rightarrow q) \in \bar{S}$. It is enough to show that $\{p \Rightarrow \perp\} \vdash (p \Rightarrow q)$, which by the deduction theorem is equivalent to $\{p, p \Rightarrow \perp\} \vdash q$, and hence (after one modus ponens) to $\{\perp\} \vdash q$. But from $\perp$, axiom 1 gives $(\neg q) \Rightarrow \perp$, which is $\neg \neg q$, and then axiom 3 gives q . $\square$

^aIf not, then $S \cup \{p\} \vdash \perp$ and $S \cup \{\neg p\} \vdash \perp$. The first gives $S \vdash (p \Rightarrow \perp)$ by the deduction theorem, that is, $S \vdash (\neg p)$; feeding this into the second gives $S \vdash \perp$.

Corollary 34.1.22 (Adequacy)

Let $S \subseteq L$ and $t \in L$. Then $S \models t$ implies $S \vdash t$.

Proof. This is the argument given above, using Theorem 34.1.21. $\square$

Putting the two halves together we have our first main theorem.

Theorem 34.1.23 (Completeness Theorem for Propositional Logic)

Let $S \subseteq L$ and $t \in L$. Then $S \models t$ if and only if $S \vdash t$.

Proof. Soundness and adequacy. $\square$

The proof above assumed P , and hence L , to be countable, since we enumerated L . We will remove that restriction in Section 34.3.3, once Zorn's lemma is available.

§34.1.6 Compactness and Decidability

Directly from completeness we get some genuinely useful consequences, which are not at all obvious from the semantic definitions.

Theorem 34.1.24 (Compactness Theorem)

Let $S \subseteq L$ and $t \in L$ with $S \models t$. Then there is a finite subset $S' \subseteq S$ with $S' \models t$.

Proof. By completeness $S \vdash t$, and a proof is a finite object, so it uses only finitely many members S' of S . Then $S' \vdash t$, so $S' \models t$. $\square$

Corollary 34.1.25 (Compactness Theorem, Equivalent Form)

Let $S \subseteq L$ be such that every finite subset of S has a model. Then S has a model.

Proof. If S had no model then $S \models \perp$, so $S' \models \perp$ for some finite $S' \subseteq S$, meaning S' has no model. $\square$

It is worth pausing on how strange this is: the hypothesis only ever talks about finitely many propositions at a time, and yet it produces a single valuation making all of S true at once. Here is a typical application.

Example 34.1.26 (Compactness and Graph Colouring)

Let G be a graph, possibly infinite, such that every finite subgraph of G is k -colourable. Then G is k -colourable.

Take primitive propositions $p_{v,i}$ for v a vertex of G and $1 \leq i \leq k$, to be read as ‘ v has colour i ’. Let S consist of the propositions

- (i) $p_{v,1} \vee \cdots \vee p_{v,k}$ for each vertex v (‘every vertex has a colour’);
- (ii) $\neg(p_{v,i} \wedge p_{v,j})$ for each vertex v and $i \neq j$ (‘no vertex has two colours’);
- (iii) $\neg(p_{u,i} \wedge p_{v,i})$ for each edge uv and each i (‘adjacent vertices differ’).

A model of S is precisely a k -colouring of G . Any finite subset S' of S mentions only finitely many vertices, and a k -colouring of the (finite) subgraph they span gives a model of S' once we colour every other vertex arbitrarily. So by compactness S has a model.

The same argument, run on a tree instead of a graph, is exactly König’s lemma: an infinite, finitely branching tree has an infinite branch. The picture to keep in mind is that each finite level can be satisfied, and compactness threads these finite solutions together into an infinite one.

Finally, in propositional logic we can settle the decision problem completely.

Theorem 34.1.27 (Decidability)

Let $S \subseteq L$ be finite and $t \in L$. Then there is an algorithm to decide, in finite time, whether $S \vdash t$.

Proof. By completeness it is enough to decide whether $S \models t$, and only the finitely many primitives appearing in $S \cup \{t\}$ matter. So we simply draw the truth table, which has finitely many rows. $\square$

Searching for a proof directly would give no such algorithm, since there are infinitely many candidate proofs; it is completeness that converts the problem into a finite one. We will see in Section 34.4 that the corresponding question for predicate logic has no such easy answer, and in Section 34.7 that some closely related questions have no algorithm at all.

§34.2 Well-Orderings and Ordinals

We now jump away from logic for a while and look at some set theory. Everything in this section is really about a single idea: we want to be able to do induction and recursion along things much longer than $\mathbb{N}$, and the orderings that let us do that are the well-orderings.

§34.2.1 Well-Orderings

Definition 34.2.1 (Total Order)

A **total order** (or **linear order**) is a pair $(X, <)$ where X is a set and $<$ is a relation on X that is

- (i) *irreflexive*: for all $x \in X$, $x \not< x$;
- (ii) *transitive*: for all $x, y, z \in X$, $x < y$ and $y < z$ implies $x < z$;
- (iii) *trichotomous*: for all $x, y \in X$, exactly one of $x < y$, $y < x$, $x = y$ holds.

We use the standard notation $y > x$ for $x < y$, and $x \leq y$ for ‘ $x < y$ or $x = y$ ’. We could instead have defined a total order in terms of $\leq$ in the obvious way, with reflexivity, transitivity, antisymmetry and trichotomy.

Example 34.2.2 (Total Orders)

Each of $(\mathbb{N}, <)$, $(\mathbb{Z}, <)$, $(\mathbb{Q}, <)$ and $(\mathbb{R}, <)$ is a total order. On the other hand $(\mathbb{N}^+, \text{‘divides’})$ is not one, as neither of 2, 3 divides the other, and nor is $(\mathcal{P}(S), \subseteq)$ once $|S| \geq 2$.

Definition 34.2.3 (Well-Ordering)

A total order $(X, <)$ is a **well-ordering** if every non-empty subset of X has a least element.

Example 34.2.4 (Well-Orderings and Non-Examples)

$(\mathbb{N}, <)$ is a well-ordering. $(\mathbb{Z}, <)$, $(\mathbb{Q}, <)$ and $(\mathbb{R}, <)$ are not, since $\mathbb{Z}$ itself, or $(0, 1) \subseteq \mathbb{R}$, has no least element. The set $\{1/2, 2/3, 3/4, \dots\} \subseteq \mathbb{R}$ is well-ordered (it has order type ω , in the language below), and so is $\{1/2, 2/3, \dots\} \cup \{1\}$, where the extra point sits above everything else. But $\{\dots, -1/3, -1/2, -1\} \subseteq \mathbb{R}$ is not, having no least element at all.

In (a) above every non-empty subset has a least element, and the order type is $\omega + 1$; in (b) the whole set has no least element, so this is not a well-ordering, even though it is a perfectly good total order. The difference is exactly that in (b) we can descend forever.

Proposition 34.2.5 (Descending Sequence Criterion)

A total order $(X, <)$ is a well-ordering if and only if there is no infinite strictly decreasing sequence $x_1 > x_2 > \dots$ in X .

Proof. If $x_1 > x_2 > \dots$ is such a sequence then $\{x_1, x_2, \dots\}$ has no least element. Conversely, if $S \subseteq X$ is non-empty with no least element, pick $x_1 \in S$; as x_1 is not least there is $x_2 \in S$ with $x_2 < x_1$, and continuing gives an infinite decreasing sequence. $\square$

The reverse direction of this used the axiom of choice, in that we chose each x_{n+1} from an infinite supply of candidates. This is one of only a handful of places in this section where choice appears, and we will discuss the axiom itself properly in Section 34.3.

The point of well-orderings is that they support induction.

Proposition 34.2.6 (Principle of Induction)

Let X be a well-ordering and let $S \subseteq X$ be such that whenever $y \in S$ for all $y < x$, we have $x \in S$. Then $S = X$.

Equivalently, if p is a property such that $p(y)$ holding for all $y < x$ implies $p(x)$, then $p(x)$ holds for all $x \in X$.

Proof. Suppose $S \neq X$. Then $X \setminus S$ is non-empty, so it has a least element x . Then every $y < x$ lies in S , so $x \in S$ by hypothesis, a contradiction. $\square$

Note that there is no separate base case: the case $x = \min X$ is the case where the hypothesis ' $y \in S$ for all $y < x$ ' is vacuous.

We will want to regard well-orderings that look the same as being the same.

Definition 34.2.7 (Order Isomorphism)

Two total orders X and Y are **order isomorphic** if there is a bijection $f : X \rightarrow Y$ with $x < y \iff f(x) < f(y)$. We call such an f an **isomorphism**.

For general total orders there can be many isomorphisms between two orders – consider $\mathbb{Z} \rightarrow \mathbb{Z}, x \mapsto x + n$. For well-orderings this cannot happen, which is the first sign of how rigid they are.

Proposition 34.2.8 (Uniqueness of Isomorphisms)

Let X, Y be isomorphic well-orderings. Then there is a unique isomorphism between them.

Proof. Let $f, g : X \rightarrow Y$ be isomorphisms. We show $f(x) = g(x)$ for all x by induction on x , using Proposition 34.2.6.

So suppose $f(y) = g(y)$ for all $y < x$, and let $S = \{f(y) \mid y < x\}$, which by assumption equals $\{g(y) \mid y < x\}$. As f is an order isomorphism, $f(x)$ is not in S , so $Y \setminus S$ is non-empty and has a least element a . Now every element of Y below $f(x)$ is of the form $f(y)$ with $y < x$, so lies in S ; hence $f(x) = a$. The identical argument gives $g(x) = a$, so $f(x) = g(x)$. $\square$

§34.2.2 Initial Segments and Recursion

Given an ordered set we can chop off the end and keep the beginning. What we are left with is an initial segment.

Definition 34.2.9 (Initial Segment)

A subset I of a totally ordered set X is an **initial segment** if $x \in I$ implies $y \in I$ for all $y < x$.

For any $x \in X$, the set $I_x = \{y \in X \mid y < x\}$ is an initial segment. Not every initial segment is of this form in a general total order: in $\mathbb{R}$ the set $\{x \mid x \leq 3\}$ is an initial segment which is not any I_x , and in $\mathbb{Q}$ so is $\{x \mid x \leq 0 \text{ or } x^2 < 2\}$. In a well-ordering, however, this is the only shape available.

Proposition 34.2.10 (Initial Segments of Well-Orderings)

Every proper initial segment of a well-ordered set X is of the form I_x for some $x \in X$.

Proof. Let $I \subsetneq X$ be an initial segment and let $x = \min(X \setminus I)$. If $y < x$ then $y \in I$ by minimality of x , and if $y \in I$ then $y < x$, since $y \geq x$ would put $x \in I$. So $I = I_x$. $\square$

We would now like to show that every subset of a well-ordering X is isomorphic to an initial segment of X . To construct the isomorphism we need to be able to define functions by recursion along X , which is the following theorem. Here $\mathcal{P}(X \times Y)$ is being used as ‘the set of all partial functions and more’, and G should be thought of as a rule telling us what to do next given everything we have done so far.

Theorem 34.2.11 (Definition by Recursion)

Let X be a well-ordering, let Y be a set, and let $G : \mathcal{P}(X \times Y) \rightarrow Y$ be any function. Then there is a unique function $f : X \rightarrow Y$ such that

$$f(x) = G(f|_{I_x}) \quad \text{for all } x \in X.$$

Proof. Say that h is an *attempt* if $h : I \rightarrow Y$ for some initial segment I of X , and $h(x) = G(h|_{I_x})$ for all $x \in I$.

If h, h' are attempts both defined at x , then $h(x) = h'(x)$, by induction on x : if they agree below x then $h|_{I_x} = h'|_{I_x}$, so $h(x) = G(h|_{I_x}) = G(h'|_{I_x}) = h'(x)$.

Next, for every x there *is* an attempt defined at x , again by induction on x . Indeed, suppose for each $y < x$ there is an attempt h_y defined at y . Let $h = \bigcup_{y < x} h_y$; by the previous paragraph the h_y agree wherever two of them are defined, so h is a function, and it is an attempt with domain I_x . Then $h' = h \cup \{(x, G(h))\}$ is an attempt defined at x .

So we may define $f : X \rightarrow Y$ by letting $f(x)$ be the common value $h(x)$ over all attempts h defined at x . This is well-defined by the first paragraph, and satisfies the recursion by construction.

For uniqueness, if f, f' both satisfy the recursion and agree below x , then $f(x) = G(f|_{I_x}) = G(f'|_{I_x}) = f'(x)$, so $f = f'$ by induction. $\square$

Before proving the result we were after, here is a small lemma that we will use several times.

Lemma 34.2.12

Let X be a well-ordering and $f : X \rightarrow X$ order-preserving. Then $f(x) \geq x$ for all $x \in X$.

Proof. If not, take the least x with $f(x) < x$. Applying f gives $f(f(x)) < f(x)$, so $f(x)$ is a smaller counterexample, contradicting minimality. $\square$

Corollary 34.2.13

A well-ordering X is never isomorphic to a proper initial segment of itself.

Proof. Suppose $f : X \rightarrow I_x$ is an isomorphism, where I_x is a proper initial segment. Regarding f as an order-preserving map $X \rightarrow X$, Lemma 34.2.12 gives $f(x) \geq x$. But $f(x) \in I_x$, so $f(x) < x$, a contradiction. $\square$

Now we can prove our result, by recursively sending the least unused element to the least unused element.

Proposition 34.2.14 (Subset Collapse)

Any subset Y of a well-ordering X is isomorphic to a unique initial segment of X .

Proof. If $f : Y \rightarrow X$ is to be an order-preserving bijection onto an initial segment of X , then it must send each x to the least element not yet used, that is,

$$f(x) = \min(X \setminus \{f(y) \mid y \in Y, y < x\}).$$

So define f by this recursion; it is well-defined, since one shows by induction that

$f(y) \leq y$ for all y , and hence x itself lies in the set we are minimising over, so that set is non-empty.

This f is order-preserving: if $y < x$ then $f(y)$ is the minimum of a set containing everything $f(x)$ is minimised over, and $f(y)$ itself is excluded from the latter, so $f(y) < f(x)$. Its image is an initial segment: if $z < f(x)$ then z is not in the set we minimised over to get $f(x)$, so $z = f(y)$ for some $y < x$. Finally, uniqueness of the initial segment follows from Corollary 34.2.13: two distinct initial segments of X are never isomorphic, since one is a proper initial segment of the other. $\square$

§34.2.3 Comparing Well-Orderings

We now know enough to compare any two well-orderings.

Definition 34.2.15 (Comparing Well-Orderings)

For well-orderings X, Y we write $X \leq Y$ if X is isomorphic to an initial segment of Y , and $X < Y$ if moreover X is not isomorphic to Y (equivalently, if X is isomorphic to a *proper* initial segment of Y).

By subset collapse, $X \leq Y$ if and only if X is isomorphic to *some subset* of Y , which is often the easier condition to check.

Proposition 34.2.16 (Trichotomy for Well-Orderings)

Let X and Y be well-orderings. Then $X \leq Y$ or $Y \leq X$; and if both, then X and Y are isomorphic.

Proof. Consider $f : X \rightarrow Y$ defined by recursion by $f(x) = \min(Y \setminus \{f(y) \mid y < x\})$. There are two cases. If f is everywhere defined, then exactly as in Proposition 34.2.14 it is an isomorphism from X onto an initial segment of Y , so $X \leq Y$. Otherwise there is a least x at which the recipe fails, meaning $\{f(y) \mid y < x\} = Y$; but then f restricted to I_x is an isomorphism $I_x \rightarrow Y$, so $Y \leq X$.

Now suppose both $X \leq Y$ and $Y \leq X$, via isomorphisms f onto an initial segment of Y and g onto an initial segment of X . Then $g \circ f$ is an isomorphism of X onto an initial segment of X , which by Corollary 34.2.13 must be all of X . So $g \circ f$ is onto X , forcing g to be onto X , and hence g (and likewise f) is an isomorphism. $\square$

§34.2.4 Constructing Larger Well-Orderings

Given some well-orderings, there are two natural ways to build a longer one: add an element at the top, or stack a nested family of them.

Definition 34.2.17 (Successor)

Given a well-ordering X , choose some $x \notin X$ and well-order $X \cup \{x\}$ by setting $y < x$ for all $y \in X$. This is the **successor** of X , written X^+ .

Clearly X^+ is a well-ordering (any non-empty subset either meets X , and takes its least element there, or is $\{x\}$) and $X < X^+$, since $X = I_x$ inside X^+ .

Definition 34.2.18 (Extensions and Nested Families)

Given well-orderings $(X, <_X)$ and $(Y, <_Y)$, we say Y **extends** X if X is an initial segment of Y and $<_X, <_Y$ agree where both are defined.

A family of well-orderings $\{X_i \mid i \in I\}$ is **nested** if for all i, j , one of X_i, X_j extends the other.

Proposition 34.2.19 (Unions of Nested Well-Orderings)

Let $\{X_i \mid i \in I\}$ be a nested family of well-orderings. Then there is a well-ordering X with $X_i \leq X$ for all i .

Proof. Let $X = \bigcup_i X_i$ with the ordering $<_X = \bigcup_i <_i$; that is, $x < y$ in X if $x, y \in X_i$ and $x <_i y$ for some i . Nestedness makes this a well-defined total order.

Given non-empty $S \subseteq X$, we have $S \cap X_i \neq \emptyset$ for some i ; let x be its least element under $<_i$. Then x is least in all of S : any $y \in S$ with $y < x$ would lie in X_i , since X_i is an initial segment of X by nestedness, and then $y \in S \cap X_i$ contradicts minimality. So X is a well-ordering, and each X_i is an initial segment of it. $\square$

§34.2.5 Ordinals

It is inconvenient to keep saying ‘a well-ordering, up to isomorphism’. So we give these isomorphism classes a name.

Definition 34.2.20 (Ordinal)

An **ordinal** is a well-ordered set, where we regard two ordinals as equal if they are isomorphic.

This is a definition to be taken in a slightly informal spirit – the isomorphism class of a well-ordering is far too big to be a set. In Section 34.5 we will give a genuine definition inside ZF (an ordinal is a transitive set totally ordered by $\in$) and check it does the same job. For now, nothing we say will depend on the difference.

Definition 34.2.21 (Order Type)

If a well-ordering X corresponds to the ordinal α , we say X has **order type** α , and write $\text{otp}(X) = \alpha$.

The order type of the unique well-ordering on a set of $k \in \mathbb{N}$ points is called k , and the order type of $(\mathbb{N}, <)$ is called ω .

Example 34.2.22 (Order Types)

In $\mathbb{R}$, the subset $\{-2, 3, \pi, 5\}$ has order type 4, the subset $\{1/2, 2/3, 3/4, \dots\}$ has order type ω , and $\{1/2, 2/3, \dots\} \cup \{1\}$ has order type $\omega + 1$ (a copy of ω with one extra point on top).

Example 34.2.23 (Countable Ordinals Live Inside $\mathbb{Q}$)

Every countable ordinal is the order type of a subset of $\mathbb{Q}$. Indeed, if α is countable then I_α is a countable well-ordering, and one may embed it into $\mathbb{Q}$ by recursion: having placed I_β inside $\mathbb{Q}$, place β above everything used so far if there is room, and otherwise squeeze it into a gap, which density allows. So the enormous ordinals of the previous list all fit inside the rationals – what changes as we ascend is not the size of the set but the shape of the ordering.

For ordinals α, β we write $\alpha \leq \beta$ if $X \leq Y$ for some (equivalently, any) X of order type α and Y of order type β ; this is well-defined since any two representatives are isomorphic. Proposition 34.2.16 says that any two ordinals are comparable, and that $\alpha \leq \beta \leq \alpha$ implies $\alpha = \beta$. We also write α^+ for the order type of X^+ .

Proposition 34.2.24 (I_α Has Order Type α)

For any ordinal α , the ordinals $\beta < \alpha$ form a set $I_\alpha = \{\beta \mid \beta < \alpha\}$, well-ordered by $<$, of order type α .

Proof. Let X be a well-ordering with $\text{otp}(X) = \alpha$. The well-orderings which are $< X$ are precisely, up to isomorphism, the proper initial segments of X , which by Proposition 34.2.10 are exactly the I_x for $x \in X$. Distinct x give non-isomorphic I_x by Corollary 34.2.13, so $x \mapsto \text{otp}(I_x)$ is an order-preserving bijection from X to I_α . $\square$

Proposition 34.2.25 (The Ordinals are Well-Ordered)

Every non-empty set S of ordinals has a least element.

Proof. Choose $\alpha \in S$. If α is least in S we are done. Otherwise $S \cap I_\alpha$ is non-empty, and I_α is well-ordered by Proposition 34.2.24, so it has a least element β . Any $\gamma \in S$ has $\gamma \geq \alpha > \beta$ or $\gamma \in I_\alpha$, in which case $\gamma \geq \beta$. So β is least in S . $\square$

So the ordinals behave in every respect like a well-ordering. They cannot literally be one, however.

Theorem 34.2.26 (Burali-Forti Paradox)

The ordinals do not form a set.

Proof. Suppose X were the set of all ordinals. By Proposition 34.2.25 it is well-ordered, so it has an order type, say α . But then X is isomorphic to I_α by Proposition 34.2.24, which is a proper initial segment of X (it omits α), contradicting Corollary 34.2.13. $\square$

This is not a paradox in the sense of an inconsistency – it is a theorem, and a useful one. We will write On for the class of all ordinals, and treat statements about it as abbreviations, exactly as we will do for classes in general in Section 34.5.

Definition 34.2.27 (Supremum)

Let $S = \{\alpha_i \mid i \in I\}$ be a set of ordinals. Then $\sup S$ is the least upper bound of S .

This exists: applying Proposition 34.2.19 to the nested family $\{I_{\alpha_i}\}$ gives an upper bound α , and then the set of upper bounds which are $\leq \alpha$ is a non-empty subset of I_α^+ , so has a least element by Proposition 34.2.25. For example $\sup\{2, 4, 6, \dots\} = \omega$, and $\sup\{\alpha\} = \alpha$.

§34.2.6 Some Ordinals

We know $0, 1, 2, \dots$ and ω . Writing $\alpha+1$ for α^+ , the successor and supremum operations already let us generate a great many ordinals:

$$\omega + 1, \omega + 2, \dots, \omega + \omega = \omega \cdot 2, \omega \cdot 2 + 1, \dots, \omega \cdot 3, \dots, \omega \cdot \omega = \omega^2, \dots$$

where each ‘ $\dots$ ’ is resolved by taking a supremum, for instance $\omega \cdot 2 = \sup\{\omega, \omega + 1, \omega + 2, \dots\}$ and $\omega^2 = \sup\{\omega, \omega \cdot 2, \omega \cdot 3, \dots\}$. The notation is justified in Section 34.2.9. Carrying on:

0	$\omega \cdot 2 + 1$	$\omega^2 + 1$	$\omega^2 \cdot 3$	$\omega^{\omega+2}$	$\varepsilon_0 + 1$
1	$\omega \cdot 2 + 2$	$\omega^2 + 2$	$\omega^2 \cdot 4$	$\vdots$	$\vdots$
2	$\omega \cdot 2 + 3$	$\omega^2 + 3$	$\omega^2 \cdot 5$	$\omega^{\omega \cdot 2}$	$\varepsilon_0 \cdot 2$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
ω	$\omega \cdot 3$	$\omega^2 + \omega$	ω^3	ω^{ω^2}	ε_0^2
$\omega + 1$	$\omega \cdot 4$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
$\omega + 2$	$\omega \cdot 5$	$\omega^2 + \omega \cdot 2$	ω^ω	ω^{ω^ω}	$\varepsilon_0^{\varepsilon_0}$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
$\omega + \omega$ $= \omega \cdot 2$	$\omega \cdot \omega$ $= \omega^2$	$\omega^2 \cdot 2$	$\omega^{\omega+1}$	$\omega^{\omega^{\dots}}$ $= \varepsilon_0$	$\varepsilon_0^{\varepsilon_0^{\dots}}$ $= \varepsilon_1$

It helps to have a picture. Drawing each ordinal as a point on a line, with the tick marks bunching up as we approach a limit, the beginning of the list looks like this.

Every ordinal in the table above is *countable*: at each step we either add one element or take a countable supremum of countable ordinals, and a countable union of countable sets is countable. It is natural to ask whether we ever escape. Since a well-ordering of a set X of order type α is the same thing as an injection of X into I_α hitting an initial segment, this is essentially the question of whether we can well-order $\mathbb{R}$. The answer is yes, and remarkably we can prove it without ever writing such an ordering down.

§34.2.7 Uncountable Ordinals and Hartogs' Lemma**Theorem 34.2.28 (Existence of an Uncountable Ordinal)**

There is an uncountable ordinal.

Proof. Let

$$A = \{R \in \mathcal{P}(\omega \times \omega) \mid R \text{ is a well-ordering of a subset of } \omega\},$$

which is a set by separation from $\mathcal{P}(\omega \times \omega)$. Then $B = \{\text{otp}(R) \mid R \in A\}$ is a set (it is the image of A under a function-class, using replacement, which we discuss in Section 34.5), and B is precisely the set of all countable ordinals – every countable ordinal is the order type of a well-ordering of a subset of ω , and conversely.

Let $\omega_1 = \sup B$. If ω_1 were countable then $\omega_1 \in B$, and so $\omega_1^+ \in B$ as well (a successor of a countable ordinal is countable), giving $\omega_1^+ \leq \sup B = \omega_1$, which is absurd. So ω_1 is uncountable. $\square$

Alternatively, and more slickly: B cannot be all of the ordinals, since the ordinals do not form a set, so some ordinal is uncountable.

By construction ω_1 is the *least* uncountable ordinal, and it has some remarkable properties. Every proper initial segment I_α of ω_1 is countable, while ω_1 itself is not; so ω_1 is uncountable but is ‘built out of’ countable pieces. Also, every sequence $\alpha_1, \alpha_2, \dots$ of ordinals below ω_1 is bounded below ω_1 , namely by $\sup\{\alpha_1, \alpha_2, \dots\}$, which is countable as a countable union of countable sets. So ω_1 cannot be reached from below by any sequence – it is very far from being ω .

The same argument, run with an arbitrary set in place of ω , gives the following, which is the workhorse of the next section.

Theorem 34.2.29 (Hartogs’ Lemma)

For every set X there is an ordinal α that does not inject into X . The least such ordinal is written $\gamma(X)$, read ‘**Hartogs’ ordinal** of X ’.

Proof. Let A be the set of pairs (Y, R) with $Y \subseteq X$ and R a well-ordering of Y ; this is a set, being a subset of $\mathcal{P}(X) \times \mathcal{P}(X \times X)$. Let $B = \{\text{otp}(R) \mid (Y, R) \in A\}$, a set by replacement, and let $\gamma = \sup\{\beta^+ \mid \beta \in B\}$.

If γ injected into X , say with image Y , then transporting the ordering of I_γ across gives a well-ordering of $Y \subseteq X$ of order type γ , so $\gamma \in B$ and hence $\gamma^+ \leq \gamma$, a contradiction. So γ does not inject into X , and by Proposition 34.2.25 there is a least such ordinal. $\square$

So $\gamma(\omega) = \omega_1$. Note that $\gamma(X)$ is a genuine ‘size barrier’ for X : no ordinal $\geq \gamma(X)$ injects into X either, since it has $\gamma(X)$ as an initial segment.

§34.2.8 Successors and Limits

Ordinals come in two flavours.

Definition 34.2.30 (Limits and Successors)

An ordinal α is a **successor** if $\alpha = \beta^+$ for some ordinal β . Otherwise α is a **limit**.

An ordinal (viewed as a well-ordered set I_α) has a greatest element if and only if it is a successor. So α is a limit precisely when it has no greatest element, and then $\alpha = \sup I_\alpha$.

We typically write λ for a limit ordinal.

Example 34.2.31

$5 = 4^+$ is a successor, and $\omega + 2 = (\omega^+)^+$ is a successor. Both ω and $\omega \cdot 2$ are limits, as is 0 (vacuously – it is not a successor of anything). This is why the clause for limits in the recursive definitions below always says ‘non-zero limit’.

Consequently, when defining something by recursion on the ordinals we give three clauses: the value at 0, the value at α^+ in terms of the value at α , and the value at a non-zero limit λ in terms of the values below λ . This is **transfinite recursion**, and it is justified by Theorem 34.2.11 applied to I_β for each β (we cannot recurse on ‘all the ordinals’ at once, since they do not form a set, so officially we define the function on I_β for each β and use uniqueness to glue).

§34.2.9 Ordinal Arithmetic

We now make formal sense of the notation $\omega + \omega$, $\omega \cdot 2$ and so on used above.

Definition 34.2.32 (Ordinal Addition, Inductive)

We define $\alpha + \beta$ by recursion on β , keeping α fixed:

$$\begin{aligned}\alpha + 0 &= \alpha, \\ \alpha + \beta^+ &= (\alpha + \beta)^+, \\ \alpha + \lambda &= \sup\{\alpha + \gamma \mid \gamma < \lambda\} \quad \text{for } \lambda \text{ a non-zero limit.}\end{aligned}$$

Proposition 34.2.33 (Addition is Not Commutative)

We have $1 + \omega \neq \omega + 1$.

Proof. On one hand $\omega + 1 = \omega + 0^+ = (\omega + 0)^+ = \omega^+$. On the other hand, ω is a non-zero limit, so $1 + \omega = \sup\{1 + n \mid n < \omega\} = \sup\{1, 2, 3, \dots\} = \omega$. And $\omega < \omega^+$. $\square$

The asymmetry comes from our decision to recurse on the right-hand argument. Addition is, however, associative.

Proposition 34.2.34 (Addition is Associative)

For all ordinals α, β, γ we have $\alpha + (\beta + \gamma) = (\alpha + \beta) + \gamma$.

Proof. We induct on γ , keeping α, β fixed. If $\gamma = 0$ then $\alpha + (\beta + 0) = \alpha + \beta = (\alpha + \beta) + 0$.

If $\gamma = \delta^+$ is a successor, then

$$\alpha + (\beta + \delta^+) = \alpha + (\beta + \delta)^+ = [\alpha + (\beta + \delta)]^+ = [(\alpha + \beta) + \delta]^+ = (\alpha + \beta) + \delta^+,$$

using the induction hypothesis in the third equality.

If $\gamma = \lambda$ is a non-zero limit, then

$$(\alpha + \beta) + \lambda = \sup\{(\alpha + \beta) + \gamma \mid \gamma < \lambda\} = \sup\{\alpha + (\beta + \gamma) \mid \gamma < \lambda\}.$$

We claim that $\beta + \lambda$ is a limit. Indeed $\beta + \lambda = \sup\{\beta + \gamma \mid \gamma < \lambda\}$, and since λ is a limit, for every $\gamma < \lambda$ there is γ' with $\gamma < \gamma' < \lambda$, whence $\beta + \gamma < \beta + \gamma'$. So this set has no greatest element.

Hence $\alpha + (\beta + \lambda) = \sup\{\alpha + \delta \mid \delta < \beta + \lambda\}$, and we must show

$$\sup\{\alpha + \delta \mid \delta < \beta + \lambda\} = \sup\{\alpha + (\beta + \gamma) \mid \gamma < \lambda\}.$$

Each element of the right-hand set is an element of the left-hand set (as $\beta + \gamma < \beta + \lambda$), so the left supremum is $\geq$ the right. Conversely, given $\delta < \beta + \lambda = \sup\{\beta + \gamma \mid \gamma < \lambda\}$ we have $\delta < \beta + \gamma$ for some $\gamma < \lambda$, so $\alpha + \delta \leq \alpha + (\beta + \gamma)$. So the left supremum is $\leq$ the right, and they are equal. $\square$

There is an alternative definition of addition in terms of actual well-orderings, obtained by writing out all the elements of α and then all the elements of β after them:

$$\alpha + \beta = \underbrace{\hspace{1.5cm}}_{\alpha} \underbrace{\hspace{1.5cm}}_{\beta}$$

Definition 34.2.35 (Ordinal Addition, Synthetic)

$\alpha + \beta$ is the order type of $\alpha \sqcup \beta$ (say $\alpha \times \{0\} \cup \beta \times \{1\}$) with all of α before all of β .

From this picture, associativity is immediate, and it is obvious why $1 + \omega = \omega$ (a dot followed by ω dots is just ω dots) while $\omega + 1 \neq \omega$ (ω dots followed by a dot has a greatest element). Reassuringly, the two definitions agree.

Proposition 34.2.36 (The Two Definitions of Addition Agree)

The inductive and synthetic definitions of addition coincide.

Proof. We write $+$ for the inductive definition and $+'$ for the synthetic one, and induct on β with α fixed.

(i) *Zero:* $\alpha + 0 = \alpha = \alpha +' 0$.

(ii) *Successor:* $\alpha + \beta^+ = (\alpha + \beta)^+ = (\alpha +' \beta)^+$, which is the order type of

$$\underbrace{\hspace{1.5cm}}_{\alpha} \underbrace{\hspace{1.5cm}}_{\beta} \underbrace{\hspace{0.5cm}}_{\bullet}$$

and that is precisely $\alpha +' \beta^+$.

(iii) *Non-zero limit:* $\alpha + \lambda = \sup\{\alpha + \gamma \mid \gamma < \lambda\} = \sup\{\alpha +' \gamma \mid \gamma < \lambda\} = \alpha +' \lambda$, where the last step is because the well-orderings $\alpha \sqcup \gamma$ for $\gamma < \lambda$ are nested, so their supremum is their union, which is $\alpha \sqcup \lambda$. $\square$

Multiplication works in exactly the same way.

Definition 34.2.37 (Ordinal Multiplication, Inductive)

We define $\alpha \cdot \beta$ by recursion on β , keeping α fixed:

$$\begin{aligned}\alpha \cdot 0 &= 0, \\ \alpha \cdot \beta^+ &= \alpha \cdot \beta + \alpha, \\ \alpha \cdot \lambda &= \sup\{\alpha \cdot \gamma \mid \gamma < \lambda\} \quad \text{for } \lambda \text{ a non-zero limit.}\end{aligned}$$

Definition 34.2.38 (Ordinal Multiplication, Synthetic)

$\alpha \cdot \beta$ is the order type of $\alpha \times \beta$, ordered by $(x, y) < (x', y')$ if $y < y'$, or if $y = y'$ and $x < x'$.

That is, β copies of α laid end to end:

$$\alpha \cdot \beta = \underbrace{\alpha \quad \alpha \quad \cdots \quad \alpha}_{\beta \text{ copies}}.$$

As with addition, the two definitions agree, by an induction identical in shape to the one above. Multiplication is associative and again not commutative, and the synthetic picture shows why very clearly.

$$\begin{array}{l} \omega \cdot 2: \quad \underbrace{\quad \quad \quad}_{\omega} \quad \underbrace{\quad \quad \quad}_{\omega} \\ 2 \cdot \omega: \quad \underbrace{\quad \quad}_{2} \quad \underbrace{\quad \quad}_{2} \quad \underbrace{\quad \quad}_{2} \quad \cdots \end{array}$$

Reading the top line, $\omega \cdot 2 = \omega + \omega$ is genuinely longer than ω ; reading the bottom line, $2 \cdot \omega$ is ω copies of a two-element set, which is just ω . So $2 \cdot \omega = \omega \neq \omega \cdot 2$.

Definition 34.2.39 (Ordinal Exponentiation)

We define α^β by recursion on β :

$$\begin{aligned}\alpha^0 &= 1, \\ \alpha^{\beta^+} &= \alpha^\beta \cdot \alpha, \\ \alpha^\lambda &= \sup\{\alpha^\gamma \mid \gamma < \lambda\} \quad \text{for } \lambda \text{ a non-zero limit.}\end{aligned}$$

Example 34.2.40

$\omega^1 = \omega^0 \cdot \omega = \omega$ and $\omega^2 = \omega \cdot \omega$, as the notation in our table suggested. But $2^\omega = \sup\{2^n \mid n < \omega\} = \sup\{1, 2, 4, 8, \dots\} = \omega$, which is countable. So ordinal exponentiation is emphatically *not* cardinal exponentiation – we will meet the latter in Section 34.6, where $2^{\aleph_0}$ is uncountable.

§34.2.10 Normal Functions and ε -Numbers

The definitions above all have the same shape: increasing, and continuous at limits. This is worth isolating.

Definition 34.2.41 (Normal Function)

A function $f : \text{On} \rightarrow \text{On}$ is **normal** if $f(\alpha) < f(\alpha^+)$ for every α , and $f(\lambda) = \sup\{f(\gamma) \mid \gamma < \lambda\}$ for every non-zero limit λ .

For example $\alpha \mapsto \beta + \alpha$ is normal for any β , and $\alpha \mapsto \beta^\alpha$ is normal for any $\beta > 1$; both are immediate from the recursive definitions.

Lemma 34.2.42

A normal function f is strictly increasing, and satisfies $f(\alpha) \geq \alpha$ for all α .

Proof. For the first part, fix α and induct on $\beta > \alpha$. If $\beta = \alpha^+$ this is the definition. If $\beta = \gamma^+$ with $\gamma > \alpha$ then $f(\alpha) < f(\gamma) < f(\gamma^+)$ by induction. If β is a limit then $f(\beta) = \sup\{f(\gamma) \mid \gamma < \beta\} \geq f(\alpha^+) > f(\alpha)$, as $\alpha^+ < \beta$.

For the second, induct on α . It is clear for 0. For successors, $f(\alpha^+) > f(\alpha) \geq \alpha$ gives $f(\alpha^+) \geq \alpha^+$. For a non-zero limit λ , $f(\lambda) = \sup\{f(\gamma) \mid \gamma < \lambda\} \geq \sup\{\gamma \mid \gamma < \lambda\} = \lambda$. $\square$

Lemma 34.2.43 (Fixed Point Lemma)

Let f be a normal function. Then for every ordinal α there is $\beta \geq \alpha$ with $f(\beta) = \beta$.

Proof. Let $\beta = \sup\{\alpha, f(\alpha), f(f(\alpha)), \dots\}$. If the sequence is eventually constant we have found a fixed point. Otherwise the sequence is strictly increasing, so β is a limit and

$$f(\beta) = \sup\{f(\gamma) \mid \gamma < \beta\} = \sup\{f(\alpha), f(f(\alpha)), \dots\} = \beta,$$

using Lemma 34.2.42 for the middle equality. In either case $\beta \geq \alpha$. $\square$

Lemma 34.2.44 (Division for Normal Functions)

Let f be a normal function and α an ordinal with $f(0) \leq \alpha$. Then there is a greatest γ with $f(\gamma) \leq \alpha$.

Proof. Let $\gamma = \sup\{\beta \mid f(\beta) \leq \alpha\}$, which is a supremum of a set of ordinals since all such β satisfy $\beta \leq f(\beta) \leq \alpha$ by Lemma 34.2.42. If the set has a greatest element we are done. Otherwise γ is a limit and $f(\gamma) = \sup\{f(\beta) \mid \beta < \gamma\} \leq \alpha$, so γ itself is the greatest such ordinal. $\square$

Applying this to the normal function $\alpha \mapsto \omega^\alpha$ gives the **ε -numbers**: the ordinals ε with $\omega^\varepsilon = \varepsilon$. The least of them is

$$\varepsilon_0 = \sup\{\omega, \omega^\omega, \omega^{\omega^\omega}, \dots\},$$

which is where the fifth column of our table was heading. There is nothing special about ε_0 – since the supremum of a set of fixed points is again a fixed point, the fixed points themselves are enumerated by a normal function $\alpha \mapsto \varepsilon_\alpha$, which then has its own fixed points, and so on. All of these ordinals are still countable, and so are dwarfed by ω_1 .

§34.2.11 Further Ordinal Arithmetic

We record a few more facts about ordinal arithmetic, all proved by inductions of the kind we have already seen, and finish with a normal form for ordinals.

Proposition 34.2.45 (Strict Monotonicity on the Right)

Let α, β, γ be ordinals with $\beta < \gamma$. Then $\alpha + \beta < \alpha + \gamma$. Consequently $\alpha + \beta = \alpha + \gamma$ implies $\beta = \gamma$.

Proof. We induct on $\gamma > \beta$. If $\gamma = \delta^+$ then $\beta \leq \delta$, so $\alpha + \beta \leq \alpha + \delta < (\alpha + \delta)^+ = \alpha + \gamma$, using the induction hypothesis if $\beta < \delta$. If γ is a limit then $\beta^+ < \gamma$, so $\alpha + \beta < \alpha + \beta^+ \leq \sup\{\alpha + \delta \mid \delta < \gamma\} = \alpha + \gamma$.

The cancellation statement follows since $\beta \neq \gamma$ would give $\alpha + \beta \neq \alpha + \gamma$ by trichotomy. $\square$

Monotonicity on the *left* is false: $1 < 2$, but $1 + \omega = 2 + \omega = \omega$. So we may cancel on the left but not on the right.

Proposition 34.2.46 (Ordinal Subtraction)

Let $\alpha \leq \beta$. Then there is a unique ordinal γ with $\alpha + \gamma = \beta$.

Proof. Take a well-ordering Y of order type β . Since $\alpha \leq \beta$, there is an initial segment I of Y of order type α , and we let $\gamma = \text{otp}(Y \setminus I)$. By the synthetic definition of addition, $\alpha + \gamma = \text{otp}(Y) = \beta$. Uniqueness is Proposition 34.2.45. $\square$

Proposition 34.2.47 (Distributivity)

For all ordinals, $\alpha \cdot (\beta + \gamma) = \alpha \cdot \beta + \alpha \cdot \gamma$.

Proof. Use the synthetic definitions: $\alpha \cdot (\beta + \gamma)$ is $\beta + \gamma$ copies of α laid end to end, which is β copies followed by γ copies. $\square$

Distributivity on the other side fails, and the smallest counterexample is a good test of the definitions: $(1 + 1) \cdot \omega = 2 \cdot \omega = \omega$, whereas $1 \cdot \omega + 1 \cdot \omega = \omega + \omega = \omega \cdot 2$.

Proposition 34.2.48 (Division Algorithm)

Let α be an ordinal and $\beta > 0$. Then there are unique ordinals γ and δ with

$$\alpha = \beta \cdot \gamma + \delta, \quad \delta < \beta.$$

Proof. The map $\gamma \mapsto \beta \cdot \gamma$ is normal, so by Lemma 34.2.44 there is a greatest γ with $\beta \cdot \gamma \leq \alpha$. By subtraction there is a unique δ with $\beta \cdot \gamma + \delta = \alpha$, and $\delta < \beta$, since $\delta \geq \beta$ would give $\beta \cdot \gamma^+ = \beta \cdot \gamma + \beta \leq \alpha$, contradicting maximality of γ . Uniqueness follows from that of γ together with Proposition 34.2.45. $\square$

Applying this repeatedly with β a power of ω gives a normal form, exactly analogous to writing a natural number in base 10.

Theorem 34.2.49 (Cantor Normal Form)

Every ordinal $\alpha > 0$ can be written uniquely as

$$\alpha = \omega^{\beta_1} \cdot n_1 + \omega^{\beta_2} \cdot n_2 + \cdots + \omega^{\beta_k} \cdot n_k$$

with $k \geq 1$, ordinals $\beta_1 > \beta_2 > \cdots > \beta_k$ and positive integers $n_1, \dots, n_k$.

Proof sketch. Since $\alpha \mapsto \omega^\alpha$ is normal, Lemma 34.2.44 gives a greatest β_1 with $\omega^{\beta_1} \leq \alpha$. Dividing by ω^{β_1} using Proposition 34.2.48 gives $\alpha = \omega^{\beta_1} \cdot \gamma + \delta$ with $\delta < \omega^{\beta_1}$, and maximality of β_1 forces γ to be a positive integer n_1 . Now $\delta < \alpha$, so we may repeat; the process terminates because the ordinals δ produced are strictly decreasing, and there is no infinite strictly decreasing sequence of ordinals. Uniqueness follows by induction, using the fact that $\omega^\beta \cdot n < \omega^{\beta'}$ whenever $\beta < \beta'$ and $n < \omega$. $\square$

Example 34.2.50 (Arithmetic in Normal Form)

Let us compute $(\omega^2 + \omega \cdot 3) + (\omega \cdot 2 + 5)$. Addition is associative, and $\omega \cdot 3 + \omega \cdot 2 = \omega \cdot 5$ by distributivity, so this is $\omega^2 + \omega \cdot 5 + 5$. On the other hand $(\omega + 1) \cdot \omega = \sup\{(\omega + 1) \cdot n \mid n < \omega\} = \sup\{\omega, \omega \cdot 2 + 1, \omega \cdot 3 + 2, \dots\} = \omega^2$, so the 1 is entirely swallowed. In general, when adding ordinals in normal form, every term of the left-hand ordinal of degree less than the leading degree of the right-hand one simply disappears.

Example 34.2.51

$\omega^2 \cdot 3 + \omega \cdot 5 + 7$ is in Cantor normal form. On the other hand ε_0 is not expressible in this way in terms of *smaller* ordinals: its normal form is ω^{ε_0} , which is the statement that ε_0 is a fixed point of $\alpha \mapsto \omega^\alpha$. So the ε -numbers are precisely the ordinals which the normal form fails to simplify.

§34.3 Posets and Zorn's Lemma

Well-orderings are very rigid objects. In this section we look at the opposite extreme – orderings where elements are allowed to be incomparable – and arrive at Zorn's lemma, which is the form in which the axiom of choice is used in practice throughout mathematics.

§34.3.1 Partial Orders and Hasse Diagrams

Definition 34.3.1 (Poset)

A **partially ordered set**, or **poset**, is a pair $(X, \leq)$ where X is a set and $\leq$ is a relation on X that is reflexive, transitive and antisymmetric (if $x \leq y$ and $y \leq x$ then $x = y$). We write $x < y$ if $x \leq y$ and $x \neq y$; in terms of $<$, a poset is exactly an irreflexive transitive relation.

Example 34.3.2 (Posets)

- (i) Any total order, for instance $(\mathbb{R}, \leq)$ or any well-ordering.
- (ii) $(\mathbb{N}^+, \text{'divides'})$, in which 2 and 3 are incomparable.
- (iii) For any set S , the power set $\mathcal{P}(S)$ ordered by $A \leq B$ if $A \subseteq B$.
- (iv) Any subset $X \subseteq \mathcal{P}(S)$ with the same ordering. Most of our applications will be of this form: X will be the set of subsets of S with some property, ordered by inclusion.
- (v) The five-element poset with $a \leq b \leq c$ and $a \leq d \leq e$ and nothing else (beyond what transitivity and reflexivity force). So $a \leq c$, but b and d are incomparable.

Small posets are best understood by drawing them.

Definition 34.3.3 (Hasse Diagram)

A **Hasse diagram** of a poset X consists of a drawing of the points of X in the plane, with an upward line from x to y whenever y **covers** x , meaning $y > x$ and there is no z with $y > z > x$.

Here are the poset (v) above on the left, and two more on the right.

The middle diagram is a warning: there is no notion of ‘height’ or ‘rank’ in a poset, since b is covered by c directly while d, e take two steps to get from a to c . In the right-hand diagram the thickened path $b < d < e$ is a chain, in the following sense.

Definition 34.3.4 (Chain and Antichain)

A subset S of a poset X is a **chain** if any two of its elements are comparable, that is, if S is totally ordered by $\leq$. It is an **antichain** if no two distinct members of S are comparable.

Example 34.3.5

In a total order, every subset is a chain and every antichain has at most one element. In $(\mathbb{N}^+, \text{'divides'})$ the set $\{1, 2, 4, 8, \dots\}$ is a chain and the set of primes is an antichain. In $\mathcal{P}(\mathbb{N})$, the sets $A_x = \{q \in \mathbb{Q} \mid q < x\}$ for $x \in \mathbb{R}$ form a chain of size $2^{\aleph_0}$.

Definition 34.3.6 (Upper Bound and Supremum)

For $S \subseteq X$, an element $x \in X$ is an **upper bound** for S if $y \leq x$ for all $y \in S$. It is a **least upper bound** or **supremum** for S if in addition $x \leq y$ for every upper bound y of S , and we then write $x = \sup S$.

Suprema are unique when they exist, by antisymmetry.

Definition 34.3.7 (Complete Poset)

A poset X is **complete** if every subset $S \subseteq X$ has a supremum.

In a complete poset there is automatically a greatest element $\sup X$ and a least element $\sup \emptyset$ (every element is vacuously an upper bound for $\emptyset$). The example to keep in mind is $\mathcal{P}(S)$, where $\sup$ is union. Note that $(\mathbb{R}, \leq)$ is *not* complete in this sense – unbounded sets have no supremum – but $[0, 1]$ is.

Definition 34.3.8 (Order-Preserving Map)

For a poset X , a function $f : X \rightarrow X$ is **order-preserving** if $x \leq y$ implies $f(x) \leq f(y)$.

Theorem 34.3.9 (Knaster–Tarski Fixed Point Theorem)

Let X be a complete poset and $f : X \rightarrow X$ order-preserving. Then f has a fixed point.

Proof. Let $E = \{x \in X \mid x \leq f(x)\}$ and $s = \sup E$. We claim $f(s) = s$.

To show $s \leq f(s)$, it is enough to show that $f(s)$ is an upper bound for E , since s is the *least* upper bound. And indeed if $x \in E$ then $x \leq s$, so $f(x) \leq f(s)$, so $x \leq f(x) \leq f(s)$.

To show $f(s) \leq s$, it is enough to show $f(s) \in E$, since s is an upper bound for E . But we have just shown $s \leq f(s)$, so $f(s) \leq f(f(s))$ as f is order-preserving, which says exactly that $f(s) \in E$. $\square$

Note that no choice, and no ordinals, were used here. As an application we get a proof of the Schröder–Bernstein theorem, which we will want in Section 34.6.

Corollary 34.3.10 (Schröder–Bernstein Theorem)

Let A, B be sets and let $f : A \rightarrow B$ and $g : B \rightarrow A$ be injections. Then there is a bijection from A to B .

Proof. We aim to partition A into P and Q , and B into R and S , in such a way that $f(P) = R$ and $g(S) = Q$. Given such a partition we may define a bijection $h : A \rightarrow B$ by taking $h = f$ on P and $h = g^{-1}$ on Q .

Since we need $S = B \setminus R = B \setminus f(P)$ and $Q = A \setminus P = g(S)$, what we want is a set $P \subseteq A$ with

$$P = A \setminus g(B \setminus f(P)).$$

Now $\mathcal{P}(A)$ is a complete poset under inclusion, and the map $P \mapsto A \setminus g(B \setminus f(P))$ is order-preserving from $\mathcal{P}(A)$ to itself, since it applies the order-reversing operation ‘complement’ twice. So it has a fixed point by Knaster–Tarski, and we are done. $\square$

§34.3.2 Zorn’s Lemma

Now to the heart of the matter. In a poset there may be no greatest element, but we can still hope for maximal ones.

Definition 34.3.11 (Maximal Element)

In a poset X , an element $x \in X$ is **maximal** if no $y \in X$ has $y > x$.

Take care to distinguish this from a *maximum* (greatest) element: in the third Hasse diagram above, e is a maximum, whereas in the first diagram c and e are both maximal and there is no maximum. Some posets have no maximal element at all, for instance $(\mathbb{R}, \leq)$ or $(\mathbb{N}^+, \text{‘divides’})$. In both of those examples there is also a chain with no upper bound ($\mathbb{N} \subseteq \mathbb{R}$, and the powers of 2 respectively), and Zorn’s lemma says that this is the only obstruction.

Theorem 34.3.12 (Zorn’s Lemma)

Assume the axiom of choice. Let X be a poset in which every chain has an upper bound. Then X has a maximal element.

Note that the empty chain must have an upper bound, so the hypothesis forces X to be non-empty; equivalently one can state the lemma for a non-empty poset in which every non-empty chain has an upper bound. Pictorially, the hypothesis says that whenever we have a chain marching upwards through X , there is something sitting above all of it, so that no chain can ‘escape’ – and then some element must be at the top.

Proof. Suppose X has no maximal element. Then for each $x \in X$ we may choose $x' \in X$ with $x' > x$, and for each chain C we may choose an upper bound $u(C)$; both of these use the axiom of choice.

Let $\gamma = \gamma(X)$ be the Hartogs' ordinal of X from Theorem 34.2.29. Pick any $x \in X$ and define x_α for $\alpha < \gamma$ by transfinite recursion:

$$\begin{aligned} x_0 &= x, \\ x_{\alpha+} &= (x_\alpha)', \\ x_\lambda &= u(\{x_\alpha \mid \alpha < \lambda\}) \quad \text{for } \lambda \text{ a non-zero limit.} \end{aligned}$$

For this to make sense we need $\{x_\alpha \mid \alpha < \lambda\}$ to be a chain, which follows by induction: at each stage we only ever add an element above everything so far.

But then $\alpha \mapsto x_\alpha$ is strictly increasing, hence injective, so we have injected γ into X , contradicting the definition of $\gamma(X)$. $\square$

The proof is short, but it should not be mistaken for an easy one: it rests on the whole apparatus of well-orderings, transfinite recursion, ordinals and Hartogs' lemma. The axiom of choice is used only in the very first line.

Example 34.3.13 (The Hypothesis of Zorn's Lemma)

- (i) In $\mathcal{P}(S)$ under inclusion, every chain has an upper bound (its union), and indeed there is a maximal element, namely S .
- (ii) In the poset of *finite* subsets of an infinite S , the chain $\{1\} \subseteq \{1, 2\} \subseteq \dots$ has no upper bound, and there is no maximal element.
- (iii) In $[0, 1)$ with the usual order, every chain has an upper bound in $[0, 1]$ but not always in $[0, 1)$, and there is no maximal element. This shows how carefully the upper bound must be checked to lie in the poset itself – it is the step that fails most often in practice.

§34.3.3 Applications of Zorn's Lemma

Proofs using Zorn's lemma nearly always look the same. We choose a poset whose elements are 'partial solutions' to our problem, usually a family of subsets ordered by inclusion; we check that the union of a chain of partial solutions is a partial solution; and then we check that a maximal partial solution is a solution.

Theorem 34.3.14 (Every Vector Space has a Basis)

Every vector space V has a basis.

Proof. Let X be the set of all linearly independent subsets of V , ordered by inclusion. Note $X \neq \emptyset$ as $\emptyset \in X$.

We claim a maximal element A of X is a basis. It is linearly independent by definition, and if it did not span then there would be some $v \in V$ outside its span, and $A \cup \{v\}$ would be linearly independent, contradicting maximality.

So we apply Zorn's lemma. Let $\{A_i \mid i \in I\}$ be a chain in X and let $A = \bigcup_{i \in I} A_i$. Then $A \supseteq A_i$ for all i , so we need only check $A \in X$, i.e. that A is linearly independent. Suppose we had a linear dependence $\lambda_1 x_1 + \cdots + \lambda_n x_n = 0$ with $x_1, \dots, x_n \in A$ and the λ_i not all zero. Each x_j lies in some A_{i_j} , and since the A_i form a chain, one of $A_{i_1}, \dots, A_{i_n}$ contains all the others, and hence contains all of $x_1, \dots, x_n$. That contradicts its linear independence. $\square$

Observe that linear algebra was used only at the very last step, to see that a maximal element does the job. This is typical. Note also that the theorem is highly non-constructive: it tells us that $\mathbb{R}$ has a basis as a vector space over $\mathbb{Q}$ (a *Hamel basis*), but no such basis can be written down.

Theorem 34.3.15 (Every Ring has a Maximal Ideal)

Let R be a non-trivial ring with 1. Then R has a maximal ideal.

Proof. Let X be the set of proper ideals of R , ordered by inclusion; it is non-empty as $\{0\} \in X$. Given a non-empty chain $\{I_j \mid j \in J\}$ in X , the union $I = \bigcup_j I_j$ is an ideal (any two elements of I lie in a common I_j , so I is closed under addition, and it is clearly closed under multiplication by R), and it is proper, since $1 \notin I_j$ for any j and so $1 \notin I$. So I is an upper bound in X . By Zorn's lemma X has a maximal element, which is by definition a maximal ideal. $\square$

A third application, this time with no algebra in sight at all.

Theorem 34.3.16 (Order-Extension Principle)

Every partial order $(X, \leq)$ can be extended to a total order on X ; that is, there is a total order $\preceq$ on X with $x \leq y$ implying $x \preceq y$.

Proof. Regard a partial order on X as a subset of $X \times X$, and let P be the set of all partial orders on X containing $\leq$, ordered by inclusion. It is non-empty as $\leq \in P$.

Given a non-empty chain in P , its union is again a partial order: reflexivity is clear, and given two or three pairs in the union we may find a single member of the chain containing all of them, in which transitivity and antisymmetry hold. So it is an upper bound, and Zorn's lemma gives a maximal $\preceq \in P$.

Finally, $\preceq$ is total. If x and y were incomparable, consider

$$R = \preceq \cup \{(a, b) \mid a \preceq x \text{ and } y \preceq b\}.$$

One checks that R is a partial order (transitivity is a short case-check, and antisymmetry uses the incomparability of x and y) which strictly contains $\preceq$, contradicting maximality. $\square$

We can also use Zorn to dispense with the countability assumption in our discussion of propositional logic, where we needed to enumerate L .

Theorem 34.3.17 (Model Existence Lemma, Uncountable Case)

Let P be any set of primitive propositions and let $S \subseteq L(P)$ be consistent. Then S has a model.

Proof. As in the proof of Theorem 34.1.21, it is enough to find a consistent $\bar{S} \supseteq S$ such that for every $t \in L$, either $t \in \bar{S}$ or $\neg t \in \bar{S}$; the valuation $v(t) = \mathbb{1}[t \in \bar{S}]$ then works verbatim.

We claim that a *maximal* consistent $\bar{S} \supseteq S$ has this property. Indeed if $t \notin \bar{S}$, then $\bar{S} \cup \{t\}$ is inconsistent by maximality, so $\bar{S} \cup \{t\} \vdash \perp$, so $\bar{S} \vdash \neg t$ by the deduction theorem. Then $\bar{S} \cup \{\neg t\}$ is consistent (anything it proves, $\bar{S}$ already proves), so $\neg t \in \bar{S}$ by maximality again.

So we must show a maximal consistent extension exists. Let $X = \{T \subseteq L \mid T \supseteq S, T \text{ consistent}\}$, ordered by inclusion, which is non-empty as $S \in X$. Let $\{T_i \mid i \in I\}$ be a non-empty chain in X and let $T = \bigcup_i T_i$. Certainly $T \supseteq S$. To see T is consistent, suppose $T \vdash \perp$. As proofs are finite, there are $t_1, \dots, t_n \in T$ with $\{t_1, \dots, t_n\} \vdash \perp$, and as the T_i are nested, some T_k contains all of the t_j – making T_k inconsistent, a contradiction. So $T \in X$ is an upper bound for the chain, and Zorn's lemma provides a maximal element of X . $\square$

§34.3.4 The Well-Ordering Principle

Zorn's lemma also delivers the result promised in Section 34.2.9, that every set can be well-ordered – including $\mathbb{R}$, for which no explicit well-ordering can be described.

Theorem 34.3.18 (Well-Ordering Principle)

Assume Zorn's lemma. Then every set S can be well-ordered.

Proof. Let X be the set of pairs (A, R) where $A \subseteq S$ and R is a well-ordering of A , ordered by $(A, R) \leq (A', R')$ if (A', R') extends (A, R) – that is, A is an initial segment of A' and R' agrees with R on A . Note $X \neq \emptyset$ as $(\emptyset, \emptyset) \in X$.

Given a non-empty chain $\{(A_i, R_i) \mid i \in I\}$ in X , the family $\{A_i\}$ is nested, so by Proposition 34.2.19 the pair $(\bigcup_i A_i, \bigcup_i R_i)$ is a well-ordering, and it clearly extends each (A_i, R_i) . So it is an upper bound.

By Zorn's lemma there is a maximal $(A, R) \in X$. If $A \neq S$ we may take $x \in S \setminus A$ and well-order $A \cup \{x\}$ by making x greater than everything in A ; this extends (A, R) strictly, contradicting maximality. So $A = S$. $\square$

§34.3.5 Zorn's Lemma and the Axiom of Choice

We assumed the axiom of choice to prove Zorn's lemma, and Zorn's lemma to prove the well-ordering principle. The circle closes with the following.

Theorem 34.3.19 (The Axiom of Choice)

Assume the well-ordering principle. Then for any family $\{A_i \mid i \in I\}$ of non-empty sets there is a **choice function** $f : I \rightarrow \bigcup_{i \in I} A_i$ with $f(i) \in A_i$ for all i .

Proof. Well-order $\bigcup_{i \in I} A_i$, and define $f(i)$ to be the least element of A_i . □

So the axiom of choice, Zorn's lemma and the well-ordering principle are all equivalent, over the other axioms of set theory. It is worth remarking on where choice was really needed: making *one* arbitrary choice is not an axiom at all – a set being non-empty means precisely that it has an element – and by induction, finitely many choices are also free. It is only the passage to infinitely many simultaneous arbitrary choices that requires an axiom.

The axiom of choice is unlike the other axioms in that the object it produces is not determined by its inputs: the union of A and B is a specific set, whereas a choice function for the family $\{1, 2\}$ could be either of two things. This is why proofs using it are non-constructive. That said, plenty of proofs that do not use choice are also non-constructive, so this should not be overstated.

§34.3.6 The Bourbaki–Witt Theorem

We close the section with a result in the same family as Zorn's lemma, but which needs no choice at all. Call a poset X **chain-complete** if every non-empty chain in X has a supremum.

Theorem 34.3.20 (Bourbaki–Witt)

Let X be a non-empty chain-complete poset and let $f : X \rightarrow X$ be *inflationary*, meaning $f(x) \geq x$ for all x . Then f has a fixed point.

Given Zorn's lemma this is immediate: a chain-complete poset satisfies the hypotheses of Zorn (a non-empty chain has its supremum as an upper bound, and the empty chain has any element of the non-empty X), so X has a maximal element x , and then $f(x) \geq x$ forces $f(x) = x$. What is interesting is that no choice is required.

Proof without choice. Fix $x_0 \in X$ and let $Y \subseteq X$ be the least subset with $x_0 \in Y$ that is closed under f and under suprema of non-empty chains (namely, the intersection of all such subsets). One checks by induction on this closure that Y is itself a chain: the point is that f and suprema are the only ways to produce new elements, and neither can create incomparability, though verifying this carefully takes some work.

Granting that Y is a chain, it has a supremum $s = \sup Y \in Y$. Then $f(s) \in Y$, so $f(s) \leq s$, while $f(s) \geq s$ as f is inflationary. So $f(s) = s$. □

The contrast with Zorn's lemma is instructive: there we had to *choose* some $x' > x$ at

each stage, and it is exactly that choice which the axiom of choice supplies. Here the function f tells us what to do next, so there is nothing to choose.

§34.4 Predicate Logic

Propositional logic cannot express any of the statements we actually care about, because it has no way of talking about *objects*. We now upgrade to predicate logic, also called *first-order logic*, in which we may quantify over the elements of a structure. Everything from Section 1 will reappear – a language, valuations (now structures), axioms, proofs, soundness, completeness, compactness – but each with more moving parts.

§34.4.1 Languages

Definition 34.4.1 (Language)

Let Ω (the **function symbols**) and Π (the **relation symbols**) be disjoint sets, and let $\alpha : \Omega \cup \Pi \rightarrow \mathbb{N}$ be a function, called the **arity**.

The **language** $L = L(\Omega, \Pi, \alpha)$ is the set of formulae, defined as follows.

- *Variables.* We have variables $x_1, x_2, \dots$ (also written $x, y, z, \dots$).
- *Terms.* These are defined inductively by
 - (i) every variable is a term;
 - (ii) if $f \in \Omega$ with $\alpha(f) = n$, and $t_1, \dots, t_n$ are terms, then $f(t_1, \dots, t_n)$ is a term.
- *Atomic formulae.* There are three sorts:
 - (i) $\perp$;
 - (ii) $(s = t)$ for any terms s, t ;
 - (iii) $\phi(t_1, \dots, t_n)$ for any $\phi \in \Pi$ with $\alpha(\phi) = n$ and terms $t_1, \dots, t_n$.
- *Formulae.* These are defined inductively by
 - (i) atomic formulae are formulae;
 - (ii) $(p \Rightarrow q)$ is a formula for any formulae p, q ;
 - (iii) $(\forall x)p$ is a formula for any formula p and variable x .

A function symbol of arity 0 is a **constant**. As before, we use the abbreviations $\neg, \wedge, \vee$, and we write $(\exists x)p$ for $\neg(\forall x)(\neg p)$.

Example 34.4.2 (The Language of Groups)

Take $\Omega = \{m, i, e\}$ and $\Pi = \emptyset$, with $\alpha(m) = 2$, $\alpha(i) = 1$ and $\alpha(e) = 0$. Then $e, x_1, m(x_1, x_2)$ and $i(m(x_1, x_1))$ are terms, and $(m(e, e) = e)$ and $(\forall x)(m(x, i(x)) = e)$ are formulae. The theory of groups is the set consisting of the associativity axiom, the identity axioms and the inverse axioms, written out in this language.

Example 34.4.3 (Other Languages)

For posets, take $\Omega = \emptyset$ and $\Pi = \{\leq\}$ with $\alpha(\leq) = 2$. For fields, take $\Omega = \{+, \cdot, -, 0, 1\}$ with the evident arities and $\Pi = \emptyset$. For graphs, take $\Omega = \emptyset$ and $\Pi = \{\sim\}$ with $\alpha(\sim) = 2$.

It cannot be stressed enough that a formula is at this stage a string of meaningless symbols; it makes no sense to ask whether it is true. In particular the symbols in Ω and Π carry no meaning beyond their arity.

Definition 34.4.4 (Closed Term)

A term is **closed** if it contains no variables.

Definition 34.4.5 (Free and Bound Variables)

An occurrence of a variable x in a formula p is **bound** if it lies inside the brackets of a quantifier $(\forall x)$, and **free** otherwise.

Definition 34.4.6 (Sentence)

A **sentence** is a formula with no free variables.

For instance, in the language of groups $(\forall x)(m(x, y) = e)$ has x bound and y free, so it is not a sentence; it says something only once we know what y is.

Definition 34.4.7 (Substitution)

For a formula p , a variable x and a term t , the **substitution** $p[t/x]$ is the formula obtained by replacing each free occurrence of x in p by t .

§34.4.2 Semantic Entailment

In propositional logic we interpreted the language in $\{0, 1\}$ using valuations. Now we must interpret it in a set carrying operations and relations of the right arities.

Definition 34.4.8 (Structure)

An **L -structure** is a non-empty set A together with a function $f_A : A^n \rightarrow A$ for each $f \in \Omega$ with $\alpha(f) = n$, and a relation $\phi_A \subseteq A^n$ for each $\phi \in \Pi$ with $\alpha(\phi) = n$.

Remark. We explicitly forbid A from being empty, which makes life much easier later on (in an empty structure $(\forall x)p$ would hold vacuously for every p , including $p = \perp$).

Example 34.4.9

In the language of groups, an L -structure is a set with a binary operation, a unary operation and a distinguished element – no axioms required. Every group is an L -structure, but so is $\mathbb{N}$ with $m(x, y) = x + y$, $i(x) = x$ and $e = 0$.

We now define what it means for a sentence to hold in a structure. The definition is a

mouthful, but after it is made we can largely forget it.

Definition 34.4.10 (Interpretation)

For each sentence p and L -structure A , the **interpretation** $p_A \in \{0, 1\}$ is defined inductively as follows.

- *Closed terms.* Define $t_A \in A$ for each closed term t by

$$(f(t_1, \dots, t_n))_A = f_A((t_1)_A, \dots, (t_n)_A)$$

for $f \in \Omega$ with $\alpha(f) = n$ and $t_1, \dots, t_n$ closed terms.

- *Atomic formulae.* We take

$$\begin{aligned} \perp_A &= 0, \\ (s = t)_A &= \mathbb{1}[s_A = t_A], \\ (\phi(t_1, \dots, t_n))_A &= \mathbb{1}[(t_1)_A, \dots, (t_n)_A \in \phi_A]. \end{aligned}$$

- *Sentences.* We take

$$\begin{aligned} (p \Rightarrow q)_A &= \mathbb{1}[\text{not } (p_A = 1 \text{ and } q_A = 0)], \\ ((\forall x)p)_A &= \mathbb{1}[p[\bar{a}/x]_{\bar{A}} = 1 \text{ for all } a \in A], \end{aligned}$$

where for $a \in A$ we form a new language L' by adding a constant $\bar{a}$, and make A into an L' -structure $\bar{A}$ by setting $\bar{a}_{\bar{A}} = a$.

The last clause is the only awkward one, and the awkwardness is unavoidable: to say that $(\forall x)p$ holds we must talk about p with x replaced by an *element* of A , and elements of A are not symbols of the language until we make them so.

Definition 34.4.11 (Theory)

A **theory** is a set of sentences.

Definition 34.4.12 (Model)

If $p_A = 1$ we say p **holds** in A , or is **true** in A , or that A is a **model** of p . For a theory S , a model of S is a structure which is a model of every $s \in S$.

Definition 34.4.13 (Semantic Entailment)

For a theory S and a sentence t , we say S **entails** t , written $S \models t$, if every model of S is a model of t . We call t a **tautology**, written $\models t$, if $\emptyset \models t$.

The word *first-order* refers to the fact that our variables range over *elements* of the structure, not over subsets of it. This restriction is what makes the theory work, and also what makes it weak, as we will see.

§34.4.3 Syntactic Implication

As before we need axioms and deduction rules. We keep the three propositional axioms and add two describing equality and two describing $\forall$.

Axiom 34.4.14 (Axioms of Predicate Logic)

- (1) $p \Rightarrow (q \Rightarrow p)$ for any formulae p, q ;
- (2) $[p \Rightarrow (q \Rightarrow r)] \Rightarrow [(p \Rightarrow q) \Rightarrow (p \Rightarrow r)]$ for any formulae p, q, r ;
- (3) $(\neg\neg p) \Rightarrow p$ for any formula p ;
- (4) $(\forall x)(x = x)$ for any variable x ;
- (5) $(\forall x)(\forall y)[(x = y) \Rightarrow (p \Rightarrow p[y/x])]$ for any variables x, y and formula p with y not occurring bound in p ;
- (6) $[(\forall x)p] \Rightarrow p[t/x]$ for any formula p , variable x and term t , with no free variable of t occurring bound in p ;
- (7) $[(\forall x)(p \Rightarrow q)] \Rightarrow [p \Rightarrow (\forall x)q]$ for any formulae p, q with x not occurring free in p .

The side conditions in (5), (6) and (7) all guard against accidental capture of variables. For example, without the condition in (6), taking p to be $(\exists y)(x \neq y)$ and t to be y would let us deduce the false statement $(\exists y)(y \neq y)$ from the true statement $(\forall x)(\exists y)(x \neq y)$.

Definition 34.4.15 (Deduction Rules)

The **deduction rules** are

- (i) *modus ponens*: from p and $p \Rightarrow q$ we may deduce q ;
- (ii) *generalisation*: from p we may deduce $(\forall x)p$, provided that no premise used in the proof of p so far has x as a free variable.

The proviso on generalisation is essential: from the premise ‘ x is even’ we must not be allowed to deduce that everything is even.

Definition 34.4.16 (Proof and Syntactic Implication)

A **proof** of p from S is a finite sequence of formulae, each of which is an axiom, or a member of S , or obtained from earlier lines by modus ponens or generalisation, and whose last line is p . If such a proof exists we write $S \vdash p$, and say S **proves** p . If $\emptyset \vdash p$ we call p a **theorem**.

As in the propositional case we say S is **consistent** if $S \not\vdash \perp$.

Example 34.4.17 (A Proof in Predicate Logic)

We show $\vdash [(\forall x)p] \Rightarrow (\exists x)p$, that is, $\vdash [(\forall x)p] \Rightarrow \neg(\forall x)(\neg p)$. By the deduction

theorem it is enough to show

$$\{(\forall x)p, (\forall x)(\neg p)\} \vdash \perp.$$

From $(\forall x)p$ and axiom (6) with $t = x$ we get p ; from $(\forall x)(\neg p)$ and axiom (6) we get $\neg p$, that is, $p \Rightarrow \perp$; and modus ponens gives $\perp$. Note where non-emptiness of structures is hiding: semantically, $[(\forall x)p] \Rightarrow (\exists x)p$ would fail in an empty structure.

Example 34.4.18 (Why Generalisation Needs its Proviso)

Without the proviso we could argue: from the premise $p(x)$ (' x is even'), deduce $(\forall x)p(x)$. But $\{p(x)\} \not\models (\forall x)p(x)$, as we see by taking the structure $\mathbb{N}$ with p interpreted as 'is even': the premise holds for some elements and the conclusion for none. Soundness would fail immediately.

§34.4.4 The Deduction Theorem

Proposition 34.4.19 (Deduction Theorem)

Let S be a set of formulae and p, q formulae. Then $S \vdash (p \Rightarrow q)$ if and only if $S \cup \{p\} \vdash q$.

Proof. The proof is exactly that of Theorem 34.1.16, except that in the backwards direction we must also handle lines obtained by generalisation.

So suppose the line $(\forall x)r$ was obtained from an earlier line r by generalisation, and by induction we have a proof of $p \Rightarrow r$ from S ; we want $S \vdash p \Rightarrow (\forall x)r$.

By the condition on generalisation, no premise used in the proof of r from $S \cup \{p\}$ has x free. Hence no premise used in our proof of $p \Rightarrow r$ from S has x free, so we may apply generalisation to get $S \vdash (\forall x)(p \Rightarrow r)$.

If x is not free in p , axiom (7) and modus ponens give $S \vdash p \Rightarrow (\forall x)r$ as required. If x is free in p , then p was not among the premises used in the proof of r from $S \cup \{p\}$, so in fact $S \vdash r$; then generalisation gives $S \vdash (\forall x)r$, and axiom (1) gives $S \vdash p \Rightarrow (\forall x)r$. $\square$

§34.4.5 Soundness

Proposition 34.4.20 (Soundness)

Let S be a theory and p a sentence. Then $S \vdash p$ implies $S \models p$.

Proof. Let A be a model of S and let $t_1, \dots, t_n = p$ be a proof of p from S . As in the propositional case we check by induction that each t_i holds in A – interpreting a formula with free variables as its universal closure. Each axiom holds in every structure (this is a routine but tedious check, one case per axiom), members of S hold as $A \models S$, and each of the two deduction rules preserves holding in A : modus ponens by the definition of $(p \Rightarrow q)_A$, and generalisation by the definition of $((\forall x)p)_A$ together with the proviso. $\square$

§34.4.6 The Model Existence Lemma

The interesting direction, as before, is adequacy, and again it reduces to the statement that a consistent theory has a model. But now we have to build an entire structure out of nothing, and the only raw material available is the language itself.

Before the proof, here are the four ideas that go into it, since the proof is otherwise unmotivated.

- (i) *Build the model out of the language.* Take the underlying set to be the set of closed terms of L , with each function symbol acting in the obvious way: $f([t_1], \dots, [t_n]) = [f(t_1, \dots, t_n)]$.
- (ii) *Quotient.* If S is the theory of fields, then $S \vdash (1 + 0 = 1)$, but ‘ $1 + 0$ ’ and ‘ 1 ’ are different strings. So we quotient the closed terms by $s \sim t$ if $S \vdash (s = t)$.
- (iii) *Make S complete.* Let S be the field axioms together with the sentence $(1 + 1 = 0) \vee (1 + 1 + 1 = 0)$. Then S proves neither disjunct, so in our quotient $[1 + 1] \neq [0]$ and $[1 + 1 + 1] \neq [0]$, and the structure we build is a field of neither characteristic 2 nor 3 – so not a model. We fix this by extending S to a *maximal* consistent theory, using Zorn’s lemma exactly as in Theorem 34.3.17.
- (iv) *Add witnesses.* Let S be the field axioms together with $(\exists x)(x \cdot x = 1 + 1)$. There need be no closed term t with $[t \cdot t] = [1 + 1]$, so again our structure fails. We fix this by adding, for each sentence $(\exists x)p$ in our theory, a brand new constant c to the language and the sentence $p[c/x]$ to the theory.

Unfortunately (iv) enlarges the language, which may destroy the maximality won in (iii), so we must alternate between the two infinitely often and take the union.

Theorem 34.4.21 (Model Existence Lemma)

Every consistent theory has a model.

Proof. Let S be consistent in the language $L = L(\Omega, \Pi)$.

Step 1: the theory. Extend S to a maximal consistent theory S_1 in L , using Zorn’s lemma as in Theorem 34.3.17. Such a theory is **complete**: for every sentence p , either $p \in S_1$ or $\neg p \in S_1$. Now add witnesses: for each sentence $(\exists x)p \in S_1$ introduce a new constant $c_{(\exists x)p}$, let C_1 be the set of these, and let

$$T_1 = S_1 \cup \{p[c_{(\exists x)p}/x] \mid (\exists x)p \in S_1\}$$

in the language $L_1 = L(\Omega \cup C_1, \Pi)$. Then T_1 is consistent: a proof of $\perp$ from T_1 uses finitely many of the new sentences, and replacing each new constant throughout the proof by a fresh variable and using $(\exists x)p \in S_1$ finitely many times converts it into a proof of $\perp$ from S_1 .

Repeat: extend T_1 to a maximal consistent S_2 in L_1 , add witnesses to get T_2 in L_2 , and so on. Let $\bar{S} = \bigcup_{n \geq 1} S_n$ in the language $\bar{L} = L(\Omega \cup \bigcup_n C_n, \Pi)$.

We claim $\bar{S}$ is consistent, complete and has witnesses. It is consistent since a proof of $\perp$ from it is finite, so comes from some S_n . It is complete: a sentence p of $\bar{L}$ is a finite string, so lies in some L_n , and S_{n+1} is complete in L_n , so proves p or $\neg p$.

And it has witnesses: if $(\exists x)p \in \bar{S}$ then $(\exists x)p \in S_n$ for some n , and T_n supplied a witness.

Step 2: the structure. On the set of closed terms of $\bar{L}$ define $s \sim t$ if $\bar{S} \vdash (s = t)$. This is an equivalence relation, by axioms (4) and (5). Let A be the set of equivalence classes, which is non-empty as $\bar{L}$ has at least one constant (if Ω had none, the witnesses supplied one – and if $\bar{S}$ has no existential sentences at all we may add a constant by hand). Make A into an $\bar{L}$ -structure by

$$f_A([t_1], \dots, [t_n]) = [f(t_1, \dots, t_n)],$$

$$\phi_A = \{([t_1], \dots, [t_n]) \mid \bar{S} \vdash \phi(t_1, \dots, t_n)\},$$

both of which are well-defined by axiom (5).

Step 3: A is a model. We claim that for every sentence p of $\bar{L}$,

$$p_A = 1 \iff \bar{S} \vdash p,$$

which finishes the proof, since $S \subseteq \bar{S}$ so every $p \in S$ holds in A (and A is an L -structure by forgetting the new constants). We induct on the structure of p .

If p is $\perp$ then $\perp_A = 0$ and $\bar{S} \nvdash \perp$. If p is $(s = t)$ for closed terms s, t , then $\bar{S} \vdash (s = t)$ if and only if $[s] = [t]$ by the definition of $\sim$, if and only if $s_A = t_A$. Relations are the same by the definition of ϕ_A .

If p is $(q \Rightarrow r)$, then since $\bar{S}$ is complete and consistent, $\bar{S} \vdash (q \Rightarrow r)$ if and only if $\bar{S} \vdash \neg q$ or $\bar{S} \vdash r$. (If $\bar{S} \nvdash \neg q$ and $\bar{S} \nvdash r$ then $\bar{S} \vdash q$ by completeness, so $\bar{S} \vdash r$ by modus ponens, a contradiction.) By induction this holds if and only if $q_A = 0$ or $r_A = 1$, which is the definition of $(q \Rightarrow r)_A = 1$.

Finally consider $(\exists x)q$, which suffices since $(\forall x)q$ is $\neg(\exists x)\neg q$. If $\bar{S} \vdash (\exists x)q$ then $(\exists x)q \in \bar{S}$ by completeness, so there is a witness c with $q[c/x] \in \bar{S}$, and by induction $q[c/x]_A = 1$, so $(\exists x)q$ holds in A . Conversely if $(\exists x)q$ holds in A , then since every element of A is $[t]$ for some closed term t , we have $q[t/x]_A = 1$ for some closed term t , so $\bar{S} \vdash q[t/x]$ by induction, and hence $\bar{S} \vdash (\exists x)q$. $\square$

Corollary 34.4.22 (Adequacy)

Let S be a theory and p a sentence. Then $S \models p$ implies $S \vdash p$.

Proof. If $S \models p$ then $S \cup \{\neg p\}$ has no model, so is inconsistent by Theorem 34.4.21. Then $S \cup \{\neg p\} \vdash \perp$, so $S \vdash \neg\neg p$ by the deduction theorem, so $S \vdash p$ by axiom (3). $\square$

Theorem 34.4.23 (Gödel's Completeness Theorem)

Let S be a theory and p a sentence. Then $S \models p$ if and only if $S \vdash p$.

Proof. Soundness and adequacy. $\square$

Remark. If L is countable, Zorn's lemma is not needed above: we can enumerate the sentences and extend S one at a time, as we did in the propositional case.

Notice that there is no analogue of the decidability theorem here: to check $S \models p$ directly we would have to inspect every L -structure, of which there are a proper class. We will see in Section 34.7 that this is not merely a failure of imagination.

§34.4.7 Compactness and the Löwenheim–Skolem Theorems

Theorem 34.4.24 (Compactness Theorem)

Let S be a theory such that every finite subset of S has a model. Then S has a model.

Proof. Replacing ‘has a model’ by ‘is consistent’ using the completeness theorem, this says that if every finite subset of S is consistent then S is consistent, which is immediate since proofs are finite. $\square$

This has some startling consequences, all obtained by the same trick: write down a theory whose finite fragments are obviously satisfiable, and conclude that the whole thing is.

Corollary 34.4.25 (Finiteness is Not First-Order)

There is no theory S in the language of groups whose models are precisely the finite groups.

Proof. Suppose S were such a theory. Let σ_k be the sentence saying ‘there are at least k elements’, namely

$$(\exists x_1) \cdots (\exists x_k) \left(\bigwedge_{i < j} x_i \neq x_j \right),$$

and let $T = S \cup \{\sigma_k \mid k \in \mathbb{N}\}$. Any finite subset of T mentions only finitely many σ_k , so has a model, namely a cyclic group of large enough order. By compactness T has a model, which is a finite group with at least k elements for every k – a contradiction. $\square$

Corollary 34.4.26

Let S be a theory with arbitrarily large finite models. Then S has an infinite model.

Proof. Add the sentences σ_k as above and apply compactness. $\square$

Corollary 34.4.27 (Connectedness is Not First-Order)

There is no theory in the language of graphs whose models are precisely the connected graphs.

Proof. Suppose S were such a theory. Add two constants a, b to the language and let

$$T = S \cup \{\delta_k \mid k \in \mathbb{N}\},$$

where δ_k is the sentence saying ‘there is no path from a to b of length k ’, which is a first-order sentence since it quantifies over the $k - 1$ intermediate vertices. Any finite subset of T mentions finitely many δ_k , and has a model: take a long path, with a and b its endpoints. So by compactness T has a model, which is a connected graph containing two vertices joined by no path at all – a contradiction. $\square$

Theorem 34.4.28 (Upward Löwenheim–Skolem)

Let S be a theory with an infinite model. Then S has an uncountable model.

Proof. Add constants $\{c_i \mid i \in I\}$ to L for some uncountable set I , and let

$$T = S \cup \{(c_i \neq c_j) \mid i, j \in I, i \neq j\}.$$

Any finite $T' \subseteq T$ mentions only finitely many of the c_i , so an infinite model of S is a model of T' once we interpret those finitely many constants as distinct elements. By compactness T has a model, which has at least $|I|$ elements. $\square$

Theorem 34.4.29 (Downward Löwenheim–Skolem)

Let L be a countable language, that is, with Ω and Π countable. Then if a theory S in L has a model, it has a countable model.

Proof. If S has a model then S is consistent by soundness, and the model constructed in the proof of Theorem 34.4.21 is countable: at each stage we add countably many constants to a countable language, and a countable union of countable sets is countable. So the set of closed terms, and hence its quotient, is countable. $\square$

Putting these together gives *Skolem’s paradox*: the theory ZF of Section 34.5 is written in a countable language, so if it has a model at all then it has a *countable* model – even though ZF proves the existence of uncountable sets. The resolution is that ‘uncountable’ is interpreted inside the model: a set x in the model is uncountable if the model contains no bijection between x and ω , and there is no reason for the model to contain every bijection that exists outside it.

§34.4.8 Categoricity

Since a first-order theory can never pin down the size of its models, we may ask for the next best thing: that it pin down the model once the size is fixed.

Definition 34.4.30 (Categoricity)

A theory S is κ -**categorical** if it has a model of cardinality κ and any two such models are isomorphic.

By the Löwenheim–Skolem theorems, a theory with an infinite model has models of many different sizes, so no such theory can be categorical outright. But $\aleph_0$ -categoricity does occur.

Theorem 34.4.31 (Cantor)

The theory of dense linear orders without endpoints is $\aleph_0$ -categorical. In particular, every countable dense linear order without endpoints is isomorphic to $(\mathbb{Q}, <)$.

Proof sketch. Let $X = \{x_1, x_2, \dots\}$ and $Y = \{y_1, y_2, \dots\}$ be two such orders, enumerated (not in order!). We build an isomorphism by a *back-and-forth* construction, extending a finite order-preserving partial map one point at a time, and alternating between the two sides so that every point gets used.

At an odd stage we take the least-indexed x not yet in the domain and find a partner for it in Y : the finitely many points already matched cut Y into finitely many intervals, and we need a point of Y in the interval corresponding to the position of x , which exists by density (or by the absence of endpoints, if x lies beyond everything matched so far). At an even stage we do the same in reverse, taking the least-indexed y not yet in the image.

Going forth at odd stages guarantees the map is defined everywhere; going back at even stages guarantees it is onto. The union of all these finite partial maps is therefore an isomorphism. $\square$

Categoricity is useful because of the following test, which we state without proof: if a theory S has no finite models and is κ -categorical for some infinite κ , then S is **complete**, meaning that for every sentence p either $S \vdash p$ or $S \vdash \neg p$. So the theory of dense linear orders without endpoints is complete, and in particular any sentence true in $\mathbb{Q}$ is provable from those axioms. The theory of the next section is very far from having this property.

§34.4.9 Peano Arithmetic and Non-Standard Models

Let us apply all this to arithmetic. Take $\Omega = \{0, s, +, \cdot\}$ with arities 0, 1, 2, 2, and $\Pi = \emptyset$. Here s is the successor function.

Definition 34.4.32 (Peano Arithmetic)

Peano arithmetic, written PA, is the theory with axioms

- (i) $(\forall x)(s(x) \neq 0)$;
- (ii) $(\forall x)(\forall y)(s(x) = s(y) \Rightarrow x = y)$;
- (iii) $(\forall y_1) \cdots (\forall y_n)[(p[0/x] \wedge (\forall x)(p \Rightarrow p[s(x)/x])) \Rightarrow (\forall x)p]$ for each formula p with free variables $x, y_1, \dots, y_n$;
- (iv) $(\forall x)(x + 0 = x)$;
- (v) $(\forall x)(\forall y)(x + s(y) = s(x + y))$;

- (vi) $(\forall x)(x \cdot 0 = 0)$;
 (vii) $(\forall x)(\forall y)(x \cdot s(y) = x \cdot y + x)$.

Axiom (iii) is the induction scheme, and the variables y_i are called *parameters*; without them we could not induct on a property like ' $x \geq y$ ' with y held fixed. Note that $\mathbb{N}$ is a model of PA, so PA is consistent.

The crucial point is that (iii) is a scheme with one instance per *formula*, and there are only countably many formulae. So PA asserts induction only for the countably many definable subsets of $\mathbb{N}$, and not for all of them. This is not a defect we can repair: a first-order language simply has no way to quantify over subsets.

The consequences are immediate. As PA has an infinite model, the upward Löwenheim–Skolem theorem gives an uncountable model of PA, which certainly is not isomorphic to $\mathbb{N}$. Such a model is called a **non-standard model of arithmetic**, and we can see what one looks like using compactness.

Example 34.4.33 (A Non-Standard Model of Arithmetic)

Add a constant c to the language and let

$$T = \text{PA} \cup \{c \neq 0, c \neq s(0), c \neq s(s(0)), \dots\}.$$

Any finite subset of T has a model, namely $\mathbb{N}$ with c interpreted as a large enough natural number. So by compactness T has a model A . Inside A the element c is greater than every $s^n(0)$, so A contains a copy of $\mathbb{N}$ followed by extra elements – and since $A \models \text{PA}$, every non-zero element has a predecessor, so those extra elements come in $\mathbb{Z}$ -shaped blocks, ordered densely. Every theorem of PA, and indeed every first-order sentence true in $\mathbb{N}$ that we care to add to T , holds in this strange structure too.

The same trick applied to the theory of ordered fields containing $\mathbb{R}$, with a constant ε and the sentences $0 < \varepsilon < 1/n$ for all n , produces an ordered field containing $\mathbb{R}$ with a non-zero infinitesimal element – a non-standard model of analysis, and the starting point for non-standard analysis.

Since the standard model $\mathbb{N}$ is not pinned down by PA, one may ask which sentences PA does prove. The completeness theorem tells us that $\text{PA} \vdash p$ if and only if p holds in *every* model, including the non-standard ones. So there is room for a sentence to be true in $\mathbb{N}$ but unprovable, and Section 34.7 shows that there is one.

§34.5 Set Theory

We have been using sets throughout, informally. We now write down axioms for them, in the first-order language of Section 34.4, and then see what the resulting universe looks like.

§34.5.1 The Axioms of ZF

Definition 34.5.1 (Zermelo–Fraenkel Set Theory)

Zermelo–Fraenkel set theory, ZF, is a first-order theory in the language with $\Omega = \emptyset$ and $\Pi = \{\in\}$, where $\alpha(\in) = 2$.

A *universe of sets* will mean a model of these axioms: a pair $(V, \in)$ where V is a set and $\in$ is a binary relation on V making the axioms true. Everything below is officially a statement of the form ‘let $(V, \in)$ be a model of ZF; then ...’, or equivalently, by the completeness theorem, ‘ZF $\vdash$...’.

Axiom 34.5.2 (Extension)

‘Sets with the same members are equal’:

$$(\forall x)(\forall y)[(\forall z)(z \in x \Leftrightarrow z \in y) \Rightarrow x = y].$$

Axiom 34.5.3 (Separation)

‘For a set x and a property p , we can form $\{z \in x \mid p(z)\}$ ’:

$$(\forall t_1) \cdots (\forall t_n)(\forall x)(\exists y)(\forall z)(z \in y \Leftrightarrow (z \in x \wedge p))$$

for each formula p with free variables $t_1, \dots, t_n, z$.

This is an axiom *scheme*, with one instance per formula p . The parameters t_i are needed to form sets such as $\{z \in x \mid z \in t\}$ for a variable t . Note carefully that we may only carve subsets out of a set we already have; the unrestricted version, allowing $\{z \mid p(z)\}$ for any p , is inconsistent by Russell’s paradox, taking $p(z)$ to be $z \notin z$.

Axiom 34.5.4 (Empty Set)

‘There is an empty set’:

$$(\exists x)(\forall y)(y \notin x).$$

We write $\emptyset$ for this set, which is unique by extension.

Axiom 34.5.5 (Pair Set)

‘We can form $\{x, y\}$ ’:

$$(\forall x)(\forall y)(\exists z)(\forall t)(t \in z \Leftrightarrow (t = x \vee t = y)).$$

We write $\{x, y\}$ for this z , and $\{x\}$ for $\{x, x\}$.

With pairs we can already encode ordered pairs and hence functions, entirely inside the language.

Definition 34.5.6 (Ordered Pair)

The **ordered pair** is $(x, y) = \{\{x\}, \{x, y\}\}$. One checks that $(x, y) = (z, t)$ if and only if $x = z$ and $y = t$, which is all we ever want from ordered pairs.

Definition 34.5.7 (Function)

We say f is a **function** if

$$(\forall x)(x \in f \Rightarrow x \text{ is an ordered pair}) \\ \wedge (\forall x)(\forall y)(\forall z)[((x, y) \in f \wedge (x, z) \in f) \Rightarrow y = z],$$

where ‘ x is an ordered pair’ abbreviates $(\exists y)(\exists z)(x = (y, z))$. We say x is the **domain** of f , written $x = \text{dom}(f)$, if f is a function and $(\forall y)(y \in x \Leftrightarrow (\exists z)((y, z) \in f))$. Then $f : x \rightarrow y$ abbreviates $(f \text{ is a function}) \wedge (x = \text{dom}(f)) \wedge (\forall z)(\forall t)((z, t) \in f \Rightarrow t \in y)$.

Back to the axioms.

Axiom 34.5.8 (Union)

‘We can form unions’:

$$(\forall x)(\exists y)(\forall z)(z \in y \Leftrightarrow (\exists t)(t \in x \wedge z \in t)).$$

We write $y = \bigcup x$; note this is the union of the members of x , so that $A \cup B$ is $\bigcup\{A, B\}$.

Intersections need no axiom: $\bigcap x$ is a subset of any member of x , so separation provides it.

Axiom 34.5.9 (Power Set)

‘We can form power sets’:

$$(\forall x)(\exists y)(\forall z)(z \in y \Leftrightarrow z \subseteq x),$$

where $z \subseteq x$ abbreviates $(\forall t)(t \in z \Rightarrow t \in x)$. We write $\mathcal{P}(x)$ for this y .

Axiom 34.5.10 (Infinity)

‘There is an infinite set’:

$$(\exists x)(\emptyset \in x \wedge (\forall y)(y \in x \Rightarrow y^+ \in x)),$$

where $y^+ = y \cup \{y\}$. A set satisfying this is called a **successor set**.

The intersection of all successor sets contained in a given one is again a successor set, so there is a least successor set; call it ω . Its members are

$$\emptyset, \{\emptyset\}, \{\emptyset, \{\emptyset\}\}, \dots$$

which we name $0, 1, 2, \dots$, so that $n = \{0, 1, \dots, n-1\}$. Minimality of ω gives induction: if $x \subseteq \omega$ is a successor set then $x = \omega$, that is,

$$(\forall x)[(x \subseteq \omega \wedge \emptyset \in x \wedge (\forall y)(y \in x \Rightarrow y^+ \in x)) \Rightarrow x = \omega].$$

We can now define ‘ x is finite’ to mean $(\exists y)(y \in \omega \wedge x \text{ bijects with } y)$, and ‘ x is countable’ to mean ‘ x is finite or x bijects with ω ’.

Axiom 34.5.11 (Foundation)

‘Every non-empty set has an $\in$ -minimal element’:

$$(\forall x)(x \neq \emptyset \Rightarrow (\exists y)(y \in x \wedge (\forall z)(z \in x \Rightarrow z \notin y))).$$

Foundation is the axiom that says sets are built up out of simpler sets: it forbids $x \in x$ (consider $\{x\}$) and infinite descending $\in$ -chains. It plays for $\in$ exactly the role that the well-ordering condition played for $<$.

Proposition 34.5.12

There is no set of all sets.

Proof. Suppose V were a set. Then by separation $R = \{x \in V \mid x \notin x\}$ is a set, and $R \in R$ if and only if $R \notin R$, a contradiction. $\square$

So separation really is the correct restriction of the naive comprehension principle: it is strong enough for everything we do, and weak enough to survive Russell’s argument. (In the presence of foundation we could argue differently, since then $x \notin x$ always, so $R = V$; but the proof above needs no such assumption.)

§34.5.2 A Digression on Classes

One axiom remains, and to state it we need to be able to say things like ‘for each $i \in I$ we have a set A_i ; now form $\{A_i \mid i \in I\}$ ’. The trouble is that the assignment $i \mapsto A_i$ may not be a function in V – it may be given by a formula rather than a set of ordered pairs.

Definition 34.5.13 (Class)

Let $(V, \in)$ be a model of ZF. A **class** is a collection C of points of V such that, for some formula p with free variable x (and possibly parameters), we have $x \in C$ if and only if $p(x)$ holds.

So classes are exactly the collections of the form $\{x \in V \mid p(x)\}$. Every set is a class, by separation. A class is a **proper class** if it is not a set, that is, if

$$\neg(\exists y)(\forall x)(x \in y \Leftrightarrow p).$$

For example V itself is a proper class, as is On by the Burali-Forti paradox. Statements about classes are always to be read as abbreviations for statements about the formulae defining them; classes are not objects of our theory.

Definition 34.5.14 (Function-Class)

A **function-class** F is a collection of ordered pairs for which there is a formula p with free variables x, y (and possibly parameters) such that $(x, y) \in F$ if and only if p holds, and such that $(x, y) \in F \wedge (x, z) \in F \Rightarrow y = z$.

Axiom 34.5.15 (Replacement)

‘The image of a set under a function-class is a set’. This is an axiom scheme, with an instance for each formula p :

$$\underbrace{(\forall t_1) \dots (\forall t_n)}_{\text{parameters}} \left[\underbrace{(\forall x)(\forall y)(\forall z)(p \wedge p[z/y] \Rightarrow y = z)}_{p \text{ is a function class}} \Rightarrow (\forall x) \underbrace{(\exists y)(\forall z)(z \in y \Leftrightarrow (\exists t)(t \in x \wedge p[t/x, z/y]))}_{y \text{ is the image of } x} \right].$$

That completes the list: **ZF** consists of extension, separation, empty set, pair set, union, power set, infinity, foundation and replacement. Notice that we have not included the axiom of choice.

Definition 34.5.16 (ZFC)

ZFC is **ZF** together with **AC**, the axiom of choice, ‘every family of non-empty sets has a choice function’:

$$(\forall f) \left[(\forall x)(x \in \text{dom } f \Rightarrow f(x) \neq \emptyset) \Rightarrow (\exists g) (\text{dom } g = \text{dom } f \wedge (\forall x)(x \in \text{dom } g \Rightarrow g(x) \in f(x))) \right],$$

where a family of sets $\{A_i \mid i \in I\}$ is officially a function $f : I \rightarrow V$ with $f(i) = A_i$.

§34.5.3 Transitive Sets

We now start to investigate what V must look like. The key notion is the following.

Definition 34.5.17 (Transitive Set)

A set x is **transitive** if every member of a member of x is a member of x :

$$(\forall y)(\forall z)((y \in z \wedge z \in x) \Rightarrow y \in x).$$

Equivalently, $y \in x$ implies $y \subseteq x$. For example $\emptyset$, $\{\emptyset\}$, $\{\emptyset, \{\emptyset\}\}$ and ω are transitive, whereas $\{\{\emptyset\}\}$ is not.

In the picture, the solid arrows are the memberships we started with, and x is transitive precisely when all the dashed arrows are present as well. The other thing the picture

shows is that following arrows downwards must terminate, which is exactly foundation, and this is what lets us do induction.

Lemma 34.5.18 (Transitive Closure)

Every set x is contained in a transitive set.

Proof. We would like to form

$$x \cup \left(\bigcup x\right) \cup \left(\bigcup\bigcup x\right) \cup \left(\bigcup\bigcup\bigcup x\right) \cup \cdots,$$

which is clearly transitive and contains x . By the union axiom, it is enough to obtain the set $\{x, \bigcup x, \bigcup\bigcup x, \dots\}$, and for that it is enough by replacement to check that $n \mapsto \bigcup^n x$ is a function-class on ω .

Define ‘ f is an attempt’ to mean

$$(f \text{ is a function}) \wedge (\text{dom } f \in \omega) \wedge (\text{dom } f \neq \emptyset) \wedge (f(0) = x) \\ \wedge (\forall n)(n \in \text{dom } f \wedge n \neq 0 \Rightarrow f(n) = \bigcup f(n-1)).$$

By the usual induction on ω , any two attempts agree wherever both are defined, and for each $n \in \omega$ there is an attempt defined at n (extend an attempt defined at $n-1$ by one step, using the union and pair set axioms). So the formula

$$p(y, z) = (\exists f)(f \text{ is an attempt} \wedge y \in \text{dom } f \wedge f(y) = z)$$

defines a function-class on ω , and we are done. $\square$

Since any intersection of transitive sets is transitive, it follows that x is contained in a *least* transitive set, called the **transitive closure** of x and written $\text{TC}(x)$.

§34.5.4 $\in$ -Induction and Foundation

We want foundation to give us the principle: if $p(x)$ holds whenever $p(y)$ holds for all $y \in x$, then p holds everywhere. This is $\in$ -induction.

Theorem 34.5.19 (Principle of $\in$ -Induction)

For each formula p with free variables $t_1, \dots, t_n, x$,

$$(\forall t_1) \cdots (\forall t_n) [(\forall x)((\forall y)(y \in x \Rightarrow p(y)) \Rightarrow p(x)) \Rightarrow (\forall x)p(x)].$$

Proof. Fix $t_1, \dots, t_n$ and suppose $\neg(\forall x)p(x)$, so $\neg p(x)$ for some x .

We would like to choose an $\in$ -minimal x with $\neg p(x)$ and apply the hypothesis, but $\{x \mid \neg p(x)\}$ need not be a set. Instead let $t = \text{TC}(\{x\})$ and $u = \{y \in t \mid \neg p(y)\}$, which is a set by separation. Then $u \neq \emptyset$ as $x \in u$, so by foundation u has an $\in$ -minimal member y . Now $\neg p(y)$; but if $z \in y$ then $z \in t$ by transitivity of t , and $z \notin u$ by minimality, so $p(z)$. So $p(z)$ holds for all $z \in y$, whence $p(y)$ by hypothesis, a contradiction. $\square$

Theorem 34.5.20

The axiom of foundation and the principle of $\in$ -induction are equivalent, in the presence of the other axioms of ZF.

Proof. We have just derived $\in$ -induction from foundation. Conversely, say that x is *regular* if

$$(\forall y)(x \in y \Rightarrow y \text{ has an } \in\text{-minimal member}).$$

Foundation says exactly that every x is regular (given non-empty y , take $x \in y$). To prove this by $\in$ -induction, it is enough to show that if every $y \in x$ is regular then x is regular.

So let z be a set with $x \in z$. If x is $\in$ -minimal in z we are done. Otherwise there is some $y \in x$ with $y \in z$; but y is regular and $y \in z$, so z has an $\in$ -minimal member. $\square$

§34.5.5 $\in$ -Recursion and Well-Founded Relations

Having induction, we want recursion: to define $F(x)$ in terms of the values $F(y)$ for $y \in x$.

Theorem 34.5.21 ($\in$ -Recursion Theorem)

Let G be an everywhere-defined function-class. Then there is a unique everywhere-defined function-class F such that

$$(\forall x)(F(x) = G(F|_x)),$$

where $F|_x = \{(y, F(y)) \mid y \in x\}$.

Proof. Note first that $F|_x$ is a set by replacement, so the statement makes sense.

Say ‘ f is an attempt’ if

$$(f \text{ is a function}) \wedge (\text{dom } f \text{ is transitive}) \wedge (\forall x)(x \in \text{dom } f \Rightarrow f(x) = G(f|_x)),$$

which makes sense as $\text{dom } f$ is transitive, so $x \in \text{dom } f$ gives $x \subseteq \text{dom } f$.

Any two attempts agree where both are defined, by $\in$ -induction: if f, f' agree at all $y \in x$ then $f|_x = f'|_x$, so $f(x) = G(f|_x) = G(f'|_x) = f'(x)$.

For each x there is an attempt defined at x , again by $\in$ -induction. Indeed, suppose each $y \in x$ has an attempt defined at y ; then for each such y there is a unique attempt f_y with domain $\text{TC}(\{y\})$, and $\{f_y \mid y \in x\}$ is a set by replacement. Put $f = \bigcup \{f_y \mid y \in x\}$, a function by the previous paragraph, and then $f' = f \cup \{(x, G(f|_x))\}$ is an attempt defined at x .

So we may define F by the formula

$$q(x, y) = (\exists f)(f \text{ is an attempt} \wedge x \in \text{dom } f \wedge f(x) = y).$$

Uniqueness of F is another $\in$ -induction. $\square$

It is worth asking what properties of the relation $\in$ we actually used. There are two.

- (i) It is **well-founded**: every non-empty set has an $\in$ -minimal member.
- (ii) It is **local**: for each y , the collection $\{x \mid x \in y\}$ is a set, which is what let us build transitive closures.

So for any well-founded, local relation given by a formula $r(x, y)$ we get r -induction and r -recursion by identical arguments. If r is a relation on a set a then locality is automatic, so we only need r to be well-founded. In particular, the induction and recursion theorems of Section 2 for well-orderings are special cases.

§34.5.6 Mostowski Collapse

One result about well-orderings remains to be generalised, namely subset collapse. Its analogue answers the question: when can a relation on a set be modelled by $\in$?

Definition 34.5.22 (Extensional Relation)

A relation r on a set a is **extensional** if

$$(\forall x, y \in a) [(\forall z \in a)(z r x \Leftrightarrow z r y) \Rightarrow x = y],$$

that is, if it obeys the axiom of extension.

Theorem 34.5.23 (Mostowski Collapse Theorem)

Let r be a well-founded extensional relation on a set a . Then there is a transitive set b and a bijection $f : a \rightarrow b$ with

$$(\forall x, y \in a)(x r y \Leftrightarrow f(x) \in f(y)).$$

Moreover b and f are unique.

Proof. Define f by r -recursion on a by

$$f(x) = \{f(y) \mid y r x\},$$

which is a set by replacement, and let $b = \{f(x) \mid x \in a\}$, again a set by replacement.

Then b is transitive by the definition of f (any member of $f(x)$ is some $f(y)$, which is in b), and f is surjective onto b by the definition of b . So it remains to show f is injective, and then $x r y \Leftrightarrow f(x) \in f(y)$ follows.

We show $(\forall y \in a)(f(x) = f(y) \Rightarrow x = y)$ for each $x \in a$, by r -induction on x . So suppose the claim for all $t r x$, and let $y \in a$ with $f(x) = f(y)$. By the definition of f we have $\{f(t) \mid t r x\} = \{f(u) \mid u r y\}$, so by the induction hypothesis $\{t \mid t r x\} = \{u \mid u r y\}$, and hence $x = y$ by extensionality.

For uniqueness, if f, f' both work then $f(x) = f'(x)$ for all $x \in a$ by r -induction. $\square$

This lets us give an honest definition of the ordinals, replacing the ‘isomorphism class’ fudge of Section 2.

Definition 34.5.24 (Ordinal, in ZF)

An **ordinal** is a transitive set that is totally ordered by $\in$.

Such a set is automatically well-ordered by $\in$, by foundation. For example $\emptyset$, $\{\emptyset\}$ and $\{\emptyset, \{\emptyset\}\}$ are ordinals, as is every $n \in \omega$ (recall $n = \{0, 1, \dots, n-1\}$), as is ω itself. Note the pleasant consequence that each ordinal *is* the set of ordinals below it, so $I_\alpha = \alpha$.

Now $\in$ on an ordinal is well-founded and extensional, so by Mostowski every well-ordering is order-isomorphic to a unique ordinal, which we call its **order type**. Hence two well-orderings are isomorphic if and only if they have the same order type, which is exactly what we wanted from ordinals in the first place.

§34.5.7 The Cumulative Hierarchy

Finally we can draw the universe. The idea is to build V up in layers, starting from nothing and taking power sets, running along all the ordinals.

Definition 34.5.25 (Von Neumann Hierarchy)

Define sets V_α for $\alpha \in \text{On}$ by transfinite recursion:

$$\begin{aligned} V_0 &= \emptyset, \\ V_{\alpha+} &= \mathcal{P}(V_\alpha), \\ V_\lambda &= \bigcup \{V_\gamma \mid \gamma < \lambda\} \quad \text{for } \lambda \text{ a non-zero limit.} \end{aligned}$$

Every set will turn out to appear somewhere in this cone. Note first that $x \subseteq V_\alpha$ if and only if $x \in V_{\alpha+}$, straight from the definition.

Lemma 34.5.26

Each V_α is transitive.

Proof. Induct on α . Certainly $V_0 = \emptyset$ is transitive. If V_α is transitive and $x \in y \in \mathcal{P}(V_\alpha)$, then $y \subseteq V_\alpha$, so $x \in V_\alpha$, so $x \subseteq V_\alpha$ by transitivity, so $x \in \mathcal{P}(V_\alpha)$. Finally a union of transitive sets is transitive, which handles limits. $\square$

Lemma 34.5.27

If $\alpha \leq \beta$ then $V_\alpha \subseteq V_\beta$.

Proof. Fix α and induct on $\beta \geq \alpha$. The case $\beta = \alpha$ is trivial. Given $V_\alpha \subseteq V_\beta$, we have $V_\beta \subseteq \mathcal{P}(V_\beta)$ – since $x \in V_\beta$ implies $x \subseteq V_\beta$ by Lemma 34.5.26 – so $V_\alpha \subseteq \mathcal{P}(V_\beta) = V_{\beta+}$. Limits are immediate from the definition. $\square$

Theorem 34.5.28 (Every Set has a Rank)

Every set x belongs to some V_α .

Proof. We show $(\forall x)(\exists \alpha)(x \in V_\alpha)$ by $\in$ -induction on x . So we may assume that each $y \in x$ lies in some V_α , and hence that each $y \in x$ has a least α with $y \subseteq V_\alpha$; call it $\text{rank}(y)$, so that $y \in V_{\text{rank}(y)+}$.

Let $\alpha = \sup\{\text{rank}(y)^+ \mid y \in x\}$, which is a set by replacement. Then $y \in V_\alpha$ for every $y \in x$ by Lemma 34.5.27, so $x \subseteq V_\alpha$ and therefore $x \in V_{\alpha+}$. $\square$

So $V = \bigcup_{\alpha \in \text{On}} V_\alpha$: the picture above really is the whole universe. This is the sense in which the axiom of foundation succeeds in saying that every set is built out of simpler sets.

Definition 34.5.29 (Rank)

The **rank** of a set x is defined by $\in$ -recursion by

$$\text{rank}(x) = \sup\{\text{rank}(y)^+ \mid y \in x\}.$$

Proposition 34.5.30

$\text{rank}(x)$ is the least α with $x \subseteq V_\alpha$, equivalently the least α with $x \in V_{\alpha+}$.

Proof. This is precisely what the proof of Theorem 34.5.28 showed, by $\in$ -induction. $\square$

For example $\text{rank}(\emptyset) = 0$, $\text{rank}(n) = n$ for $n \in \omega$, $\text{rank}(\omega) = \omega$, and $\text{rank}(\alpha) = \alpha$ for every ordinal α . Note also that V_ω is precisely the collection of *hereditarily finite* sets – those which are finite, whose members are finite, and so on – and it is a model of every axiom of ZF except infinity.

Example 34.5.31 (Some Ranks)

We have $\text{rank}(\emptyset) = 0$, and $\text{rank}(\{x\}) = \text{rank}(x)^+$. So $\text{rank}(n) = n$ for $n \in \omega$, and more generally $\text{rank}(\alpha) = \alpha$ for every ordinal α : by $\in$ -induction, $\text{rank}(\alpha) = \sup\{\text{rank}(\beta)^+ \mid \beta \in \alpha\} = \sup\{\beta^+ \mid \beta < \alpha\} = \alpha$. Also $\text{rank}(\{\omega, \{\omega\}\}) = \omega + 2$.

Example 34.5.32 (V_ω and $V_{\omega+\omega}$)

The set V_ω consists of the **hereditarily finite** sets: those which are finite, all of whose members are finite, and so on. It is a model of every axiom of ZF except infinity, so infinity is not a consequence of the others. Similarly $V_{\omega+\omega}$ satisfies every axiom except replacement – the function-class $n \mapsto V_{\omega+n}$ has image unbounded in $V_{\omega+\omega}$ – so replacement does not follow from the rest either. Note that $V_{\omega+\omega}$ is a perfectly comfortable place to do most of mathematics: it contains $\mathbb{N}$, $\mathbb{R}$, all the usual function spaces, and so on.

Remark. The axiom of foundation is not needed for ordinary mathematics – one never wants a set with $x \in x$ – and indeed ZF without foundation is consistent if ZF is. What foundation buys us is precisely the picture above: it says that V has no ‘extra’ sets floating outside the cumulative hierarchy. Without it, $\bigcup_\alpha V_\alpha$ would still be a perfectly good model of the other axioms, in which foundation then holds.

§34.5.8 The Reflection Principle

We close this section with a striking consequence of replacement, which says that any finite piece of the theory of V is already visible in some V_α .

Theorem 34.5.33 (Reflection Principle)

Let $p_1, \dots, p_n$ be formulae. Then for every ordinal β there is $\alpha > \beta$ such that each p_i holds in V_α (with all parameters taken from V_α) if and only if it holds in V .

Proof sketch. We may assume the p_i are closed under subformulae. For each subformula of the form $(\exists x)q(x, \vec{y})$ define a function-class sending $\vec{y}$ to the least γ such that, if such an x exists at all, one exists in V_γ ; this is legitimate by replacement, since the ordinals are well-ordered. Given $\alpha_0 = \beta$, let α_{k+1} be an ordinal above α_k large enough that $V_{\alpha_{k+1}}$ contains a witness for every existential subformula with parameters in V_{α_k} , and set $\alpha = \sup_k \alpha_k$. Then V_α has a witness for each existential subformula whose parameters lie in V_α , and an induction on the structure of the formulae shows that each p_i holds in V_α if and only if it holds in V . $\square$

One consequence is worth noting: assuming ZF is consistent, it is not finitely axiomatizable. For suppose ZF were equivalent to a finite list of sentences $p_1, \dots, p_n$. Applying reflection to these gives an ordinal α with each p_i holding in V_α , so ZF would prove that some *set* is a model of ZF; by the soundness theorem this gives $\text{ZF} \vdash \text{Con}(\text{ZF})$, contradicting Gödel’s second incompleteness theorem in Section 34.7.

§34.6 Cardinals

Ordinals measure the *length* of a well-ordering. Cardinals measure the *size* of a set. We work in ZFC throughout, and note where choice is used.

§34.6.1 Cardinality

We write $x \leftrightarrow y$ to mean $(\exists f)(f \text{ is a bijection from } x \text{ to } y)$. We would like to attach to each set x an object $\text{card}(x)$ such that $\text{card}(x) = \text{card}(y)$ if and only if $x \leftrightarrow y$. The

obvious candidate, the collection of all sets bijecting with x , is a proper class, so we must be cleverer. In ZFC there is an easy fix.

Definition 34.6.1 (Cardinality)

The **cardinality** of a set x , written $\text{card}(x)$, is the least ordinal α with $x \leftrightarrow \alpha$.

This exists by the well-ordering principle: some well-ordering of x has an order type α with $x \leftrightarrow \alpha$, and then Proposition 34.2.25 gives a least one.

Remark (Scott's Trick). In ZF alone there may be no ordinal bijecting with x . Instead define the **essential rank** of x to be the least α such that some y with $y \leftrightarrow x$ has $\text{rank}(y) = \alpha$, and set

$$\text{card}(x) = \{y \in V_{\alpha+} \mid y \leftrightarrow x\},$$

which is a non-empty set with the required property. This device – replacing an equivalence class by its members of least rank – works for any equivalence relation on V .

Definition 34.6.2 (Cardinal)

A set m is a **cardinal** if $m = \text{card}(x)$ for some set x .

We use lower case letters m, n for cardinals and the corresponding upper case letters M, N for sets having those cardinalities.

Definition 34.6.3 (Cardinal Inequality)

For cardinals m, n we write $m \leq n$ if M injects into N , and $m < n$ if $m \leq n$ and $m \neq n$.

This is well-defined (independent of representatives), and it is a partial order: antisymmetry is precisely the Schröder–Bernstein theorem, Corollary 34.3.10. In ZFC it is a total order, since any two sets can be well-ordered and then compared by Proposition 34.2.16.

§34.6.2 The Alephs

Which ordinals are cardinals? Since $\omega \leftrightarrow \omega + 1 \leftrightarrow \omega \cdot 2 \leftrightarrow \omega^2$, most of them are not.

Definition 34.6.4 (Initial Ordinal)

An ordinal α is **initial** if no $\beta < \alpha$ has $\beta \leftrightarrow \alpha$; that is, if it is the least ordinal of its cardinality.

So the cardinals which are ordinals are exactly the initial ordinals. Every finite ordinal is initial, as are ω and $\gamma(x)$ for any set x (by minimality in Hartogs' lemma).

Definition 34.6.5 (The Omegas)

Define ω_α for $\alpha \in \text{On}$ by transfinite recursion:

$$\begin{aligned}\omega_0 &= \omega, \\ \omega_{\alpha+} &= \gamma(\omega_\alpha),\end{aligned}$$

$$\omega_\lambda = \sup\{\omega_\alpha \mid \alpha < \lambda\} \quad \text{for } \lambda \text{ a non-zero limit.}$$

Proposition 34.6.6

Each ω_α is initial, and every infinite initial ordinal is some ω_α .

Proof. That each ω_α is initial follows by induction: γ of an ordinal is initial, and a supremum of initial ordinals is initial (if $\beta < \omega_\lambda$ bijected with ω_λ then $\beta < \omega_\alpha$ for some $\alpha < \lambda$, and ω_λ would inject into ω_α).

Conversely let $\delta \geq \omega$ be initial. By induction $\omega_\alpha \geq \alpha$ for every α , so the ω_α are unbounded and there is a least ϵ with $\delta < \omega_\epsilon$. This ϵ is not a limit (else $\delta < \omega_\alpha$ for some $\alpha < \epsilon$) and not zero (as $\delta \geq \omega = \omega_0$), so $\epsilon = \alpha^+$ and $\omega_\alpha \leq \delta < \omega_{\alpha^+} = \gamma(\omega_\alpha)$. Then δ injects into ω_α , so being initial forces $\delta = \omega_\alpha$. $\square$

Definition 34.6.7 (Aleph)

We write $\aleph_\alpha = \text{card}(\omega_\alpha)$.

We use a separate symbol because card may be defined by Scott's trick rather than as an ordinal. From the proposition, the $\aleph_\alpha$ are precisely the cardinalities of the infinite sets – or, in ZF without choice, of the infinite *well-orderable* sets.

§34.6.3 Cardinal Arithmetic**Definition 34.6.8 (Cardinal Arithmetic)**

For cardinals m, n we define

$$m + n = \text{card}(M \sqcup N), \quad mn = \text{card}(M \times N), \quad m^n = \text{card}(M^N),$$

where $M^N = \{f \mid f \text{ is a function } N \rightarrow M\}$.

These do not depend on the choice of representatives. Unlike ordinal arithmetic, cardinal addition and multiplication are commutative and associative, and satisfy the usual laws such as $(m^n)^p = m^{np}$ – the last because a function $P \rightarrow (N \rightarrow M)$ is the same thing as a function $N \times P \rightarrow M$. Note that the notation clashes with ordinal arithmetic: $2^\omega = \omega$ as ordinals, but $2^{\aleph_0} > \aleph_0$ as cardinals. Which is meant is always determined by whether the symbols are ordinals or cardinals.

Example 34.6.9

$\mathbb{R} \leftrightarrow \mathcal{P}(\omega) \leftrightarrow \{0, 1\}^\omega$, so $\text{card}(\mathbb{R}) = \text{card}(\mathcal{P}(\omega)) = 2^{\aleph_0}$.

Example 34.6.10 (How Many Sequences of Reals?)

A real sequence is a function $\omega \rightarrow \mathbb{R}$, so the answer is

$$\text{card}(\mathbb{R}^\omega) = (2^{\aleph_0})^{\aleph_0} = 2^{\aleph_0 \cdot \aleph_0} = 2^{\aleph_0} = \text{card}(\mathbb{R}),$$

using $\aleph_0 \aleph_0 = \aleph_0$, which holds since $\omega \times \omega \leftrightarrow \omega$.

Theorem 34.6.11 (Cantor)

For every cardinal m we have $m < 2^m$.

Proof. Certainly $m \leq 2^m$, as $x \mapsto \{x\}$ injects M into $\mathcal{P}(M)$. Suppose $f : M \rightarrow \mathcal{P}(M)$ were a bijection, and let $A = \{x \in M \mid x \notin f(x)\}$. Then $A = f(a)$ for some $a \in M$, and now $a \in A$ if and only if $a \notin f(a) = A$, which is absurd. $\square$

Example 34.6.12 (More Cardinal Computations)

- (i) There are $2^{\aleph_0}$ continuous functions $\mathbb{R} \rightarrow \mathbb{R}$. Each is determined by its restriction to $\mathbb{Q}$, so there are at most $\text{card}(\mathbb{R}^{\mathbb{Q}}) = (2^{\aleph_0})^{\aleph_0} = 2^{\aleph_0}$ of them, and at least that many since the constants are continuous.
- (ii) There are $2^{2^{\aleph_0}}$ functions $\mathbb{R} \rightarrow \mathbb{R}$ altogether, namely $\text{card}(\mathbb{R}^{\mathbb{R}}) = (2^{\aleph_0})^{2^{\aleph_0}} = 2^{\aleph_0 \cdot 2^{\aleph_0}} = 2^{2^{\aleph_0}}$. So ‘almost no’ function is continuous.
- (iii) The set of finite sequences from an infinite set X has the same cardinality as X , since $\sum_{n < \omega} m^n = \aleph_0 \cdot m = m$ using Theorem 34.6.13. In particular there are only countably many formulae in a countable language, which is the fact we used repeatedly in Sections 34.4 and 34.7.

That last fact generalises completely, and it makes cardinal addition and multiplication of infinite cardinals utterly uninteresting.

Theorem 34.6.13

For every ordinal α we have $\aleph_\alpha \aleph_\alpha = \aleph_\alpha$.

Proof. We induct on α . Define a well-ordering of $\omega_\alpha \times \omega_\alpha$ by ‘going up in squares’: set $(x, y) < (z, w)$ if

- $\max(x, y) < \max(z, w)$; or
- $\max(x, y) = \max(z, w) = \beta$, and one of: $y < \beta$ and $z < \beta$; or $x = z = \beta$ and $y < w$; or $y = w = \beta$ and $x < z$.

In words, we enumerate the pairs by sweeping out successively larger square blocks, and within the β -th block we go up the left edge and then along the top.

Given $\delta \in \omega_\alpha \times \omega_\alpha$ we have $\delta \in \beta \times \beta$ for some $\beta < \omega_\alpha$, as ω_α is a limit. By the induction hypothesis $\beta \times \beta \leftrightarrow \beta$ (or β is finite), so the initial segment I_δ is contained in $\beta \times \beta$ and hence

$$\text{card}(I_\delta) \leq \text{card}(\beta \times \beta) = \text{card}(\beta) < \text{card}(\omega_\alpha).$$

So every proper initial segment of our well-ordering is smaller than ω_α , meaning its order type is at most ω_α . Hence $\omega_\alpha \times \omega_\alpha$ injects into ω_α , and the reverse injection

is obvious, so they biject by Schröder–Bernstein. $\square$

Corollary 34.6.14

For ordinals $\alpha \leq \beta$ we have $\aleph_\alpha + \aleph_\beta = \aleph_\alpha \aleph_\beta = \aleph_\beta$.

Proof. $\aleph_\beta \leq \aleph_\alpha + \aleph_\beta \leq 2\aleph_\beta \leq \aleph_\alpha \aleph_\beta \leq \aleph_\beta^2 = \aleph_\beta$. $\square$

So, for instance, $X \sqcup X \leftrightarrow X$ and $X \times X \leftrightarrow X$ for every infinite set X – results which in ZF alone are not provable.

Cardinal *exponentiation*, by contrast, is genuinely hard. We know $m < 2^m$ for all m by Cantor’s diagonal argument, so $\aleph_0 < 2^{\aleph_0}$, and $\aleph_1 \leq 2^{\aleph_0}$ since $2^{\aleph_0}$ is the cardinality of an uncountable well-orderable set. Whether equality holds – the **Continuum Hypothesis** – is independent of ZFC: Gödel showed it is consistent with ZFC, and Cohen showed its negation is too. ZFC does not even decide whether $2^{\aleph_0} < 2^{\aleph_1}$.

It is convenient to name the cardinals obtained by iterating the power set.

Definition 34.6.15 (Beth Numbers)

Define $\beth_0 = \aleph_0$, $\beth_{\alpha+} = 2^{\beth_\alpha}$, and $\beth_\lambda = \sup\{\beth_\alpha \mid \alpha < \lambda\}$ for a non-zero limit λ .

So $\beth_1 = 2^{\aleph_0} = \text{card}(\mathbb{R})$, and by Cantor’s theorem $\beth_\alpha \geq \aleph_\alpha$ for all α . The **generalised continuum hypothesis** is the assertion that $\beth_\alpha = \aleph_\alpha$ for every α , that is, that $2^{\aleph_\alpha} = \aleph_{\alpha+}$; like the continuum hypothesis it is independent of ZFC. Note that $\beth_\omega$ is a cardinal with $\beth_\omega = \sup_n \beth_n$, so it is a limit of cardinals reached from below by a sequence of length ω – which brings us to our last topic.

§34.6.4 Cofinality

There is, however, one genuine constraint on cardinal exponentiation, and it comes from the following notion.

Definition 34.6.16 (Cofinality)

The **cofinality** $\text{cf}(\alpha)$ of a limit ordinal α is the least order type of a subset of α which is unbounded in α . An infinite cardinal ω_α is **regular** if $\text{cf}(\omega_\alpha) = \omega_\alpha$, and **singular** otherwise.

Example 34.6.17

$\text{cf}(\omega) = \omega$, so ω is regular. Also $\text{cf}(\omega_1) = \omega_1$: we saw in Section 34.2.9 that every countable subset of ω_1 is bounded, so no subset of order type less than ω_1 is unbounded. On the other hand $\text{cf}(\omega \cdot 2) = \omega$, and $\text{cf}(\aleph_\omega) = \omega$ since $\aleph_\omega = \sup\{\aleph_n \mid n < \omega\}$, so $\aleph_\omega$ is singular.

The argument for ω_1 generalises: for any α , the cardinal $\aleph_{\alpha+}$ is regular, since a union of $\aleph_\alpha$ sets each of size $\aleph_\alpha$ has size $\aleph_\alpha$ by Theorem 34.6.13. So successor cardinals are regular (in ZFC), and only limit cardinals such as $\aleph_\omega$ can be singular.

Proposition 34.6.18

For any limit ordinal α , the ordinal $\text{cf}(\alpha)$ is a regular cardinal.

Proof. Let $\gamma = \text{cf}(\alpha)$ and let $S \subseteq \alpha$ be unbounded of order type γ . If $T \subseteq \gamma$ were unbounded in γ of order type $\delta < \gamma$, then the corresponding subset of S would be unbounded in α and have order type δ , contradicting minimality of γ . So $\text{cf}(\gamma) = \gamma$. In particular γ is initial, since a bijection with a smaller ordinal would give an unbounded subset of order type less than γ . $\square$

Cofinality bounds exponentiation from below.

Theorem 34.6.19 (König)

For every infinite cardinal m we have $\text{cf}(2^m) > m$.

Proof sketch. Suppose $2^m = \sup\{n_i \mid i \in I\}$ with $|I| \leq m$ and each $n_i < 2^m$. Writing 2^m as the set of functions $M \rightarrow \{0, 1\}$ and splitting it into $|I|$ pieces of size n_i , a diagonal argument produces a function differing from everything in every piece, which is a contradiction. $\square$

In particular $2^{\aleph_0} \neq \aleph_\omega$, since $\text{cf}(\aleph_\omega) = \omega$. So although ZFC is nearly silent about $2^{\aleph_0}$, it is not completely silent.

§34.7 Incompleteness

We finish by returning to Peano arithmetic. Our aim is to show that PA is *incomplete*: there is a sentence p with $\text{PA} \not\vdash p$ and $\text{PA} \not\vdash \neg p$. Since one of $p, \neg p$ must hold in $\mathbb{N}$, this produces a sentence which is true (in $\mathbb{N}$) but unprovable.

Note that this is not in tension with the completeness theorem, which says that $\text{PA} \vdash p$ whenever p holds in every model of PA. What it will show is that the non-standard models of Section 34.4 cannot be legislated away.

The strategy is beautiful and simple to state: we find a sentence p which asserts ‘ p is not provable in PA’. Then p is true if and only if p is unprovable. If p were false, it would be provable and hence true by soundness, a contradiction; so p is true, and therefore unprovable. All the work is in making a sentence of arithmetic talk about sentences of arithmetic.

Throughout, ‘true’ means true in $\mathbb{N}$ and ‘provable’ means provable in PA.

§34.7.1 Definability

Definition 34.7.1 (Definable)

A subset $S \subseteq \mathbb{N}$ is **definable** if there is a formula p with one free variable x such that for all $m \in \mathbb{N}$, we have $m \in S$ if and only if $p[m/x]$ is true. A function $f : \mathbb{N} \rightarrow \mathbb{N}$ is **definable** if there is a formula p with free variables x, y such that $f(m) = n$ if and only if $p[m/x, n/y]$ is true.

Example 34.7.2

The set of squares is definable by $(\exists y)(y \cdot y = x)$. The set of primes is definable by

$$x \neq 1 \wedge (\forall y)(\forall z)(y \cdot z = x \Rightarrow (y = 1 \vee z = 1)).$$

The function $x \mapsto \lfloor x/2 \rfloor$ is definable by $(x = 2y) \vee (x = 2y + 1)$. The set of powers of 2 is definable by ‘every prime dividing x equals 2’.

Since there are only countably many formulae, only countably many subsets of $\mathbb{N}$ are definable. The fact we need, which we shall not prove, is a converse of sorts: *every function or set given by an algorithm is definable in PA*.

The precise statement runs through primitive recursion.

Definition 34.7.3 (Primitive Recursive)

The **primitive recursive** functions $\mathbb{N}^k \rightarrow \mathbb{N}$ are those obtained from

- (i) the constant 0, the successor function s , and the projections $(x_1, \dots, x_k) \mapsto x_i$, by finitely many applications of
- (ii) *composition*: from g and $h_1, \dots, h_m$ form $\vec{x} \mapsto g(h_1(\vec{x}), \dots, h_m(\vec{x}))$;
- (iii) *primitive recursion*: from g and h form the function f satisfying $f(\vec{x}, 0) = g(\vec{x})$ and $f(\vec{x}, n^+) = h(\vec{x}, n, f(\vec{x}, n))$.

Addition, multiplication, exponentiation, factorials, ‘the n th prime’, bounded sums and products, and the characteristic functions of ‘ x divides y ’ and ‘ x is prime’ are all primitive recursive, by writing down the recursions. One then shows that every primitive recursive function is definable in PA, essentially by coding the finite sequence of intermediate values with the prime-power trick of the next section. Every function we need below is primitive recursive, so we may take definability for granted.

§34.7.2 Coding

The language of PA has the symbols

$$0, s, +, \cdot, =, \perp, \Rightarrow, (,), \forall, x, ',$$

where variables are $x, x', x'', \dots$. Assign to each symbol a number, say $v(0) = 1$, $v(s) = 2$, $\dots$, $v(') = 12$. Then encode a formula p with symbols $\sigma_1 \sigma_2 \dots \sigma_n$ by

$$c(p) = 2^{v(\sigma_1)} 3^{v(\sigma_2)} 5^{v(\sigma_3)} \dots (n\text{th prime})^{v(\sigma_n)}.$$

symbols	(	∀	x	)	(	x	=	0	)
	↓	↓	↓	↓	↓	↓	↓	↓	↓
codes	8	10	11	9	8	11	5	1	9
					↓				

$$c(p) = 2^8 \cdot 3^{10} \cdot 5^{11} \cdot 7^9 \cdot 11^8 \cdot 13^{11} \cdot 17^5 \cdot 19^1 \cdot 23^9$$

By unique factorisation, we can recover p from $c(p)$. Not every number codes a formula, and we write S_n for the formula coded by n , taking $S_n = \perp$ if n codes nothing.

The point of all this is that the syntactic notions we care about become arithmetical statements about codes, each of which is decided by an algorithm and hence is definable:

- (i) ‘ n codes a formula’;
- (ii) ‘ n codes a formula with exactly one free variable’;
- (iii) ‘ l, m, n code formulae and S_n follows from S_l, S_m by modus ponens’, and similarly for generalisation;
- (iv) ‘ n codes a logical axiom or an axiom of PA’.

Sequences of formulae are coded the same way, by

$$s(p_1, \dots, p_n) = 2^{c(p_1)} 3^{c(p_2)} \dots (n\text{th prime})^{c(p_n)},$$

and then ‘ n codes a proof’ and ‘ n codes a proof of S_m ’ are definable too. Let $\theta(m, n)$ be a formula defining ‘ n codes a proof of S_m ’. Then

$$\phi(m) = (\exists n) \theta(m, n)$$

defines ‘ S_m is provable’.

§34.7.3 Gödel’s Incompleteness Theorems

Now for the clever bit. Consider the statement

$$\chi(m) = \text{‘}m \text{ codes a formula } S_m \text{ with one free variable, and } S_m[m/x] \text{ is unprovable’}.$$

This is again decided by an algorithm applied to the definable ingredients above, so it is definable: there is a formula p with one free variable such that $\chi(m)$ holds if and only if $p[m/x]$ is true.

Let $N = c(p)$, so $S_N = p$. Then $p[N/x]$ says precisely that N codes a formula with one free variable whose substitution instance at N is unprovable. But that substitution instance is $S_N[N/x] = p[N/x]$ itself. So

$$p[N/x] \text{ asserts that } p[N/x] \text{ is unprovable,}$$

which is exactly the self-referential sentence we wanted.

Theorem 34.7.4 (Gödel’s First Incompleteness Theorem)

PA is incomplete: there is a sentence which is true in $\mathbb{N}$ but not provable in PA.

Proof. Let q be the sentence $p[N/x]$ constructed above, so that q is true if and only if q is unprovable. If q is false then q is provable, hence true by soundness – a contradiction. So q is true, and therefore unprovable. As q is true, $\neg q$ is false and so also unprovable, again by soundness. $\square$

Note that nothing in this argument is special to PA: it applies to any consistent theory strong enough to code its own syntax, and to which we have added any true sentences we like. So we cannot repair PA by adding axioms, provided that we can still recognise the axioms algorithmically.

Theorem 34.7.5 (Gödel's Second Incompleteness Theorem)

$\text{PA} \not\vdash \text{Con}(\text{PA})$, where $\text{Con}(\text{PA})$ is the sentence $(\forall n)(n \text{ does not code a proof of } \perp)$.

Proof sketch. Examining the proof above, the only external ingredient was soundness, which we used via the existence of a model of PA – and any model would do. So the argument formalises inside PA itself, to give

$$\text{PA} \cup \{\text{Con}(\text{PA})\} \vdash q.$$

If $\text{PA} \vdash \text{Con}(\text{PA})$ we would then have $\text{PA} \vdash q$, contradicting the first incompleteness theorem. $\square$

Finally, let T be the set of all sentences true in $\mathbb{N}$. This is a complete theory extending PA , so the argument above must break down for it – and the only step which can fail is the definability of the syntactic notions. So we obtain the following.

Theorem 34.7.6 (Undecidability of Truth)

There is no algorithm to decide whether a sentence of arithmetic is true in $\mathbb{N}$. Equivalently, the set $\{c(p) \mid p \in T\}$ is not definable.

Remark (The Entscheidungsproblem). In Section 34.4 we noted that there is no analogue of the decidability theorem for predicate logic. The methods of this section are what settle the matter: the set of theorems of predicate logic in a language with a single binary relation symbol is not decidable, since one may code arithmetic into it. What *is* true is that the theorems are recursively enumerable – by the completeness theorem we may simply enumerate all proofs – so validity is semi-decidable. Truth in $\mathbb{N}$, by the theorem above, is not even that.

The same phenomena occur higher up. ZFC proves that PA has a model, namely ω , so $\text{ZFC} \vdash \text{Con}(\text{PA})$ – which by the second incompleteness theorem shows that ZFC is strictly stronger than PA . But ZFC can code its own syntax just as well as PA can, so if ZFC is consistent then ZFC is incomplete, and $\text{ZFC} \not\vdash \text{Con}(\text{ZFC})$. There is no escape by moving to a stronger theory: any consistent, recognisable set of axioms strong enough to do arithmetic will leave some true statement unproved.

35 Number Fields

Number theory begins with the integers, and the single most important fact about the integers is that every one of them factors into primes in exactly one way. An enormous amount of elementary number theory is really just this statement being pushed around. So it is natural, when we want to solve an equation like $y^2 + 2 = x^3$ or $x^2 + y^2 = p$, to enlarge $\mathbb{Z}$ a little – to work in $\mathbb{Z}[\sqrt{-2}]$ or $\mathbb{Z}[i]$ – and hope that unique factorisation survives the move. Sometimes it does, and then the equation falls apart in a few lines. The trouble is that usually it does not: in $\mathbb{Z}[\sqrt{-5}]$ we have the notorious

$$6 = 2 \cdot 3 = (1 + \sqrt{-5})(1 - \sqrt{-5}),$$

and all four factors are irreducible. Unique factorisation of *elements* is simply false in general.

The great insight, due to Kummer and then Dedekind, is that nothing is really lost – we were just looking at the wrong objects. If instead of elements we factor *ideals*, unique factorisation comes back, exactly and in complete generality, in the ring of integers of any number field. The extent to which ideals fail to be principal – that is, the extent to which the ideal-theoretic picture differs from the element-theoretic one – is measured by a finite abelian group, the **class group**, and computing this group for a given field is one of the central occupations of the subject. The other central object is the group of units, whose structure is pinned down by Dirichlet’s unit theorem and which is intimately bound up with Pell’s equation.

Both of the two big finiteness theorems – finiteness of the class group, and the rank of the unit group – are proved by the same startling device: we embed our number field into a Euclidean space so that its ring of integers becomes a *lattice*, and then apply a piece of convex geometry due to Minkowski. Arithmetic questions become questions about counting lattice points in convex bodies. That this works at all is one of the small miracles of mathematics.

This article constitutes my notes for the ‘Number Fields’ course, held in Lent 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§35.1 Introduction

§35.1.1 A Motivating Problem

Which integers can be written as $x^2 + y^2$? The answer is classical and completely satisfying: an odd prime p is a sum of two squares exactly when $p \equiv 1 \pmod{4}$. The slick proof, which we will give properly in Section 35.10, goes as follows. Factor

$$p = x^2 + y^2 = (x + iy)(x - iy)$$

in the ring $\mathbb{Z}[i]$ of Gaussian integers. This ring turns out to be Euclidean, hence a principal ideal domain, hence a unique factorisation domain; and in a UFD one can chase the factorisation of p around and read off the answer from whether -1 is a square mod p .

Emboldened, we might ask: which integers are of the form $x^2 + 5y^2$? Now we would like to factor

$$n = x^2 + 5y^2 = (x + y\sqrt{-5})(x - y\sqrt{-5})$$

in $\mathbb{Z}[\sqrt{-5}]$, and the argument collapses – because $\mathbb{Z}[\sqrt{-5}]$ is *not* a unique factorisation domain:

$$6 = 2 \cdot 3 = (1 + \sqrt{-5})(1 - \sqrt{-5}),$$

with all four factors irreducible and no two associate. This is a genuine obstruction, not an artefact of a bad proof, and understanding it is the whole point of this course.

§35.1.2 Kummer's Idea

The resolution, due to Kummer in the 1840s and refined by Dedekind, is that unique factorisation has not really failed: we have simply been factoring the wrong objects. Kummer imagined ‘ideal numbers’ – hypothetical divisors, not present in the ring, which would refine 2, 3 and $1 \pm \sqrt{-5}$ into common building blocks. Dedekind made this precise by replacing an ideal number with the set of things it divides, that is, with an *ideal* of the ring. In $\mathbb{Z}[\sqrt{-5}]$ the relevant ideals are

$$\mathfrak{p} = (2, 1 + \sqrt{-5}), \quad \mathfrak{q}_1 = (3, 1 + \sqrt{-5}), \quad \mathfrak{q}_2 = (3, 1 - \sqrt{-5}),$$

and one computes that

$$(2) = \mathfrak{p}^2, \quad (3) = \mathfrak{q}_1 \mathfrak{q}_2, \quad (1 + \sqrt{-5}) = \mathfrak{p} \mathfrak{q}_1, \quad (1 - \sqrt{-5}) = \mathfrak{p} \mathfrak{q}_2.$$

So the two apparently different factorisations of 6 are both the same factorisation

$$(6) = \mathfrak{p} \cdot \mathfrak{p} \cdot \mathfrak{q}_1 \cdot \mathfrak{q}_2,$$

merely bracketed in two ways. Unique factorisation was there all along; it just could not be seen at the level of elements. The main theorem of Section 35.4 is that this always happens: in the ring of integers of *any* number field, every nonzero ideal factors uniquely into prime ideals.

Of course, we then want to know how badly the ideals fail to be principal – because that is what stops us from converting statements about ideals back into statements about elements. The answer is a group, the class group, and one of the two big theorems of the course is that it is finite.

§35.1.3 What We Will Do

The plan of the course is as follows.

- Sections 35.2–35.3 set up the basic objects: number fields K , their rings of integers $\mathcal{O}_K$, and the numerical invariants attached to them – norms, traces, integral bases and the discriminant d_K .
- Sections 35.4–35.5 develop the ideal theory: $\mathcal{O}_K$ is a Dedekind domain, ideals factor uniquely into primes, and the failure of principality is measured by Cl_K .
- Section 35.6 answers the question ‘what are the prime ideals?’. They all sit above rational primes, and Dedekind’s criterion reduces finding them to factoring a polynomial mod p . The primes that behave badly – the *ramified* ones – are exactly the divisors of d_K .

- Section 35.7 is the geometric heart. We embed $\mathcal{O}_K$ into $\mathbb{R}^n$ as a lattice and apply Minkowski's convex body theorem to deduce that Cl_K is finite, with an explicit bound. Section 35.8 puts this to work computing class groups.
- Section 35.9 determines the unit group $\mathcal{O}_K^\times$ by the same geometric method: Dirichlet's unit theorem. In the real quadratic case this is the theory of Pell's equation.
- Section 35.10 solves some Diophantine equations, and Section 35.11 (non-examinable) shows how the class number and the regulator appear together as the residue of the Dedekind zeta function.

Throughout, the reader should keep two examples in mind: the quadratic fields $\mathbb{Q}(\sqrt{d})$, where everything can be computed by hand, and the cyclotomic fields $\mathbb{Q}(\zeta_m)$, which are where the subject came from and where it is still headed.

§35.2 Algebraic Integers

§35.2.1 Number Fields

We will work throughout with finite extensions of $\mathbb{Q}$. Recall from Galois Theory that if $K \subseteq L$ are fields with $\dim_K L < \infty$, we write $[L : K]$ for this dimension and call L/K a finite extension; every element of L is then algebraic over K .

Definition 35.2.1 (Number Field)

A **number field** is a finite extension of $\mathbb{Q}$. Its **degree** is $[K : \mathbb{Q}]$.

So $\mathbb{Q}$, $\mathbb{Q}(i)$, $\mathbb{Q}(\sqrt{2})$, $\mathbb{Q}(\sqrt[3]{2})$ and $\mathbb{Q}(\zeta_5)$ are all number fields, of degrees 1, 2, 2, 3 and 4 respectively. Since $\mathbb{Q}$ has characteristic zero, every number field is a separable extension of $\mathbb{Q}$, and so by the primitive element theorem every number field has the form $K = \mathbb{Q}(\alpha)$ for a single α . We will use this constantly.

Inside $\mathbb{Q}$ sits $\mathbb{Z}$, and it is the arithmetic of $\mathbb{Z}$ that we care about. What we want, then, is the analogue of $\mathbb{Z}$ inside a general number field K . There is an obvious wrong answer – take everything that is a root of *some* polynomial over $\mathbb{Q}$, which gives all of K – and the correct answer comes from insisting on *monic integer* polynomials.

Definition 35.2.2 (Algebraic Integer)

Let K be a number field. An element $\alpha \in K$ is an **algebraic integer** if there is a monic polynomial $f \in \mathbb{Z}[x]$ with $f(\alpha) = 0$. We write

$$\mathcal{O}_K = \{\alpha \in K : \alpha \text{ is an algebraic integer}\}$$

for the set of algebraic integers of K , called the **ring of integers** of K .

Calling $\mathcal{O}_K$ a ring is jumping the gun – that it is closed under addition and multiplication is the first thing we have to prove, and it is not obvious. But let us first make sure that the definition does the right thing over $\mathbb{Q}$.

Lemma 35.2.3

$$\mathcal{O}_{\mathbb{Q}} = \mathbb{Z}.$$

Proof. If $a \in \mathbb{Z}$ then $x - a$ is monic with integer coefficients and kills a , so $\mathbb{Z} \subseteq \mathcal{O}_{\mathbb{Q}}$. Conversely suppose $\alpha = r/s \in \mathbb{Q}$ with r, s coprime and $s \geq 1$, and suppose

$$\alpha^n + a_{n-1}\alpha^{n-1} + \cdots + a_0 = 0$$

with all $a_i \in \mathbb{Z}$. Multiplying through by s^n gives

$$r^n = -s(a_{n-1}r^{n-1} + a_{n-2}r^{n-2}s + \cdots + a_0s^{n-1}),$$

so $s \mid r^n$. If $s > 1$, pick a prime $p \mid s$; then $p \mid r^n$, so $p \mid r$, contradicting coprimality. Hence $s = 1$ and $\alpha \in \mathbb{Z}$. $\square$

This is a reassuring start, and it also explains a piece of terminology: elements of $\mathbb{Z}$ are sometimes called **rational integers** when we need to distinguish them from algebraic integers. The picture to keep in mind is a square, with $\mathcal{O}_K$ playing the role for K that $\mathbb{Z}$ plays for $\mathbb{Q}$.

$$\begin{array}{ccc} & \text{field of fractions} & \\ \mathcal{O}_K & \hookrightarrow & K \\ \uparrow & & \uparrow \\ \mathbb{Z} & \hookrightarrow & \mathbb{Q} \\ & \text{field of fractions} & \end{array}$$

We will justify both ‘field of fractions’ labels shortly. Note straight away that $\alpha \in \mathcal{O}_K$ does *not* imply $1/\alpha \in \mathcal{O}_K$ – for instance $2 \in \mathcal{O}_{\mathbb{Q}} = \mathbb{Z}$ but $1/2 \notin \mathbb{Z}$. Understanding exactly which α have $1/\alpha \in \mathcal{O}_K$ is the theory of units, which we take up in Section 35.9.

§35.2.2 Integrality

The obstacle to showing $\mathcal{O}_K$ is a ring is that the Galois-theoretic argument – that $\alpha \pm \beta$ and $\alpha\beta$ are algebraic whenever α, β are – produces polynomials that need not be monic over $\mathbb{Z}$. We need a genuinely different idea, and the right one is a piece of commutative algebra which we may as well set up in general.

Definition 35.2.4 (Integral)

Let $R \subseteq S$ be commutative rings with 1.

- (i) An element $\alpha \in S$ is **integral over R** if there is a monic $f \in R[x]$ with $f(\alpha) = 0$.
- (ii) S is **integral over R** if every $\alpha \in S$ is integral over R .
- (iii) S is **finitely generated as an R -module** if there are $\alpha_1, \dots, \alpha_n \in S$ such that every element of S is an R -linear combination of the α_i ; equivalently, the map $R^n \rightarrow S$, $(r_1, \dots, r_n) \mapsto \sum r_i \alpha_i$, is surjective.

So $\alpha \in K$ is an algebraic integer precisely when it is integral over $\mathbb{Z}$. If $\alpha_1, \dots, \alpha_r \in S$ we write $R[\alpha_1, \dots, \alpha_r]$ for the subring of S generated by R and the α_i ; this is the image of the evaluation map $R[x_1, \dots, x_r] \rightarrow S$ sending $x_i \mapsto \alpha_i$. Beware that being finitely generated as a *module* is much stronger than being finitely generated as a *ring*: $\mathbb{Z}[x]$ is

generated as a ring by one element over $\mathbb{Z}$, but is very far from being a finitely generated $\mathbb{Z}$ -module.

The two notions are linked by the following pair of results, and the link is the whole point.

Proposition 35.2.5

Let $R \subseteq S$ be rings and let $s \in S$ be integral over R . Then $R[s]$ is a finitely generated R -module. More generally, if $s_1, \dots, s_n \in S$ are each integral over R , then $R[s_1, \dots, s_n]$ is a finitely generated R -module.

Proof. The ring $R[s]$ is spanned as an R -module by $1, s, s^2, \dots$. By hypothesis there are $a_0, \dots, a_{n-1} \in R$ with $s^n = a_{n-1}s^{n-1} + \dots + a_0$. Let $M = R \cdot 1 + Rs + \dots + Rs^{n-1}$. Then $sM \subseteq M$: indeed $s \cdot s^i = s^{i+1} \in M$ for $i < n-1$, and $s \cdot s^{n-1} = s^n \in M$ by the displayed relation. Hence M contains $s^n, s^{n+1}, \dots$ by induction, so $M = R[s]$, which is therefore generated by the n elements $1, s, \dots, s^{n-1}$.

For the general statement, first note the transitivity of finite generation: if $A \subseteq B \subseteq C$ with B a finitely generated A -module, say with generators b_i , and C a finitely generated B -module, say with generators c_j , then the products $b_i c_j$ generate C as an A -module. Now put $S_i = R[s_1, \dots, s_i]$, so $S_0 = R$ and $S_{i+1} = S_i[s_{i+1}]$. Each s_{i+1} is integral over R and hence over the larger ring S_i , so S_{i+1} is a finitely generated S_i -module by the first part. Transitivity gives the result. $\square$

Now for the converse direction, which is the clever one. The proof is essentially the proof of the Cayley–Hamilton theorem, and it is worth appreciating that it is entirely constructive: it hands us the monic polynomial explicitly, as a characteristic polynomial.

Theorem 35.2.6

Let $R \subseteq S$ be rings with S a finitely generated R -module. Then S is integral over R .

Proof. Let $\alpha_1, \dots, \alpha_n$ generate S as an R -module; since $1 \in S$ we may assume that $\alpha_1 = 1$ after enlarging the generating set. Fix $s \in S$. Each $s\alpha_i$ lies in S , so we may write

$$s\alpha_i = \sum_{j=1}^n b_{ij}\alpha_j$$

for some $b_{ij} \in R$. Setting $B = (b_{ij}) \in \text{Mat}_n(R)$ and $v = (\alpha_1, \dots, \alpha_n)^T$, this says

$$(sI - B)v = 0.$$

Recall that for any square matrix X over a commutative ring we have $\text{adj}(X)X = (\det X)I$. Multiplying on the left by $\text{adj}(sI - B)$ therefore gives $\det(sI - B)v = 0$; looking at the first coordinate and using $\alpha_1 = 1$ yields

$$\det(sI - B) = 0.$$

But $f(t) = \det(tI - B)$ is a monic polynomial of degree n with coefficients in R , and $f(s) = 0$. So s is integral over R . $\square$

Combining the two results gives exactly what we wanted.

Corollary 35.2.7

Let K be a number field. Then $\mathcal{O}_K$ is a subring of K .

Proof. Let $\alpha, \beta \in \mathcal{O}_K$. By Proposition 35.2.5, $\mathbb{Z}[\alpha, \beta]$ is a finitely generated $\mathbb{Z}$ -module, so by Theorem 35.2.6 every element of $\mathbb{Z}[\alpha, \beta]$ is integral over $\mathbb{Z}$. In particular $\alpha \pm \beta$ and $\alpha\beta$ are algebraic integers, and $0, 1 \in \mathcal{O}_K$ trivially. $\square$

The same argument gives transitivity of integrality, which we will want later.

Corollary 35.2.8 (Transitivity of Integrality)

Let $A \subseteq B \subseteq C$ be rings with B integral over A and C integral over B . Then C is integral over A .

Proof. Let $c \in C$ and let $c^n + b_{n-1}c^{n-1} + \cdots + b_0 = 0$ with $b_i \in B$. Put $B_0 = A[b_0, \dots, b_{n-1}]$ and $C_0 = B_0[c]$. Then B_0 is a finitely generated A -module, since each b_i is integral over A ; and C_0 is a finitely generated B_0 -module, since c is integral over B_0 (the displayed relation has coefficients in B_0). By transitivity of finite generation, C_0 is a finitely generated A -module, so Theorem 35.2.6 shows c is integral over A . $\square$

Remark. The passage to the finitely generated subring C_0 is essential: C itself might be enormous. For example the set of *all* algebraic integers in $\mathbb{C}$ is a ring which is integral over $\mathbb{Z}$, but it is nowhere near being a finitely generated $\mathbb{Z}$ -module. This kind of manoeuvre – reduce to a finitely generated situation, then apply the determinant trick – is one of the standard moves of commutative algebra, and it is worth internalising.

§35.2.3 Minimal Polynomials

To decide whether a given α is an algebraic integer, we would rather not have to hunt for a monic integer polynomial. Happily we do not have to: it is enough to look at the minimal polynomial.

Recall that for α algebraic over a field K , the **minimal polynomial** $p_\alpha \in K[x]$ is the monic polynomial of least degree with $p_\alpha(\alpha) = 0$, and that it divides every polynomial in $K[x]$ killing α (divide with remainder and use minimality); in particular it is unique and irreducible.

Proposition 35.2.9

Let K be a number field and $\alpha \in K$, with minimal polynomial $p_\alpha \in \mathbb{Q}[x]$. Then $\alpha \in \mathcal{O}_K$ if and only if $p_\alpha \in \mathbb{Z}[x]$.

Proof. If $p_\alpha \in \mathbb{Z}[x]$ then α is integral over $\mathbb{Z}$ by definition, since p_α is monic.

Conversely suppose $\alpha \in \mathcal{O}_K$, say $h(\alpha) = 0$ with $h \in \mathbb{Z}[x]$ monic. Then $p_\alpha \mid h$ in $\mathbb{Q}[x]$. Let M be a splitting field for p_α containing K , and let $\alpha_1, \dots, \alpha_m \in M$ be the roots of p_α . Each α_i is a root of h , hence is an algebraic integer. But the coefficients

of $p_\alpha = \prod_i (x - \alpha_i)$ are (up to sign) the elementary symmetric functions of the α_i , hence are algebraic integers by Corollary 35.2.7 applied in M . They also lie in $\mathbb{Q}$, so by Lemma 35.2.3 they lie in $\mathbb{Z}$. $\square$

Remark. There is a second proof, from IB Groups, Rings and Modules: p_α is monic and divides the monic integer polynomial h in $\mathbb{Q}[x]$, so writing $h = p_\alpha g$ with $g \in \mathbb{Q}[x]$ monic, Gauss's lemma forces both p_α and g to lie in $\mathbb{Z}[x]$. Either argument is fine; the first has the advantage of not needing h to be around.

This makes it easy to check membership of $\mathcal{O}_K$ in practice. For example $\frac{1}{2}(1 + \sqrt{5})$ has minimal polynomial $x^2 - x - 1 \in \mathbb{Z}[x]$, so it is an algebraic integer, whereas $\frac{1}{2}(1 + \sqrt{3})$ has minimal polynomial $x^2 - x - \frac{1}{2} \notin \mathbb{Z}[x]$ and so is not.

We can also now justify the ‘field of fractions’ claim from the picture above. The point is that any element of K becomes an algebraic integer after multiplication by a suitable rational integer – we can always clear denominators.

Lemma 35.2.10

Let K be a number field and $\alpha \in K$. Then there is a nonzero $n \in \mathbb{Z}$ with $n\alpha \in \mathcal{O}_K$. Consequently $\text{Frac}(\mathcal{O}_K) = K$.

Proof. Let $g(x) = x^m + c_{m-1}x^{m-1} + \cdots + c_0 \in \mathbb{Q}[x]$ be the minimal polynomial of α , and choose $n \in \mathbb{Z}_{>0}$ with $nc_i \in \mathbb{Z}$ for all i . Then

$$h(x) = n^m g\left(\frac{x}{n}\right) = x^m + nc_{m-1}x^{m-1} + n^2c_{m-2}x^{m-2} + \cdots + n^mc_0$$

is monic with integer coefficients (as $n^{m-i}c_i \in \mathbb{Z}$ for $i \leq m-1$), and $h(n\alpha) = n^m g(\alpha) = 0$. So $n\alpha \in \mathcal{O}_K$.

For the consequence, $\text{Frac}(\mathcal{O}_K) \subseteq K$ is clear, and any $\alpha \in K$ can be written as $(n\alpha)/n$ with $n\alpha \in \mathcal{O}_K$ and $n \in \mathbb{Z} \subseteq \mathcal{O}_K$. $\square$

§35.2.4 Quadratic Fields

Before developing more theory it is worth computing $\mathcal{O}_K$ in the simplest interesting case, both because we will use the answer constantly and because it already contains a surprise.

Definition 35.2.11 (Quadratic Field)

A **quadratic field** is a number field of degree 2.

Every quadratic field is of the form $\mathbb{Q}(\sqrt{d})$ for a unique squarefree $d \in \mathbb{Z} \setminus \{0, 1\}$. Indeed if $[K : \mathbb{Q}] = 2$ and $\alpha \in K \setminus \mathbb{Q}$ then $K = \mathbb{Q}(\alpha)$ and α satisfies a quadratic over $\mathbb{Q}$; completing the square writes $K = \mathbb{Q}(\sqrt{c})$ for some $c \in \mathbb{Q}$, and scaling c by squares of rationals reduces to squarefree $d \in \mathbb{Z}$. We call K **real quadratic** if $d > 0$ and **imaginary quadratic** if $d < 0$.

Lemma 35.2.12

Let $d \in \mathbb{Z}$ be squarefree, $d \neq 0, 1$, and let $K = \mathbb{Q}(\sqrt{d})$. Then

$$\mathcal{O}_K = \begin{cases} \mathbb{Z}[\sqrt{d}] & \text{if } d \equiv 2, 3 \pmod{4}, \\ \mathbb{Z}\left[\frac{1}{2}(1 + \sqrt{d})\right] & \text{if } d \equiv 1 \pmod{4}. \end{cases}$$

Proof. Write $\alpha = x + y\sqrt{d}$ with $x, y \in \mathbb{Q}$. If $y = 0$ then $\alpha \in \mathcal{O}_K$ iff $\alpha \in \mathbb{Z}$ by Lemma 35.2.3. If $y \neq 0$ then the minimal polynomial of α is

$$p_\alpha(t) = (t - x)^2 - dy^2 = t^2 - 2xt + (x^2 - dy^2),$$

so by Proposition 35.2.9, $\alpha \in \mathcal{O}_K$ if and only if $2x \in \mathbb{Z}$ and $x^2 - dy^2 \in \mathbb{Z}$.

Suppose these hold. Then $4x^2 - 4dy^2 \in \mathbb{Z}$ and $4x^2 \in \mathbb{Z}$, so $4dy^2 \in \mathbb{Z}$. Write $y = r/s$ in lowest terms; then $s^2 \mid 4dr^2$, so $s^2 \mid 4d$, and as d is squarefree this forces $s \mid 2$. So we may write $x = u/2$ and $y = v/2$ with $u, v \in \mathbb{Z}$, and the conditions become

$$u^2 - dv^2 \equiv 0 \pmod{4}.$$

Squares are 0 or 1 mod 4. If u, v are both even we get $x, y \in \mathbb{Z}$. If u is odd then $u^2 \equiv 1$, so we need $dv^2 \equiv 1 \pmod{4}$, forcing v odd and $d \equiv 1 \pmod{4}$. If u is even and v odd then $d \equiv 0 \pmod{4}$, impossible as d is squarefree.

So if $d \equiv 2, 3 \pmod{4}$ we must have u, v both even, giving $\mathcal{O}_K = \mathbb{Z} \oplus \mathbb{Z}\sqrt{d} = \mathbb{Z}[\sqrt{d}]$. If $d \equiv 1 \pmod{4}$ then $u \equiv v \pmod{2}$ is exactly the condition, and $\{u/2 + (v/2)\sqrt{d} : u \equiv v \pmod{2}\} = \mathbb{Z} \oplus \mathbb{Z} \cdot \frac{1}{2}(1 + \sqrt{d})$, which is the ring $\mathbb{Z}[\frac{1}{2}(1 + \sqrt{d})]$: note $\frac{1}{2}(1 + \sqrt{d})$ has minimal polynomial $t^2 - t + \frac{1}{4}(1 - d) \in \mathbb{Z}[x]$ precisely because $d \equiv 1 \pmod{4}$. $\square$

The case $d \equiv 1 \pmod{4}$ is the surprise: the naive guess $\mathbb{Z}[\sqrt{d}]$ is too small, and misses half of the integers. This will matter enormously.

Example 35.2.13

Let us record the two most important cases.

- (i) $d = -1$: here $-1 \equiv 3 \pmod{4}$, so $\mathcal{O}_{\mathbb{Q}(i)} = \mathbb{Z}[i]$, the **Gaussian integers**. Embedded in $\mathbb{C}$ this is the square lattice.
- (ii) $d = -3$: here $-3 \equiv 1 \pmod{4}$, so $\mathcal{O}_{\mathbb{Q}(\sqrt{-3})} = \mathbb{Z}[\omega]$ where $\omega = \frac{1}{2}(1 + \sqrt{-3}) = e^{i\pi/3}$. These are the **Eisenstein integers**, and embedded in $\mathbb{C}$ they form the triangular lattice – strictly bigger than $\mathbb{Z}[\sqrt{-3}]$, which is a rectangular sublattice of index 2.

Here are the two pictures, drawn in $\mathbb{C}$.

In both cases $\mathcal{O}_K$ sits inside $\mathbb{C}$ as a lattice; that this always happens, in a suitable sense, is the content of Section 35.7.

Example 35.2.14

$\mathcal{O}_{\mathbb{Q}(\sqrt{5})} = \mathbb{Z}[\frac{1}{2}(1 + \sqrt{5})] = \mathbb{Z}[\varphi]$, where φ is the golden ratio, with $\varphi^2 = \varphi + 1$. On the other hand $\mathcal{O}_{\mathbb{Q}(\sqrt{2})} = \mathbb{Z}[\sqrt{2}]$ and $\mathcal{O}_{\mathbb{Q}(\sqrt{-5})} = \mathbb{Z}[\sqrt{-5}]$, since $2, 3 \equiv 2, 3 \pmod{4}$.

§35.3 Norms, Traces and Discriminants

§35.3.1 The Norm and the Trace

Two extremely useful invariants attach to an element of a field extension, and we met both in Galois Theory. The idea is to remember that L is a vector space over K , and that multiplication by an element of L is a K -linear map.

Definition 35.3.1 (Norm and Trace)

Let L/K be a finite extension of degree n and let $\alpha \in L$. Multiplication by α ,

$$m_\alpha : L \rightarrow L, \quad m_\alpha(y) = \alpha y,$$

is a K -linear endomorphism. We define the **norm** and **trace** of α relative to L/K by

$$N_{L/K}(\alpha) = \det(m_\alpha) \in K, \quad \text{Tr}_{L/K}(\alpha) = \text{tr}(m_\alpha) \in K.$$

When $K = \mathbb{Q}$ and L is understood we simply write $N(\alpha)$ and $\text{Tr}(\alpha)$.

Since $\alpha \mapsto m_\alpha$ is a K -algebra homomorphism $L \rightarrow \text{End}_K(L)$, the norm is multiplicative and the trace is K -linear:

$$N_{L/K}(\alpha\beta) = N_{L/K}(\alpha) N_{L/K}(\beta), \quad \text{Tr}_{L/K}(\alpha + \beta) = \text{Tr}_{L/K}(\alpha) + \text{Tr}_{L/K}(\beta).$$

Also $N_{L/K}(\alpha) = 0$ if and only if $\alpha = 0$, so $N_{L/K} : L^\times \rightarrow K^\times$ is a group homomorphism.

Example 35.3.2

Let $L = K(\sqrt{d})$ with $d \in K$ not a square, and let $\alpha = x + y\sqrt{d}$. In the basis $1, \sqrt{d}$

we have $\alpha \cdot 1 = x + y\sqrt{d}$ and $\alpha \cdot \sqrt{d} = dy + x\sqrt{d}$, so

$$m_\alpha = \begin{pmatrix} x & dy \\ y & x \end{pmatrix},$$

giving

$$\text{Tr}_{L/K}(x + y\sqrt{d}) = 2x, \quad \text{N}_{L/K}(x + y\sqrt{d}) = x^2 - dy^2.$$

Notice that these are exactly $\alpha + \bar{\alpha}$ and $\alpha\bar{\alpha}$, where $\bar{\alpha} = x - y\sqrt{d}$ is the conjugate. For $d = -1$ the norm is the familiar $|x + iy|^2$.

Recall from Galois Theory the relationship between m_α and the minimal polynomial: if p_α is the minimal polynomial of α over K , then the characteristic polynomial of m_α on L is

$$\det(xI - m_\alpha) = p_\alpha(x)^{[L:K(\alpha)]}.$$

(The reason is that L is a free $K(\alpha)$ -module of rank $[L : K(\alpha)]$, and on $K(\alpha)$ with basis $1, \alpha, \dots, \alpha^{\deg p_\alpha - 1}$ the matrix of m_α is the companion matrix of p_α .) Comparing coefficients gives, when $p_\alpha(t) = \prod_{i=1}^r (t - \alpha_i)$ splits in some extension,

$$\text{N}_{L/K}(\alpha) = \left(\prod_{i=1}^r \alpha_i \right)^{[L:K(\alpha)]}, \quad \text{Tr}_{L/K}(\alpha) = [L : K(\alpha)] \sum_{i=1}^r \alpha_i.$$

This has an immediate consequence for algebraic integers, which will be our main computational tool for recognising them.

Lemma 35.3.3

Let K be a number field and $\alpha \in \mathcal{O}_K$. Then $\text{N}_{K/\mathbb{Q}}(\alpha) \in \mathbb{Z}$ and $\text{Tr}_{K/\mathbb{Q}}(\alpha) \in \mathbb{Z}$.

Proof. By Proposition 35.2.9 the minimal polynomial p_α has integer coefficients, and the characteristic polynomial of m_α is a power of p_α , hence also lies in $\mathbb{Z}[x]$. The norm and trace are, up to sign, coefficients of this characteristic polynomial. $\square$

Remark. The converse is false in general, but true in the quadratic case: if $[K : \mathbb{Q}] = 2$ and $\alpha \in K \setminus \mathbb{Q}$, then the characteristic polynomial of m_α is the minimal polynomial, and it equals $x^2 - \text{Tr}(\alpha)x + \text{N}(\alpha)$. So $\alpha \in \mathcal{O}_K$ if and only if $\text{Tr}(\alpha), \text{N}(\alpha) \in \mathbb{Z}$. This is exactly what we used in the proof of Lemma 35.2.12.

§35.3.2 Embeddings

For number fields there is a much better description of the norm and trace, in terms of the embeddings into $\mathbb{C}$. Let $K = \mathbb{Q}(\theta)$ be a number field of degree n , with θ having minimal polynomial p_θ of degree n , so that $K \cong \mathbb{Q}[x]/(p_\theta)$ and $1, \theta, \dots, \theta^{n-1}$ is a $\mathbb{Q}$ -basis of K .

Lemma 35.3.4

There are exactly n field embeddings $K \hookrightarrow \mathbb{C}$.

Proof. As p_θ is irreducible over $\mathbb{Q}$ and $\mathbb{Q}$ has characteristic zero, $\gcd(p_\theta, p'_\theta) = 1$, so p_θ has n distinct roots $\theta_1, \dots, \theta_n \in \mathbb{C}$. A field homomorphism $\mathbb{Q}[x]/(p_\theta) \rightarrow \mathbb{C}$ is automatically $\mathbb{Q}$ -linear, hence determined by the image of x , which must be a root of p_θ ; and each root gives such a homomorphism. These n maps are distinct since they differ on θ . $\square$

Some of these embeddings land in $\mathbb{R}$ and some do not, and the ones that do not come in conjugate pairs since complex conjugation permutes the roots of a real polynomial.

Definition 35.3.5 (Signature)

Let K be a number field of degree n . Let r be the number of embeddings $K \hookrightarrow \mathbb{R}$ and let s be the number of conjugate pairs of non-real embeddings $K \hookrightarrow \mathbb{C}$, so that $r + 2s = n$. We call (r, s) the **signature** of K , and label the embeddings

$$\sigma_1, \dots, \sigma_r : K \rightarrow \mathbb{R}, \quad \sigma_{r+1}, \overline{\sigma_{r+1}}, \dots, \sigma_{r+s}, \overline{\sigma_{r+s}} : K \rightarrow \mathbb{C}.$$

Since r counts the real roots of p_θ , and r can also be described as the number of embeddings of K into $\mathbb{R}$ (a description not mentioning θ), the pair (r, s) is an invariant of K and not of the chosen generator. Here is the picture: the conjugates of θ sit in $\mathbb{C}$, some on the real axis and the rest in mirror-image pairs.

Here $n = 7$, $r = 3$ and $s = 2$. Each root gives one embedding $\sigma_i : K \rightarrow \mathbb{C}$, determined by $\theta \mapsto \theta_i$.

Lemma 35.3.6

Let K be a number field of degree n with embeddings $\sigma_1, \dots, \sigma_n : K \rightarrow \mathbb{C}$. Then for all $\beta \in K$,

$$\mathrm{Tr}_{K/\mathbb{Q}}(\beta) = \sum_{i=1}^n \sigma_i(\beta), \quad \mathrm{N}_{K/\mathbb{Q}}(\beta) = \prod_{i=1}^n \sigma_i(\beta).$$

We call the numbers $\sigma_i(\beta)$ the **conjugates** of β .

Proof. Let p_β have degree r and roots $\beta_1, \dots, \beta_r$, and let $m = [K : \mathbb{Q}(\beta)]$, so $n = rm$. Each embedding $\mathbb{Q}(\beta) \rightarrow \mathbb{C}$ sends β to some β_j , and each of these r embeddings extends in exactly m ways to K (by Lemma 35.3.4 applied to $K/\mathbb{Q}(\beta)$, or by counting: there are n embeddings of K in total, distributed among the r embeddings of $\mathbb{Q}(\beta)$). So the multiset $\{\sigma_i(\beta)\}$ is $\{\beta_1, \dots, \beta_r\}$ with each element repeated m times, and the result follows from the formulae recorded above. $\square$

Example 35.3.7

If $K = \mathbb{Q}(\sqrt{d})$ with d squarefree, the two embeddings send $\sqrt{d} \mapsto \pm\sqrt{d}$, so the conjugates of $a + b\sqrt{d}$ are $a \pm b\sqrt{d}$, recovering Example 35.3.2. If $d > 0$ the signature is $(2, 0)$; if $d < 0$ it is $(0, 1)$. For $K = \mathbb{Q}(\sqrt[3]{2})$ the conjugates of $\sqrt[3]{2}$ are $\sqrt[3]{2}, \omega\sqrt[3]{2}, \omega^2\sqrt[3]{2}$ with $\omega = e^{2\pi i/3}$, so the signature is $(1, 1)$. For $K = \mathbb{Q}(\zeta_m)$ with $m > 2$ there are no real embeddings at all, so the signature is $(0, \varphi(m)/2)$.

§35.3.3 The Discriminant of a Basis

We now build a numerical invariant out of the trace. The construction is a quadratic form, and the crucial fact is that it is nondegenerate.

Definition 35.3.8 (Discriminant of a Tuple)

Let L/K be a finite extension of degree n and let $\alpha_1, \dots, \alpha_n \in L$. Define

$$\Delta(\alpha_1, \dots, \alpha_n) = \det (\mathrm{Tr}_{L/K}(\alpha_i \alpha_j))_{i,j} \in K,$$

the determinant of the Gram matrix of the **trace form** $(x, y) \mapsto \mathrm{Tr}_{L/K}(xy)$.

Proposition 35.3.9

Let L/K be a finite separable extension of degree n with distinct K -embeddings $\sigma_1, \dots, \sigma_n$ into an algebraic closure $\overline{K}$, and let $\alpha_1, \dots, \alpha_n \in L$. Then

$$\Delta(\alpha_1, \dots, \alpha_n) = \det (\sigma_i(\alpha_j))^2.$$

Moreover $\Delta(\alpha_1, \dots, \alpha_n) \neq 0$ if and only if $\alpha_1, \dots, \alpha_n$ is a K -basis of L ; equivalently, the trace form is nondegenerate.

Proof. Let $S = (\sigma_i(\alpha_j))_{i,j}$. Then the (i, j) entry of $S^T S$ is

$$\sum_{k=1}^n \sigma_k(\alpha_i) \sigma_k(\alpha_j) = \sum_{k=1}^n \sigma_k(\alpha_i \alpha_j) = \mathrm{Tr}_{L/K}(\alpha_i \alpha_j),$$

using Lemma 35.3.6 (whose proof works verbatim for any finite separable extension). Taking determinants gives the first claim.

For the second, first take the basis $1, \theta, \dots, \theta^{n-1}$ where $L = K(\theta)$, which exists by the primitive element theorem. Then S is the Vandermonde matrix $(\sigma_i(\theta)^{j-1})$, so

$$\Delta(1, \theta, \dots, \theta^{n-1}) = \prod_{i < j} (\sigma_i(\theta) - \sigma_j(\theta))^2,$$

which is nonzero: if $\sigma_i(\theta) = \sigma_j(\theta)$ then $\sigma_i = \sigma_j$ on $K(\theta) = L$, so $i = j$. Now if $\alpha_1, \dots, \alpha_n$ is any other basis, say $\alpha_i = \sum_j a_{ij} \theta^{j-1}$ with $A = (a_{ij}) \in \mathrm{GL}_n(K)$, then a direct computation with the Gram matrices gives

$$\Delta(\alpha_1, \dots, \alpha_n) = (\det A)^2 \Delta(1, \theta, \dots, \theta^{n-1}) \neq 0.$$

Finally, if the α_i are linearly dependent then so are the columns of the Gram matrix, and $\Delta = 0$. $\square$

Remark. Taking $\alpha_i = \theta^{i-1}$ we recover the discriminant of a polynomial from Galois Theory: if $p_\theta(t) = \prod_i (t - \sigma_i(\theta))$ then

$$\text{disc}(p_\theta) = \prod_{i < j} (\sigma_i(\theta) - \sigma_j(\theta))^2 = \Delta(1, \theta, \dots, \theta^{n-1}).$$

So the two uses of the word ‘discriminant’ agree, and we write $\text{disc}(\theta)$ for this common value. In practice it is computed from the resultant formula

$$\text{disc}(f) = (-1)^{n(n-1)/2} N(f'(\theta)).$$

The relevance to us is the following, which is the engine of everything in this section.

Lemma 35.3.10

Let K be a number field of degree n and let $\alpha_1, \dots, \alpha_n \in \mathcal{O}_K$. Then $\Delta(\alpha_1, \dots, \alpha_n) \in \mathbb{Z}$. If moreover the α_i form a $\mathbb{Q}$ -basis of K , then $\Delta(\alpha_1, \dots, \alpha_n)$ is a nonzero integer.

Proof. Each $\alpha_i \alpha_j$ lies in $\mathcal{O}_K$, so $\text{Tr}(\alpha_i \alpha_j) \in \mathbb{Z}$ by Lemma 35.3.3; hence the Gram matrix has integer entries and its determinant is an integer. Nonvanishing is Proposition 35.3.9. $\square$

We record for reference two further standard properties, both proved in Galois Theory.

Proposition 35.3.11 (Transitivity)

Let $M/L/K$ be finite extensions. Then for all $\alpha \in M$,

$$\text{Tr}_{L/K}(\text{Tr}_{M/L}(\alpha)) = \text{Tr}_{M/K}(\alpha), \quad N_{L/K}(N_{M/L}(\alpha)) = N_{M/K}(\alpha).$$

In particular, if $\alpha \in L$ then $N_{M/K}(\alpha) = N_{L/K}(\alpha)^{[M:L]}$ and $\text{Tr}_{M/K}(\alpha) = [M : L] \text{Tr}_{L/K}(\alpha)$.

Example 35.3.12 (Discriminant of a Cubic)

For a cubic $f(x) = x^3 + ax + b$ (any cubic can be brought to this form by a substitution $x \mapsto x - c$, which does not change the discriminant), one has

$$\text{disc}(f) = -4a^3 - 27b^2.$$

So $\text{disc}(x^3 - 2) = -27 \cdot 4 = -108$, matching Example 35.3.17, and $\text{disc}(x^3 - x - 1) = 4 - 27 = -23$. Note also that the sign of $\text{disc}(f)$ detects the signature: if f has three real roots then $\prod_{i < j} (\theta_i - \theta_j)^2 > 0$, while if it has one real root and a conjugate pair the product is negative. So a cubic field has signature $(3, 0)$ or $(1, 1)$ according as $d_K > 0$ or $d_K < 0$. More generally $\text{sign}(d_K) = (-1)^s$ for any number field.

§35.3.4 Integral Bases

Definition 35.3.13 (Integral Basis)

Let K be a number field of degree n . An **integral basis** for K is a tuple $\alpha_1, \dots, \alpha_n \in \mathcal{O}_K$ such that

$$\mathcal{O}_K = \mathbb{Z}\alpha_1 \oplus \dots \oplus \mathbb{Z}\alpha_n.$$

Note that an integral basis is automatically a $\mathbb{Q}$ -basis of K : it spans K over $\mathbb{Q}$ by Lemma 35.2.10, and n spanning elements in an n -dimensional space are independent. So an integral basis exhibits $\mathcal{O}_K$ as a free abelian group of rank n sitting inside K in the tidiest possible way. The following existence theorem is the reason the theory works at all.

Theorem 35.3.14 (Existence of Integral Bases)

Every number field K of degree n has an integral basis. In particular $\mathcal{O}_K \cong \mathbb{Z}^n$ as an abelian group.

Proof. Start with any $\mathbb{Q}$ -basis $\beta_1, \dots, \beta_n$ of K ; by Lemma 35.2.10 we may scale each β_i by a nonzero integer so that all $\beta_i \in \mathcal{O}_K$, without destroying the basis property. So the set

$$\mathcal{B} = \{(\alpha_1, \dots, \alpha_n) : \alpha_i \in \mathcal{O}_K \text{ forming a } \mathbb{Q}\text{-basis of } K\}$$

is nonempty, and by Lemma 35.3.10 the quantity $|\Delta(\alpha_1, \dots, \alpha_n)|$ is a positive integer for each element of $\mathcal{B}$. Choose $(\alpha_1, \dots, \alpha_n) \in \mathcal{B}$ minimising $|\Delta(\alpha_1, \dots, \alpha_n)|$.

We claim this is an integral basis. Certainly $\bigoplus \mathbb{Z}\alpha_i \subseteq \mathcal{O}_K$. Suppose not conversely, so there is $x \in \mathcal{O}_K$ with $x = \sum_i \lambda_i \alpha_i$, $\lambda_i \in \mathbb{Q}$, and some $\lambda_i \notin \mathbb{Z}$; relabelling, say $\lambda_1 \notin \mathbb{Z}$. Write $\lambda_1 = m + \varepsilon$ with $m \in \mathbb{Z}$ and $0 < \varepsilon < 1$, and put

$$\alpha'_1 = x - m\alpha_1 = \varepsilon\alpha_1 + \lambda_2\alpha_2 + \dots + \lambda_n\alpha_n \in \mathcal{O}_K.$$

Then $\alpha'_1, \alpha_2, \dots, \alpha_n$ is again a $\mathbb{Q}$ -basis of K consisting of algebraic integers (the change of basis matrix from $\alpha_1, \dots, \alpha_n$ is lower triangular with diagonal $\varepsilon, 1, \dots, 1$, so has determinant $\varepsilon \neq 0$), so lies in $\mathcal{B}$, and by the transformation rule in the proof of Proposition 35.3.9,

$$\Delta(\alpha'_1, \alpha_2, \dots, \alpha_n) = \varepsilon^2 \Delta(\alpha_1, \dots, \alpha_n).$$

Since $0 < \varepsilon^2 < 1$ this has strictly smaller absolute value, contradicting minimality. $\square$

Integral bases are far from unique: if $\alpha_1, \dots, \alpha_n$ is one, and $g \in \text{GL}_n(\mathbb{Z})$, then applying g gives another, and all integral bases arise this way. But $\det g = \pm 1$ for $g \in \text{GL}_n(\mathbb{Z})$, so $(\det g)^2 = 1$ and the discriminant does not notice. This gives us a genuine invariant of the field.

Definition 35.3.15 (Discriminant of a Number Field)

Let K be a number field with integral basis $\alpha_1, \dots, \alpha_n$. The **discriminant** of K is

$$d_K = \Delta(\alpha_1, \dots, \alpha_n) \in \mathbb{Z} \setminus \{0\},$$

which by the above does not depend on the choice of integral basis.

The discriminant is one of the two or three most important invariants attached to a number field. It knows about ramification (Section 35.6), it controls the size of the class group (Section 35.7), and – via the theorem of Hermite and Minkowski – there are only finitely many number fields with any given discriminant.

Example 35.3.16 (Quadratic Fields)

Let $K = \mathbb{Q}(\sqrt{d})$ with d squarefree. If $d \equiv 2, 3 \pmod{4}$ then $1, \sqrt{d}$ is an integral basis and

$$d_K = \det \begin{pmatrix} 1 & \sqrt{d} \\ 1 & -\sqrt{d} \end{pmatrix}^2 = (-2\sqrt{d})^2 = 4d.$$

If $d \equiv 1 \pmod{4}$ then $1, \frac{1}{2}(1 + \sqrt{d})$ is an integral basis and

$$d_K = \det \begin{pmatrix} 1 & \frac{1}{2}(1 + \sqrt{d}) \\ 1 & \frac{1}{2}(1 - \sqrt{d}) \end{pmatrix}^2 = (-\sqrt{d})^2 = d.$$

So $d_K \in \{d, 4d\}$. It is often cleaner to phrase results about quadratic fields in terms of d_K : note that $K = \mathbb{Q}(\sqrt{d_K})$ in both cases, that $d_K \equiv 0, 1 \pmod{4}$, and that

$$1, \frac{1}{2}(d_K + \sqrt{d_K})$$

is an integral basis in both cases. Integers arising as d_K for a quadratic field are called **fundamental discriminants**.

Remark (Stickelberger). Not every integer is a discriminant. Writing $\det(\sigma_i(\alpha_j)) = P - N$, where P is the sum of the terms of the determinant coming from even permutations and N those from odd ones, we have $d_K = (P - N)^2 = (P + N)^2 - 4PN$. Both $P + N$ and PN are fixed by every permutation of the embeddings, hence are rational; and they are algebraic integers, hence lie in $\mathbb{Z}$. So

$$d_K \equiv (P + N)^2 \equiv 0 \text{ or } 1 \pmod{4}.$$

This is **Stickelberger's criterion**, and it is consistent with what we found for quadratic fields, where d_K is d (with $d \equiv 1 \pmod{4}$) or $4d$.

Example 35.3.17 (Cubic Fields)

Let $K = \mathbb{Q}(\sqrt[3]{2})$. We have $\text{disc}(x^3 - 2) = -108$. If $1, \sqrt[3]{2}, \sqrt[3]{4}$ were not an integral basis, then $\mathbb{Z}[\sqrt[3]{2}] \subsetneq \mathcal{O}_K$ would have some index $m > 1$, and (as we shall see in Lemma 35.3.19) $\text{disc}(\sqrt[3]{2}) = m^2 d_K$, so $m^2 \mid 108$, giving $m \in \{2, 3, 6\}$. One can rule these out directly; the upshot is $\mathcal{O}_K = \mathbb{Z}[\sqrt[3]{2}]$ and $d_K = -108$.

Contrast this with $K = \mathbb{Q}(\alpha)$ where $\alpha^3 - \alpha^2 - 2\alpha - 8 = 0$. Here $\text{disc}(\alpha) = -2012 = -4 \cdot 503$, and 503 is prime, so the index of $\mathbb{Z}[\alpha]$ in $\mathcal{O}_K$ is 1 or 2. In fact it is 2: the element

$$\beta = \frac{1}{2}(\alpha^2 + \alpha)$$

has minimal polynomial $x^3 - 3x^2 - 10x - 8 \in \mathbb{Z}[x]$, so $\beta \in \mathcal{O}_K \setminus \mathbb{Z}[\alpha]$. Thus $d_K = -503$ and $1, \alpha, \beta$ is an integral basis. We will meet this field again in Section 35.6: it is the standard example of a field which is *not monogenic*, meaning $\mathcal{O}_K \neq \mathbb{Z}[\gamma]$ for every γ .

Example 35.3.18 (Cyclotomic Fields)

Let p be an odd prime and $K = \mathbb{Q}(\zeta_p)$ where $\zeta_p = e^{2\pi i/p}$. From Galois Theory, ζ_p has minimal polynomial the cyclotomic polynomial

$$\Phi_p(x) = \frac{x^p - 1}{x - 1} = 1 + x + \cdots + x^{p-1},$$

irreducible by Eisenstein applied to $\Phi_p(x+1)$, so $[K : \mathbb{Q}] = p-1$ and the signature is $(0, (p-1)/2)$. One shows (see Section 35.6.5) that $\mathcal{O}_K = \mathbb{Z}[\zeta_p]$ and

$$d_K = (-1)^{(p-1)/2} p^{p-2}.$$

For instance $d_{\mathbb{Q}(\zeta_5)} = 5^3 = 125$ and $d_{\mathbb{Q}(\zeta_7)} = -7^5 = -16807$, which one can check directly by computing $\text{disc}(\Phi_5)$ and $\text{disc}(\Phi_7)$. For $p = 3$ this gives $d_{\mathbb{Q}(\zeta_3)} = -3$, consistent with $\mathbb{Q}(\zeta_3) = \mathbb{Q}(\sqrt{-3})$ and Example 35.3.16.

The following criterion, which we will prove in more generality in Section 35.5, is the standard practical tool: it says that a squarefree discriminant certifies an integral basis for free.

Lemma 35.3.19 (Index and Discriminant)

Let K be a number field of degree n and let $\alpha_1, \dots, \alpha_n \in \mathcal{O}_K$ be a $\mathbb{Q}$ -basis of K . Let $M = \bigoplus_i \mathbb{Z}\alpha_i \subseteq \mathcal{O}_K$. Then $[\mathcal{O}_K : M]$ is finite and

$$\Delta(\alpha_1, \dots, \alpha_n) = [\mathcal{O}_K : M]^2 d_K.$$

In particular, if $\Delta(\alpha_1, \dots, \alpha_n)$ is squarefree then $M = \mathcal{O}_K$ and $d_K = \Delta(\alpha_1, \dots, \alpha_n)$.

Proof. Let $\gamma_1, \dots, \gamma_n$ be an integral basis, and write $\alpha_i = \sum_j a_{ij} \gamma_j$ with $A = (a_{ij}) \in \text{Mat}_n(\mathbb{Z})$. Since both are $\mathbb{Q}$ -bases of K , $\det A \neq 0$, so M has finite index in $\mathcal{O}_K$. By Smith normal form there are $P, Q \in \text{GL}_n(\mathbb{Z})$ with PAQ diagonal, say with entries $d_1, \dots, d_n$; changing bases on both sides accordingly, $\mathcal{O}_K/M \cong \bigoplus_i \mathbb{Z}/d_i\mathbb{Z}$, so $[\mathcal{O}_K : M] = |d_1 \cdots d_n| = |\det A|$. Now the transformation rule gives

$$\Delta(\alpha_1, \dots, \alpha_n) = (\det A)^2 \Delta(\gamma_1, \dots, \gamma_n) = [\mathcal{O}_K : M]^2 d_K. \quad \square$$

Example 35.3.20

The polynomial $x^3 - x - 1$ has discriminant -23 , which is squarefree. Hence if α is a root, $\mathcal{O}_{\mathbb{Q}(\alpha)} = \mathbb{Z}[\alpha]$ and $d_{\mathbb{Q}(\alpha)} = -23$. Similarly $x^3 + x + 1$ has discriminant -31 , giving a cubic field of discriminant -31 .

§35.4 Ideals and Unique Factorisation**§35.4.1 Units and Irreducibles**

Let us begin with the multiplicative structure of $\mathcal{O}_K$. Recall that $u \in \mathcal{O}_K$ is a **unit** if $u^{-1} \in \mathcal{O}_K$, and we write $\mathcal{O}_K^\times$ for the group of units. There is a beautifully simple criterion.

Lemma 35.4.1

Let K be a number field and $x \in \mathcal{O}_K$. Then $x \in \mathcal{O}_K^\times$ if and only if $N_{K/\mathbb{Q}}(x) = \pm 1$.

Proof. If x is a unit then $1 = N(1) = N(x)N(x^{-1})$ with both factors in $\mathbb{Z}$ by Lemma 35.3.3, so $N(x) = \pm 1$.

Conversely suppose $N(x) = \pm 1$. Fix the embedding σ_1 and identify K with $\sigma_1(K) \subseteq \mathbb{C}$. By Lemma 35.3.6,

$$\pm 1 = N(x) = x \sigma_2(x) \cdots \sigma_n(x),$$

so $x^{-1} = \pm \prod_{i=2}^n \sigma_i(x)$. Each $\sigma_i(x)$ is a root of the minimal polynomial of x , which lies in $\mathbb{Z}[x]$, hence is an algebraic integer; so x^{-1} is an algebraic integer. It also lies in K , so $x^{-1} \in \mathcal{O}_K$. $\square$

Example 35.4.2

Let $K = \mathbb{Q}(\sqrt{d})$ with $d < 0$ squarefree. If $d \equiv 2, 3 \pmod{4}$ then $N(a + b\sqrt{d}) = a^2 + |d|b^2 = 1$ forces $b = 0$, $a = \pm 1$ unless $d = -1$, where we also get $a = 0$, $b = \pm 1$. So

$$\mathcal{O}_{\mathbb{Q}(i)}^\times = \{\pm 1, \pm i\}, \quad \mathcal{O}_{\mathbb{Q}(\sqrt{d})}^\times = \{\pm 1\} \text{ for } d \leq -2, d \equiv 2, 3 \pmod{4}.$$

If $d \equiv 1 \pmod{4}$ the norm of $\frac{1}{2}(u + v\sqrt{d})$ is $\frac{1}{4}(u^2 + |d|v^2)$, and $u^2 + |d|v^2 = 4$ has extra solutions only for $d = -3$, giving the six sixth-roots of unity. So imaginary quadratic fields have finite unit group – and, as we shall see, they are essentially the only fields with this property.

Example 35.4.3

By contrast, in $\mathbb{Z}[\sqrt{2}]$ we have $N(1 + \sqrt{2}) = 1 - 2 = -1$, so $1 + \sqrt{2}$ is a unit – and so are all its powers $(1 + \sqrt{2})^n$, which are pairwise distinct real numbers. So $\mathcal{O}_{\mathbb{Q}(\sqrt{2})}^\times$ is infinite. Finding solutions of $N(x) = \pm 1$ in a real quadratic field is exactly solving **Pell's equation** $a^2 - db^2 = \pm 1$, and we will return to this in Section 35.9.

Recall that $x \in \mathcal{O}_K$ is **irreducible** if x is not zero or a unit, and $x = ab$ implies a or b is a unit; and that x, y are **associates** if $x = uy$ for a unit u . Since $|N(x)|$ is a positive integer for $x \neq 0$, and $|N(x)| = 1$ exactly for units, an easy induction on $|N(x)|$ shows that every nonzero non-unit of $\mathcal{O}_K$ is a product of irreducibles. The trouble is uniqueness.

§35.4.2 The Failure of Unique Factorisation**Example 35.4.4**

Let $K = \mathbb{Q}(\sqrt{-5})$, so $\mathcal{O}_K = \mathbb{Z}[\sqrt{-5}]$ and $N(a + b\sqrt{-5}) = a^2 + 5b^2$. Then

$$6 = 2 \cdot 3 = (1 + \sqrt{-5})(1 - \sqrt{-5}).$$

The norms of the four factors are 4, 9, 6, 6. All four are irreducible: for instance if $2 = \alpha\beta$ with neither a unit then $4 = N(\alpha)N(\beta)$ with both factors > 1 , so $N(\alpha) = 2$, i.e. $a^2 + 5b^2 = 2$, which has no integer solutions. The same argument rules out norms

3 and 6 being $N(\alpha)N(\beta)$ nontrivially, since $a^2 + 5b^2 \in \{2, 3\}$ is insoluble. Moreover 2 and $1 \pm \sqrt{-5}$ are not associates, as the units are just ± 1 and the norms differ. So $\mathcal{O}_K$ is not a UFD.

Example 35.4.5

Similarly in $\mathbb{Z}[\sqrt{-5}]$ we have $21 = 3 \cdot 7 = (1 + 2\sqrt{-5})(1 - 2\sqrt{-5})$, with norms 9, 49, 21, 21; again all four factors are irreducible since $a^2 + 5b^2 \in \{3, 7\}$ is insoluble.

Recall from IB Groups, Rings and Modules that $\text{ED} \Rightarrow \text{PID} \Rightarrow \text{UFD}$, and that in a UFD irreducibles are prime. So $\mathbb{Z}[\sqrt{-5}]$ is not a PID either – indeed $(2, 1 + \sqrt{-5})$ is not principal.

Now, here is Kummer’s idea. In Example 35.4.4 the element 2 ought morally to factor further, into ‘ideal numbers’ which are not elements of the ring. Dedekind’s formulation replaces these ideal numbers with honest *ideals*. Watch what happens if we set

$$\mathfrak{p} = (2, 1 + \sqrt{-5}), \quad \mathfrak{q}_1 = (3, 1 + \sqrt{-5}), \quad \mathfrak{q}_2 = (3, 1 - \sqrt{-5}).$$

We will verify shortly that

$$\mathfrak{p}^2 = (2), \quad \mathfrak{q}_1 \mathfrak{q}_2 = (3), \quad \mathfrak{p} \mathfrak{q}_1 = (1 + \sqrt{-5}), \quad \mathfrak{p} \mathfrak{q}_2 = (1 - \sqrt{-5}),$$

so that the two factorisations of 6 become

$$(6) = \mathfrak{p}^2 \mathfrak{q}_1 \mathfrak{q}_2 = (\mathfrak{p} \mathfrak{q}_1)(\mathfrak{p} \mathfrak{q}_2),$$

which are the *same* factorisation into the ideals $\mathfrak{p}, \mathfrak{q}_1, \mathfrak{q}_2$, just bracketed differently. Unique factorisation was there all along; we simply could not see the factors.

§35.4.3 Arithmetic of Ideals

Let us set up the algebra. All our ideals will be ideals of $\mathcal{O}_K$, and we use the standard fraktur letters $\mathfrak{a}, \mathfrak{b}, \mathfrak{p}$ for them. Given $x_1, \dots, x_n \in \mathcal{O}_K$ we write $(x_1, \dots, x_n) = \sum_i x_i \mathcal{O}_K$ for the ideal they generate.

Definition 35.4.6 (Sum and Product of Ideals)

For ideals $\mathfrak{a}, \mathfrak{b} \subseteq \mathcal{O}_K$, define

$$\mathfrak{a} + \mathfrak{b} = \{x + y : x \in \mathfrak{a}, y \in \mathfrak{b}\}, \quad \mathfrak{a} \mathfrak{b} = \left\{ \sum_{i=1}^m x_i y_i : m \geq 0, x_i \in \mathfrak{a}, y_i \in \mathfrak{b} \right\}.$$

Both are ideals, the product is associative and commutative, and $\mathcal{O}_K = (1)$ is an identity for it. Concretely, $(x_1, \dots, x_n)(y_1, \dots, y_m) = (\{x_i y_j\}_{i,j})$; in particular $(x)(y) = (xy)$, so the principal ideals form a submonoid isomorphic to $\mathcal{O}_K \setminus \{0\}$ modulo units. Note also $\mathfrak{a} \mathfrak{b} \subseteq \mathfrak{a} \cap \mathfrak{b} \subseteq \mathfrak{a}$.

Example 35.4.7

Let us do the promised calculation in $\mathbb{Z}[\sqrt{-5}]$. With $\mathfrak{p} = (2, 1 + \sqrt{-5})$,

$$\mathfrak{p}^2 = (4, 2(1 + \sqrt{-5}), (1 + \sqrt{-5})^2) = (4, 2 + 2\sqrt{-5}, -4 + 2\sqrt{-5}).$$

Every generator is divisible by 2, so $\mathfrak{p}^2 \subseteq (2)$; and $(2 + 2\sqrt{-5}) - (-4 + 2\sqrt{-5}) = 6$, so

$\mathfrak{p}^2 \ni 6 - 4 = 2$, giving $\mathfrak{p}^2 = (2)$. Similarly with $\mathfrak{q}_1 = (3, 1 + \sqrt{-5})$, $\mathfrak{q}_2 = (3, 1 - \sqrt{-5})$,

$$\mathfrak{q}_1 \mathfrak{q}_2 = (9, 3(1 - \sqrt{-5}), 3(1 + \sqrt{-5}), 6) = (3),$$

since $9 - 6 = 3$ lies in the left-hand ideal and every generator is a multiple of 3. Finally

$$\mathfrak{p} \mathfrak{q}_1 = (6, 2(1 + \sqrt{-5}), 3(1 + \sqrt{-5}), (1 + \sqrt{-5})^2),$$

which contains $3(1 + \sqrt{-5}) - 2(1 + \sqrt{-5}) = 1 + \sqrt{-5}$; and each generator is a multiple of $1 + \sqrt{-5}$ (as $6 = (1 + \sqrt{-5})(1 - \sqrt{-5})$), so $\mathfrak{p} \mathfrak{q}_1 = (1 + \sqrt{-5})$.

Recall that an ideal $\mathfrak{p} \trianglelefteq R$ is **prime** if $R/\mathfrak{p}$ is an integral domain, equivalently $\mathfrak{p} \neq R$ and $xy \in \mathfrak{p} \Rightarrow x \in \mathfrak{p}$ or $y \in \mathfrak{p}$. *Throughout this course we additionally require prime ideals to be nonzero*, since the zero ideal is a nuisance and plays no role in factorisation.

§35.4.4 $\mathcal{O}_K$ is a Dedekind Domain

Everything we prove about factorisation rests on four properties of $\mathcal{O}_K$. We isolate them first. The key preliminary observation is that quotients of $\mathcal{O}_K$ are finite.

Lemma 35.4.8

Let K be a number field of degree n and let $\mathfrak{a} \trianglelefteq \mathcal{O}_K$ be a nonzero ideal. Then $\mathfrak{a} \cap \mathbb{Z} \neq \{0\}$, and $\mathcal{O}_K/\mathfrak{a}$ is finite. Moreover $\mathfrak{a} \cong \mathbb{Z}^n$ as an abelian group.

Proof. Pick $0 \neq \alpha \in \mathfrak{a}$ with minimal polynomial $x^m + a_{m-1}x^{m-1} + \cdots + a_0 \in \mathbb{Z}[x]$; note $a_0 \neq 0$ since the minimal polynomial is irreducible and $\alpha \neq 0$. Rearranging,

$$a_0 = -\alpha (\alpha^{m-1} + a_{m-1}\alpha^{m-2} + \cdots + a_1),$$

where the bracket lies in $\mathcal{O}_K$ and $\alpha \in \mathfrak{a}$, so $a_0 \in \mathfrak{a} \cap \mathbb{Z}$ and this is nonzero.

Now $a_0 \mathcal{O}_K \subseteq \mathfrak{a} \subseteq \mathcal{O}_K$, so $\mathcal{O}_K/a_0 \mathcal{O}_K$ surjects onto $\mathcal{O}_K/\mathfrak{a}$. But by Theorem 35.3.14, $\mathcal{O}_K \cong \mathbb{Z}^n$ as an abelian group, so

$$\mathcal{O}_K/a_0 \mathcal{O}_K \cong \mathbb{Z}^n/a_0 \mathbb{Z}^n \cong (\mathbb{Z}/a_0 \mathbb{Z})^n$$

is finite of order $|a_0|^n$. Hence $\mathcal{O}_K/\mathfrak{a}$ is finite. Finally $\mathfrak{a}$ is a subgroup of $\mathbb{Z}^n$, hence free of rank at most n ; and since $\mathcal{O}_K/\mathfrak{a}$ is finite the rank is exactly n , so $\mathfrak{a} \cong \mathbb{Z}^n$. $\square$

Proposition 35.4.9

Let K be a number field. Then

- (i) $\mathcal{O}_K$ is an integral domain;
- (ii) $\mathcal{O}_K$ is Noetherian;
- (iii) $\mathcal{O}_K$ is **integrally closed** in $K = \text{Frac}(\mathcal{O}_K)$: if $x \in K$ is integral over $\mathcal{O}_K$, then $x \in \mathcal{O}_K$;
- (iv) every nonzero prime ideal of $\mathcal{O}_K$ is maximal.

Proof. (i) $\mathcal{O}_K$ is a subring of the field K .

(ii) By Theorem 35.3.14, $\mathcal{O}_K \cong \mathbb{Z}^n$ is a Noetherian $\mathbb{Z}$ -module (every subgroup of $\mathbb{Z}^n$ is generated by at most n elements), so every ideal of $\mathcal{O}_K$ is finitely generated even as an abelian group, a fortiori as an ideal.

(iii) $\mathcal{O}_K$ is integral over $\mathbb{Z}$ by definition. If $x \in K$ is integral over $\mathcal{O}_K$ then x is integral over $\mathbb{Z}$ by transitivity (Corollary 35.2.8), so x is an algebraic integer in K , i.e. $x \in \mathcal{O}_K$.

(iv) Let $\mathfrak{p}$ be a nonzero prime. By Lemma 35.4.8, $\mathcal{O}_K/\mathfrak{p}$ is a finite integral domain, hence a field (for $0 \neq a \in \mathcal{O}_K/\mathfrak{p}$, the map $x \mapsto ax$ is injective hence surjective, so a is invertible). So $\mathfrak{p}$ is maximal. $\square$

Definition 35.4.10 (Dedekind Domain)

A **Dedekind domain** is a Noetherian, integrally closed integral domain in which every nonzero prime ideal is maximal.

So the content of Proposition 35.4.9 is that $\mathcal{O}_K$ is a Dedekind domain, and almost everything we do in this section works verbatim for a general Dedekind domain. The class of examples to have in mind besides $\mathcal{O}_K$ is the coordinate rings of smooth affine curves.

Remark. Condition (iv) is a dimension condition: it says that $\mathcal{O}_K$ has **Krull dimension** 1, i.e. the longest chain of prime ideals is $(0) \subsetneq \mathfrak{p}$. It genuinely fails in higher dimension: in $\mathbb{C}[x, y]$ the ideal (x) is prime but is properly contained in the prime (x, y) .

§35.4.5 Fractional Ideals

The goal is now unique factorisation of ideals into primes. The heart of the matter is showing that ideals have *inverses*, which forces us out of $\mathcal{O}_K$ and into K . First, two lemmas.

Lemma 35.4.11

Let $\mathfrak{p}$ be a prime ideal of a ring R and let $\mathfrak{a}, \mathfrak{b} \subseteq R$. If $\mathfrak{a}\mathfrak{b} \subseteq \mathfrak{p}$ then $\mathfrak{a} \subseteq \mathfrak{p}$ or $\mathfrak{b} \subseteq \mathfrak{p}$.

Proof. If not, pick $a \in \mathfrak{a} \setminus \mathfrak{p}$ and $b \in \mathfrak{b} \setminus \mathfrak{p}$. Then $ab \in \mathfrak{a}\mathfrak{b} \subseteq \mathfrak{p}$, contradicting primality. $\square$

Lemma 35.4.12

Let $\mathfrak{a} \subseteq \mathcal{O}_K$ be a nonzero ideal. Then $\mathfrak{a}$ contains a product of nonzero prime ideals.

Proof. Suppose not. Since $\mathcal{O}_K$ is Noetherian, the nonempty set of nonzero ideals failing the conclusion has a maximal element $\mathfrak{a}$. Now $\mathfrak{a}$ is not prime (a prime contains itself) and $\mathfrak{a} \neq \mathcal{O}_K$ (which contains any prime). So there are $x, y \in \mathcal{O}_K$ with $xy \in \mathfrak{a}$ but $x, y \notin \mathfrak{a}$. Then $\mathfrak{a} \subsetneq \mathfrak{a} + (x)$ and $\mathfrak{a} \subsetneq \mathfrak{a} + (y)$, so by maximality each of these

contains a product of primes, say $\mathfrak{p}_1 \cdots \mathfrak{p}_r \subseteq \mathfrak{a} + (x)$ and $\mathfrak{q}_1 \cdots \mathfrak{q}_s \subseteq \mathfrak{a} + (y)$. But

$$\mathfrak{p}_1 \cdots \mathfrak{p}_r \mathfrak{q}_1 \cdots \mathfrak{q}_s \subseteq (\mathfrak{a} + (x))(\mathfrak{a} + (y)) \subseteq \mathfrak{a} + (xy) = \mathfrak{a},$$

since $xy \in \mathfrak{a}$. This contradicts the choice of $\mathfrak{a}$. $\square$

The next lemma is the technical crux. Part (ii) says that the would-be inverse of a proper ideal genuinely contains something new.

Lemma 35.4.13

Let K be a number field.

(i) Let $\mathfrak{a} \leq \mathcal{O}_K$ be a nonzero ideal and $x \in K$ with $x\mathfrak{a} \subseteq \mathfrak{a}$. Then $x \in \mathcal{O}_K$.

(ii) Let $\mathfrak{a} \leq \mathcal{O}_K$ be a nonzero proper ideal. Then

$$\mathfrak{a}^* := \{y \in K : y\mathfrak{a} \subseteq \mathcal{O}_K\}$$

strictly contains $\mathcal{O}_K$.

Proof. (i) By Lemma 35.4.8, $\mathfrak{a}$ is a free abelian group with basis $\alpha_1, \dots, \alpha_n$. Since $x\mathfrak{a} \subseteq \mathfrak{a}$ we may write $x\alpha_i = \sum_j a_{ij}\alpha_j$ with $a_{ij} \in \mathbb{Z}$, so with $A = (a_{ij})$ we get $(xI - A)(\alpha_1, \dots, \alpha_n)^T = 0$. As the α_i are not all zero and we are working inside the field K , we get $\det(xI - A) = 0$. This is a monic integer polynomial relation for x , so $x \in \mathcal{O}_K$.

(ii) If the conclusion holds for $\mathfrak{a}$ it holds for any nonzero ideal contained in $\mathfrak{a}$ (as $\mathfrak{a}' \subseteq \mathfrak{a}$ gives $\mathfrak{a}^* \subseteq (\mathfrak{a}')^*$). So we may assume $\mathfrak{a} = \mathfrak{p}$ is maximal, hence prime. Pick $0 \neq \alpha \in \mathfrak{p}$. By Lemma 35.4.12 there are primes with $\mathfrak{p}_1 \cdots \mathfrak{p}_r \subseteq (\alpha) \subseteq \mathfrak{p}$; choose such a product with r minimal. By Lemma 35.4.11 some $\mathfrak{p}_i \subseteq \mathfrak{p}$, say $\mathfrak{p}_1 \subseteq \mathfrak{p}$; but $\mathfrak{p}_1$ is maximal, so $\mathfrak{p}_1 = \mathfrak{p}$.

By minimality of r we have $\mathfrak{p}_2 \cdots \mathfrak{p}_r \not\subseteq (\alpha)$ (interpreting the empty product as $\mathcal{O}_K$), so pick $\beta \in \mathfrak{p}_2 \cdots \mathfrak{p}_r \setminus (\alpha)$. Then

$$\beta\mathfrak{p} \subseteq \mathfrak{p} \mathfrak{p}_2 \cdots \mathfrak{p}_r = \mathfrak{p}_1 \cdots \mathfrak{p}_r \subseteq (\alpha),$$

so $(\beta/\alpha)\mathfrak{p} \subseteq \mathcal{O}_K$, i.e. $\beta/\alpha \in \mathfrak{p}^*$. But $\beta \notin (\alpha)$ means $\beta/\alpha \notin \mathcal{O}_K$. $\square$

Definition 35.4.14 (Fractional Ideal)

A **fractional ideal** of K is a nonzero finitely generated $\mathcal{O}_K$ -submodule of K .

To distinguish them, honest ideals $\mathfrak{a} \leq \mathcal{O}_K$ are called **integral ideals**. Products of fractional ideals are defined exactly as before.

Lemma 35.4.15

A nonzero $\mathcal{O}_K$ -submodule $\mathfrak{q} \subseteq K$ is a fractional ideal if and only if there is $0 \neq c \in \mathcal{O}_K$ with $c\mathfrak{q} \subseteq \mathcal{O}_K$ an integral ideal. In that case $\mathfrak{q} \cong \mathbb{Z}^n$ as an abelian group.

Proof. If $\mathfrak{q}$ is finitely generated, say by $x_1, \dots, x_r \in K$, write $x_i = y_i/n_i$ with $y_i \in \mathcal{O}_K$ and $n_i \in \mathbb{Z}_{\neq 0}$ (Lemma 35.2.10), and take $c = n_1 \cdots n_r$; then $c\mathfrak{q} \subseteq \mathcal{O}_K$ is an $\mathcal{O}_K$ -submodule of $\mathcal{O}_K$, i.e. an ideal. Conversely if $c\mathfrak{q}$ is a nonzero ideal then it is finitely generated (indeed $\cong \mathbb{Z}^n$ by Lemma 35.4.8), and multiplication by c is an $\mathcal{O}_K$ -module isomorphism $\mathfrak{q} \rightarrow c\mathfrak{q}$, so $\mathfrak{q}$ is finitely generated and $\mathfrak{q} \cong \mathbb{Z}^n$. $\square$

In particular, for a nonzero integral ideal $\mathfrak{a}$ the set $\mathfrak{a}^* = \{y \in K : y\mathfrak{a} \subseteq \mathcal{O}_K\}$ is a fractional ideal: it is an $\mathcal{O}_K$ -module, and $\alpha\mathfrak{a}^* \subseteq \mathcal{O}_K$ for any $0 \neq \alpha \in \mathfrak{a}$.

Theorem 35.4.16 (Invertibility of Fractional Ideals)

Every fractional ideal $\mathfrak{q}$ of K is invertible: there is a fractional ideal $\mathfrak{r}$ with $\mathfrak{q}\mathfrak{r} = \mathcal{O}_K$. Moreover

$$\mathfrak{q}^{-1} = \{x \in K : x\mathfrak{q} \subseteq \mathcal{O}_K\}.$$

Proof. By Lemma 35.4.15 we may write $\mathfrak{q} = \frac{1}{c}\mathfrak{a}$ with $\mathfrak{a}$ integral, and $\mathfrak{q}$ is invertible if and only if $\mathfrak{a}$ is (multiply an inverse by c). So it suffices to treat integral ideals.

Suppose for contradiction that some nonzero integral ideal is not invertible. As $\mathcal{O}_K$ is Noetherian, choose $\mathfrak{a}$ maximal among non-invertible nonzero integral ideals; note $\mathfrak{a} \neq \mathcal{O}_K$, which is its own inverse. Let $\mathfrak{b} = \mathfrak{a}^*$, a fractional ideal. Since $1 \in \mathcal{O}_K \subseteq \mathfrak{b}$ we have $\mathfrak{a} \subseteq \mathfrak{a}\mathfrak{b} \subseteq \mathcal{O}_K$, the last inclusion by definition of $\mathfrak{a}^*$.

If $\mathfrak{a} = \mathfrak{a}\mathfrak{b}$ then every $x \in \mathfrak{b}$ satisfies $x\mathfrak{a} \subseteq \mathfrak{a}$, so $\mathfrak{b} \subseteq \mathcal{O}_K$ by Lemma 35.4.13(i) – contradicting Lemma 35.4.13(ii). Hence $\mathfrak{a} \subsetneq \mathfrak{a}\mathfrak{b} \subseteq \mathcal{O}_K$. If $\mathfrak{a}\mathfrak{b} = \mathcal{O}_K$ then $\mathfrak{a}$ is invertible, a contradiction; so $\mathfrak{a} \subsetneq \mathfrak{a}\mathfrak{b} \subsetneq \mathcal{O}_K$, and by maximality $\mathfrak{a}\mathfrak{b}$ is invertible, say $(\mathfrak{a}\mathfrak{b})\mathfrak{c} = \mathcal{O}_K$. But then $\mathfrak{a}(\mathfrak{b}\mathfrak{c}) = \mathcal{O}_K$, so $\mathfrak{a}$ is invertible after all. Contradiction.

Finally, writing $X = \{x \in K : x\mathfrak{q} \subseteq \mathcal{O}_K\}$, certainly $\mathfrak{q}^{-1} \subseteq X$, so

$$\mathcal{O}_K = \mathfrak{q}\mathfrak{q}^{-1} \subseteq \mathfrak{q}X \subseteq \mathcal{O}_K,$$

forcing $\mathfrak{q}X = \mathcal{O}_K$ and hence $X = \mathfrak{q}^{-1}\mathfrak{q}X = \mathfrak{q}^{-1}$. $\square$

Remark. Unwinding, the theorem says exactly: *for every nonzero ideal $\mathfrak{a} \leq \mathcal{O}_K$ there is an ideal $\mathfrak{b}$ with $\mathfrak{a}\mathfrak{b}$ principal*. That is a very concrete statement, and it is the one to remember. In Example 35.4.7 we saw it in action: $\mathfrak{p}\mathfrak{p} = (2)$, $\mathfrak{q}_1\mathfrak{q}_2 = (3)$.

§35.4.6 To Contain is to Divide

Definition 35.4.17 (Divisibility of Ideals)

For ideals $\mathfrak{a}, \mathfrak{b} \leq \mathcal{O}_K$ we say $\mathfrak{a}$ **divides** $\mathfrak{b}$, written $\mathfrak{a} \mid \mathfrak{b}$, if there is an ideal $\mathfrak{c}$ with $\mathfrak{b} = \mathfrak{a}\mathfrak{c}$.

Since $\mathfrak{a}\mathfrak{c} \subseteq \mathfrak{a}$, divisibility implies containment. The converse is the slogan of the subject, and it is now a short argument.

Corollary 35.4.18 (To Contain is to Divide)

Let $\mathfrak{a}, \mathfrak{b}, \mathfrak{c} \leq \mathcal{O}_K$ be nonzero integral ideals. Then

- (i) $\mathfrak{b} \subseteq \mathfrak{a} \iff \mathfrak{b}\mathfrak{c} \subseteq \mathfrak{a}\mathfrak{c}$;

$$(ii) \mathfrak{a} \mid \mathfrak{b} \iff \mathfrak{ac} \mid \mathfrak{bc};$$

$$(iii) \mathfrak{a} \mid \mathfrak{b} \iff \mathfrak{b} \subseteq \mathfrak{a}.$$

Proof. In (i) and (ii) the forward implications are immediate, and the backward ones follow by multiplying by $\mathfrak{c}^{-1}$ and using Theorem 35.4.16. For (iii), we have already seen $\Rightarrow$. Conversely suppose $\mathfrak{b} \subseteq \mathfrak{a}$. Choose $\mathfrak{c}$ with $\mathfrak{ac} = (\alpha)$ principal (Theorem 35.4.16 and the remark following it). By (i), $\mathfrak{bc} \subseteq (\alpha)$. Writing $\mathfrak{bc} = (\beta_1, \dots, \beta_r)$, each $\beta_i \in (\alpha)$, so $\beta_i = \alpha\beta'_i$ with $\beta'_i \in \mathcal{O}_K$, giving

$$\mathfrak{bc} = (\beta'_1, \dots, \beta'_r)(\alpha) = (\beta'_1, \dots, \beta'_r)\mathfrak{ac}.$$

Cancelling $\mathfrak{c}$ by (ii) gives $\mathfrak{b} = (\beta'_1, \dots, \beta'_r)\mathfrak{a}$, so $\mathfrak{a} \mid \mathfrak{b}$. $\square$

We can now harvest the main theorem.

Theorem 35.4.19 (Unique Factorisation of Ideals)

Every nonzero ideal $\mathfrak{a} \subseteq \mathcal{O}_K$ can be written as a product of prime ideals,

$$\mathfrak{a} = \mathfrak{p}_1^{a_1} \cdots \mathfrak{p}_r^{a_r}$$

with $\mathfrak{p}_i$ distinct primes and $a_i \geq 1$, and this expression is unique up to reordering. (The empty product is $\mathcal{O}_K$.)

Proof. Existence. Suppose some nonzero ideal is not a product of primes; by Noetherianity choose $\mathfrak{a}$ maximal such. Then $\mathfrak{a} \neq \mathcal{O}_K$ (the empty product) and $\mathfrak{a}$ is not prime, so $\mathfrak{a}$ is not maximal; choose an ideal $\mathfrak{b}$ with $\mathfrak{a} \subsetneq \mathfrak{b} \subsetneq \mathcal{O}_K$. By Corollary 35.4.18(iii), $\mathfrak{a} = \mathfrak{bc}$ for some ideal $\mathfrak{c}$, and $\mathfrak{c} \supsetneq \mathfrak{a}$ with $\mathfrak{c} \neq \mathcal{O}_K$ (else $\mathfrak{ba} = \mathfrak{a}$ would give $\mathfrak{b} = \mathcal{O}_K$ on cancelling). So $\mathfrak{a} \subsetneq \mathfrak{b}$ and $\mathfrak{a} \subsetneq \mathfrak{c}$, and by maximality both $\mathfrak{b}$ and $\mathfrak{c}$ are products of primes – hence so is $\mathfrak{a}$, a contradiction.

Uniqueness. Note first that if $\mathfrak{p}$ is prime and $\mathfrak{p} \mid \mathfrak{ab}$, then $\mathfrak{ab} \subseteq \mathfrak{p}$, so $\mathfrak{a} \subseteq \mathfrak{p}$ or $\mathfrak{b} \subseteq \mathfrak{p}$ by Lemma 35.4.11, i.e. $\mathfrak{p} \mid \mathfrak{a}$ or $\mathfrak{p} \mid \mathfrak{b}$. So primes behave like primes. Now suppose $\mathfrak{p}_1 \cdots \mathfrak{p}_r = \mathfrak{q}_1 \cdots \mathfrak{q}_s$ with all factors prime (repetitions allowed). Then $\mathfrak{p}_1$ divides the right-hand side, so $\mathfrak{p}_1 \mid \mathfrak{q}_i$ for some i , say $i = 1$; then $\mathfrak{q}_1 \subseteq \mathfrak{p}_1$, and as $\mathfrak{q}_1$ is maximal, $\mathfrak{q}_1 = \mathfrak{p}_1$. Multiplying by $\mathfrak{p}_1^{-1}$ and inducting on r gives the result. $\square$

Corollary 35.4.20

The nonzero fractional ideals of K form an abelian group I_K under multiplication, and I_K is free abelian on the set of nonzero prime ideals of $\mathcal{O}_K$. A fractional ideal $\prod_{\mathfrak{p}} \mathfrak{p}^{a_{\mathfrak{p}}}$ is integral if and only if all $a_{\mathfrak{p}} \geq 0$.

Proof. It is a group by Theorem 35.4.16. Any fractional ideal is $\mathfrak{ab}^{-1}$ with $\mathfrak{a}, \mathfrak{b}$ integral (Lemma 35.4.15), so the primes generate; and freeness is the uniqueness in Theorem 35.4.19. The last statement follows since $\prod \mathfrak{p}^{a_{\mathfrak{p}}} \subseteq \mathcal{O}_K$ if and only if $\mathcal{O}_K$ divides it. $\square$

So the arithmetic of ideals in $\mathcal{O}_K$ looks exactly like the arithmetic of positive integers, with the primes of $\mathbb{Z}$ replaced by the prime ideals of $\mathcal{O}_K$. For example, given $\mathfrak{a} = \prod \mathfrak{p}^{a_{\mathfrak{p}}}$

and $\mathfrak{b} = \prod \mathfrak{p}^{b_p}$, we have $\mathfrak{a} \mid \mathfrak{b}$ iff $a_p \leq b_p$ for all $\mathfrak{p}$, and

$$\mathfrak{a} + \mathfrak{b} = \prod_{\mathfrak{p}} \mathfrak{p}^{\min(a_p, b_p)} = \gcd(\mathfrak{a}, \mathfrak{b}), \quad \mathfrak{a} \cap \mathfrak{b} = \prod_{\mathfrak{p}} \mathfrak{p}^{\max(a_p, b_p)} = \text{lcm}(\mathfrak{a}, \mathfrak{b}),$$

the first because $\mathfrak{a} + \mathfrak{b}$ is the smallest ideal containing both, i.e. the largest dividing both. The divisors of an ideal form the same sort of lattice as the divisors of an integer. Here, for instance, is the divisor lattice of $\mathfrak{a} = \mathfrak{p}^2 \mathfrak{q}$, drawn with the larger ideals – that is, the divisors – higher up.

Example 35.4.21

In $\mathbb{Z}[\sqrt{-5}]$, Example 35.4.7 gives the prime factorisations

$$(6) = \mathfrak{p}^2 \mathfrak{q}_1 \mathfrak{q}_2, \quad (2) = \mathfrak{p}^2, \quad (3) = \mathfrak{q}_1 \mathfrak{q}_2, \quad (1 + \sqrt{-5}) = \mathfrak{p} \mathfrak{q}_1, \quad (1 - \sqrt{-5}) = \mathfrak{p} \mathfrak{q}_2,$$

so that the two ‘different’ factorisations $6 = 2 \cdot 3 = (1 + \sqrt{-5})(1 - \sqrt{-5})$ correspond to the two ways of splitting $\{\mathfrak{p}, \mathfrak{p}, \mathfrak{q}_1, \mathfrak{q}_2\}$ into two pairs. (That $\mathfrak{p}, \mathfrak{q}_1, \mathfrak{q}_2$ really are prime we will see in Section 35.6; for now, note that $\mathfrak{p}^2 = (2)$ has $\mathcal{O}_K/\mathfrak{p}$ of size 2, hence a field.) Unique factorisation of ideals holds; it is unique factorisation of *elements* that fails, because not every ideal is principal.

§35.5 The Class Group and the Ideal Norm

§35.5.1 The Class Group

We have a map

$$K^\times \longrightarrow I_K, \quad x \longmapsto (x),$$

sending an element to the principal fractional ideal it generates. It is a group homomorphism since $(x)(y) = (xy)$. Its kernel is $\{x \in K^\times : (x) = \mathcal{O}_K\} = \mathcal{O}_K^\times$, and its image is the subgroup $P_K \leq I_K$ of principal fractional ideals. The cokernel is the object we want.

Definition 35.5.1 (Class Group)

The **ideal class group** of a number field K is

$$\text{Cl}_K = I_K / P_K.$$

We write $[\mathfrak{a}]$ for the class of $\mathfrak{a}$, and $h_K = |\text{Cl}_K|$ for the **class number**.

Thus $[\mathfrak{a}] = [\mathfrak{b}]$ if and only if $\mathfrak{b} = \gamma \mathfrak{a}$ for some $\gamma \in K^\times$, and $[\mathfrak{a}] = 1$ if and only if $\mathfrak{a}$ is principal. Everything fits into a single exact sequence, which is worth committing to memory:

$$1 \longrightarrow \mathcal{O}_K^\times \longrightarrow K^\times \longrightarrow I_K \longrightarrow \mathrm{Cl}_K \longrightarrow 1.$$

The two ends of this sequence are the two main theorems of the course: Cl_K is *finite*, and $\mathcal{O}_K^\times$ is finitely generated of a rank we can write down. Pictorially, Cl_K chops the group of fractional ideals into finitely many cosets of the principal ones.

The class group measures precisely the failure of unique factorisation.

Theorem 35.5.2

For a number field K the following are equivalent:

- (i) $\mathcal{O}_K$ is a principal ideal domain;
- (ii) $\mathcal{O}_K$ is a unique factorisation domain;
- (iii) Cl_K is trivial.

Proof. (i) $\iff$ (iii) is the definition, and (i) $\Rightarrow$ (ii) is a general fact from IB Groups, Rings and Modules.

For (ii) $\Rightarrow$ (i), let $\mathfrak{p}$ be a nonzero prime ideal and pick $0 \neq x \in \mathfrak{p}$. Factor $x = \alpha_1 \cdots \alpha_r$ into irreducibles. Since $\mathfrak{p}$ is prime, some $\alpha_i \in \mathfrak{p}$, so $(\alpha_i) \subseteq \mathfrak{p}$. In a UFD irreducibles are prime, so (α_i) is a nonzero prime ideal, hence maximal by Proposition 35.4.9(iv); as $\mathfrak{p} \neq \mathcal{O}_K$ we get $(\alpha_i) = \mathfrak{p}$. So every prime ideal is principal, and by Theorem 35.4.19 every ideal is a product of primes, hence principal. $\square$

Remark. This is a genuinely useful equivalence, and not one that holds in general rings: an arbitrary UFD need not be a PID ($\mathbb{Z}[x]$, say). What makes it work is Dedekind-ness, specifically that nonzero primes are maximal.

Example 35.5.3

In $\mathbb{Z}[\sqrt{-5}]$, the ideal $\mathfrak{p} = (2, 1 + \sqrt{-5})$ is not principal: if $\mathfrak{p} = (\beta)$ then $\mathfrak{p}^2 = (2)$ would give $\beta^2 = 2u$ for a unit $u = \pm 1$, so $N(\beta)^2 = 4$ and $N(\beta) = 2$; but $a^2 + 5b^2 = 2$ is insoluble. So $[\mathfrak{p}] \neq 1$ while $[\mathfrak{p}]^2 = [(2)] = 1$, and $\mathrm{Cl}_{\mathbb{Q}(\sqrt{-5})}$ contains an element of order 2. We will see in Section 35.8 that in fact $\mathrm{Cl}_{\mathbb{Q}(\sqrt{-5})} \cong \mathbb{Z}/2\mathbb{Z}$.

Example 35.5.4

Here is a useful trick in quadratic fields. Let $K = \mathbb{Q}(\sqrt{d})$ and write $\bar{\cdot}$ for the nontrivial automorphism. For an ideal $\mathfrak{a}$, the conjugate $\bar{\mathfrak{a}} = \{\bar{\alpha} : \alpha \in \mathfrak{a}\}$ is again an ideal, and $[\bar{\mathfrak{a}}] = [\mathfrak{a}]^{-1}$, because $\mathfrak{a}\bar{\mathfrak{a}}$ is always principal. Indeed one can always write $\mathfrak{a} = (b, \alpha)$

with $b \in \mathbb{Z}$, and then

$$\mathfrak{a}\bar{\mathfrak{a}} = (b^2, b\alpha, b\bar{\alpha}, \alpha\bar{\alpha}) = (b^2, b\alpha, b\operatorname{Tr}(\alpha), N(\alpha)) = (b\alpha, c),$$

where $c = \gcd(b^2, b\operatorname{Tr}(\alpha), N(\alpha))$, using $b\bar{\alpha} = b\operatorname{Tr}(\alpha) - b\alpha$. Now $x = b\alpha/c$ has $\operatorname{Tr}(x) = b\operatorname{Tr}(\alpha)/c \in \mathbb{Z}$ and $N(x) = (b^2/c)(N(\alpha)/c) \in \mathbb{Z}$, so $x \in \mathcal{O}_K$ and $c \mid b\alpha$. Hence $\mathfrak{a}\bar{\mathfrak{a}} = (c)$ is principal. In particular, in Example 35.4.7, $\mathfrak{q}_2 = \bar{\mathfrak{q}}_1$ and indeed $[\mathfrak{q}_2] = [\mathfrak{q}_1]^{-1}$.

§35.5.2 The Norm of an Ideal

We now attach a positive integer to each ideal, generalising $|N(\alpha)|$.

Definition 35.5.5 (Ideal Norm)

Let $\mathfrak{a} \subseteq \mathcal{O}_K$ be a nonzero ideal. Its **norm** is

$$N(\mathfrak{a}) = |\mathcal{O}_K/\mathfrak{a}| = [\mathcal{O}_K : \mathfrak{a}],$$

which is finite by Lemma 35.4.8.

By Lagrange's theorem $N(\mathfrak{a}) \cdot 1 = 0$ in $\mathcal{O}_K/\mathfrak{a}$, so $N(\mathfrak{a}) \in \mathfrak{a} \cap \mathbb{Z}$; equivalently $\mathfrak{a} \mid (N(\mathfrak{a}))$.

Example 35.5.6

For p a rational prime and $n = [K : \mathbb{Q}]$, we have $\mathcal{O}_K/(p) \cong (\mathbb{Z}/p\mathbb{Z})^n$, so $N((p)) = p^n$. More generally $N((m)) = |m|^n$ for $0 \neq m \in \mathbb{Z}$.

The essential property is multiplicativity, which is what makes the norm a useful book-keeping device.

Proposition 35.5.7 (Multiplicativity of the Norm)

Let $\mathfrak{a}, \mathfrak{b} \subseteq \mathcal{O}_K$ be nonzero ideals. Then $N(\mathfrak{a}\mathfrak{b}) = N(\mathfrak{a})N(\mathfrak{b})$.

Proof. By unique factorisation and induction it suffices to treat $\mathfrak{b} = \mathfrak{p}$ prime. From the tower $\mathfrak{a}\mathfrak{p} \subseteq \mathfrak{a} \subseteq \mathcal{O}_K$ and the third isomorphism theorem,

$$N(\mathfrak{a}\mathfrak{p}) = [\mathcal{O}_K : \mathfrak{a}\mathfrak{p}] = [\mathcal{O}_K : \mathfrak{a}] [\mathfrak{a} : \mathfrak{a}\mathfrak{p}] = N(\mathfrak{a}) |\mathfrak{a}/\mathfrak{a}\mathfrak{p}|,$$

so it suffices to show $|\mathfrak{a}/\mathfrak{a}\mathfrak{p}| = N(\mathfrak{p})$.

By unique factorisation $\mathfrak{a} \neq \mathfrak{a}\mathfrak{p}$, so choose $\alpha \in \mathfrak{a} \setminus \mathfrak{a}\mathfrak{p}$. We claim the map of abelian groups

$$\phi : \mathcal{O}_K/\mathfrak{p} \rightarrow \mathfrak{a}/\mathfrak{a}\mathfrak{p}, \quad x + \mathfrak{p} \mapsto \alpha x + \mathfrak{a}\mathfrak{p}$$

is a well-defined isomorphism; this gives the result. It is well defined since $\alpha\mathfrak{p} \subseteq \mathfrak{a}\mathfrak{p}$.

Injectivity. Since $(\alpha) \subseteq \mathfrak{a}$, Corollary 35.4.18 gives $(\alpha) = \mathfrak{a}\mathfrak{c}$ for some ideal $\mathfrak{c}$. Suppose $\alpha x \in \mathfrak{a}\mathfrak{p}$. Then $x\mathfrak{a}\mathfrak{c} = x(\alpha) \subseteq \mathfrak{a}\mathfrak{p}$, so multiplying by $\mathfrak{a}^{-1}$, $x\mathfrak{c} \subseteq \mathfrak{p}$. As $\mathfrak{p}$ is prime, either $x \in \mathfrak{p}$ or $\mathfrak{c} \subseteq \mathfrak{p}$. But $\mathfrak{c} \subseteq \mathfrak{p}$ would give $(\alpha) = \mathfrak{a}\mathfrak{c} \subseteq \mathfrak{a}\mathfrak{p}$, contradicting the choice of α . So $x \in \mathfrak{p}$, and ϕ is injective.

Surjectivity. We must show $(\alpha) + \mathfrak{a}\mathfrak{p} = \mathfrak{a}$. We know $\mathfrak{a}\mathfrak{p} \subsetneq (\alpha) + \mathfrak{a}\mathfrak{p} \subseteq \mathfrak{a}$, and multiplying by $\mathfrak{a}^{-1}$ gives

$$\mathfrak{p} \subsetneq ((\alpha) + \mathfrak{a}\mathfrak{p}) \mathfrak{a}^{-1} \subseteq \mathcal{O}_K.$$

Since $\mathfrak{p}$ is maximal, the middle term is $\mathcal{O}_K$, so $(\alpha) + \mathfrak{a}\mathfrak{p} = \mathfrak{a}$ as required. $\square$

Remark. The conceptual proof runs as follows. By the Chinese remainder theorem $\mathcal{O}_K / \prod \mathfrak{p}_i^{a_i} \cong \prod \mathcal{O}_K / \mathfrak{p}_i^{a_i}$, so we reduce to prime powers; and then

$$|\mathcal{O}_K / \mathfrak{p}^e| = |\mathcal{O}_K / \mathfrak{p}| \cdot |\mathfrak{p} / \mathfrak{p}^2| \cdots |\mathfrak{p}^{e-1} / \mathfrak{p}^e| = N(\mathfrak{p})^e,$$

because each $\mathfrak{p}^i / \mathfrak{p}^{i+1}$ is a 1-dimensional vector space over the field $\mathcal{O}_K / \mathfrak{p}$ (it is nonzero by unique factorisation, and any $x \in \mathfrak{p}^i \setminus \mathfrak{p}^{i+1}$ generates, since $(x) + \mathfrak{p}^{i+1} = \mathfrak{p}^i$ by the maximality argument above). This last point is special to Dedekind domains: in $\mathbb{F}_p[x, y]$ with $\mathfrak{p} = (x, y)$ the quotient $\mathfrak{p} / \mathfrak{p}^2$ is 2-dimensional. The proof we gave packages both steps at once.

The norm of an ideal and the norm of an element agree where they should.

Lemma 35.5.8

Let $0 \neq \alpha \in \mathcal{O}_K$. Then $N((\alpha)) = |N_{K/\mathbb{Q}}(\alpha)|$.

Proof. Let $\gamma_1, \dots, \gamma_n$ be an integral basis of $\mathcal{O}_K$; then $\alpha\gamma_1, \dots, \alpha\gamma_n$ is a $\mathbb{Z}$ -basis of (α) . Using Proposition 35.3.9,

$$\begin{aligned} \Delta(\alpha\gamma_1, \dots, \alpha\gamma_n) &= \det(\sigma_i(\alpha\gamma_j))^2 = \det(\sigma_i(\alpha)\sigma_i(\gamma_j))^2 \\ &= \left(\prod_i \sigma_i(\alpha) \right)^2 \det(\sigma_i(\gamma_j))^2 = N_{K/\mathbb{Q}}(\alpha)^2 d_K. \end{aligned}$$

On the other hand, by Lemma 35.3.19 applied to the $\mathbb{Z}$ -basis $\alpha\gamma_i$ of (α) ,

$$\Delta(\alpha\gamma_1, \dots, \alpha\gamma_n) = [\mathcal{O}_K : (\alpha)]^2 d_K = N((\alpha))^2 d_K.$$

Comparing and taking positive square roots gives the result. $\square$

More generally the same computation identifies the discriminant of any ideal.

Lemma 35.5.9

Let $\mathfrak{a} \subseteq \mathcal{O}_K$ be a nonzero ideal and let $\alpha_1, \dots, \alpha_n$ be a $\mathbb{Z}$ -basis of $\mathfrak{a}$ (which exists by Lemma 35.4.8). Then the α_i form a $\mathbb{Q}$ -basis of K and

$$\Delta(\alpha_1, \dots, \alpha_n) = N(\mathfrak{a})^2 d_K.$$

Proof. This is exactly Lemma 35.3.19 with $M = \mathfrak{a}$, once we note that $[\mathcal{O}_K : \mathfrak{a}] = N(\mathfrak{a})$ and that a $\mathbb{Z}$ -basis of $\mathfrak{a}$ is a $\mathbb{Q}$ -basis of K (since $\mathfrak{a} \supseteq m\mathcal{O}_K$ for some $m \neq 0$, and $\mathfrak{a}$ has rank n). $\square$

We record two consequences that we shall use constantly.

Corollary 35.5.10

Let K be a number field.

- (i) For each $m \geq 1$ there are only finitely many ideals $\mathfrak{a} \leq \mathcal{O}_K$ with $N(\mathfrak{a}) = m$.
- (ii) If $N(\mathfrak{a})$ is prime then $\mathfrak{a}$ is a prime ideal.
- (iii) If $\mathfrak{a} \subseteq \mathfrak{b}$ and $N(\mathfrak{a}) = N(\mathfrak{b})$ then $\mathfrak{a} = \mathfrak{b}$.

Proof. (i) If $N(\mathfrak{a}) = m$ then $m \in \mathfrak{a}$, so $\mathfrak{a} \mid (m)$; and (m) has only finitely many divisors by unique factorisation. (Alternatively: such $\mathfrak{a}$ correspond to ideals of the finite ring $\mathcal{O}_K/m\mathcal{O}_K$.)

(ii) $\mathcal{O}_K/\mathfrak{a}$ has prime order, so is $\mathbb{Z}/p\mathbb{Z}$, a field; hence $\mathfrak{a}$ is maximal, so prime.

(iii) By Corollary 35.4.18, $\mathfrak{a} = \mathfrak{b}\mathfrak{c}$ for some ideal $\mathfrak{c}$, and taking norms $N(\mathfrak{c}) = 1$, so $\mathfrak{c} = \mathcal{O}_K$. $\square$

§35.6 Factorisation of Primes

Unique factorisation of ideals reduces all questions about ideals to questions about prime ideals, so we had better understand what the prime ideals of $\mathcal{O}_K$ look like. It turns out that they all sit above rational primes, and that finding them amounts to factoring polynomials mod p .

§35.6.1 Primes Above p **Lemma 35.6.1**

Let $\mathfrak{p} \leq \mathcal{O}_K$ be a nonzero prime ideal. Then there is a unique rational prime p with $\mathfrak{p} \mid (p)$, namely the one with $\mathfrak{p} \cap \mathbb{Z} = p\mathbb{Z}$. Moreover $N(\mathfrak{p}) = p^f$ for some $1 \leq f \leq n = [K : \mathbb{Q}]$.

Proof. $\mathfrak{p} \cap \mathbb{Z}$ is an ideal of $\mathbb{Z}$, hence $= m\mathbb{Z}$ for some $m \geq 0$, and $m \neq 0$ by Lemma 35.4.8. If $m = ab$ with $a, b \in \mathbb{Z}$, then $ab \in \mathfrak{p}$ so $a \in \mathfrak{p}$ or $b \in \mathfrak{p}$, giving $m \mid a$ or $m \mid b$; hence $m = p$ is prime. Then $p \in \mathfrak{p}$, so $(p) \subseteq \mathfrak{p}$ and $\mathfrak{p} \mid (p)$ by Corollary 35.4.18. Uniqueness is clear since $\mathfrak{p} \cap \mathbb{Z}$ determines p , and if $\mathfrak{p} \mid (q)$ for a prime $q \neq p$ then $q \in \mathfrak{p} \cap \mathbb{Z} = p\mathbb{Z}$, absurd.

Writing $(p) = \mathfrak{p}\mathfrak{a}$ and taking norms, $p^n = N(\mathfrak{p})N(\mathfrak{a})$, so $N(\mathfrak{p}) = p^f$ with $1 \leq f \leq n$ (note $N(\mathfrak{p}) > 1$ as $\mathfrak{p} \neq \mathcal{O}_K$). $\square$

So to find all the prime ideals of $\mathcal{O}_K$, it is enough to factorise (p) for each rational prime p . This motivates the following language.

Definition 35.6.2 (Ramification Index and Residue Degree)

Let p be a rational prime and let

$$p\mathcal{O}_K = \mathfrak{p}_1^{e_1} \cdots \mathfrak{p}_g^{e_g}$$

be its factorisation into distinct primes. We say $\mathfrak{p}_i$ **lies above** p , written $\mathfrak{p}_i \mid p$. The integer e_i is the **ramification index** of $\mathfrak{p}_i$ over p , and f_i defined by $N(\mathfrak{p}_i) = p^{f_i}$ is the **residue degree**. Equivalently $f_i = [\mathcal{O}_K/\mathfrak{p}_i : \mathbb{F}_p]$, since $\mathcal{O}_K/\mathfrak{p}_i$ is a finite field containing $\mathbb{F}_p = \mathbb{Z}/p\mathbb{Z}$.

Theorem 35.6.3 (The Fundamental Identity)

With the notation above, $\sum_{i=1}^g e_i f_i = n = [K : \mathbb{Q}]$.

Proof. Take norms in $p\mathcal{O}_K = \prod_i \mathfrak{p}_i^{e_i}$ and use Proposition 35.5.7:

$$p^n = N((p)) = \prod_i N(\mathfrak{p}_i)^{e_i} = p^{\sum_i e_i f_i}. \quad \square$$

The picture to have in mind is a tower, with p at the bottom in $\mathbb{Z}$ and the primes above it in $\mathcal{O}_K$, each labelled with its e and f .

Definition 35.6.4 (Split, Inert, Ramified)

Let p be a rational prime and $p\mathcal{O}_K = \prod_i \mathfrak{p}_i^{e_i}$ as above. We say p is

- **ramified** in K if $e_i > 1$ for some i , and **unramified** otherwise;
- **inert** in K if $g = 1$ and $e_1 = 1$, so that (p) stays prime;
- **totally split** (or **split completely**) if $g = n$, so that $e_i = f_i = 1$ for all i ;
- **totally ramified** if $g = 1$ and $e_1 = n$.

We will see that only finitely many primes ramify, namely the divisors of d_K .

In the Galois case the picture is much more uniform, because the Galois group shuffles the primes above p among themselves.

Proposition 35.6.5 (Splitting in Galois Extensions)

Let $K/\mathbb{Q}$ be Galois with group G , and let p be a rational prime with $p\mathcal{O}_K = \mathfrak{p}_1^{e_1} \cdots \mathfrak{p}_g^{e_g}$. Then G acts transitively on $\{\mathfrak{p}_1, \dots, \mathfrak{p}_g\}$. Consequently $e_1 = \cdots = e_g =: e$ and $f_1 = \cdots = f_g =: f$, and

$$efg = n = [K : \mathbb{Q}].$$

Proof. First note that G preserves $\mathcal{O}_K$: if α satisfies a monic $h \in \mathbb{Z}[x]$ and $\tau \in G$, then $h(\tau\alpha) = \tau(h(\alpha)) = 0$, so $\tau\alpha \in \mathcal{O}_K$. Hence τ permutes the ideals of $\mathcal{O}_K$, preserving primality and fixing (p) , so it permutes $\{\mathfrak{p}_1, \dots, \mathfrak{p}_g\}$.

Suppose the action is not transitive, so some $\mathfrak{q} = \mathfrak{p}_j$ is not of the form $\tau(\mathfrak{p}_1)$ for any τ . By the Chinese remainder theorem (the $\tau(\mathfrak{p}_1)$ and $\mathfrak{q}$ being distinct maximal ideals) pick $x \in \mathcal{O}_K$ with

$$x \equiv 0 \pmod{\mathfrak{q}}, \quad x \equiv 1 \pmod{\tau(\mathfrak{p}_1)} \text{ for all } \tau \in G.$$

Then $N_{K/\mathbb{Q}}(x) = \prod_{\tau \in G} \tau(x) \in \mathfrak{q} \cap \mathbb{Z} = p\mathbb{Z} \subseteq \mathfrak{p}_1$, so some $\tau(x) \in \mathfrak{p}_1$, i.e. $x \in \tau^{-1}(\mathfrak{p}_1)$ – contradicting $x \equiv 1$ there.

Finally, applying τ to the factorisation of (p) permutes the $\mathfrak{p}_i$ while fixing (p) , so by uniqueness the exponents match up: $e_i = e_j$ whenever $\tau(\mathfrak{p}_i) = \mathfrak{p}_j$. And τ induces an isomorphism $\mathcal{O}_K/\mathfrak{p}_i \rightarrow \mathcal{O}_K/\tau(\mathfrak{p}_i)$, so the f_i agree too. Transitivity then makes all e_i and all f_i equal, and Theorem 35.6.3 becomes $efg = n$. $\square$

Example 35.6.6

In $\mathbb{Q}(i)$, $n = 2$, so (e, f, g) is $(1, 1, 2)$ for split primes, $(1, 2, 1)$ for inert primes and $(2, 1, 1)$ for the ramified prime 2 – exactly the trichotomy of Proposition 35.6.11. In $\mathbb{Q}(\zeta_7)$, $n = 6$, and the possible unramified behaviours are $(1, f, 6/f)$ for $f \mid 6$. Contrast this with $\mathbb{Q}(\sqrt[3]{2})$, which is *not* Galois: there we found $(5) = \mathfrak{p}_1\mathfrak{p}_2$ with $f_1 = 1$ and $f_2 = 2$, which is impossible in a Galois extension.

§35.6.2 Dedekind's Criterion

Suppose we can write $\mathcal{O}_K = \mathbb{Z}[\alpha]$ for some α with minimal polynomial $g \in \mathbb{Z}[x]$. Then

$$\mathcal{O}_K/p\mathcal{O}_K \cong \mathbb{Z}[x]/(g(x), p) \cong \mathbb{F}_p[x]/(\bar{g}(x)),$$

and the ideals of $\mathcal{O}_K$ containing p correspond to the ideals of this ring, which correspond in turn to the monic factors of $\bar{g}$ in $\mathbb{F}_p[x]$. So factoring (p) becomes factoring a polynomial mod p – a completely mechanical task. Remarkably, this works even when $\mathbb{Z}[\alpha] \neq \mathcal{O}_K$, provided p does not divide the index.

Theorem 35.6.7 (Dedekind's Criterion)

Let K be a number field, let $\alpha \in \mathcal{O}_K$ with $K = \mathbb{Q}(\alpha)$ and minimal polynomial $g \in \mathbb{Z}[x]$, and let p be a prime with $p \nmid [\mathcal{O}_K : \mathbb{Z}[\alpha]]$. Let

$$\bar{g} = \bar{\varphi}_1^{e_1} \cdots \bar{\varphi}_g^{e_g}$$

be the factorisation of $\bar{g} = g \bmod p$ into distinct monic irreducibles in $\mathbb{F}_p[x]$, and lift each $\bar{\varphi}_i$ to a monic $\varphi_i \in \mathbb{Z}[x]$ of the same degree. Then

$$p\mathcal{O}_K = \mathfrak{p}_1^{e_1} \cdots \mathfrak{p}_g^{e_g}, \quad \mathfrak{p}_i = (p, \varphi_i(\alpha)),$$

the $\mathfrak{p}_i$ are distinct primes, and $N(\mathfrak{p}_i) = p^{f_i}$ with $f_i = \deg \varphi_i$.

Proof. Step 1: the ideals $\mathfrak{q}_i = (p, \varphi_i(\alpha)) \trianglelefteq \mathbb{Z}[\alpha]$ are prime with $\mathbb{Z}[\alpha]/\mathfrak{q}_i \cong \mathbb{F}_p[x]/(\bar{\varphi}_i)$. Consider the surjective ring homomorphism $\mathbb{Z}[x] \rightarrow \mathbb{F}_p[x]/(\bar{\varphi}_i)$ given by reduction mod p followed by reduction mod $\bar{\varphi}_i$. Its kernel contains p and φ_i ; conversely, if f maps to zero then $\bar{\varphi}_i \mid \bar{f}$, so $\bar{f} = \bar{\varphi}_i \bar{h}$ for some $\bar{h}$, and lifting $\bar{h}$ to $h \in \mathbb{Z}[x]$ gives $f - \varphi_i h \in p\mathbb{Z}[x]$. So the kernel is exactly (p, φ_i) . Since $g(\alpha) = 0$ and $\bar{\varphi}_i \mid \bar{g}$, the map factors through $\mathbb{Z}[x]/(g) \cong \mathbb{Z}[\alpha]$, and the same argument shows that the induced map $\mathbb{Z}[\alpha] \rightarrow \mathbb{F}_p[x]/(\bar{\varphi}_i)$ has kernel $\mathfrak{q}_i = (p, \varphi_i(\alpha))$. As $\bar{\varphi}_i$ is irreducible, $\mathbb{F}_p[x]/(\bar{\varphi}_i) \cong \mathbb{F}_{p^{f_i}}$ is a field, so $\mathfrak{q}_i$ is prime with $|\mathbb{Z}[\alpha]/\mathfrak{q}_i| = p^{f_i}$.

Step 2: $\iota : \mathbb{Z}[\alpha]/p\mathbb{Z}[\alpha] \rightarrow \mathcal{O}_K/p\mathcal{O}_K$ is an isomorphism. Write $M = \mathcal{O}_K/\mathbb{Z}[\alpha]$, a finite abelian group of order coprime to p by hypothesis. Multiplication by p on M is injective (its kernel is a p -group inside a group of order prime to p), hence bijective as M is finite. Now the kernel of ι is $(\mathbb{Z}[\alpha] \cap p\mathcal{O}_K)/p\mathbb{Z}[\alpha]$, and an element of this is $x \in \mathbb{Z}[\alpha]$ with $x = py$, $y \in \mathcal{O}_K$; then $py \equiv 0$ in M , so $y \in \mathbb{Z}[\alpha]$ and $x \in p\mathbb{Z}[\alpha]$. So ι is injective. For surjectivity we need $\mathcal{O}_K = \mathbb{Z}[\alpha] + p\mathcal{O}_K$, i.e. $pM = M$, which is the surjectivity of multiplication by p on M . Comparing orders, ι is an isomorphism.

Step 3. By Step 2, ideals of $\mathcal{O}_K$ containing p correspond to ideals of $\mathbb{Z}[\alpha]$ containing p , with $\mathfrak{q} \mapsto \mathfrak{q}\mathcal{O}_K$ and $\mathfrak{p} \mapsto \mathfrak{p} \cap \mathbb{Z}[\alpha]$, and the quotients agree. So each $\mathfrak{p}_i := \mathfrak{q}_i\mathcal{O}_K = (p, \varphi_i(\alpha))$ is a prime ideal of $\mathcal{O}_K$ with $N(\mathfrak{p}_i) = p^{f_i}$, and $\mathfrak{p}_i \neq \mathfrak{p}_j$ for $i \neq j$ since $\bar{\varphi}_i, \bar{\varphi}_j$ are coprime, whence $\mathfrak{q}_i + \mathfrak{q}_j = \mathbb{Z}[\alpha]$.

Step 4: the factorisation. Since $(p, \varphi_i(\alpha))^{e_i} \subseteq (p, \varphi_i(\alpha)^{e_i})$, we get

$$\mathfrak{p}_1^{e_1} \cdots \mathfrak{p}_g^{e_g} \subseteq (p, \varphi_1(\alpha)^{e_1} \cdots \varphi_g(\alpha)^{e_g}).$$

Now $\overline{\varphi_1^{e_1} \cdots \varphi_g^{e_g}} = \bar{g}$, so $\varphi_1^{e_1} \cdots \varphi_g^{e_g} = g + ps$ for some $s \in \mathbb{Z}[x]$, and evaluating at α (where $g(\alpha) = 0$) shows the right-hand ideal is $(p, ps(\alpha)) = (p)$. So $\prod_i \mathfrak{p}_i^{e_i} \subseteq (p)$. But $\deg g = n$ gives $\sum_i e_i f_i = n$, so

$$N\left(\prod_i \mathfrak{p}_i^{e_i}\right) = p^{\sum_i e_i f_i} = p^n = N((p)),$$

and Corollary 35.5.10(iii) forces equality. $\square$

Remark. The hypothesis $p \nmid [\mathcal{O}_K : \mathbb{Z}[\alpha]]$ is essential but mild in practice: for any fixed α generating K with $\alpha \in \mathcal{O}_K$, only finitely many primes divide the index, so Dedekind's criterion factors (p) for all but finitely many p . Different lifts φ_i give the same ideal, since they differ by a multiple of $p \in \mathfrak{p}_i$.

Example 35.6.8

Let $K = \mathbb{Q}(\sqrt[3]{2})$, so $\mathcal{O}_K = \mathbb{Z}[\sqrt[3]{2}]$ and $g = x^3 - 2$; the index is 1, so Dedekind applies to every p .

- (i) $p = 2$: $\bar{g} = x^3$, so $(2) = \mathfrak{p}^3$ with $\mathfrak{p} = (2, \sqrt[3]{2}) = (\sqrt[3]{2})$. So 2 is totally ramified, with $e = 3, f = 1$.
- (ii) $p = 3$: $\bar{g} = x^3 - 2 = x^3 + 1 = (x + 1)^3$ in $\mathbb{F}_3[x]$, so $(3) = (3, 1 + \sqrt[3]{2})^3$; again totally ramified.
- (iii) $p = 5$: 2 is a cube mod 5 (namely $3^3 = 27 \equiv 2$), and $x^3 - 2 = (x - 3)(x^2 + 3x + 4)$ in $\mathbb{F}_5[x]$, the quadratic factor being irreducible as its discriminant $9 - 16 =$

$-7 \equiv 3$ is not a square mod 5. So

$$(5) = (5, \sqrt[3]{2} - 3) (5, \sqrt[3]{4} + 3\sqrt[3]{2} + 4),$$

with $(e, f) = (1, 1)$ and $(1, 2)$; indeed $1 \cdot 1 + 1 \cdot 2 = 3$.

(iv) $p = 7$: the cubes mod 7 are $\{0, 1, 6\}$, so $x^3 - 2$ has no root mod 7; being cubic it is irreducible, and 7 is inert with $f = 3$.

(v) $p = 31$: here $x^3 - 2 \equiv (x - 4)(x - 7)(x - 20)$, so 31 is totally split.

Notice that 2 and 3 ramify, and $d_K = -108 = -2^2 \cdot 3^3$. This is not a coincidence.

Example 35.6.9 (A Non-Monogenic Field)

Return to $K = \mathbb{Q}(\alpha)$ with $\alpha^3 - \alpha^2 - 2\alpha - 8 = 0$, where $d_K = -503$ and $[\mathcal{O}_K : \mathbb{Z}[\alpha]] = 2$ (Example 35.3.17). Dedekind's criterion does *not* apply at $p = 2$; and indeed $\bar{g} = x^2(x + 1)$ in $\mathbb{F}_2[x]$ would predict $(2) = \mathfrak{p}^2\mathfrak{q}$, which is wrong. In fact 2 splits completely, $(2) = \mathfrak{p}_1\mathfrak{p}_2\mathfrak{p}_3$ with all $e_i = f_i = 1$ (one checks this using the integral basis $1, \alpha, \beta$).

This has a striking consequence: for *every* $\gamma \in \mathcal{O}_K \setminus \mathbb{Z}$, the index $[\mathcal{O}_K : \mathbb{Z}[\gamma]]$ is even, so $\mathcal{O}_K \neq \mathbb{Z}[\gamma]$. Indeed, if $2 \nmid [\mathcal{O}_K : \mathbb{Z}[\gamma]]$ then Dedekind's criterion would say that the minimal polynomial of γ has three distinct roots in $\mathbb{F}_2$ – but $\mathbb{F}_2$ only has two elements. So K has no integral basis of the form $1, \gamma, \gamma^2$: it is not **monogenic**. The same argument gives a general obstruction.

Corollary 35.6.10

Let $p < n = [K : \mathbb{Q}]$ be a prime and suppose $\mathcal{O}_K = \mathbb{Z}[\alpha]$ for some α . Then p does not split completely in K .

Proof. If p split completely then, by Dedekind's criterion, the minimal polynomial of α would have n distinct roots in $\mathbb{F}_p$; but $|\mathbb{F}_p| = p < n$. $\square$

§35.6.3 Primes in Quadratic Fields

The quadratic case is worth doing completely, because it is where we shall do most of our computations, and because the answer is a beautiful reformulation of quadratic reciprocity.

Proposition 35.6.11

Let $K = \mathbb{Q}(\sqrt{d})$ with d squarefree, and let p be an odd prime. Then

$$p\mathcal{O}_K = \begin{cases} \mathfrak{p}_1\mathfrak{p}_2 \text{ with } \mathfrak{p}_1 \neq \mathfrak{p}_2 & \text{if } \left(\frac{d}{p}\right) = 1 \quad (p \text{ splits}), \\ \mathfrak{p} \text{ prime} & \text{if } \left(\frac{d}{p}\right) = -1 \quad (p \text{ inert}), \\ \mathfrak{p}^2 & \text{if } p \mid d \quad (p \text{ ramifies}), \end{cases}$$

where $\left(\frac{\cdot}{p}\right)$ is the Legendre symbol. Explicitly, if $r^2 \equiv d \pmod{p}$ then $\mathfrak{p}_{1,2} = (p, \sqrt{d} \mp r)$.

$r)$, and in the ramified case $\mathfrak{p} = (p, \sqrt{d})$.

Proof. Whether $d \equiv 1 \pmod{4}$ or not, $\mathbb{Z}[\sqrt{d}] \subseteq \mathcal{O}_K$ has index 1 or 2, which is coprime to the odd prime p . So Dedekind's criterion applies with $\alpha = \sqrt{d}$, $g = x^2 - d$, and we simply factor $x^2 - d$ in $\mathbb{F}_p[x]$: it has two distinct roots, no roots, or a repeated root according as d is a nonzero square, a nonsquare, or zero mod p . $\square$

The prime 2 needs separate treatment, and here the $d \pmod{4}$ dichotomy resurfaces.

Lemma 35.6.12

Let $K = \mathbb{Q}(\sqrt{d})$ with d squarefree. Then 2 splits if $d \equiv 1 \pmod{8}$, is inert if $d \equiv 5 \pmod{8}$, and ramifies if $d \equiv 2, 3 \pmod{4}$.

Proof. If $d \equiv 1 \pmod{4}$ then $\mathcal{O}_K = \mathbb{Z}[\alpha]$ with $\alpha = \frac{1}{2}(1 + \sqrt{d})$, whose minimal polynomial is $x^2 - x + \frac{1}{4}(1 - d)$; the index is 1 so Dedekind applies. Modulo 2 this is $x^2 + x + c$ where $c = \frac{1}{4}(1 - d) \pmod{2}$. If $d \equiv 1 \pmod{8}$ then $c = 0$ and we get $x(x + 1)$, so 2 splits. If $d \equiv 5 \pmod{8}$ then $c = 1$ and $x^2 + x + 1$ is irreducible over $\mathbb{F}_2$, so 2 is inert.

If $d \equiv 2, 3 \pmod{4}$ then $\mathcal{O}_K = \mathbb{Z}[\sqrt{d}]$ and $x^2 - d$ reduces mod 2 to x^2 or $x^2 + 1 = (x + 1)^2$, so 2 ramifies. $\square$

Comparing with Example 35.3.16 – where $d_K = d$ if $d \equiv 1 \pmod{4}$ and $4d$ otherwise – gives a clean statement.

Corollary 35.6.13

Let $K = \mathbb{Q}(\sqrt{d})$ be a quadratic field. A prime p ramifies in K if and only if $p \mid d_K$.

Proof. For odd p : p ramifies iff $p \mid d$, and since $d_K \in \{d, 4d\}$ this holds iff $p \mid d_K$. For $p = 2$: by Lemma 35.6.12, 2 ramifies iff $d \equiv 2, 3 \pmod{4}$, which is exactly when $d_K = 4d$ is even; and if $d \equiv 1 \pmod{4}$ then $d_K = d$ is odd. $\square$

Here are the three behaviours side by side, drawn as towers.

Example 35.6.14

Let $K = \mathbb{Q}(\sqrt{-5})$, so $d_K = -20$.

- $p = 2$: $-5 \equiv 3 \pmod{4}$, so 2 ramifies: $(2) = (2, 1 + \sqrt{-5})^2$, as we computed directly in Example 35.4.7.
- $p = 3$: $x^2 + 5 \equiv x^2 - 1 = (x - 1)(x + 1) \pmod{3}$, so $(3) = (3, \sqrt{-5} - 1)(3, \sqrt{-5} + 1)$

1).

- $p = 5$: $5 \mid d_K$, so 5 ramifies: $(5) = (\sqrt{-5})^2$.
- $p = 7$: the squares mod 7 are 1, 2, 4, and $-5 \equiv 2$, so 7 splits: indeed $x^2 + 5 \equiv (x-3)(x+3) \pmod{7}$.
- $p = 11$: $-5 \equiv 6 \pmod{11}$, and 6 is not a square mod 11, so 11 is inert.

This confirms in particular that the ideals $\mathfrak{p}, \mathfrak{q}_1, \mathfrak{q}_2$ of Example 35.4.7 really are prime.

Example 35.6.15

Let $K = \mathbb{Q}(\sqrt{-11})$, so $-11 \equiv 1 \pmod{4}$ and $\mathcal{O}_K = \mathbb{Z}[\frac{1}{2}(1 + \sqrt{-11})]$, in which $\mathbb{Z}[\sqrt{-11}]$ has index 2. To factor (5) we may use $\alpha = \sqrt{-11}$, since $5 \nmid 2$: modulo 5 we have $x^2 + 11 \equiv x^2 + 1 = (x-2)(x+2)$, so

$$(5) = (5, \sqrt{-11} - 2)(5, \sqrt{-11} + 2).$$

§35.6.4 Ramification and the Discriminant

Corollary 35.6.13 is a special case of a general and important theorem.

Theorem 35.6.16 (Ramification and the Discriminant)

Let K be a number field and p a rational prime. Then p ramifies in K if and only if $p \mid d_K$. In particular only finitely many primes ramify.

We shall not give the full proof, but the idea in the direction we use most is clear from Dedekind's criterion: if $\mathcal{O}_K = \mathbb{Z}[\alpha]$ with minimal polynomial g , then p ramifies exactly when $\bar{g}$ has a repeated factor in $\mathbb{F}_p[x]$, which happens exactly when $\text{disc}(\bar{g}) = 0$ in $\mathbb{F}_p$, i.e. when $p \mid \text{disc}(g) = d_K$. The general case is handled by reducing to this one after localising.

Example 35.6.17

In Example 35.6.8 we found that exactly 2 and 3 ramify in $\mathbb{Q}(\sqrt[3]{2})$, and $d_K = -108 = -2^2 3^3$. In Example 35.6.9, $d_K = -503$ is prime, so 503 is the only ramified prime; in particular 2 is unramified, consistent with $(2) = \mathfrak{p}_1 \mathfrak{p}_2 \mathfrak{p}_3$.

The theorem has a famous consequence, once we know (Section 35.7) that $|d_K| > 1$ whenever $K \neq \mathbb{Q}$: *every number field other than $\mathbb{Q}$ has at least one ramified prime*. Equivalently, $\mathbb{Q}$ admits no unramified extensions. This is the arithmetic analogue of the fact that the sphere is simply connected.

§35.6.5 Cyclotomic Fields

We finish the section with the other family of number fields that everyone should know. Let $\zeta = \zeta_m = e^{2\pi i/m}$ and $K = \mathbb{Q}(\zeta_m)$, the m th **cyclotomic field**.

Proposition 35.6.18

Let $K = \mathbb{Q}(\zeta_m)$. Then

- (i) $[K : \mathbb{Q}] = \varphi(m)$, and $K/\mathbb{Q}$ is Galois with $\text{Gal}(K/\mathbb{Q}) \cong (\mathbb{Z}/m\mathbb{Z})^\times$, the class of r acting by $\zeta_m \mapsto \zeta_m^r$;
- (ii) $\mathcal{O}_K = \mathbb{Z}[\zeta_m]$;
- (iii) a prime p ramifies in K if and only if $p \mid m$ (for $m \not\equiv 2 \pmod{4}$);
- (iv) if $p \nmid m$, then $p\mathcal{O}_K$ is a product of $\varphi(m)/f$ distinct primes each of residue degree f , where f is the multiplicative order of p modulo m . In particular p splits completely if and only if $p \equiv 1 \pmod{m}$.

Proof. Parts (i) is from Galois Theory: the minimal polynomial of ζ_m is the cyclotomic polynomial Φ_m , of degree $\varphi(m)$. Part (ii) we take on trust in general (for $m = p$ prime it is a standard exercise, sketched below), and (iii) follows from (ii) and Theorem 35.6.16.

For (iv), assume $p \nmid m$; by (ii) and Theorem 35.6.7 we must factor Φ_m in $\mathbb{F}_p[x]$. Since $p \nmid m$, the polynomial $x^m - 1$ is separable mod p , so $\bar{\Phi}_m = \bar{\gamma}_1 \cdots \bar{\gamma}_g$ with distinct irreducible factors $\bar{\gamma}_i$ (this re-proves that p is unramified). The Galois group $G \cong (\mathbb{Z}/m\mathbb{Z})^\times$ preserves $\mathcal{O}_K$, hence acts on the set of primes above p , and acts transitively on the roots of Φ_m ; so it permutes the $\bar{\gamma}_i$ transitively and they all have the same degree f' , say, with $gf' = \varphi(m)$.

It remains to show $f' = f = \text{ord}_m(p)$. In $\mathbb{F}_p[x]/(\bar{\gamma}_1) \cong \mathbb{F}_{p^{f'}}$, the image of x is the image of ζ_m , which is a root of $x^m - 1$ of exact order m (as $x^m - 1$ is separable mod p and $\Phi_m \mid x^m - 1$). So m divides $|\mathbb{F}_{p^{f'}}^\times| = p^{f'} - 1$, giving $p^{f'} \equiv 1 \pmod{m}$ and hence $f \mid f'$. Conversely the Frobenius $\alpha \mapsto \alpha^p$ generates $\text{Gal}(\mathbb{F}_{p^{f'}}/\mathbb{F}_p)$, and it acts on ζ_m as the element $p \in (\mathbb{Z}/m\mathbb{Z})^\times$, which has order f ; so $f' \mid f$. Hence $f = f'$. $\square$

Example 35.6.19 (The Prime Case)

Let p be an odd prime and $K = \mathbb{Q}(\zeta_p)$, so $[K : \mathbb{Q}] = p - 1$. Put $\lambda = 1 - \zeta_p$. Since

$$\Phi_p(x) = \frac{x^p - 1}{x - 1} = \prod_{k=1}^{p-1} (x - \zeta_p^k),$$

setting $x = 1$ gives

$$p = \Phi_p(1) = \prod_{k=1}^{p-1} (1 - \zeta_p^k) = N_{K/\mathbb{Q}}(\lambda).$$

Moreover $(1 - \zeta_p^k)/(1 - \zeta_p) = 1 + \zeta_p + \cdots + \zeta_p^{k-1} \in \mathbb{Z}[\zeta_p]$ is a unit for $1 \leq k \leq p - 1$ (its inverse is $(1 - \zeta_p)/(1 - \zeta_p^k)$, of the same shape after writing $\zeta_p = (\zeta_p^k)^{k'}$ with $kk' \equiv 1$). Hence all the $1 - \zeta_p^k$ are associates and

$$(p) = (\lambda)^{p-1}.$$

So p is totally ramified in $\mathbb{Q}(\zeta_p)$, with $e = p - 1$, $f = g = 1$, and $N((\lambda)) = p$, so (λ) is prime.

One deduces $\mathcal{O}_K = \mathbb{Z}[\zeta_p]$ as follows. From $\text{disc}(\Phi_p) = (-1)^{(p-1)/2} p^{p-2}$, the index $m = [\mathcal{O}_K : \mathbb{Z}[\zeta_p]]$ satisfies $m^2 \mid p^{p-2}$, so m is a power of p ; and one checks using the totally ramified prime λ that $p \nmid m$. Hence $m = 1$ and $d_K = (-1)^{(p-1)/2} p^{p-2}$.

Example 35.6.20

Take $m = 8$, so $\Phi_8(x) = x^4 + 1$ and $K = \mathbb{Q}(\zeta_8)$ has degree 4 with $\text{Gal}(K/\mathbb{Q}) \cong (\mathbb{Z}/8\mathbb{Z})^\times \cong (\mathbb{Z}/2\mathbb{Z})^2$. Then 2 is totally ramified. For odd p , the order of $p \bmod 8$ is 1 if $p \equiv 1 \pmod{8}$ and 2 otherwise. So $p \equiv 1 \pmod{8}$ splits completely into four primes, and every other odd p factors into two primes of residue degree 2. For instance $x^4 + 1$ factors into four linear factors mod 17, and into two irreducible quadratics mod 3.

Example 35.6.21

Take $m = 7$, so $K = \mathbb{Q}(\zeta_7)$ has degree 6 and $\text{Gal}(K/\mathbb{Q}) \cong (\mathbb{Z}/7\mathbb{Z})^\times$ is cyclic of order 6, generated by the class of 3.

- $p = 7$ is totally ramified: $(7) = (1 - \zeta_7)^6$, by Example 35.6.19.
- $p = 2$: the powers of 2 mod 7 are 2, 4, 1, so $f = 3$ and $(2) = \mathfrak{p}_1 \mathfrak{p}_2$ with $N(\mathfrak{p}_i) = 8$. Correspondingly Φ_7 factors mod 2 into two irreducible cubics, namely $(x^3 + x + 1)(x^3 + x^2 + 1)$.
- $p = 3$: the class of 3 generates the whole group, so $f = 6$ and 3 is inert; equivalently Φ_7 is irreducible mod 3.
- $p = 29 \equiv 1 \pmod{7}$: here $f = 1$, so 29 splits completely into six primes of norm 29.

In each case $\sum e_i f_i = 6$, as it must.

Remark (Cyclotomic Fields and Reciprocity). Since $\text{Gal}(\mathbb{Q}(\zeta_p)/\mathbb{Q})$ is cyclic of order $p - 1$, it has a unique subgroup of index 2, so $\mathbb{Q}(\zeta_p)$ contains a unique quadratic subfield. Comparing discriminants (only p ramifies, and the discriminant of $\mathbb{Q}(\sqrt{d})$ must therefore be $\pm p$) shows that this subfield is

$$\mathbb{Q}(\sqrt{p^*}), \quad p^* = (-1)^{(p-1)/2} p.$$

Now Proposition 35.6.18(iv) says that the splitting of q in $\mathbb{Q}(\zeta_p)$ depends only on $q \bmod p$; hence so does its splitting in the subfield $\mathbb{Q}(\sqrt{p^*})$, which by Proposition 35.6.11 is governed by $\left(\frac{p^*}{q}\right)$. So $\left(\frac{p^*}{q}\right)$ depends only on $q \bmod p$ – and unwinding this is precisely the law of quadratic reciprocity. This is the first hint of *class field theory*: abelian extensions of $\mathbb{Q}$ are exactly the subfields of cyclotomic fields, and splitting in them is governed by congruences.

§35.7 The Geometry of Numbers

We now come to the geometric heart of the course. The idea is due to Minkowski, and it is disarmingly simple: realise $\mathcal{O}_K$ as a lattice in a Euclidean space, and use the fact

that a large enough convex body must contain a lattice point. From this one deduces that every ideal class contains an ideal of small norm, and hence that the class group is finite.

§35.7.1 Lattices

Definition 35.7.1 (Discrete)

A subset $X \subseteq \mathbb{R}^n$ is **discrete** if $X \cap C$ is finite for every compact $C \subseteq \mathbb{R}^n$; equivalently, if every $x \in X$ has $\varepsilon > 0$ with $B_\varepsilon(x) \cap X = \{x\}$.

Proposition 35.7.2

Let $\Lambda \subseteq \mathbb{R}^n$ be a subgroup of $(\mathbb{R}^n, +)$. Then Λ is discrete if and only if

$$\Lambda = \mathbb{Z}x_1 \oplus \cdots \oplus \mathbb{Z}x_m$$

for some $x_1, \dots, x_m \in \mathbb{R}^n$ linearly independent over $\mathbb{R}$.

Proof. ($\Leftarrow$) Extend $x_1, \dots, x_m$ to a basis of $\mathbb{R}^n$ and let $g \in \mathrm{GL}_n(\mathbb{R})$ take x_i to the standard basis vector e_i . Discreteness is preserved by g , and $\bigoplus_{i \leq m} \mathbb{Z}e_i$ is visibly discrete.

($\Rightarrow$) Choose $y_1, \dots, y_m \in \Lambda$ that are $\mathbb{R}$ -linearly independent with m maximal, so $m \leq n$, and let $V = \mathrm{span}_{\mathbb{R}}(y_1, \dots, y_m)$; by maximality $\Lambda \subseteq V$. Let

$$X = \{\sum_i \lambda_i y_i : \lambda_i \in [0, 1]\},$$

a compact set, so $X \cap \Lambda$ is finite. Put $\Lambda_0 = \bigoplus_i \mathbb{Z}y_i \subseteq \Lambda$. Any $\lambda \in \Lambda$ can be written as $\lambda = \lambda_0 + \lambda_1$ with $\lambda_0 \in \Lambda_0$ (the integer parts of the coordinates) and $\lambda_1 \in X \cap \Lambda$ (the fractional parts). Hence $[\Lambda : \Lambda_0] \leq |X \cap \Lambda| < \infty$.

Let $D = [\Lambda : \Lambda_0]$. By Lagrange, $D\Lambda \subseteq \Lambda_0$, so

$$\Lambda_0 \subseteq \Lambda \subseteq \frac{1}{D}\Lambda_0 \cong \mathbb{Z}^m.$$

So Λ is a subgroup of a free abelian group of rank m , hence free of rank at most m ; and it contains Λ_0 of rank m , so has rank exactly m . A $\mathbb{Z}$ -basis $x_1, \dots, x_m$ of Λ then spans V over $\mathbb{R}$, so is $\mathbb{R}$ -linearly independent. $\square$

Definition 35.7.3 (Lattice, Covolume)

A **lattice** in $\mathbb{R}^n$ is a discrete subgroup $\Lambda \subseteq \mathbb{R}^n$ of rank n , i.e. one with $\Lambda = \bigoplus_{i=1}^n \mathbb{Z}x_i$ for an $\mathbb{R}$ -basis $x_1, \dots, x_n$ of $\mathbb{R}^n$. The **fundamental parallelotope** is

$$P = \{\sum_i \lambda_i x_i : \lambda_i \in [0, 1)\},$$

and the **covolume** of Λ is $\mathrm{covol}(\Lambda) = \mathrm{vol}(P) = |\det A|$, where A is the matrix whose rows are the x_i .

If $x'_1, \dots, x'_n$ is another $\mathbb{Z}$ -basis then the change of basis matrix lies in $\mathrm{GL}_n(\mathbb{Z})$ and has determinant ± 1 , so the covolume is well defined. The point of P is that it is a

fundamental domain: the translates $\gamma + P$ for $\gamma \in \Lambda$ tile $\mathbb{R}^n$ exactly.

Example 35.7.4

$\mathbb{Z}^n \subseteq \mathbb{R}^n$ is a lattice of covolume 1. On the other hand $\mathbb{Z}\sqrt{2} + \mathbb{Z}\sqrt{3} \subseteq \mathbb{R}$ is a subgroup that is *not* discrete – it is dense, by an argument with continued fractions – and correspondingly it is not free of rank 1.

§35.7.2 Minkowski's Theorem

Theorem 35.7.5 (Minkowski)

Let $\Lambda \subseteq \mathbb{R}^n$ be a lattice and $S \subseteq \mathbb{R}^n$ measurable.

- (i) If $\text{vol}(S) > \text{covol}(\Lambda)$ then there exist $x \neq y$ in S with $x - y \in \Lambda$.
- (ii) Suppose in addition that S is convex and symmetric about 0 (that is, $s \in S \Rightarrow -s \in S$). If either
 - (a) $\text{vol}(S) > 2^n \text{covol}(\Lambda)$, or
 - (b) $\text{vol}(S) \geq 2^n \text{covol}(\Lambda)$ and S is closed and bounded,
 then S contains a nonzero point of Λ .

Proof. (i) Let P be a fundamental parallelotope. Since the translates $\gamma + P$ ($\gamma \in \Lambda$) partition $\mathbb{R}^n$,

$$\text{vol}(S) = \sum_{\gamma \in \Lambda} \text{vol}(S \cap (P + \gamma)) = \sum_{\gamma \in \Lambda} \text{vol}((S - \gamma) \cap P),$$

by translation invariance of volume. If the sets $(S - \gamma) \cap P$ were pairwise disjoint, they would all sit inside P and we would get $\text{vol}(P) \geq \text{vol}(S)$, contrary to hypothesis. So there are $\gamma \neq \mu$ in Λ and a point in $(S - \gamma) \cap (S - \mu)$, i.e. there are $x, y \in S$ with $x - \gamma = y - \mu$. Then $x - y = \gamma - \mu \in \Lambda \setminus \{0\}$, so in particular $x \neq y$.

(ii)(a) Apply (i) to $S' = \frac{1}{2}S$, which has $\text{vol}(S') = 2^{-n} \text{vol}(S) > \text{covol}(\Lambda)$. So there are $y \neq z \in S'$ with $y - z \in \Lambda \setminus \{0\}$. But $2y, 2z \in S$, so $-2z \in S$ by symmetry, and

$$y - z = \frac{1}{2}(2y) + \frac{1}{2}(-2z) \in S$$

by convexity. So $y - z$ is a nonzero lattice point in S .

(ii)(b) For each integer $m \geq 1$ apply (a) to $S_m = (1 + \frac{1}{m})S$, which is convex, symmetric and of volume $(1 + \frac{1}{m})^n \text{vol}(S) > 2^n \text{covol}(\Lambda)$. This gives $\gamma_m \in (S_m \cap \Lambda) \setminus$

$\{0\}$. Now $S_m \subseteq S_1 = 2S$ for all m (by convexity and $0 \in S$), and $S_1 \cap \Lambda$ is finite since S_1 is compact and Λ discrete. So some value γ occurs infinitely often among the γ_m , and then

$$\gamma \in \bigcap_{m \geq 1} S_m = \overline{S} = S$$

as S is closed. Hence $\gamma \in (S \cap \Lambda) \setminus \{0\}$. $\square$

Here is part (ii)(a) in a picture. The shaded region is $S' = \frac{1}{2}S$; if its area exceeds the covolume then two of its points differ by a lattice vector, and doubling turns that into a lattice point inside S itself.

Remark. The bounds are sharp. Take $\Lambda = \mathbb{Z}^n$, so $\text{covol}(\Lambda) = 1$, and $S = (-1, 1)^n$, which is open, convex, symmetric, of volume exactly 2^n , and contains no nonzero lattice point. Closing it up to $[-1, 1]^n$ makes case (b) apply, and indeed $\pm e_i \in S \cap \Lambda$.

§35.7.3 The Minkowski Embedding

We now put K into a Euclidean space. Let K have degree n and signature (r, s) , with embeddings $\sigma_1, \dots, \sigma_r : K \rightarrow \mathbb{R}$ and $\sigma_{r+1}, \dots, \sigma_{r+s} : K \rightarrow \mathbb{C}$ (one from each conjugate pair). Define

$$\sigma : K \longrightarrow \mathbb{R}^r \times \mathbb{C}^s \cong \mathbb{R}^{r+2s} = \mathbb{R}^n,$$

$$\sigma(x) = (\sigma_1(x), \dots, \sigma_r(x), \text{Re } \sigma_{r+1}(x), \text{Im } \sigma_{r+1}(x), \dots, \text{Re } \sigma_{r+s}(x), \text{Im } \sigma_{r+s}(x)).$$

This is an injective $\mathbb{Q}$ -linear map, called the **Minkowski embedding**. Its whole purpose is the following.

Lemma 35.7.6

Let $\mathfrak{a} \subseteq \mathcal{O}_K$ be a nonzero ideal. Then $\sigma(\mathfrak{a})$ is a lattice in $\mathbb{R}^n$, with

$$\text{covol}(\sigma(\mathfrak{a})) = 2^{-s} |d_K|^{1/2} N(\mathfrak{a}).$$

In particular $\text{covol}(\sigma(\mathcal{O}_K)) = 2^{-s} |d_K|^{1/2}$.

Proof. Let $\gamma_1, \dots, \gamma_n$ be a $\mathbb{Z}$ -basis of $\mathfrak{a}$. Then $\sigma(\mathfrak{a}) = \bigoplus_i \mathbb{Z} \sigma(\gamma_i)$, so it suffices to compute $|\det(\sigma(\gamma_1), \dots, \sigma(\gamma_n))|$ and check it is nonzero.

Consider first the matrix $S = (\sigma_i(\gamma_j))$ where now $\sigma_1, \dots, \sigma_n$ runs over *all* n embed-

dings. By Lemma 35.5.9,

$$(\det S)^2 = \Delta(\gamma_1, \dots, \gamma_n) = N(\mathfrak{a})^2 d_K, \quad \text{so } |\det S| = N(\mathfrak{a}) |d_K|^{1/2} \neq 0.$$

The matrix of σ differs from S by replacing each conjugate pair of rows $(z, \bar{z})$ by $(\operatorname{Re} z, \operatorname{Im} z)$, and

$$\begin{pmatrix} \operatorname{Re} z \\ \operatorname{Im} z \end{pmatrix} = \frac{1}{2} \begin{pmatrix} 1 & 1 \\ -i & i \end{pmatrix} \begin{pmatrix} z \\ \bar{z} \end{pmatrix},$$

a matrix of determinant $\frac{1}{2} \cdot \frac{1}{2}(i + i) = \frac{i}{2}$, of absolute value $\frac{1}{2}$. Doing this for each of the s pairs multiplies the absolute determinant by 2^{-s} , giving

$$\operatorname{covol}(\sigma(\mathfrak{a})) = 2^{-s} N(\mathfrak{a}) |d_K|^{1/2} \neq 0,$$

which in particular shows $\sigma(\gamma_1), \dots, \sigma(\gamma_n)$ are $\mathbb{R}$ -independent, so $\sigma(\mathfrak{a})$ is a lattice. $\square$

Example 35.7.7

For K imaginary quadratic, $(r, s) = (0, 1)$ and σ is just the inclusion $K \subseteq \mathbb{C} = \mathbb{R}^2$ (after choosing a square root of d), which is what we drew for $\mathbb{Z}[i]$ and $\mathbb{Z}[\omega]$ in Section 1. The lemma says $\operatorname{covol}(\mathcal{O}_K) = \frac{1}{2} |d_K|^{1/2}$: for $\mathbb{Z}[i]$, $d_K = -4$ gives covolume 1, correct for the unit square lattice; for $\mathbb{Z}[\omega]$, $d_K = -3$ gives $\frac{\sqrt{3}}{2}$, correct for the triangular lattice with unit side.

For $K = \mathbb{Q}(\sqrt{d})$ real quadratic, $(r, s) = (2, 0)$ and $\sigma(x) = (x, \bar{x})$ using the two real embeddings; here $\operatorname{covol}(\mathcal{O}_K) = |d_K|^{1/2}$. For instance $\sigma(\mathbb{Z}[\sqrt{2}])$ is the lattice spanned by $(1, 1)$ and $(\sqrt{2}, -\sqrt{2})$, of covolume $2\sqrt{2} = \sqrt{8} = |d_K|^{1/2}$.

The reason this embedding is the right one is that the norm becomes a product of coordinates:

$$N_{K/\mathbb{Q}}(x) = \prod_{i=1}^r \sigma_i(x) \prod_{j=1}^s |\sigma_{r+j}(x)|^2,$$

so bounding $|N(x)|$ is bounding a product of coordinates – exactly the sort of thing the AM–GM inequality handles.

§35.7.4 The Minkowski Bound

Proposition 35.7.8 (Minkowski Bound)

Let K be a number field of degree n and signature (r, s) , and let $\mathfrak{a} \subseteq \mathcal{O}_K$ be a nonzero ideal. Then there is $\alpha \in \mathfrak{a}$, $\alpha \neq 0$, with

$$|N_{K/\mathbb{Q}}(\alpha)| \leq C_K N(\mathfrak{a}), \quad \text{where } C_K = \left(\frac{4}{\pi}\right)^s \frac{n!}{n^n} |d_K|^{1/2}$$

is the **Minkowski constant** of K .

Proof. For $t > 0$ let

$$B(t) = \left\{ (y_1, \dots, y_r, z_1, \dots, z_s) \in \mathbb{R}^r \times \mathbb{C}^s : \sum_{i=1}^r |y_i| + 2 \sum_{j=1}^s |z_j| \leq t \right\}.$$

This set is closed, bounded, convex and symmetric about 0, and (see below) has volume

$$\text{vol}(B(t)) = 2^r \left(\frac{\pi}{2}\right)^s \frac{t^n}{n!}.$$

Choose t so that $\text{vol}(B(t)) = 2^n \text{covol}(\sigma(\mathfrak{a})) = 2^n 2^{-s} |d_K|^{1/2} N(\mathfrak{a})$; solving,

$$t^n = \left(\frac{4}{\pi}\right)^s n! |d_K|^{1/2} N(\mathfrak{a}),$$

using $n - r - s = s$. By Minkowski's theorem 35.7.5(ii)(b) there is a nonzero $\alpha \in \mathfrak{a}$ with $\sigma(\alpha) \in B(t)$.

Write $\sigma(\alpha) = (y_1, \dots, y_r, z_1, \dots, z_s)$. Then $|N(\alpha)| = \prod_i |y_i| \prod_j |z_j|^2$, a product of n nonnegative reals whose sum is at most t . By AM–GM,

$$|N(\alpha)|^{1/n} \leq \frac{1}{n} \left(\sum_i |y_i| + 2 \sum_j |z_j| \right) \leq \frac{t}{n},$$

so $|N(\alpha)| \leq t^n / n^n = C_K N(\mathfrak{a})$. □

It remains to justify the volume formula, which we do by induction.

Lemma 35.7.9

Write $B_{r,s}(t)$ for the set above, sitting in $\mathbb{R}^r \times \mathbb{C}^s \cong \mathbb{R}^n$ with $n = r + 2s$. Then

$$\text{vol}(B_{r,s}(t)) = 2^r \left(\frac{\pi}{2}\right)^s \frac{t^n}{n!}.$$

Proof. We induct on $r + s$. If $r + s = 1$ there are two cases. For $(r, s) = (1, 0)$, $B_{1,0}(t) = [-t, t]$ has length $2t$, matching $2^1 t^1 / 1!$. For $(r, s) = (0, 1)$, $B_{0,1}(t) = \{z \in \mathbb{C} : 2|z| \leq t\}$ is a disc of radius $t/2$ and area $\pi t^2 / 4$, matching $(\pi/2) t^2 / 2!$.

For the inductive step in the real direction, slice along the new real coordinate y : the slice at height y is $B_{r,s}(t - |y|)$, so

$$\begin{aligned} \text{vol}(B_{r+1,s}(t)) &= \int_{-t}^t \text{vol}(B_{r,s}(t - |y|)) \, dy = 2 \int_0^t 2^r \left(\frac{\pi}{2}\right)^s \frac{(t - y)^n}{n!} \, dy \\ &= 2^{r+1} \left(\frac{\pi}{2}\right)^s \frac{t^{n+1}}{(n+1)!}, \end{aligned}$$

which is the formula in dimension $n + 1$.

In the complex direction, slice along the new complex coordinate z and write $z = \frac{1}{2} \rho e^{i\theta}$, so that the constraint reads $\rho \leq t$ and the slice is $B_{r,s}(t - \rho)$. The area

element is $|z| \, d|z| \, d\theta = \frac{1}{4} \rho \, d\rho \, d\theta$, so

$$\text{vol}(B_{r,s+1}(t)) = \int_0^{2\pi} \int_0^t \frac{\rho}{4} \, \text{vol}(B_{r,s}(t-\rho)) \, d\rho \, d\theta = \frac{2\pi}{4} \cdot 2^r \left(\frac{\pi}{2}\right)^s \int_0^t \frac{\rho(t-\rho)^n}{n!} \, d\rho.$$

Now $\int_0^t \rho(t-\rho)^n \, d\rho = t^{n+2}/((n+1)(n+2))$ by the substitution $\rho \mapsto t-\rho$ and the beta integral, so the right-hand side is $2^r(\pi/2)^{s+1}t^{n+2}/(n+2)!$, as required. $\square$

§35.7.5 Finiteness of the Class Group

Theorem 35.7.10 (Finiteness of the Class Group)

Let K be a number field. Then every ideal class of K contains an integral ideal $\mathfrak{b}$ with $N(\mathfrak{b}) \leq C_K$. Consequently Cl_K is finite, and it is generated by the classes of the prime ideals $\mathfrak{p}$ with $N(\mathfrak{p}) \leq C_K$.

Proof. Let $c \in \text{Cl}_K$ and pick an integral ideal $\mathfrak{a}$ with $[\mathfrak{a}] = c^{-1}$ (possible: any fractional ideal in c^{-1} can be scaled into $\mathcal{O}_K$). By Proposition 35.7.8 there is $0 \neq \alpha \in \mathfrak{a}$ with $|N(\alpha)| \leq C_K N(\mathfrak{a})$. Since $\alpha \in \mathfrak{a}$ we have $(\alpha) \subseteq \mathfrak{a}$, so $(\alpha) = \mathfrak{a}\mathfrak{b}$ for some integral ideal $\mathfrak{b}$ (Corollary 35.4.18). Taking norms and using Lemma 35.5.8,

$$N(\mathfrak{a}) N(\mathfrak{b}) = N((\alpha)) = |N(\alpha)| \leq C_K N(\mathfrak{a}),$$

so $N(\mathfrak{b}) \leq C_K$. And $[\mathfrak{b}] = [\mathfrak{a}]^{-1} = c$ since $\mathfrak{a}\mathfrak{b}$ is principal.

For finiteness: by Corollary 35.5.10(i) there are only finitely many ideals of norm at most C_K , so there are only finitely many classes. For the generation statement, if $N(\mathfrak{b}) \leq C_K$ and $\mathfrak{b} = \prod \mathfrak{p}_i^{a_i}$, then each $N(\mathfrak{p}_i) \leq N(\mathfrak{b}) \leq C_K$ by multiplicativity, so $[\mathfrak{b}]$ is a product of classes of small-norm primes. $\square$

This is a genuinely remarkable theorem, and it gives a completely effective algorithm: to compute Cl_K , list the primes $p \leq C_K$, factor each (p) using Dedekind's criterion, and then find the relations among the resulting classes. We will do this in Section 35.8.

Example 35.7.11

For K imaginary quadratic, $n = 2$, $s = 1$ and $C_K = \frac{2}{\pi}|d_K|^{1/2}$. For K real quadratic, $s = 0$ and $C_K = \frac{1}{2}|d_K|^{1/2}$. For $K = \mathbb{Q}(\sqrt{-7})$, $d_K = -7$ and $C_K = 2\sqrt{7}/\pi \approx 1.68 < 2$, so there are no primes of norm $\leq C_K$ at all and Cl_K is trivial: $\mathbb{Z}[\frac{1}{2}(1 + \sqrt{-7})]$ is a PID. The same works for $d = -1, -2, -3$.

The Minkowski bound also gives a lower bound for the discriminant, since applying it to the trivial class produces an ideal of norm at least 1.

Theorem 35.7.12 (Hermite–Minkowski)

Let K be a number field of degree $n \geq 2$. Then

$$|d_K| \geq \frac{\pi}{3} \left(\frac{3\pi}{4}\right)^{n-1} > 1.$$

In particular $|d_K| > 1$, so by Theorem 35.6.16 at least one prime ramifies in K .

Proof. Applying Theorem 35.7.10 to the trivial class gives an ideal $\mathfrak{b}$ with $1 \leq N(\mathfrak{b}) \leq C_K$, so $C_K \geq 1$, i.e.

$$|d_K|^{1/2} \geq \left(\frac{\pi}{4}\right)^s \frac{n^n}{n!} \geq \left(\frac{\pi}{4}\right)^{n/2} \frac{n^n}{n!} =: a_n^{1/2},$$

using $\pi/4 < 1$ and $s \leq n/2$. Now $a_n = \left(\frac{\pi}{4}\right)^n \left(\frac{n^n}{n!}\right)^2$ satisfies $a_2 = \frac{\pi^2}{4}$ and

$$\frac{a_{n+1}}{a_n} = \frac{\pi}{4} \left(1 + \frac{1}{n}\right)^{2n} \geq \frac{\pi}{4} \cdot 4 = \pi > \frac{3\pi}{4},$$

since $(1 + 1/n)^n \geq 2$ for $n \geq 1$. Hence

$$a_n \geq \frac{\pi^2}{4} \left(\frac{3\pi}{4}\right)^{n-2} = \frac{\pi}{3} \left(\frac{3\pi}{4}\right)^{n-1},$$

and $\frac{\pi}{3} \cdot \frac{3\pi}{4} = \frac{\pi^2}{4} > 2$, so the bound exceeds 1 for all $n \geq 2$. $\square$

Remark. Minkowski's theorem also implies (with more work) **Hermite's theorem**: for each D there are only finitely many number fields with $|d_K| \leq D$. So the discriminant is a genuinely rigid invariant. The smallest discriminants in absolute value in low degree are -3 (for $\mathbb{Q}(\sqrt{-3})$), -23 (for the cubic field $\mathbb{Q}(\alpha)$ with $\alpha^3 = \alpha + 1$, whose discriminant we computed in Section 2) and 117 in degree 4; compare these with the bound above, which gives $|d_K| \geq 2.4, 5.8, 13.7$ for $n = 2, 3, 4$.

§35.8 Computing Class Groups

Theorem 35.7.10 turns the computation of Cl_K into a finite, mechanical procedure. Let us set out the recipe and then run it several times.

- (1) Compute d_K and the Minkowski constant $C_K = \left(\frac{4}{\pi}\right)^s \frac{n!}{n^n} |d_K|^{1/2}$.
- (2) For each rational prime $p \leq C_K$, factor $p\mathcal{O}_K$ using Dedekind's criterion. The primes $\mathfrak{p}$ with $N(\mathfrak{p}) \leq C_K$ obtained this way generate Cl_K .
- (3) Decide which of these $\mathfrak{p}$ are principal, usually by asking whether there is $\alpha \in \mathcal{O}_K$ with $|N(\alpha)| = N(\mathfrak{p})$ – a norm-form equation.
- (4) Find relations. The most efficient source of relations is to factor (α) for elements α of small norm: each such factorisation is a relation in Cl_K .

Throughout, we use freely that in a quadratic field $[\bar{\mathfrak{a}}] = [\mathfrak{a}]^{-1}$ (Example 35.5.4), and that $N(a + b\sqrt{d}) = a^2 - db^2$.

Example 35.8.1 ($K = \mathbb{Q}(\sqrt{-5})$)

Here $d_K = -20$ and $C_K = \frac{2}{\pi} \sqrt{20} \approx 2.847$. So Cl_K is generated by primes of norm ≤ 2 , i.e. primes above 2. By Example 35.6.14, $(2) = \mathfrak{p}^2$ with $\mathfrak{p} = (2, 1 + \sqrt{-5})$ of norm 2.

Is $\mathfrak{p}$ principal? If $\mathfrak{p} = (\beta)$ then $N(\beta) = \pm 2$, i.e. $a^2 + 5b^2 = 2$, which is insoluble. So

$[\mathfrak{p}] \neq 1$, while $[\mathfrak{p}]^2 = [(2)] = 1$. Hence

$$\text{Cl}_{\mathbb{Q}(\sqrt{-5})} \cong \mathbb{Z}/2\mathbb{Z}, \quad h_K = 2.$$

In particular $\mathbb{Z}[\sqrt{-5}]$ is not a UFD, which we knew, and the failure is as mild as it could possibly be.

Example 35.8.2 ($K = \mathbb{Q}(\sqrt{-23})$)

Here $-23 \equiv 1 \pmod{4}$, so $d_K = -23$, $\mathcal{O}_K = \mathbb{Z}[\alpha]$ with $\alpha = \frac{1}{2}(1 + \sqrt{-23})$ of minimal polynomial $x^2 - x + 6$, and $C_K = \frac{2}{\pi}\sqrt{23} \approx 3.05$. So we need the primes above 2 and 3.

Modulo 2: $x^2 - x + 6 \equiv x^2 + x = x(x+1)$, so $(2) = \mathfrak{p}\bar{\mathfrak{p}}$ with $\mathfrak{p} = (2, \alpha)$, $\bar{\mathfrak{p}} = (2, \alpha - 1)$, each of norm 2. Modulo 3: $x^2 - x + 6 \equiv x^2 - x = x(x-1)$, so $(3) = \mathfrak{q}\bar{\mathfrak{q}}$ with $\mathfrak{q} = (3, \alpha)$, $\bar{\mathfrak{q}} = (3, \alpha - 1)$, each of norm 3.

Norms of elements: $N(\frac{1}{2}(u + v\sqrt{-23})) = \frac{1}{4}(u^2 + 23v^2)$ with $u \equiv v \pmod{2}$. So $N(\gamma) = m$ requires $u^2 + 23v^2 = 4m$. For $m = 2$: $u^2 + 23v^2 = 8$ is insoluble, so $\mathfrak{p}$ is not principal. For $m = 3$: $u^2 + 23v^2 = 12$ is insoluble, so $\mathfrak{q}$ is not principal. For $m = 4$: $u^2 + 23v^2 = 16$ forces $v = 0, u = \pm 4$, giving $\gamma = \pm 2$ and $(\gamma) = (2) = \mathfrak{p}\bar{\mathfrak{p}}$; so $\mathfrak{p}^2$ is not principal either (if it were, $\mathfrak{p}^2 = (\gamma)$ with $N(\gamma) = 4$, forcing $\mathfrak{p}^2 = (2) = \mathfrak{p}\bar{\mathfrak{p}}$ and so $\mathfrak{p} = \bar{\mathfrak{p}}$, false).

Now for a relation. Take $m = 6$: $u^2 + 23v^2 = 24$ has the solution $u = v = 1$, giving

$$\gamma = \frac{1}{2}(1 + \sqrt{-23}) = \alpha, \quad N(\alpha) = 6.$$

Since $\alpha \in \mathfrak{p}$ and $\alpha \in \mathfrak{q}$, we get $(\alpha) = \mathfrak{p}\mathfrak{q}$. Hence $[\mathfrak{q}] = [\mathfrak{p}]^{-1}$, so $\text{Cl}_K = \langle [\mathfrak{p}] \rangle$ is cyclic.

Finally take $m = 8$: the equation $u^2 + 23v^2 = 32$ has the solution $u = 3, v = 1$, giving $\beta = \frac{1}{2}(3 + \sqrt{-23})$ with $N(\beta) = 8$. Now (β) has norm $8 = 2^3$, so it is a product of three primes above 2, that is $(\beta) = \mathfrak{p}^a \bar{\mathfrak{p}}^{3-a}$. If both $\mathfrak{p}$ and $\bar{\mathfrak{p}}$ occurred then $(2) = \mathfrak{p}\bar{\mathfrak{p}}$ would divide (β) , forcing $\beta/2 = \frac{1}{4}(3 + \sqrt{-23}) \in \mathcal{O}_K$; but that element has norm 2, which we have seen is impossible. So $(\beta) = \mathfrak{p}^3$ or $\bar{\mathfrak{p}}^3$, and either way $[\mathfrak{p}]^3 = 1$.

Since $[\mathfrak{p}] \neq 1$ and $[\mathfrak{p}]^2 \neq 1$, the class $[\mathfrak{p}]$ has order 3, and

$$\text{Cl}_{\mathbb{Q}(\sqrt{-23})} \cong \mathbb{Z}/3\mathbb{Z}, \quad h_K = 3.$$

Example 35.8.3 ($K = \mathbb{Q}(\sqrt{-17})$)

Here $-17 \equiv 3 \pmod{4}$, so $d_K = -17$, $\mathcal{O}_K = \mathbb{Z}[\sqrt{-17}]$ and $C_K = \frac{2}{\pi}\sqrt{17} \approx 5.25$. We need the primes above 2, 3, 5.

- $p = 2$: $x^2 + 17 \equiv x^2 + 1 = (x+1)^2 \pmod{2}$, so $(2) = \mathfrak{p}^2$ with $\mathfrak{p} = (2, 1 + \sqrt{-17})$, $N(\mathfrak{p}) = 2$.
- $p = 3$: $x^2 + 17 \equiv x^2 - 1 = (x-1)(x+1) \pmod{3}$, so $(3) = \mathfrak{q}\bar{\mathfrak{q}}$ with $\mathfrak{q} = (3, 1 + \sqrt{-17})$, $N(\mathfrak{q}) = 3$.
- $p = 5$: $x^2 + 17 \equiv x^2 + 2 \pmod{5}$, and $-2 \equiv 3$ is not a square mod 5, so 5 is inert and contributes the trivial class.

Now $N(a + b\sqrt{-17}) = a^2 + 17b^2$, which never equals 2 or 3, so neither $\mathfrak{p}$ nor $\mathfrak{q}$ is principal. For a relation, note

$$N(1 + \sqrt{-17}) = 18 = 2 \cdot 3^2.$$

Since $1 + \sqrt{-17}$ lies in both $\mathfrak{p}$ and $\mathfrak{q}$, and the only primes of norm 2 and 3 dividing $(1 + \sqrt{-17})$ are $\mathfrak{p}$ and $\mathfrak{q}, \bar{\mathfrak{q}}$, we must have $(1 + \sqrt{-17}) = \mathfrak{p}\mathfrak{q}^2$ (it cannot involve both $\mathfrak{q}$ and $\bar{\mathfrak{q}}$, since $\mathfrak{q}\bar{\mathfrak{q}} = (3)$ and $3 \nmid 1 + \sqrt{-17}$). Hence in Cl_K ,

$$[\mathfrak{p}][\mathfrak{q}]^2 = 1, \quad [\mathfrak{p}]^2 = 1,$$

so $[\mathfrak{q}]^4 = [\mathfrak{p}]^{-2} = 1$ and $[\mathfrak{q}]^2 = [\mathfrak{p}]^{-1} = [\mathfrak{p}] \neq 1$. Therefore $[\mathfrak{q}]$ has order 4, and since $\text{Cl}_K = \langle [\mathfrak{p}], [\mathfrak{q}] \rangle = \langle [\mathfrak{q}] \rangle$,

$$\text{Cl}_{\mathbb{Q}(\sqrt{-17})} \cong \mathbb{Z}/4\mathbb{Z}, \quad h_K = 4.$$

Example 35.8.4 ($K = \mathbb{Q}(\sqrt{-14})$)

Here $d_K = -56$ and $C_K = \frac{2}{\pi}\sqrt{56} \approx 4.76$, so we need primes above 2 and 3. Modulo 2, $x^2 + 14 \equiv x^2$, so $(2) = \mathfrak{p}^2$ with $\mathfrak{p} = (2, \sqrt{-14})$. Modulo 3, $x^2 + 14 \equiv x^2 + 2 \equiv x^2 - 1$, so $(3) = \mathfrak{q}\bar{\mathfrak{q}}$ with $\mathfrak{q} = (3, 1 + \sqrt{-14})$.

Neither is principal, since $a^2 + 14b^2 \in \{2, 3\}$ is insoluble. But $N(2 + \sqrt{-14}) = 18 = 2 \cdot 3^2$ and $2 + \sqrt{-14} \in \mathfrak{p}$, so exactly as before $(2 + \sqrt{-14}) = \mathfrak{p}\mathfrak{q}^2$ (up to replacing $\mathfrak{q}$ by $\bar{\mathfrak{q}}$). So $[\mathfrak{q}]^4 = 1$ and $[\mathfrak{q}]^2 = [\mathfrak{p}] \neq 1$, giving

$$\text{Cl}_{\mathbb{Q}(\sqrt{-14})} \cong \mathbb{Z}/4\mathbb{Z}, \quad h_K = 4.$$

Real quadratic fields work the same way, but the Minkowski constant is smaller by a factor of $8/\pi$, which often makes life easier.

Example 35.8.5 ($K = \mathbb{Q}(\sqrt{10})$)

Here $10 \equiv 2 \pmod{4}$, so $d_K = 40$, $\mathcal{O}_K = \mathbb{Z}[\sqrt{10}]$, and $C_K = \frac{1}{2}\sqrt{40} \approx 3.16$. We need the primes above 2 and 3.

- $p = 2$: $x^2 - 10 \equiv x^2 \pmod{2}$, so $(2) = \mathfrak{p}^2$ with $\mathfrak{p} = (2, \sqrt{10})$, $N(\mathfrak{p}) = 2$.
- $p = 3$: $x^2 - 10 \equiv x^2 - 1 = (x - 1)(x + 1) \pmod{3}$, so $(3) = \mathfrak{q}\bar{\mathfrak{q}}$ with $\mathfrak{q} = (3, \sqrt{10} - 1)$, $N(\mathfrak{q}) = 3$.

Now $N(a + b\sqrt{10}) = a^2 - 10b^2$. If this is ± 2 then $a^2 \equiv \pm 2 \pmod{5}$; but the squares mod 5 are 0, 1, 4, and $\pm 2 \equiv 2, 3$. So $\mathfrak{p}$ is not principal. Likewise $a^2 - 10b^2 = \pm 3$ forces $a^2 \equiv \pm 3 \equiv 3, 2 \pmod{5}$, impossible; so $\mathfrak{q}$ is not principal.

For a relation, $N(2 + \sqrt{10}) = 4 - 10 = -6$, so $(2 + \sqrt{10}) = \mathfrak{p}\mathfrak{q}$ or $\mathfrak{p}\bar{\mathfrak{q}}$. Either way $[\mathfrak{q}] = [\mathfrak{p}]^{-1} = [\mathfrak{p}]$ (as $[\mathfrak{p}]^2 = 1$), so $\text{Cl}_K = \langle [\mathfrak{p}] \rangle$ has order 2:

$$\text{Cl}_{\mathbb{Q}(\sqrt{10})} \cong \mathbb{Z}/2\mathbb{Z}, \quad h_K = 2.$$

Concretely, the failure of unique factorisation is visible in

$$6 = 2 \cdot 3 = (\sqrt{10} + 2)(\sqrt{10} - 2),$$

where all four factors are irreducible (their norms are 4, 9, 6, 6, and $a^2 - 10b^2 = \pm 2, \pm 3$ are insoluble) and no two are associates. The ideal-theoretic resolution is

$$(6) = \mathfrak{p}^2 \mathfrak{q} \bar{\mathfrak{q}}, \quad (2) = \mathfrak{p}^2, \quad (3) = \mathfrak{q} \bar{\mathfrak{q}}, \quad (\sqrt{10} + 2) = \mathfrak{p} \mathfrak{q}, \quad (\sqrt{10} - 2) = \mathfrak{p} \bar{\mathfrak{q}},$$

exactly as in the $\mathbb{Q}(\sqrt{-5})$ story.

Example 35.8.6 ($K = \mathbb{Q}(\sqrt{-6})$)

Here $d_K = -24$ and $C_K = \frac{2}{\pi} \sqrt{24} \approx 3.12$, so we need primes above 2 and 3. Both ramify: $x^2 + 6 \equiv x^2 \pmod{2}$ and $\pmod{3}$, so

$$(2) = \mathfrak{p}_2^2, \quad \mathfrak{p}_2 = (2, \sqrt{-6}); \quad (3) = \mathfrak{p}_3^2, \quad \mathfrak{p}_3 = (3, \sqrt{-6}).$$

Neither is principal, as $a^2 + 6b^2 \in \{2, 3\}$ is insoluble. But $N(\sqrt{-6}) = 6$, and $\sqrt{-6}$ lies in both, so $(\sqrt{-6}) = \mathfrak{p}_2 \mathfrak{p}_3$ and hence $[\mathfrak{p}_3] = [\mathfrak{p}_2]^{-1} = [\mathfrak{p}_2]$. So $\text{Cl}_K = \langle [\mathfrak{p}_2] \rangle$ has order 2 and $h_K = 2$.

Example 35.8.7 ($K = \mathbb{Q}(\sqrt{15})$)

Here $15 \equiv 3 \pmod{4}$, so $d_K = 60$, $\mathcal{O}_K = \mathbb{Z}[\sqrt{15}]$ and $C_K = \frac{1}{2} \sqrt{60} \approx 3.87$: again the primes above 2 and 3. Modulo 2, $x^2 - 15 \equiv x^2 + 1 = (x+1)^2$, so $(2) = \mathfrak{p}_2^2$ with $\mathfrak{p}_2 = (2, 1 + \sqrt{15})$; modulo 3, $x^2 - 15 \equiv x^2$, so $(3) = \mathfrak{p}_3^2$ with $\mathfrak{p}_3 = (3, \sqrt{15})$.

For principality we need $a^2 - 15b^2 = \pm 2$ or ± 3 . Reducing mod 5 gives $a^2 \equiv \pm 2$ or ± 3 , i.e. $a^2 \in \{2, 3\} \pmod{5}$; but the squares mod 5 are 0, 1, 4. So neither prime is principal. Finally $N(3 + \sqrt{15}) = 9 - 15 = -6$, and $3 + \sqrt{15}$ lies in both $\mathfrak{p}_2$ and $\mathfrak{p}_3$, so $(3 + \sqrt{15}) = \mathfrak{p}_2 \mathfrak{p}_3$ and $[\mathfrak{p}_3] = [\mathfrak{p}_2]$. Hence

$$\text{Cl}_{\mathbb{Q}(\sqrt{15})} \cong \mathbb{Z}/2\mathbb{Z}, \quad h_K = 2.$$

Example 35.8.8 (A Non-Cyclic Class Group: $K = \mathbb{Q}(\sqrt{-30})$)

All our examples so far have had cyclic class group, which is a little misleading. Here $d_K = -120$ and $C_K = \frac{2}{\pi} \sqrt{120} \approx 6.97$, so we need the primes above 2, 3, 5. All three divide d_K , so all three ramify:

$$(2) = \mathfrak{p}_2^2, \quad (3) = \mathfrak{p}_3^2, \quad (5) = \mathfrak{p}_5^2,$$

$$\mathfrak{p}_2 = (2, \sqrt{-30}), \quad \mathfrak{p}_3 = (3, \sqrt{-30}), \quad \mathfrak{p}_5 = (5, \sqrt{-30}).$$

None is principal, since $a^2 + 30b^2 \in \{2, 3, 5\}$ is insoluble; so each class $[\mathfrak{p}_i]$ has order exactly 2. Also $N(\sqrt{-30}) = 30$ and $\sqrt{-30}$ lies in all three primes, so

$$(\sqrt{-30}) = \mathfrak{p}_2 \mathfrak{p}_3 \mathfrak{p}_5, \quad \text{giving} \quad [\mathfrak{p}_2][\mathfrak{p}_3][\mathfrak{p}_5] = 1.$$

So $\text{Cl}_K = \langle [\mathfrak{p}_2], [\mathfrak{p}_3] \rangle$, a quotient of $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$. Finally $[\mathfrak{p}_2][\mathfrak{p}_3] \neq 1$, since $\mathfrak{p}_2 \mathfrak{p}_3$ has norm 6 and $a^2 + 30b^2 = 6$ is insoluble. Hence

$$\text{Cl}_{\mathbb{Q}(\sqrt{-30})} \cong \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}, \quad h_K = 4.$$

Notice how the ramified primes did all the work: this is typical, and is the beginning of **genus theory**, which computes the 2-torsion of Cl_K for a quadratic field purely in terms of the number of prime divisors of d_K .

Example 35.8.9 (Fields of Class Number One)

If $C_K < 2$ there are no primes to consider at all and $h_K = 1$ automatically. For imaginary quadratic K this reads $\frac{2}{\pi}|d_K|^{1/2} < 2$, i.e. $|d_K| < \pi^2 \approx 9.87$, which happens for $d = -1, -2, -3, -7$. A little more work handles $d = -11, -19, -43, -67, -163$. In fact these nine are all:

Theorem 35.8.10 (Baker–Heegner–Stark)

$\mathcal{O}_{\mathbb{Q}(\sqrt{-d})}$ is a UFD (equivalently a PID) for $d > 0$ squarefree precisely when

$$d \in \{1, 2, 3, 7, 11, 19, 43, 67, 163\}.$$

This is a deep theorem, conjectured by Gauss and settled only in the 1960s. By contrast, it is conjectured – and completely open – that infinitely many *real* quadratic fields have class number one; numerically they seem to be rather common.

Example 35.8.11 (A Cubic Field)

Let $K = \mathbb{Q}(\sqrt[3]{2})$, with $n = 3$, $(r, s) = (1, 1)$ and $d_K = -108$. Then

$$C_K = \frac{4}{\pi} \cdot \frac{3!}{3^3} \cdot \sqrt{108} \approx 2.94,$$

so Cl_K is generated by primes of norm 2. From Example 35.6.8, the only one is $\mathfrak{p} = (2, \sqrt[3]{2}) = (\sqrt[3]{2})$, which is principal. Hence $h_K = 1$ and $\mathbb{Z}[\sqrt[3]{2}]$ is a PID.

Example 35.8.12 (A Cyclotomic Field)

Let $K = \mathbb{Q}(\zeta_5)$, with $n = 4$, $(r, s) = (0, 2)$ and $d_K = 125$. Then

$$C_K = \left(\frac{4}{\pi}\right)^2 \frac{4!}{4^4} \sqrt{125} \approx 1.70 < 2,$$

so there are no prime ideals of norm at most C_K , and $h_K = 1$: the ring $\mathbb{Z}[\zeta_5]$ is a PID.

For $\mathbb{Q}(\zeta_7)$ the bound is larger, $C_K = \left(\frac{4}{\pi}\right)^3 \frac{6!}{6^6} \sqrt{7^5} \approx 4.13$, so we must look at the primes of norm at most 4. But the primes above 2 have residue degree 3 and hence norm 8, the primes above 3 have residue degree 6 and hence norm 729, and the unique prime above 7 has norm 7; so again there is nothing to consider and $h_K = 1$.

This cannot go on forever – for $\mathbb{Q}(\zeta_{11})$ the bound is already about 59 – but in fact $h_{\mathbb{Q}(\zeta_p)} = 1$ for all $p \leq 19$. The first failure is $p = 23$, where $h = 3$; and the first **irregular** prime, meaning one with $p \mid h_{\mathbb{Q}(\zeta_p)}$, is $p = 37$. This is exactly where Kummer’s proof of Fermat’s Last Theorem breaks down (see Section 35.10).

Remark. There is a classical dictionary, going back to Gauss, between ideal classes in

$\mathbb{Q}(\sqrt{D})$ and binary quadratic forms. To a form $q(x, y) = ax^2 + bxy + cy^2$ with $a, b, c \in \mathbb{Z}$ and discriminant $D = b^2 - 4ac$, associate the ideal

$$\mathfrak{a}_q = \left(a, \frac{-b + \sqrt{D}}{2} \right) \trianglelefteq \mathcal{O}_{\mathbb{Q}(\sqrt{D})}.$$

For $D < 0$ and $a > 0$, one can show that $[\mathfrak{a}_q] = [\mathfrak{a}_{q'}]$ if and only if q and q' are equivalent under the action of $SL_2(\mathbb{Z})$ on forms. So h_K is the number of $SL_2(\mathbb{Z})$ -orbits of positive definite binary quadratic forms of discriminant D – Gauss’s *class number*, computed by his reduction theory long before ideals were invented. For example the two classes for $D = -20$ correspond to the reduced forms $x^2 + 5y^2$ and $2x^2 + 2xy + 3y^2$.

§35.9 Dirichlet’s Unit Theorem

We turn to the other end of the exact sequence

$$1 \longrightarrow \mathcal{O}_K^\times \longrightarrow K^\times \longrightarrow I_K \longrightarrow \text{Cl}_K \longrightarrow 1,$$

namely the unit group $\mathcal{O}_K^\times$. We saw in Example 35.4.2 that imaginary quadratic fields have finite unit group, whereas $\mathbb{Z}[\sqrt{2}]^\times$ contains the infinite cyclic group generated by $1 + \sqrt{2}$. Dirichlet’s theorem explains this completely: the answer depends only on the signature.

Definition 35.9.1 (Roots of Unity)

Let $\mu_K = \{\alpha \in K : \alpha^m = 1 \text{ for some } m \geq 1\}$ be the group of roots of unity in K .

Theorem 35.9.2 (Dirichlet’s Unit Theorem)

Let K be a number field of signature (r, s) . Then μ_K is finite and cyclic, and

$$\mathcal{O}_K^\times \cong \mu_K \times \mathbb{Z}^{r+s-1}.$$

So for K imaginary quadratic, $(r, s) = (0, 1)$ and the rank is 0: the unit group is finite, as we found. For K real quadratic, $(r, s) = (2, 0)$ and the rank is 1, so $\mathcal{O}_K^\times = \{\pm \varepsilon^n : n \in \mathbb{Z}\}$ for a single ε – this is the statement that Pell’s equation has infinitely many solutions, all generated by one. For $K = \mathbb{Q}(\sqrt[3]{2})$, $(r, s) = (1, 1)$ and the rank is again 1.

§35.9.1 The Logarithmic Embedding

The Minkowski embedding turns multiplication into a product of coordinates, and the norm condition $N(u) = \pm 1$ into a multiplicative constraint. Taking logarithms turns this into a linear constraint, which is what we can attack with lattices.

Definition 35.9.3 (Logarithmic Embedding)

Let K have signature (r, s) with embeddings as above. Define

$$\ell : K^\times \rightarrow \mathbb{R}^{r+s},$$

$$\ell(x) = (\log|\sigma_1(x)|, \dots, \log|\sigma_r(x)|, 2\log|\sigma_{r+1}(x)|, \dots, 2\log|\sigma_{r+s}(x)|).$$

The factors of 2 on the complex coordinates are there so that ℓ interacts correctly with the norm; and ℓ does not depend on which member of each conjugate pair we chose, since conjugates have the same absolute value. Since $\log|ab| = \log|a| + \log|b|$, the map ℓ is a group homomorphism from $(K^\times, \times)$ to $(\mathbb{R}^{r+s}, +)$.

Lemma 35.9.4

Let $L = \ell(\mathcal{O}_K^\times) \subseteq \mathbb{R}^{r+s}$. Then

- (i) L is a discrete subgroup of $\mathbb{R}^{r+s}$;
- (ii) $\ker(\ell|_{\mathcal{O}_K^\times}) = \mu_K$, which is a finite cyclic group;
- (iii) L is contained in the hyperplane $H = \{(y_1, \dots, y_{r+s}) : \sum_i y_i = 0\}$.

Proof. (i) and (ii). The map ℓ factors as

$$\mathcal{O}_K^\times \xrightarrow{\sigma} (\mathbb{R}^\times)^r \times (\mathbb{C}^\times)^s \xrightarrow{j} \mathbb{R}^{r+s},$$

where $j(y_1, \dots, y_r, z_1, \dots, z_s) = (\log|y_1|, \dots, 2\log|z_s|)$. For $A > 0$,

$$j^{-1}([-A, A]^{r+s}) = \{(y_i, z_j) : e^{-A} \leq |y_i| \leq e^A, e^{-A/2} \leq |z_j| \leq e^{A/2}\}$$

is a closed and bounded, hence compact, subset of $\mathbb{R}^n$. Since $\sigma(\mathcal{O}_K)$ is a lattice (Lemma 35.7.6), hence discrete, the intersection of this compact set with $\sigma(\mathcal{O}_K^\times) \subseteq \sigma(\mathcal{O}_K)$ is finite. So $L \cap [-A, A]^{r+s}$ is finite for every A , which gives discreteness, and taking $A \rightarrow 0$ shows the kernel of ℓ on $\mathcal{O}_K^\times$ is finite.

A finite subgroup of $K^\times$ consists of elements of finite order, so $\ker \ell \subseteq \mu_K$; conversely every root of unity has all conjugates of absolute value 1, so lies in $\ker \ell$. Hence $\ker \ell = \mu_K$ is finite. Finally, embedding $K \hookrightarrow \mathbb{C}$ realises μ_K as a finite subgroup of $\mathbb{C}^\times$, hence as a group of m th roots of unity for some m ; subgroups of cyclic groups are cyclic.

(iii) If $u \in \mathcal{O}_K^\times$ then $N(u) = \pm 1$ by Lemma 35.4.1, so

$$0 = \log|N(u)| = \sum_{i=1}^r \log|\sigma_i(u)| + \sum_{j=1}^s 2\log|\sigma_{r+j}(u)|,$$

which is exactly the statement that $\ell(u) \in H$. □

Since $H \cong \mathbb{R}^{r+s-1}$, part (i) and Proposition 35.7.2 give $L \cong \mathbb{Z}^a$ for some $a \leq r + s - 1$. The content of Dirichlet's theorem is that a is as large as possible.

Theorem 35.9.5 (Dirichlet, Lattice Form)

$L = \ell(\mathcal{O}_K^\times)$ is a full lattice in $H \cong \mathbb{R}^{r+s-1}$; that is, $L \cong \mathbb{Z}^{r+s-1}$.

Granting this, Theorem 35.9.2 follows at once: we have a short exact sequence

$$1 \rightarrow \mu_K \rightarrow \mathcal{O}_K^\times \xrightarrow{\ell} L \rightarrow 0$$

with $L \cong \mathbb{Z}^{r+s-1}$ free, so the sequence splits and $\mathcal{O}_K^\times \cong \mu_K \times \mathbb{Z}^{r+s-1}$.

Here is the picture for a field with $r+s=3$ (for instance a totally real cubic field, where $(r,s)=(3,0)$): the image L is a rank-2 lattice sitting inside the plane $y_1 + y_2 + y_3 = 0$.

$$L = \ell(\mathcal{O}_K^\times) \subseteq H = \{y_1 + y_2 + y_3 = 0\}$$

§35.9.2 Proof of Dirichlet's Theorem

The strategy is to manufacture, for each coordinate k , a unit whose logarithmic image is negative in every coordinate except the k th. A linear algebra lemma then shows that such vectors are as independent as they can be. The manufacturing is done by Minkowski's theorem.

Lemma 35.9.6

Fix $1 \leq k \leq r+s$ and let $0 \neq \alpha \in \mathcal{O}_K$ with $\ell(\alpha) = (a_1, \dots, a_{r+s})$. Then there is $0 \neq \beta \in \mathcal{O}_K$ with

$$|\mathbf{N}(\beta)| \leq \left(\frac{2}{\pi}\right)^s |d_K|^{1/2} \quad \text{and} \quad b_i < a_i \text{ for all } i \neq k,$$

where $\ell(\beta) = (b_1, \dots, b_{r+s})$.

Proof. For positive reals $c_1, \dots, c_{r+s}$ let

$$S = \{(y_1, \dots, y_r, z_1, \dots, z_s) \in \mathbb{R}^r \times \mathbb{C}^s : |y_i| \leq c_i \ (i \leq r), |z_j|^2 \leq c_{r+j} \ (j \leq s)\},$$

a closed, bounded, convex, symmetric set of volume $\text{vol}(S) = 2^r \pi^s c_1 \cdots c_{r+s}$. Choose c_i with $0 < c_i < e^{a_i}$ for $i \neq k$, and then define c_k so that

$$c_1 c_2 \cdots c_{r+s} = \left(\frac{2}{\pi}\right)^s |d_K|^{1/2},$$

which makes $\text{vol}(S) = 2^r \pi^s (2/\pi)^s |d_K|^{1/2} = 2^{r+s} |d_K|^{1/2} = 2^n \text{covol}(\sigma(\mathcal{O}_K))$, using $r+2s=n$ and Lemma 35.7.6. By Minkowski's theorem there is $0 \neq \beta \in \mathcal{O}_K$ with $\sigma(\beta) \in S$. Then

$$|\mathbf{N}(\beta)| = \prod_{i \leq r} |y_i| \prod_{j \leq s} |z_j|^2 \leq c_1 \cdots c_{r+s} = \left(\frac{2}{\pi}\right)^s |d_K|^{1/2},$$

and for $i \neq k$ the i th coordinate of $\ell(\beta)$ is at most $\log c_i < a_i$. □

Lemma 35.9.7

Let $A = (a_{ij}) \in \text{Mat}_m(\mathbb{R})$ satisfy $a_{ii} > 0$, $a_{ij} < 0$ for $i \neq j$, and $\sum_j a_{ij} \geq 0$ for all i . Then $\text{rank } A \geq m - 1$.

Proof. We show the first $m - 1$ columns $v_1, \dots, v_{m-1}$ are linearly independent. Suppose $\sum_{i=1}^{m-1} t_i v_i = 0$ with not all t_i zero. Choose $k \leq m - 1$ with $|t_k|$ maximal, and rescale so that $t_k = 1$ and $|t_i| \leq 1$ for all i . Reading off the k th coordinate,

$$0 = \sum_{i=1}^{m-1} t_i a_{ki} = a_{kk} + \sum_{\substack{i \neq k \\ i \leq m-1}} t_i a_{ki}.$$

Now $a_{ki} < 0$ for $i \neq k$ and $t_i \leq 1$, so $t_i a_{ki} \geq a_{ki}$. Hence

$$0 \geq \sum_{i=1}^{m-1} a_{ki} > \sum_{i=1}^m a_{ki} \geq 0,$$

where the strict inequality is because $a_{km} < 0$. This is a contradiction. $\square$

Proof of Theorem 35.9.5. Fix k with $1 \leq k \leq r + s$. Starting from any $\alpha_1 \in \mathcal{O}_K$ nonzero and applying Lemma 35.9.6 repeatedly, we obtain a sequence $\alpha_1, \alpha_2, \dots \in \mathcal{O}_K \setminus \{0\}$ such that

$$|N(\alpha_t)| \leq M := \left(\frac{2}{\pi}\right)^s |d_K|^{1/2} \quad \text{for } t \geq 2,$$

and for each $i \neq k$ the i th coordinate of $\ell(\alpha_t)$ is strictly decreasing in t .

There are only finitely many integers of absolute value at most M , so by pigeonhole some value m occurs as $N(\alpha_t)$ infinitely often. There are also only finitely many residues modulo $m\mathcal{O}_K$ (Lemma 35.4.8), so again by pigeonhole there are $t < t'$ with $N(\alpha_t) = N(\alpha_{t'}) = m$ and $\alpha_t \equiv \alpha_{t'} \pmod{m\mathcal{O}_K}$. Then $\alpha_{t'} = \alpha_t + m\gamma$ for some $\gamma \in \mathcal{O}_K$, and since $m/\alpha_t = \pm \prod_{i \geq 2} \sigma_i(\alpha_t)$ is an algebraic integer lying in K , we get $m/\alpha_t \in \mathcal{O}_K$ and hence

$$\frac{\alpha_{t'}}{\alpha_t} = 1 + \frac{m}{\alpha_t} \gamma \in \mathcal{O}_K.$$

Symmetrically $\alpha_t/\alpha_{t'} \in \mathcal{O}_K$, so $u_k := \alpha_{t'}/\alpha_t \in \mathcal{O}_K^\times$.

By construction $\ell(u_k) = \ell(\alpha_{t'}) - \ell(\alpha_t)$ has i th coordinate strictly negative for every $i \neq k$. Since $\ell(u_k) \in H$ its coordinates sum to zero, so its k th coordinate is strictly positive.

Doing this for each $k = 1, \dots, r + s$ produces units $u_1, \dots, u_{r+s}$, and the matrix A with k th row $\ell(u_k)$ satisfies the hypotheses of Lemma 35.9.7 with $m = r + s$ (the row sums are zero). So $\text{rank } A \geq r + s - 1$, and since the rows lie in the hyperplane H of dimension $r + s - 1$, we get $\text{rank } A = r + s - 1$ exactly. Hence $\ell(u_1), \dots, \ell(u_{r+s})$ span H , so L contains $r + s - 1$ linearly independent vectors and is a discrete subgroup of H : by Proposition 35.7.2, $L \cong \mathbb{Z}^{r+s-1}$ is a full lattice in H . $\square$

Definition 35.9.8 (Fundamental Units, Regulator)

A set of units $\varepsilon_1, \dots, \varepsilon_{r+s-1}$ whose images $\ell(\varepsilon_i)$ form a $\mathbb{Z}$ -basis of L is called a system of **fundamental units**: every unit is then uniquely $\zeta \varepsilon_1^{n_1} \cdots \varepsilon_{r+s-1}^{n_{r+s-1}}$ with $\zeta \in \mu_K$ and $n_i \in \mathbb{Z}$. The **regulator** of K is

$$R_K = \text{covol}(L \subseteq H),$$

computed as the absolute value of the determinant of any $(r+s-1) \times (r+s-1)$ minor of the matrix with rows $\ell(\varepsilon_1), \dots, \ell(\varepsilon_{r+s-1})$.

Example 35.9.9

If $r+s-1 = 0$ (that is, $K = \mathbb{Q}$ or K imaginary quadratic) then $R_K = 1$ by convention. If K is real quadratic with fundamental unit $\varepsilon > 1$, then $\ell(\varepsilon) = (\log \varepsilon, -\log \varepsilon)$ and $R_K = \log \varepsilon$.

§35.9.3 Real Quadratic Fields and Pell's Equation

The rank-1 case deserves a closer look, since it is by far the most computable and has a beautiful classical shadow. Let $K = \mathbb{Q}(\sqrt{d})$ with $d > 0$ squarefree, so $(r, s) = (2, 0)$ and $\mu_K = \{\pm 1\}$ (as $K \subseteq \mathbb{R}$). Dirichlet's theorem gives

$$\mathcal{O}_K^\times = \{\pm \varepsilon^n : n \in \mathbb{Z}\}$$

for a **fundamental unit** ε , unique if we insist $\varepsilon > 1$ under the embedding $\sqrt{d} > 0$.

Since $N(x + y\sqrt{d}) = x^2 - dy^2$, this is the classical statement about **Pell's equation**: the integer solutions of $x^2 - dy^2 = \pm 1$ (or ± 4 , when $d \equiv 1 \pmod{4}$ and we allow half-integers) are all obtained from a single one by taking powers. Geometrically, $\sigma(\mathcal{O}_K)$ is a lattice in $\mathbb{R}^2$ and the units are precisely its points on the two hyperbolas $y_1 y_2 = \pm 1$.

$\sigma(\mathbb{Z}[\sqrt{2}])$ and the hyperbolas $y_1 y_2 = \pm 1$

Here $\varepsilon = 1 + \sqrt{2}$ has $\sigma(\varepsilon) = (1 + \sqrt{2}, 1 - \sqrt{2}) \approx (2.414, -0.414)$, lying on the dashed branch $y_1 y_2 = -1$ because $N(\varepsilon) = -1$; its inverse $\varepsilon^{-1} = \sqrt{2} - 1$ has $\sigma(\varepsilon^{-1}) \approx (0.414, -2.414)$. The square $\varepsilon^2 = 3 + 2\sqrt{2}$ lands at $(5.83, 0.17)$ on the solid hyperbola $y_1 y_2 = 1$, off the right-hand edge of the picture. As n increases, $\sigma(\varepsilon^n)$ marches off along the hyperbolas, hugging the axes ever more closely – and *every* lattice point on either hyperbola is one of these.

We can prove the rank-1 case of Dirichlet's theorem directly, and the proof is instructive.

Theorem 35.9.10 (Pell)

Let $K = \mathbb{Q}(\sqrt{d})$ with $d > 0$ squarefree. Then $\mathcal{O}_K^\times$ is infinite. Equivalently, $x^2 - dy^2 = 1$ has infinitely many integer solutions.

Proof. Recall $\sigma(x) = (x, \bar{x})$ and $\text{covol}(\sigma(\mathcal{O}_K)) = |d_K|^{1/2}$. For $t > 0$ let

$$S_t = \{(y_1, y_2) \in \mathbb{R}^2 : |y_1| \leq t, |y_2| \leq |d_K|^{1/2}/t\},$$

a closed convex symmetric rectangle whose area is $4|d_K|^{1/2}$, that is, $2^2 \text{covol}(\sigma(\mathcal{O}_K))$. By Minkowski's theorem there is a nonzero $\alpha_t \in \mathcal{O}_K$ with $\sigma(\alpha_t) \in S_t$, and then

$$1 \leq |N(\alpha_t)| = |y_1 y_2| \leq |d_K|^{1/2}.$$

We now produce infinitely many distinct such α . Having chosen $t_1 > t_2 > \dots > t_N > 0$, the set $S_{t_N} \cap \sigma(\mathcal{O}_K)$ is finite (compact meets discrete), and every element of it has nonzero first coordinate (as σ_1 is injective and $\alpha \neq 0$); so we may choose $t_{N+1} > 0$ smaller than all of these first coordinates in absolute value. Then $\alpha_{t_{N+1}}$ is different from all previous α_{t_i} .

So there are infinitely many $\alpha \in \mathcal{O}_K$ with $1 \leq |N(\alpha)| \leq |d_K|^{1/2}$. By pigeonhole some value m is attained infinitely often; and since there are only finitely many ideals of norm $|m|$ (Corollary 35.5.10), some ideal (β) arises as (α) for infinitely many α . For any two such, α/α' is a unit, and distinct α give distinct units. So $\mathcal{O}_K^\times$ is infinite.

Finally, $\mathcal{O}_K^\times$ infinite gives a unit $u \neq \pm 1$ with $N(u) = \pm 1$; then u^2 has norm 1, and writing $u^2 = x + y\sqrt{d}$ (or $\frac{1}{2}(x + y\sqrt{d})$, in which case take u^6) gives infinitely many solutions of $x^2 - dy^2 = 1$ from the powers of u^2 . $\square$

Corollary 35.9.11

$\mathcal{O}_K^\times = \{\pm \varepsilon^n : n \in \mathbb{Z}\}$ for some ε .

Proof. Identify K with $\sigma_1(K) \subseteq \mathbb{R}$. By the theorem there is a unit $u \neq \pm 1$, and $|u| \neq 1$ (since $|u| = 1$ with u real forces $u = \pm 1$); replacing u by u^{-1} if necessary, $E := |u| > 1$. The set

$$\{\alpha \in \mathcal{O}_K : N(\alpha) = \pm 1, 1 < |\alpha| \leq E\}$$

is finite, since $\mathcal{O}_K$ is discrete in $\mathbb{R}^2$ and this set has bounded coordinates ($|\alpha| \leq E$ and $|\bar{\alpha}| = 1/|\alpha| \leq 1$). It is nonempty (it contains u or $-u$), so choose ε in it with $|\varepsilon|$ minimal, and replace ε by $-\varepsilon$ if needed so that $\varepsilon > 1$.

Now let $v \in \mathcal{O}_K^\times$ with $v > 0$; we claim $v = \varepsilon^N$ for some $N \in \mathbb{Z}$. Write $\log v / \log \varepsilon = N + \gamma$ with $N \in \mathbb{Z}$ and $0 \leq \gamma < 1$. Then $w = v\varepsilon^{-N}$ is a unit with $1 \leq w = \varepsilon^\gamma < \varepsilon$, so by minimality $w = 1$, i.e. $\gamma = 0$. Since every unit is $\pm$ a positive one, we are done. $\square$

§35.9.4 Finding Fundamental Units

Locating ε in practice is a matter of searching, and the search can be made short by the following observation: if $\varepsilon = a + b\sqrt{d} > 1$ is a unit with $\bar{\varepsilon} = \pm\varepsilon^{-1}$, then $|\bar{\varepsilon}| < 1$, so

$$2a = \varepsilon + \bar{\varepsilon} > 0 \quad \text{and} \quad 2b\sqrt{d} = \varepsilon - \bar{\varepsilon} > 0,$$

so $a, b > 0$. Hence the fundamental unit is the one with smallest positive b , and we can simply try $b = 1, 2, 3, \dots$ and test whether $db^2 \pm 1$ (or $db^2 \pm 4$) is a square.

Example 35.9.12

Let $d = 2$. Guess $\varepsilon = 1 + \sqrt{2}$, which has $N(\varepsilon) = -1$, so it is a unit. It is fundamental: any smaller unit $u = a + b\sqrt{2} > 1$ would have $a, b \geq 1$ by the above, hence $u \geq 1 + \sqrt{2} = \varepsilon$. So $\mathcal{O}_{\mathbb{Q}(\sqrt{2})}^\times = \{\pm(1 + \sqrt{2})^n\}$ and $R_K = \log(1 + \sqrt{2}) \approx 0.881$.

Example 35.9.13

Let $d = 11$, so $\mathcal{O}_K = \mathbb{Z}[\sqrt{11}]$. Trying $b = 1, 2, 3$: $11 - 1 = 10$, $11 + 1 = 12$, 44 ± 1 , $99 + 1 = 100 = 10^2$. So $\varepsilon^{-1} = 10 - 3\sqrt{11}$ has norm $100 - 99 = 1$ and $\varepsilon = 10 + 3\sqrt{11} \approx 19.95$ is a unit.

Let us verify it is fundamental without appealing to the search. Suppose $u = a + b\sqrt{11}$ is a unit with $1 < u < \varepsilon$. If $N(u) = -1$ then $a^2 - 11b^2 = -1$, so $a^2 \equiv -1 \pmod{11}$; but -1 is not a square mod 11 (the squares are 1, 3, 4, 5, 9). So $N(u) = 1$ and $\bar{u} = u^{-1}$, giving $0 < \bar{u} < 1$. Adding the inequalities $1 < u < 10 + 3\sqrt{11}$ and $-1 < -\bar{u} < 0$:

$$0 < u - \bar{u} = 2b\sqrt{11} < 10 + 3\sqrt{11} < 7\sqrt{11},$$

so $b \in \{1, 2, 3\}$. But $11b^2 + 1 \in \{12, 45, 100\}$ and only 100 is a square, forcing $u = \varepsilon$. So ε is fundamental.

Example 35.9.14

Some fundamental units, to give a sense of how erratically they grow:

d	2	3	5	6	7	11
ε	$1 + \sqrt{2}$	$2 + \sqrt{3}$	$\frac{1}{2}(1 + \sqrt{5})$	$5 + 2\sqrt{6}$	$8 + 3\sqrt{7}$	$10 + 3\sqrt{11}$
d	13	19	31	46		
ε	$\frac{1}{2}(3 + \sqrt{13})$	$170 + 39\sqrt{19}$	$1520 + 273\sqrt{31}$	$24335 + 3588\sqrt{46}$		

The case $d = 5$ is the golden ratio φ , with $\varphi^2 = \varphi + 1$ and $N(\varphi) = -1$. The jump at $d = 19$ and again at $d = 46$ is typical: the size of ε is roughly e^{R_K} , and the regulator behaves very irregularly.

Example 35.9.15 (A Cubic Field)

Let $K = \mathbb{Q}(\sqrt[3]{2})$, with signature $(1, 1)$, so the unit rank is $r+s-1 = 1$ and $\mu_K = \{\pm 1\}$ (as $K \subseteq \mathbb{R}$). Consider

$$\varepsilon = \sqrt[3]{2} - 1.$$

Its minimal polynomial is $(x+1)^3 - 2 = x^3 + 3x^2 + 3x - 1$, whose constant term is

-1 , so $N(\varepsilon) = (-1)^3(-1) = 1$ and ε is a unit. In fact it is fundamental, so

$$\mathcal{O}_{\mathbb{Q}(\sqrt[3]{2})}^\times = \left\{ \pm \left(\sqrt[3]{2} - 1 \right)^n : n \in \mathbb{Z} \right\}, \quad R_K = \log \frac{1}{\sqrt[3]{2} - 1} \approx 1.347.$$

Note that $\varepsilon \approx 0.26 < 1$, so it is $\varepsilon^{-1} = 1 + \sqrt[3]{2} + \sqrt[3]{4} \approx 3.85$ that is the ‘large’ generator; and $\ell(\varepsilon) = (\log|\varepsilon|, -\log|\varepsilon|)$ since the two coordinates must sum to zero.

Remark (Continued Fractions). There is a systematic algorithm. Every real number has a continued fraction expansion

$$t = a_0 + \frac{1}{a_1 + \frac{1}{a_2 + \frac{1}{a_3 + \cdots}}} = [a_0, a_1, a_2, \dots], \quad a_0 = \lfloor t \rfloor,$$

and a classical theorem of Lagrange says that t is a quadratic irrational if and only if this expansion is eventually periodic. For $\sqrt{d}$ the expansion is purely periodic after the first term, say $\sqrt{d} = [a_0, \overline{a_1, \dots, a_m}]$, and then (this is non-examinable, and should not be quoted in exams) if $p/q = [a_0, a_1, \dots, a_{m-1}]$ in lowest terms, the number $p + q\sqrt{d}$ is a unit, and is fundamental when $d \equiv 2, 3 \pmod{4}$.

For instance $\sqrt{7} = [2, \overline{1, 1, 1, 4}]$, and $[2, 1, 1, 1] = 2 + \frac{1}{1 + \frac{1}{1 + \frac{1}{1}}}$ giving $8 + 3\sqrt{7}$ with

$(8 + 3\sqrt{7})(8 - 3\sqrt{7}) = 64 - 63 = 1$. This algorithm runs in time polynomial in R_K , but *not* in $\log|d_K|$; no polynomial-time algorithm is known, and the difficulty is closely related to the erratic growth in the table above.

§35.10 Diophantine Applications

Having built the machinery, let us see it pay for itself. The pattern in each case is the same: an equation over $\mathbb{Z}$ factorises in $\mathcal{O}_K$ for a suitable K , unique factorisation of *ideals* lets us conclude that each factor is (say) a perfect cube as an ideal, and then the class group tells us whether we may promote this to a statement about elements.

The following two observations are what make the pattern work.

Lemma 35.10.1

Let $\mathfrak{a}, \mathfrak{b} \subseteq \mathcal{O}_K$ be coprime nonzero ideals (that is, $\mathfrak{a} + \mathfrak{b} = \mathcal{O}_K$) with $\mathfrak{a}\mathfrak{b} = \mathfrak{c}^m$ for some ideal $\mathfrak{c}$ and $m \geq 1$. Then $\mathfrak{a} = \mathfrak{d}^m$ and $\mathfrak{b} = \mathfrak{e}^m$ for some ideals $\mathfrak{d}, \mathfrak{e}$.

Proof. Write $\mathfrak{a} = \prod_{\mathfrak{p}} \mathfrak{p}^{a_{\mathfrak{p}}}$ and $\mathfrak{b} = \prod_{\mathfrak{p}} \mathfrak{p}^{b_{\mathfrak{p}}}$. Coprimality says no $\mathfrak{p}$ has both $a_{\mathfrak{p}} > 0$ and $b_{\mathfrak{p}} > 0$. The hypothesis says $a_{\mathfrak{p}} + b_{\mathfrak{p}} \equiv 0 \pmod{m}$ for every $\mathfrak{p}$, so for each $\mathfrak{p}$ one of $a_{\mathfrak{p}}, b_{\mathfrak{p}}$ is zero and the other is divisible by m . Take $\mathfrak{d} = \prod_{\mathfrak{p}} \mathfrak{p}^{a_{\mathfrak{p}}/m}$ and $\mathfrak{e} = \prod_{\mathfrak{p}} \mathfrak{p}^{b_{\mathfrak{p}}/m}$. $\square$

Lemma 35.10.2

Suppose $\gcd(m, h_K) = 1$ and $\mathfrak{d} \trianglelefteq \mathcal{O}_K$ is an ideal with $\mathfrak{d}^m$ principal. Then $\mathfrak{d}$ is principal.

Proof. In Cl_K we have $[\mathfrak{d}]^m = 1$, so the order of $[\mathfrak{d}]$ divides m ; it also divides $h_K = |\text{Cl}_K|$ by Lagrange. As $\gcd(m, h_K) = 1$, the order is 1. $\square$

§35.10.1 Sums of Two Squares

The oldest application, and still the prettiest.

Theorem 35.10.3 (Fermat)

An odd prime p is a sum of two integer squares if and only if $p \equiv 1 \pmod{4}$, and then the representation is unique up to signs and order.

Proof. Work in $\mathcal{O}_{\mathbb{Q}(i)} = \mathbb{Z}[i]$, which has $d_K = -4$ and $C_K = \frac{2}{\pi} \cdot 2 < 2$, so $h_K = 1$ and $\mathbb{Z}[i]$ is a PID. Note $N(a + bi) = a^2 + b^2$.

If $p = a^2 + b^2$ then modulo 4 the right-hand side is 0, 1 or 2, and p is odd, so $p \equiv 1 \pmod{4}$.

Conversely suppose $p \equiv 1 \pmod{4}$. Then -1 is a quadratic residue mod p (as the group $\mathbb{F}_p^\times$ is cyclic of order $p - 1 \equiv 0 \pmod{4}$, so contains an element of order 4), so $x^2 + 1$ has a root mod p and factors as $(x - r)(x + r)$. By Dedekind's criterion, p splits: $(p) = \mathfrak{p}\bar{\mathfrak{p}}$ with $N(\mathfrak{p}) = p$. Since $\mathbb{Z}[i]$ is a PID, $\mathfrak{p} = (a + bi)$ for some a, b , and $p = N(\mathfrak{p}) = a^2 + b^2$.

For uniqueness, a representation $p = a^2 + b^2$ gives $(p) = (a + bi)(a - bi)$, a factorisation into primes of norm p ; by unique factorisation these must be $\mathfrak{p}$ and $\bar{\mathfrak{p}}$ in some order, so $a + bi$ is an associate of $a' + b'i$ or of $a' - b'i$, and the units of $\mathbb{Z}[i]$ are $\pm 1, \pm i$, which permute (a, b) up to signs and order. $\square$

Example 35.10.4

$5 = 1^2 + 2^2$, $13 = 2^2 + 3^2$, $17 = 1^2 + 4^2$, $29 = 2^2 + 5^2$; whereas 3, 7, 11, 19 are not sums of two squares. Note $2 = 1^2 + 1^2$ is the ramified case: $(2) = (1 + i)^2$ up to units.

Corollary 35.10.5

A positive integer n is a sum of two squares if and only if every prime $q \equiv 3 \pmod{4}$ divides n to an even power.

Proof. n is a sum of two squares if and only if $n = N(\alpha)$ for some $\alpha \in \mathbb{Z}[i]$, i.e. $n = N(\mathfrak{a})$ for some ideal $\mathfrak{a}$ (using $h_K = 1$). Now N is multiplicative and, by Proposition 35.6.11, the primes of $\mathbb{Z}[i]$ have norms: 2 (from $(2) = (1 + i)^2$), p and p (for $p \equiv 1 \pmod{4}$, which splits), and q^2 (for $q \equiv 3 \pmod{4}$, which is inert). So the norms of ideals are exactly the integers in which each $q \equiv 3 \pmod{4}$ appears with

even exponent. □

Example 35.10.6 (The Form $x^2 + 2y^2$)

The same argument runs in $\mathbb{Z}[\sqrt{-2}]$, which is also a PID (its Minkowski constant is $\frac{2}{\pi}\sqrt{8} \approx 1.80 < 2$). An odd prime p is of the form $x^2 + 2y^2$ if and only if p splits in $\mathbb{Q}(\sqrt{-2})$, which by Proposition 35.6.11 happens exactly when $\left(\frac{-2}{p}\right) = 1$, that is, when

$$p \equiv 1, 3 \pmod{8}.$$

So $3 = 1 + 2$, $11 = 9 + 2$, $17 = 9 + 8$, $19 = 1 + 18$, whereas $5, 7, 13, 23$ are not of this form. The reader may enjoy checking that the same method with $\mathbb{Z}[\omega]$, $\omega = \frac{1}{2}(-1 + \sqrt{-3})$, gives: p is of the form $x^2 + xy + y^2$ if and only if $p \equiv 1 \pmod{3}$.

Remark. It is essential here that the relevant ring has class number one. For $x^2 + 5y^2$ the class number is 2, and the correct statement splits into two cases according to the ideal class: an odd prime $p \neq 5$ is of the form $x^2 + 5y^2$ if $p \equiv 1, 9 \pmod{20}$, and of the form $2x^2 + 2xy + 3y^2$ – the other reduced quadratic form of discriminant -20 – if $p \equiv 3, 7 \pmod{20}$. This is exactly the phenomenon the class group was invented to describe.

§35.10.2 Mordell Equations

The equation $y^2 = x^3 + k$ is called a **Mordell equation**. Mordell proved that it has only finitely many integer solutions for each $k \neq 0$, but finding them is another matter; in favourable cases number fields do it in a page.

Theorem 35.10.7

The only integer solutions of $y^2 = x^3 - 2$ are $(x, y) = (3, \pm 5)$.

Proof. Write the equation as $y^2 + 2 = x^3$ and work in $K = \mathbb{Q}(\sqrt{-2})$, where $\mathcal{O}_K = \mathbb{Z}[\sqrt{-2}]$, $d_K = -8$, $N(a + b\sqrt{-2}) = a^2 + 2b^2$ and $\mathcal{O}_K^\times = \{\pm 1\}$. Since $C_K = \frac{2}{\pi}\sqrt{8} \approx 1.80 < 2$, we have $h_K = 1$.

Step 1: y is odd. If y were even then $x^3 = y^2 + 2 \equiv 2 \pmod{4}$, so x^3 is even, hence x is even and $8 \mid x^3$ – contradicting $x^3 \equiv 2 \pmod{4}$.

Step 2: the ideals $(y + \sqrt{-2})$ and $(y - \sqrt{-2})$ are coprime. Suppose a prime $\mathfrak{p}$ divides both. Then $\mathfrak{p}$ divides their difference $(2\sqrt{-2}) = (\sqrt{-2})^3$, so $\mathfrak{p} = (\sqrt{-2})$, the unique prime above 2. Then $\mathfrak{p} \mid (y + \sqrt{-2})$ gives $\mathfrak{p} \mid (y)$, so $2 = N(\mathfrak{p})$ divides $N((y)) = y^2$, making y even – contradicting Step 1.

Step 3: cubes. We have $(y + \sqrt{-2})(y - \sqrt{-2}) = (x)^3$ with the factors coprime, so by Lemma 35.10.1 there is an ideal $\mathfrak{d}$ with $(y + \sqrt{-2}) = \mathfrak{d}^3$. As $h_K = 1$, $\mathfrak{d} = (\gamma)$ is principal, so $y + \sqrt{-2} = u\gamma^3$ for a unit $u = \pm 1$; and $\pm 1 = (\pm 1)^3$, so absorbing the unit into γ ,

$$y + \sqrt{-2} = (a + b\sqrt{-2})^3 \quad \text{for some } a, b \in \mathbb{Z}.$$

Step 4: solve. Expanding,

$$(a + b\sqrt{-2})^3 = a^3 - 6ab^2 + (3a^2b - 2b^3)\sqrt{-2},$$

so comparing coefficients of $\sqrt{-2}$,

$$1 = 3a^2b - 2b^3 = b(3a^2 - 2b^2).$$

Hence $b \mid 1$. If $b = 1$ then $3a^2 - 2 = 1$, so $a = \pm 1$; if $b = -1$ then $3a^2 - 2 = -1$, so $3a^2 = 1$, impossible. So $b = 1$, $a = \pm 1$, and

$$y = a^3 - 6ab^2 = a^3 - 6a = \mp 5,$$

giving $y = \pm 5$ and $x^3 = 25 + 2 = 27$, so $x = 3$. $\square$

Now an example where the class group genuinely intervenes.

Theorem 35.10.8

The equation $y^2 = x^3 - 5$ has no integer solutions.

Proof. Write $y^2 + 5 = x^3$ and work in $K = \mathbb{Q}(\sqrt{-5})$, so $\mathcal{O}_K = \mathbb{Z}[\sqrt{-5}]$, $\mathcal{O}_K^\times = \{\pm 1\}$ and $h_K = 2$ by Example 35.8.1.

Step 1: x is odd. If x were even then $8 \mid x^3$, so $y^2 \equiv -5 \equiv 3 \pmod{8}$; but squares mod 8 are 0, 1, 4.

Step 2: coprimality. Suppose a prime $\mathfrak{p}$ divides $(y + \sqrt{-5})$ and $(y - \sqrt{-5})$. Then $\mathfrak{p} \mid (2\sqrt{-5})$, so $\mathfrak{p}$ is the prime $\mathfrak{p}_2 = (2, 1 + \sqrt{-5})$ above 2 or the prime $\mathfrak{p}_5 = (\sqrt{-5})$ above 5.

If $\mathfrak{p} = \mathfrak{p}_2$ then $\mathfrak{p}_2 \mid (y + \sqrt{-5})(y - \sqrt{-5}) = (x)^3$, so $\mathfrak{p}_2 \mid (x)$ and $2 = N(\mathfrak{p}_2)$ divides x^2 , making x even – contradicting Step 1.

If $\mathfrak{p} = \mathfrak{p}_5$ then similarly $5 \mid x^2$, so $5 \mid x$ and $125 \mid x^3$. Then $y^2 = x^3 - 5 \equiv -5 \pmod{25}$, so $5 \mid y^2$, so $5 \mid y$ and $25 \mid y^2$; but then $25 \mid x^3 - y^2 = 5$, absurd.

Step 3: cubes. As before $(y + \sqrt{-5}) = \mathfrak{d}^3$ for some ideal $\mathfrak{d}$. Now $\gcd(3, h_K) = \gcd(3, 2) = 1$, so Lemma 35.10.2 applies: $\mathfrak{d} = (\gamma)$ is principal. Absorbing the unit $\pm 1 = (\pm 1)^3$,

$$y + \sqrt{-5} = (a + b\sqrt{-5})^3 = a^3 - 15ab^2 + (3a^2b - 5b^3)\sqrt{-5}.$$

Step 4: solve. Comparing coefficients, $1 = b(3a^2 - 5b^2)$, so $b = \pm 1$. If $b = 1$ then $3a^2 = 6$, so $a^2 = 2$, impossible; if $b = -1$ then $3a^2 = 4$, impossible. So there are no solutions. $\square$

Remark. Step 3 is exactly where the class group earns its keep, and it is where the argument would break down if 3 divided h_K . If instead we had tried this with $\mathbb{Q}(\sqrt{-26})$, whose class number is 6, the argument would fail – and indeed $y^2 = x^3 - 26$ *does* have solutions, namely $(3, \pm 1)$ and $(35, \pm 207)$. Similarly, one must never forget the unit-absorbing step: it works here only because the unit group is $\{\pm 1\}$ and every unit is a cube. Over a real quadratic field, with its infinite unit group, considerably more care is

needed.

§35.10.3 Cyclotomic Fields and Fermat's Last Theorem

Kummer's original motivation for inventing ideal numbers was Fermat's equation

$$x^p + y^p = z^p, \quad p \text{ an odd prime.}$$

In $\mathbb{Q}(\zeta_p)$ the left-hand side factors completely:

$$x^p + y^p = \prod_{i=0}^{p-1} (x + \zeta_p^i y).$$

Suppose x, y, z are pairwise coprime integers with $p \nmid xyz$ (this is **Case I**). One checks that the ideals $(x + \zeta_p^i y)$ are pairwise coprime, so their product being $(z)^p$ forces

$$(x + \zeta_p y) = \mathfrak{a}^p$$

for some ideal $\mathfrak{a}$, by Lemma 35.10.1. So far this is exactly the Mordell argument. The step that fails in general is the promotion of $\mathfrak{a}^p$ principal to $\mathfrak{a}$ principal: this needs $p \nmid h_{\mathbb{Q}(\zeta_p)}$.

Definition 35.10.9 (Regular Prime)

An odd prime p is **regular** if $p \nmid h_{\mathbb{Q}(\zeta_p)}$.

Theorem 35.10.10 (Kummer)

If p is a regular prime then $x^p + y^p = z^p$ has no solutions in nonzero integers.

The remaining work, which we do not do here, is to control the units of $\mathbb{Z}[\zeta_p]$ (there is a lemma of Kummer saying that every unit is ζ_p^a times a real unit), and to handle Case II where $p \mid xyz$ by a descent.

The smallest irregular prime is 37, and the first few are 37, 59, 67, 101, 103, 131, 149, 157. Kummer gave a beautiful criterion: p is irregular precisely when p divides the numerator of one of the Bernoulli numbers $B_2, B_4, \dots, B_{p-3}$. It is known that infinitely many primes are irregular; whether infinitely many are regular is, remarkably, still open, although heuristics suggest about $e^{-1/2} \approx 61\%$ of primes should be.

Example 35.10.11

For $p \leq 19$ one has $h_{\mathbb{Q}(\zeta_p)} = 1$, so all these primes are regular and Fermat's equation has no solutions for these exponents. The first failure of $h = 1$ is $p = 23$, where $h_{\mathbb{Q}(\zeta_{23})} = 3$; but $23 \nmid 3$, so 23 is still regular.

Remark. Of course, Fermat's Last Theorem is now a theorem of Wiles for all $n \geq 3$, by a route – modular forms and Galois representations – with no visible relation to Kummer's. But Kummer's approach is the origin of algebraic number theory, and the class group of $\mathbb{Q}(\zeta_p)$ remains an object of intense study; the Herbrand–Ribet theorem, for instance, describes exactly which pieces of it are nontrivial in terms of Bernoulli numbers.

§35.11 The Dedekind Zeta Function

This final section is non-examinable. Its purpose is to show that the two invariants we have worked so hard to compute – the class number h_K and the regulator R_K – are not isolated curiosities, but appear together as the residue of a single analytic function; and to use this to prove Dirichlet's theorem on primes in arithmetic progressions, a result about $\mathbb{Z}$ whose only known proofs go through number fields.

§35.11.1 Dirichlet Series

Euler's proof that there are infinitely many primes runs as follows. By unique factorisation in $\mathbb{Z}$,

$$\prod_{p \text{ prime}} \left(1 - \frac{1}{p}\right)^{-1} = \prod_p \left(1 + \frac{1}{p} + \frac{1}{p^2} + \dots\right) = \sum_{n \geq 1} \frac{1}{n},$$

since each n arises exactly once when the product is expanded. The right-hand side diverges, so the product cannot be finite. This is already better than Euclid's proof, because it says something quantitative; but it says nothing about primes in a fixed congruence class, since there is no such product formula for $\prod_{p \equiv a(q)}$. Dirichlet's idea was to introduce a variable.

Definition 35.11.1 (Riemann Zeta Function)

For $s \in \mathbb{C}$ with $\operatorname{Re}(s) > 1$, define $\zeta(s) = \sum_{n \geq 1} n^{-s}$.

More generally, a **Dirichlet series** is a function of the form $\sum_{n \geq 1} a_n n^{-s}$ for a sequence (a_n) of complex numbers. Convergence is controlled by the partial sums of the a_n .

Lemma 35.11.2

Suppose $a_1 + \dots + a_N = O(N^r)$ for some $r \in \mathbb{R}$. Then $\sum_{n \geq 1} a_n n^{-s}$ converges to a holomorphic function on $\operatorname{Re}(s) > r$.

Proof. Write $T(N) = a_1 + \dots + a_N$, so $|T(N)| \leq BN^r$ for some constant B . Abel summation gives

$$\sum_{n=1}^N a_n n^{-s} = \sum_{n=1}^{N-1} T(n) (n^{-s} - (n+1)^{-s}) + \frac{T(N)}{N^s}.$$

If $\operatorname{Re}(s) > r$ then $|T(N)/N^s| \leq BN^{r-\operatorname{Re}(s)} \rightarrow 0$, so it suffices to show that the sum $\sum_n T(n) (n^{-s} - (n+1)^{-s})$ converges absolutely. Now

$$n^{-s} - (n+1)^{-s} = s \int_n^{n+1} \frac{dx}{x^{s+1}},$$

and $n^r \leq x^r$ for $x \in [n, n+1]$ when $r \geq 0$ (and $n^r \leq (x-1)^r$ otherwise, which is

handled the same way), so

$$|T(n)||n^{-s} - (n+1)^{-s}| \leq B|s| \int_n^{n+1} \frac{dx}{x^{\operatorname{Re}(s)+1-r}},$$

and summing over n gives a convergent integral $\int_1^\infty x^{r-\operatorname{Re}(s)-1} dx$. Holomorphy follows since the convergence is locally uniform. $\square$

Proposition 35.11.3 (i) $\zeta(s)$ converges to a holomorphic function on $\operatorname{Re}(s) > 1$;

(ii) on that region, $\zeta(s) = \prod_p (1 - p^{-s})^{-1}$, the **Euler product**;

(iii) $\zeta(s) - \frac{1}{s-1}$ extends holomorphically to $\operatorname{Re}(s) > 0$. In particular ζ has a simple pole at $s = 1$ with residue 1.

Proof. (i) is Lemma 35.11.2 with $a_n = 1$, so $T(N) = N = O(N)$.

(ii) Let $p_1, \dots, p_m$ be the first m primes and X the set of positive integers all of whose prime factors lie among them. Expanding geometric series and using unique factorisation, $\prod_{i \leq m} (1 - p_i^{-s})^{-1} = \sum_{n \in X} n^{-s}$, so

$$\left| \zeta(s) - \prod_{i \leq m} (1 - p_i^{-s})^{-1} \right| = \left| \sum_{n \notin X} n^{-s} \right| \leq \sum_{n > m} n^{-\operatorname{Re}(s)} \rightarrow 0,$$

using $1, \dots, m \in X$.

(iii) Since $\frac{1}{s-1} = \sum_{n \geq 1} \int_n^{n+1} t^{-s} dt$, we get

$$\zeta(s) - \frac{1}{s-1} = \sum_{n \geq 1} \int_n^{n+1} (n^{-s} - t^{-s}) dt,$$

and each term is $O(|s|n^{-\operatorname{Re}(s)-1})$ by the mean value theorem, so the sum converges locally uniformly for $\operatorname{Re}(s) > 0$. $\square$

§35.11.2 The Dedekind Zeta Function

The Euler product is exactly the analytic shadow of unique factorisation, so it should have an analogue in any $\mathcal{O}_K$.

Definition 35.11.4 (Dedekind Zeta Function)

Let K be a number field. Its **Dedekind zeta function** is

$$\zeta_K(s) = \sum_{0 \neq \mathfrak{a} \leq \mathcal{O}_K} N(\mathfrak{a})^{-s} = \sum_{n \geq 1} \frac{a_n}{n^s}, \quad a_n = \# \{ \mathfrak{a} \leq \mathcal{O}_K : N(\mathfrak{a}) = n \},$$

which is a finite count by Corollary 35.5.10.

Theorem 35.11.5 (Analytic Class Number Formula)

Let K be a number field of degree n and signature (r, s) . Then

- (i) $\zeta_K(s)$ converges to a holomorphic function on $\operatorname{Re}(s) > 1$;
- (ii) on that region $\zeta_K(s) = \prod_{\mathfrak{p}} (1 - N(\mathfrak{p})^{-s})^{-1}$, the product over nonzero primes of $\mathcal{O}_K$;
- (iii) ζ_K extends meromorphically to $\operatorname{Re}(s) > 1 - \frac{1}{n}$ with a simple pole at $s = 1$ of residue

$$\operatorname{Res}_{s=1} \zeta_K(s) = \frac{2^r (2\pi)^s h_K R_K}{|\mu_K| |d_K|^{1/2}}.$$

Part (ii) is a formal consequence of unique factorisation of ideals and multiplicativity of the norm, exactly as in Proposition 35.11.3(ii). Parts (i) and (iii) follow from Lemma 35.11.2 together with the counting estimate

$$a_1 + \cdots + a_N = \frac{2^r (2\pi)^s h_K R_K}{|\mu_K| |d_K|^{1/2}} \cdot N + O(N^{1-1/n}),$$

which is proved by counting lattice points of bounded norm in each ideal class – a substantial but entirely geometric computation of the same flavour as the Minkowski bound.

It is worth pausing over this formula. On the left is an analytic object built out of counting ideals; on the right sit *every* invariant we have studied: the class number, the regulator, the number of roots of unity, the discriminant and the signature. It is one of the most beautiful formulae in mathematics, and it is the prototype for a vast web of conjectures (Birch–Swinnerton-Dyer, Bloch–Kato) relating special values of L -functions to arithmetic invariants.

Example 35.11.6

For $K = \mathbb{Q}$ we have $r = 1, s = 0, h = 1, R = 1, |\mu| = 2, |d| = 1$, and the formula reads $\operatorname{Res}_{s=1} \zeta(s) = 2/2 = 1$, agreeing with Proposition 35.11.3(iii).

§35.11.3 Factorisation and Dirichlet L -functions

For $K \neq \mathbb{Q}$ the function ζ_K factors, and the factors are interesting. Take $K = \mathbb{Q}(\sqrt{d})$ quadratic with $D = d_K$. Grouping the Euler product by rational primes and using Proposition 35.6.11:

- if p ramifies, $(p) = \mathfrak{p}^2$ with $N(\mathfrak{p}) = p$, contributing $(1 - p^{-s})^{-1}$;
- if p is inert, $N(\mathfrak{p}) = p^2$, contributing $(1 - p^{-2s})^{-1} = (1 - p^{-s})^{-1} (1 + p^{-s})^{-1}$;
- if p splits, two primes of norm p , contributing $(1 - p^{-s})^{-2}$.

In every case the contribution is $(1 - p^{-s})^{-1} (1 - \chi_D(p)p^{-s})^{-1}$ where

$$\chi_D(p) = \begin{cases} 0 & p \text{ ramifies,} \\ -1 & p \text{ inert,} \\ +1 & p \text{ splits} \end{cases} \quad \left(= \left(\frac{D}{p} \right) \text{ for odd } p \right).$$

Extending χ_D multiplicatively to all $n \geq 1$ and setting

$$L(\chi_D, s) = \prod_p (1 - \chi_D(p)p^{-s})^{-1} = \sum_{n \geq 1} \frac{\chi_D(n)}{n^s},$$

we have shown

$$\zeta_{\mathbb{Q}(\sqrt{d})}(s) = \zeta(s) L(\chi_D, s).$$

Definition 35.11.7 (Dirichlet Character)

A **Dirichlet character** of modulus q is a function $\chi : \mathbb{Z} \rightarrow \mathbb{C}$ of the form

$$\chi(n) = \begin{cases} \omega(n \bmod q) & \gcd(n, q) = 1, \\ 0 & \text{otherwise,} \end{cases}$$

for a group homomorphism $\omega : (\mathbb{Z}/q\mathbb{Z})^\times \rightarrow \mathbb{C}^\times$. It is **trivial** if $\omega \equiv 1$.

Such χ are completely multiplicative, so $L(\chi, s) = \prod_p (1 - \chi(p)p^{-s})^{-1} = \sum_n \chi(n)n^{-s}$ makes sense for $\operatorname{Re}(s) > 1$.

Theorem 35.11.8

For d squarefree with $D = d_{\mathbb{Q}(\sqrt{d})}$, the function χ_D is a Dirichlet character of modulus $|D|$.

The proof is a case analysis using quadratic reciprocity; in fact the statement is essentially *equivalent* to quadratic reciprocity, which is a striking way to view that theorem: the law of quadratic reciprocity is the assertion that the splitting behaviour of p in $\mathbb{Q}(\sqrt{d})$ depends only on p modulo d_K .

Example 35.11.9

Let $K = \mathbb{Q}(i)$, so $D = -4$. For odd p , $\chi_{-4}(p) = \left(\frac{-1}{p}\right) = (-1)^{(p-1)/2}$, and $\chi_{-4}(2) = 0$ since 2 ramifies. So $\chi_{-4}(n) = (-1)^{(n-1)/2}$ for n odd and 0 for n even, and

$$L(\chi_{-4}, s) = 1 - \frac{1}{3^s} + \frac{1}{5^s} - \frac{1}{7^s} + \dots$$

Comparing residues at $s = 1$ in $\zeta_{\mathbb{Q}(i)} = \zeta \cdot L(\chi_{-4}, \cdot)$ and using Theorem 35.11.5 with $r = 0, s = 1, h = 1, R = 1, |\mu| = 4, |d| = 4$:

$$L(\chi_{-4}, 1) = \operatorname{Res}_{s=1} \zeta_{\mathbb{Q}(i)}(s) = \frac{(2\pi) \cdot 1 \cdot 1}{4 \cdot 2} = \frac{\pi}{4},$$

which is Leibniz's formula $1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \dots = \frac{\pi}{4}$. The class number formula *proves* Leibniz's series.

Lemma 35.11.10

If χ is a nontrivial Dirichlet character, then $L(\chi, s)$ is holomorphic on $\operatorname{Re}(s) > 0$.

Proof. By orthogonality of characters of the finite abelian group $(\mathbb{Z}/q\mathbb{Z})^\times$, applied to the trivial character and $\omega \neq 1$,

$$\sum_{n=aq+1}^{(a+1)q} \chi(n) = \sum_{u \in (\mathbb{Z}/q\mathbb{Z})^\times} \omega(u) = 0$$

for every a . Hence the partial sums $\sum_{n \leq N} \chi(n)$ are bounded, i.e. $O(N^0)$, and Lemma 35.11.2 applies with $r = 0$. $\square$

Corollary 35.11.11

If $D < 0$ is a fundamental discriminant then

$$L(\chi_D, 1) = \frac{2\pi h_{\mathbb{Q}(\sqrt{D})}}{|\mu_{\mathbb{Q}(\sqrt{D})}| |D|^{1/2}} \neq 0.$$

Proof. Both sides of $\zeta_{\mathbb{Q}(\sqrt{D})} = \zeta \cdot L(\chi_D, \cdot)$ have a simple pole at $s = 1$; comparing residues and using $\text{Res}_{s=1} \zeta = 1$ together with Theorem 35.11.5 (with $r = 0$, $s = 1$, $R = 1$) gives the formula. It is nonzero since $h \geq 1$. $\square$

§35.11.4 Primes in Arithmetic Progressions

To handle general moduli we need the cyclotomic analogue of the factorisation above. Let $q \geq 1$, $L = \mathbb{Q}(\zeta_q)$ and $G = \text{Gal}(L/\mathbb{Q}) \cong (\mathbb{Z}/q\mathbb{Z})^\times$, of order $\varphi(q)$. By Proposition 35.6.18, for $p \nmid q$ the primes above p number $\varphi(q)/f$ and have norm p^f , where f is the order of p in G . So these primes contribute

$$(1 - p^{-fs})^{-\varphi(q)/f}$$

to ζ_L . Let $\omega_1 = 1, \omega_2, \dots, \omega_{\varphi(q)}$ be the characters of the abelian group G , and χ_i the corresponding Dirichlet characters mod q . Restricted to the cyclic subgroup $\langle p \rangle$ of order f , the ω_i run over the f characters of $\langle p \rangle$, each $\varphi(q)/f$ times; so $\omega_1(p), \dots, \omega_{\varphi(q)}(p)$ are exactly the f th roots of unity, each repeated $\varphi(q)/f$ times. Since $1 - t^f = \prod_{\gamma^f=1} (1 - \gamma t)$, putting $t = p^{-s}$ gives

$$(1 - p^{-fs})^{-\varphi(q)/f} = \prod_{i=1}^{\varphi(q)} (1 - \omega_i(p)p^{-s})^{-1}.$$

Multiplying over all $p \nmid q$ and accounting for the finitely many $p \mid q$ by a correction factor $C(s)$ (a finite product of terms $(1 - p^{-fs})^{-1}$, holomorphic and nonvanishing at $s = 1$):

$$\zeta_{\mathbb{Q}(\zeta_q)}(s) = C(s) \prod_{i=1}^{\varphi(q)} L(\chi_i, s) = C'(s) \zeta(s) \prod_{i=2}^{\varphi(q)} L(\chi_i, s).$$

Theorem 35.11.12

If χ is a nontrivial Dirichlet character then $L(\chi, 1) \neq 0$.

Proof. Every nontrivial Dirichlet character mod q is one of the χ_i above with $i \neq 1$. By Lemma 35.11.10, each such $L(\chi_i, s)$ is holomorphic at $s = 1$. Now compare orders of vanishing at $s = 1$ in the displayed factorisation: the left-hand side has a *simple* pole by Theorem 35.11.5, and on the right ζ contributes a simple pole while C' is holomorphic and nonzero. So $\prod_{i \geq 2} L(\chi_i, 1)$ must be finite and nonzero, whence each factor is nonzero. $\square$

Theorem 35.11.13 (Dirichlet)

Let a, q be coprime positive integers. Then there are infinitely many primes $p \equiv a \pmod{q}$.

Proof. Orthogonality of the columns of the character table of $(\mathbb{Z}/q\mathbb{Z})^\times$ gives, for any n ,

$$\frac{1}{\varphi(q)} \sum_{i=1}^{\varphi(q)} \overline{\chi_i(a)} \chi_i(n) = \begin{cases} 1 & n \equiv a \pmod{q}, \\ 0 & \text{otherwise,} \end{cases}$$

valid even when $\gcd(n, q) > 1$ since then every $\chi_i(n) = 0$. Hence for real $s > 1$,

$$\sum_{p \equiv a \pmod{q}} p^{-s} = \frac{1}{\varphi(q)} \sum_i \overline{\chi_i(a)} \sum_p \chi_i(p) p^{-s}.$$

Now expand the logarithm of the Euler product: for $\operatorname{Re}(s) > 1$,

$$\log L(\chi, s) = - \sum_p \log(1 - \chi(p)p^{-s}) = \sum_p \frac{\chi(p)}{p^s} + \sum_{p, m \geq 2} \frac{\chi(p^m)}{mp^{ms}},$$

and the double sum is bounded as $s \rightarrow 1^+$, since

$$\sum_{p, m \geq 2} p^{-ms} = \sum_p \frac{1}{p^s(p^s - 1)} \leq \sum_{n \geq 2} \frac{1}{n(n-1)} < \infty.$$

So, up to a bounded function,

$$\sum_{p \equiv a \pmod{q}} p^{-s} \sim \frac{1}{\varphi(q)} \sum_i \overline{\chi_i(a)} \log L(\chi_i, s).$$

For $i = 1$ we have $L(\chi_1, s) = \zeta(s) \prod_{p|q} (1 - p^{-s})$, which has a simple pole at $s = 1$, so $\log L(\chi_1, s) \sim \log \frac{1}{s-1} \rightarrow \infty$. For $i \geq 2$, Lemma 35.11.10 and Theorem 35.11.12 say $L(\chi_i, s)$ is holomorphic and nonzero at $s = 1$, so $\log L(\chi_i, s)$ stays bounded. Therefore

$$\sum_{p \equiv a \pmod{q}} p^{-s} \sim \frac{1}{\varphi(q)} \log \frac{1}{s-1} \rightarrow \infty \quad \text{as } s \rightarrow 1^+,$$

which is impossible if there are only finitely many such primes. $\square$

The proof gives more than infinitude: the factor $1/\varphi(q)$ says that the primes are **equidistributed** among the $\varphi(q)$ invertible classes mod q , in the sense of Dirichlet density.

Remark. This is the tip of a very large iceberg. For $L/\mathbb{Q}$ Galois with group G , the zeta function factors as

$$\zeta_L(s) = \prod_{\rho} L(\rho, s)^{\dim \rho},$$

the product over irreducible complex representations of G , where the $L(\rho, s)$ are **Artin L -functions**; the factorisation mirrors the decomposition of the regular representation, and $L(\mathbb{1}, s) = \zeta(s)$. Artin conjectured that $L(\rho, s)$ is entire for $\rho \neq \mathbb{1}$, which is still open. For one-dimensional ρ , matching $L(\rho, s)$ with a Dirichlet L -function is the content of class field theory – the vast generalisation of quadratic reciprocity – and the higher-dimensional case is the Langlands programme. All of it begins with the observation that unique factorisation of ideals gives an Euler product.

§35.12 Further Directions

We close with a brief and impressionistic look at where the subject goes next; none of this is examinable, but all of it is the natural continuation of what we have done.

§35.12.1 Class Field Theory

We saw in Section 35.6.5 that the splitting of a prime q in $\mathbb{Q}(\zeta_m)$ depends only on q modulo m , and that this fact, restricted to the quadratic subfield of $\mathbb{Q}(\zeta_p)$, is quadratic reciprocity. The Kronecker–Weber theorem says that this example is exhaustive:

Theorem 35.12.1 (Kronecker–Weber)

Every finite abelian extension of $\mathbb{Q}$ is contained in some cyclotomic field $\mathbb{Q}(\zeta_m)$.

So the abelian extensions of $\mathbb{Q}$ are completely understood, and splitting in them is always governed by congruence conditions. Class field theory does the same for an arbitrary number field K : it classifies the abelian extensions of K in terms of data intrinsic to K . The simplest instance is the **Hilbert class field** H of K , the maximal unramified abelian extension, which satisfies

$$\mathrm{Gal}(H/K) \cong \mathrm{Cl}_K, \quad [H : K] = h_K,$$

and in which a prime $\mathfrak{p}$ of K splits completely if and only if $\mathfrak{p}$ is principal. So the class group – which we introduced as a measure of the failure of unique factorisation – turns out to be a Galois group.

Example 35.12.2

Take $K = \mathbb{Q}(\sqrt{-5})$, with $h_K = 2$. Its Hilbert class field is $H = K(i) = \mathbb{Q}(i, \sqrt{5})$, of degree 2 over K . This gives a slick explanation of the congruence conditions in the remark of Section 35.10: whether p is $x^2 + 5y^2$ or $2x^2 + 2xy + 3y^2$ is governed by whether p splits completely in H .

For K imaginary quadratic there is a beautiful explicit theory – **complex multiplication** – generating the abelian extensions of K using special values of elliptic modular functions, in exact analogy with the way roots of unity, i.e. special values of $e^{2\pi iz}$, generate the abelian extensions of $\mathbb{Q}$. Doing the same for a general base field is Hilbert’s twelfth problem, and it is still open.

§35.12.2 How Do Class Groups Behave?

We computed a handful of class groups, and they looked rather arbitrary. That impression is correct, and it has been made precise. The **Cohen–Lenstra heuristics** predict, roughly, that the odd part of the class group of a random imaginary quadratic field is a random finite abelian group, weighted inversely by the size of its automorphism group. The predictions are strikingly accurate numerically, and some cases are now theorems; but the basic questions remain hard. It is not known, for instance, whether infinitely many real quadratic fields have class number one, even though numerically they appear to make up more than three quarters of all real quadratic fields.

What *is* known is a strong contrast between the two cases. For imaginary quadratic fields, $h_K \rightarrow \infty$ as $|d_K| \rightarrow \infty$ – indeed $h_K \gg |d_K|^{1/2-\varepsilon}$ by Siegel’s theorem – which is why the list of nine class number one fields in Section 35.8 is finite. For real quadratic fields the class number formula ties h_K to $h_K R_K$, and the regulator can be enormous (recall the fundamental unit for $d = 46$), so a large $|d_K|$ is perfectly compatible with $h_K = 1$.

§35.12.3 Beyond Number Fields

Everything in this course had a geometric shadow. A Dedekind domain is precisely the coordinate ring of a smooth affine curve, and the analogy

$$\mathbb{Z} \longleftrightarrow \mathbb{F}_q[t], \quad \mathbb{Q} \longleftrightarrow \mathbb{F}_q(t), \quad \text{number field} \longleftrightarrow \text{function field of a curve}$$

is close enough to be genuinely useful in both directions. Under it, the class group of $\mathcal{O}_K$ corresponds to the Picard group of a curve, the unit theorem corresponds to a statement about functions with prescribed poles, and the Dedekind zeta function corresponds to the zeta function of a curve over a finite field – where the Riemann hypothesis is a theorem of Weil.

Finally, the pattern of Section 35.10 – factor a Diophantine equation in a suitable ring, use the class group to control the factors – is the ancestor of the modern theory. It is superseded by the theory of elliptic curves for equations like $y^2 = x^3 + k$, where Mordell’s theorem says the rational points form a finitely generated abelian group (a statement whose proof is a descent argument in the same spirit as Dirichlet’s unit theorem), and ultimately by the machinery of modular forms and Galois representations that settled Fermat’s Last Theorem. But all of it starts here, with the observation that $6 = 2 \cdot 3 = (1 + \sqrt{-5})(1 - \sqrt{-5})$.

36 Number Theory

Number theory is the study of the integers, which is to say the study of the two operations $+$ and $\times$ and the friction between them. Addition on its own is dull, and multiplication on its own is not much better; it is the fact that the primes – the atoms of multiplication – are scattered so unpredictably along the additive line $\dots, -1, 0, 1, 2, \dots$ that gives the subject its character. Almost every question we will ask has an embarrassingly simple statement, and almost none of them has an easy answer.

This article constitutes my notes for the ‘Number Theory’ course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§36.1 Introduction

Familiarity with IA Numbers and Sets is assumed throughout, and the first two sections are largely a review of that material – albeit a review conducted with rather different priorities. Where in IA we were content to know that a greatest common divisor exists, here we will care how quickly we can find one; where in IA the primes were a curiosity, here we will want to count them.

Before we start on any of that, it is worth being clear about the sort of questions the subject is trying to answer. Here are three, all of which are still open.

Conjecture 36.1.1 (Twin Prime Conjecture). There are infinitely many primes p for which $p + 2$ is also prime.

Nobody knows. The best that is known, following a spectacular breakthrough of Zhang in 2013 and the subsequent Polymath project, is that there are infinitely many primes p such that at least one of $p + 2, p + 4, \dots, p + 246$ is prime. That is a long way from $246 = 2$, but it is infinitely closer than we were before.

Conjecture 36.1.2 (Riemann Hypothesis). Writing $\pi(x)$ for the number of primes at most x and

$$\text{Li}(x) = \int_2^x \frac{dt}{\log t},$$

we have $|\pi(x) - \text{Li}(x)| \leq \sqrt{x} \log x$ for all $x \geq 3$.

This is one of many equivalent formulations, and it says that the primes are distributed as regularly as one could possibly hope. We will meet the Riemann zeta function in §6, and see where the hypothesis actually lives. The best unconditional result in this direction is of the shape

$$|\pi(x) - \text{Li}(x)| \leq \frac{Cx}{(\log x)^{3/4}} e^{-c\sqrt{\log x}},$$

which is very much weaker.

Conjecture 36.1.3. There is a polynomial-time algorithm which, given $N = pq$ with p and q prime, returns p .

Here the consensus is that the answer is ‘no’, and a great deal of the world’s cryptography is betting on it. We will look at what *can* be done in §8. Notice the change of flavour: this is a question about *algorithms*, and one of the pleasant surprises of the course is how naturally the algorithmic questions sit alongside the classical ones.

Since we will be making claims about algorithms, we should say what we mean.

Definition 36.1.4 (Polynomial Time)

An algorithm taking an integer $N > 0$ as input runs in **polynomial time** if it terminates after at most $C(\log N)^k$ elementary operations, for some constants $C, k > 0$. If the input is a list $N_1, \dots, N_s$, we ask instead for at most $C(\max_i \log N_i)^k$ operations.

The point of taking $\log N$ rather than N is that $\log N$ is (up to a constant) the number of *digits* of N , which is how long it takes merely to write N down. Addition and multiplication of integers run in polynomial time, and we will see shortly that so does Euclid’s algorithm. Trial division does not: to factor $N = pq$ with p, q each of fifty digits by dividing by every integer up to $\sqrt{N}$ would take of the order of 10^{50} divisions, which at a generous 2^{30} divisions per second is around 10^{33} years.

§36.2 Euclid’s Algorithm

We begin at the beginning, with division.

Theorem 36.2.1 (Division Algorithm)

Given $a, b \in \mathbb{Z}$ with $b > 0$, there exist $q, r \in \mathbb{Z}$ with $a = bq + r$ and $0 \leq r < b$. Moreover q and r are unique.

Proof. Let $S = \{a - nb : n \in \mathbb{Z}\}$. Then S contains some nonnegative integer (take n very negative if $a < 0$), so by well-ordering it contains a least nonnegative element r , say $r = a - qb$. We must have $r < b$, as otherwise $r - b \in S$ would be nonnegative and smaller than r . So $a = qb + r$ as required.

For uniqueness, if $a = qb + r = q'b + r'$ with $0 \leq r, r' < b$ then $b(q - q') = r' - r$, and $|r' - r| < b$ forces $q = q'$ and hence $r = r'$. $\square$

Definition 36.2.2

If $r = 0$ above, we write $b \mid a$ and say that b **divides** a ; otherwise we write $b \nmid a$.

Given $a_1, \dots, a_n \in \mathbb{Z}$ not all zero, let

$$I = \{\lambda_1 a_1 + \dots + \lambda_n a_n \mid \lambda_i \in \mathbb{Z}\}$$

be the set of integer combinations of the a_i . Note that for $a, b \in I$ and $l, m \in \mathbb{Z}$ we have $la + mb \in I$; in the language of IB Groups, Rings and Modules, I is an ideal of $\mathbb{Z}$. The following lemma says that $\mathbb{Z}$ is a principal ideal domain, though we will not need to say it that way.

Lemma 36.2.3

$I = d\mathbb{Z} = \{md \mid m \in \mathbb{Z}\}$ for some $d > 0$.

Proof. Let d be the least positive element of I , which exists since I contains a nonzero element and is closed under negation. Certainly $d\mathbb{Z} \subseteq I$. Conversely, if $a \in I$ then we may write $a = qd + r$ with $0 \leq r < d$. If $r = 0$ then $a \in d\mathbb{Z}$. Otherwise $r = a - qd$ is an element of I which is positive and smaller than d , a contradiction. $\square$

In particular $d \mid a_i$ for all i , since each $a_i \in I = d\mathbb{Z}$. Conversely, if $c \mid a_i$ for all i then every integer combination of the a_i is a multiple of c , so $d\mathbb{Z} = I \subseteq c\mathbb{Z}$ and hence $c \mid d$. Thus d deserves its name.

Definition 36.2.4

We write $d = \gcd(a_1, \dots, a_n)$, or more compactly $(a_1, \dots, a_n)$, and call d the **greatest common divisor** of $a_1, \dots, a_n$. If $(a, b) = 1$ we say a and b are **coprime**.

Corollary 36.2.5 (Bézout)

Suppose $a, b, c \in \mathbb{Z}$ with a, b not both 0. Then there exist $x, y \in \mathbb{Z}$ with $ax + by = c$ if and only if $(a, b) \mid c$.

Proof. The set of achievable c is exactly $I = (a, b)\mathbb{Z}$ by Lemma 36.2.3. $\square$

This is all very well, but it is not yet an *algorithm*: Lemma 36.2.3 produces d by minimising over an infinite set. The algorithm is due to Euclid, and consists of iterating the division algorithm.

Theorem 36.2.6 (Euclid's Algorithm)

Given $a, b \in \mathbb{N}$ with $a > b$, set $r_0 = b$ and apply the division algorithm repeatedly:

$$\begin{aligned} a &= q_1 r_0 + r_1, \\ r_0 &= q_2 r_1 + r_2, \\ r_1 &= q_3 r_2 + r_3, \\ &\vdots \\ r_{k-2} &= q_k r_{k-1} + r_k, \\ r_{k-1} &= q_{k+1} r_k + 0, \end{aligned}$$

where $0 < r_i < r_{i-1}$ for $i \leq k$. Then $r_k = (a, b)$.

Proof. The sequence $r_0 > r_1 > \dots \geq 0$ is a strictly decreasing sequence of nonnegative integers, so it does terminate. Reading the last line upwards, $r_k \mid r_{k-1}$, then $r_k \mid r_{k-2}$, and so on all the way up, so $r_k \mid b$ and $r_k \mid a$; hence $r_k \leq (a, b)$. Reading downwards instead, if $m \mid a$ and $m \mid b$ then $m \mid r_1$, then $m \mid r_2$, and so on, so $m \mid r_k$. Taking $m = (a, b)$ gives $(a, b) \leq r_k$, and so $(a, b) = r_k$. $\square$

Unwinding the equations from the bottom expresses r_k as an integer combination of a and b , which is a constructive form of [Corollary 36.2.5](#). Let us do one.

Example 36.2.7

Take $a = 4321$ and $b = 1234$. Euclid's algorithm gives

$$4321 = 3 \times 1234 + 619,$$

$$1234 = 1 \times 619 + 615,$$

$$619 = 1 \times 615 + 4,$$

$$615 = 153 \times 4 + 3,$$

$$4 = 1 \times 3 + 1,$$

$$3 = 3 \times 1 + 0,$$

so $(4321, 1234) = 1$. Working back up,

$$\begin{aligned} 1 &= 4 - 3 = 4 - (615 - 153 \times 4) = 154 \times 4 - 615 \\ &= 154 \times (619 - 615) - 615 = 154 \times 619 - 155 \times 615 \\ &= 154 \times 619 - 155 \times (1234 - 619) = 309 \times 619 - 155 \times 1234 \\ &= 309 \times (4321 - 3 \times 1234) - 155 \times 1234 = 309 \times 4321 - 1082 \times 1234. \end{aligned}$$

One checks that $309 \times 4321 = 1335189$ and $1082 \times 1234 = 1335188$, so indeed the difference is 1.

There is a pleasant way to see the algorithm. Take an $a \times b$ rectangle and repeatedly cut off the largest square you can; the algorithm terminates exactly when the remaining rectangle is tiled by squares, and the side of the last square is (a, b) .

Here $30 = 1 \times 18 + 12$, then $18 = 1 \times 12 + 6$, then $12 = 2 \times 6$, and $(30, 18) = 6$ is the side of the smallest square.

How fast is this? The key observation is that $r_{i+1} \leq r_{i-1}/2$ always. Indeed, if $r_{i+1} < r_i/2$ then certainly $r_{i+1} < r_{i-1}/2$ since $r_i < r_{i-1}$; and if instead $r_{i+1} \geq r_i/2$, then from $r_{i-1} = q_{i+1}r_i + r_{i+1}$ with $q_{i+1} \geq 1$ we get $r_{i-1} \geq r_i + r_{i+1} \geq 2r_{i+1}$. So the remainders at least halve every two steps, and the algorithm terminates after $O(\log b)$ divisions.

Corollary 36.2.8

Euclid's algorithm runs in polynomial time.

Contrast this with the 'obvious' method of computing (a, b) , namely factorising both and comparing: nobody knows how to factorise in polynomial time, and Euclid's algorithm

cheerfully avoids the need to.

Definition 36.2.9

An integer $n > 1$ is **prime** if its only positive divisors are 1 and n ; otherwise it is **composite**.

Lemma 36.2.10 (Euclid's Lemma)

Let p be prime and $a, b \in \mathbb{Z}$. Then $p \mid ab$ if and only if $p \mid a$ or $p \mid b$.

Proof. The ‘if’ direction is clear. Conversely, suppose $p \mid ab$ but $p \nmid a$. Then (a, p) divides p and is not p , so $(a, p) = 1$ and by Bézout there are $x, y \in \mathbb{Z}$ with $ax + py = 1$. Multiplying by b ,

$$b = b(ax + py) = x(ab) + (by)p,$$

and p divides both terms on the right, so $p \mid b$. $\square$

This fails badly for composite numbers: $6 \mid 4 \times 9$ but $6 \nmid 4$ and $6 \nmid 9$. It is precisely this property that makes the primes the right atoms.

Theorem 36.2.11 (Fundamental Theorem of Arithmetic)

Every integer $n > 1$ can be written as a product of primes, and this factorisation is unique up to reordering.

Proof. Existence follows by strong induction: either n is prime, or $n = ab$ with $1 < a, b < n$ and we apply the inductive hypothesis to each of a, b .

For uniqueness, suppose some $n > 1$ has two genuinely different factorisations and take the least such n , say

$$n = p_1 \cdots p_k = q_1 \cdots q_l.$$

Then $p_1 \mid q_1 \cdots q_l$, so by Euclid's lemma $p_1 \mid q_i$ for some i , and since q_i is prime, $p_1 = q_i$. Relabelling, $p_1 = q_1$, and then $n/p_1 = p_2 \cdots p_k = q_2 \cdots q_l$ is a smaller integer with two different factorisations unless $k = l$ and the remaining primes agree after reordering. This contradicts minimality. $\square$

Remark. Collecting multiplicities, every $n \geq 1$ has a unique expression $n = \prod_p p^{v_p(n)}$ where the product is over primes and all but finitely many exponents vanish. If $m = \prod_p p^{\alpha_p}$ and $n = \prod_p p^{\beta_p}$ then

$$(m, n) = \prod_p p^{\min(\alpha_p, \beta_p)}, \quad [m, n] = \prod_p p^{\max(\alpha_p, \beta_p)},$$

where $[m, n]$ denotes the least common multiple, and in particular $(m, n)[m, n] = mn$. This is a perfectly good *description* of the gcd, and a perfectly awful way to *compute* it.

Definition 36.2.12

For a prime p and $n \geq 1$, the exponent $v_p(n)$ above is the **p -adic valuation** of n .

We record the basic properties: $v_p(mn) = v_p(m) + v_p(n)$, and $p^k \mid n$ if and only if $v_p(n) \geq k$. A slightly less obvious formula, which we will need when we come to Bertrand's postulate, is Legendre's:

$$v_p(n!) = \sum_{i=1}^{\infty} \left\lfloor \frac{n}{p^i} \right\rfloor,$$

the point being that among $1, \dots, n$ exactly $\lfloor n/p^i \rfloor$ are divisible by p^i , and each such contributes one to the count for every i up to its valuation.

Finally, the oldest theorem in the subject.

Theorem 36.2.13 (Euclid)

There are infinitely many primes.

Proof. Suppose there were only finitely many, say $p_1, \dots, p_k$. Then $N = p_1 p_2 \cdots p_k + 1$ is greater than 1, so it has a prime factor; but that factor is some p_i , which then divides $N - p_1 \cdots p_k = 1$, a contradiction. $\square$

Remark. It is worth noticing what this argument does and does not give. It shows that the k -th prime is at most $p_1 \cdots p_{k-1} + 1$, which yields the bound $p_k \leq 2^{2^k}$ and hence $\pi(x) \gg \log \log x$. That is a spectacularly bad bound – the truth is $\pi(x) \sim x / \log x$ – and improving it will occupy us in §6.

§36.3 Congruences

§36.3.1 Modular Inverses

Definition 36.3.1

Let $n \geq 1$ be an integer. We say a is **congruent** to b modulo n , written $a \equiv b \pmod{n}$, if $n \mid a - b$.

This is an equivalence relation on $\mathbb{Z}$, and we write $\mathbb{Z}/n\mathbb{Z}$ for the set of equivalence classes $a + n\mathbb{Z}$. The operations

$$(a + n\mathbb{Z}) + (b + n\mathbb{Z}) = (a + b) + n\mathbb{Z}, \quad (a + n\mathbb{Z})(b + n\mathbb{Z}) = ab + n\mathbb{Z}$$

are well defined, making $\mathbb{Z}/n\mathbb{Z}$ into a ring. The whole point of working modulo n is that it turns an infinite problem into a finite one; the price is that we lose information, and much of the art lies in choosing n so as to lose the right information.

Lemma 36.3.2

Let $a \in \mathbb{Z}$ and $n \geq 1$. The following are equivalent.

- (i) $(a, n) = 1$.
- (ii) There is $b \in \mathbb{Z}$ with $ab \equiv 1 \pmod{n}$.
- (iii) $a + n\mathbb{Z}$ generates the additive group $(\mathbb{Z}/n\mathbb{Z}, +)$.

When these hold we call b a **multiplicative inverse** of a modulo n .

Proof. (i) $\Rightarrow$ (ii). By Bézout there are b, c with $ab + cn = 1$, so $ab \equiv 1 \pmod{n}$.
(ii) $\Rightarrow$ (i). If $ab - 1 = kn$ then $ab - kn = 1$, so any common divisor of a and n divides 1.
(ii) $\Rightarrow$ (iii). The subgroup generated by a contains $ba \equiv 1$, hence contains everything.
(iii) $\Rightarrow$ (ii). If a generates then some multiple ba of a is congruent to 1. $\square$

Note that Euclid's algorithm computes the inverse for us, and does so in polynomial time; this is the reason that modular arithmetic is computationally cheap.

Definition 36.3.3

We write $(\mathbb{Z}/n\mathbb{Z})^\times$ for the group of units of $\mathbb{Z}/n\mathbb{Z}$, that is the set of classes satisfying the conditions of [Lemma 36.3.2](#).

Definition 36.3.4 (Euler's Totient Function)

Let $\phi(n) = |(\mathbb{Z}/n\mathbb{Z})^\times|$, so that $\phi(n)$ is the number of $1 \leq a \leq n$ with $(a, n) = 1$. By convention $\phi(1) = 1$.

Theorem 36.3.5 (Euler–Fermat)

If $a, n \in \mathbb{Z}$ with $n \geq 1$ and $(a, n) = 1$, then $a^{\phi(n)} \equiv 1 \pmod{n}$.

Proof. By Lagrange's theorem applied to the group $(\mathbb{Z}/n\mathbb{Z})^\times$, the order of a divides the order $\phi(n)$ of the group. $\square$

Theorem 36.3.6 (Fermat's Little Theorem)

If p is prime and $a \in \mathbb{Z}$, then $a^p \equiv a \pmod{p}$. If moreover $p \nmid a$, then $a^{p-1} \equiv 1 \pmod{p}$.

Proof. If $p \mid a$ both sides are 0. Otherwise $(a, p) = 1$ and $\phi(p) = p - 1$, so [Theorem 36.3.5](#) applies. $\square$

Remark. There is a proof of Fermat's little theorem which avoids group theory entirely: by the binomial theorem, $a^p - (a - 1)^p \equiv 1 \pmod{p}$ since $p \mid \binom{p}{j}$ for $0 < j < p$, and then one inducts on a .

§36.3.2 Systems of Linear Congruences

Suppose we want x with

$$x \equiv 4 \pmod{7}, \quad x \equiv 5 \pmod{12}.$$

The trick is to solve the two 'pure' problems first. If we can find u with $u \equiv 1 \pmod{7}$ and $u \equiv 0 \pmod{12}$, and v with $v \equiv 0 \pmod{7}$ and $v \equiv 1 \pmod{12}$, then $x = 4u + 5v$

works. And finding u and v is just Bézout: since $(7, 12) = 1$ we have $7 \times (-5) + 12 \times 3 = 1$, so we may take $u = 36$ and $v = -35$. Then $x = 4 \times 36 + 5 \times (-35) = -31$, and indeed $-31 = -35 + 4 \equiv 4 \pmod{7}$ and $-31 = -36 + 5 \equiv 5 \pmod{12}$. The general solution is $x \equiv -31 \equiv 53 \pmod{84}$.

Generalising is straightforward.

Theorem 36.3.7 (Chinese Remainder Theorem)

Let $m_1, \dots, m_k \in \mathbb{N}$ be pairwise coprime and let $a_1, \dots, a_k \in \mathbb{Z}$. Then the system

$$x \equiv a_i \pmod{m_i}, \quad 1 \leq i \leq k$$

has a solution x , unique modulo $M = m_1 \cdots m_k$.

Proof. Write $M_i = M/m_i$. Since the m_j are pairwise coprime, $(m_i, M_i) = 1$, so there is b_i with $M_i b_i \equiv 1 \pmod{m_i}$. Also $M_i b_i \equiv 0 \pmod{m_j}$ for $j \neq i$, since $m_j \mid M_i$. Hence $x = \sum_i a_i b_i M_i$ satisfies $x \equiv a_i b_i M_i \equiv a_i \pmod{m_i}$ for each i .

For uniqueness, if x and y both satisfy the system then $m_i \mid x - y$ for all i , and since the m_i are pairwise coprime, $M \mid x - y$. $\square$

Algebraically the theorem says that the reduction map

$$\theta : \mathbb{Z}/M\mathbb{Z} \longrightarrow \mathbb{Z}/m_1\mathbb{Z} \times \cdots \times \mathbb{Z}/m_k\mathbb{Z}$$

is an isomorphism of rings. It is worth drawing the picture in a small case, since it makes the statement obvious: below is $\mathbb{Z}/15\mathbb{Z}$ laid out as a 3×5 grid, the row recording the residue mod 3 and the column the residue mod 5. Every cell is filled exactly once, which is precisely the content of the theorem.

		mod 5				
		0	1	2	3	4
mod 3	0	0	6	12	3	9
	1	10	1	7	13	4
	2	5	11	2	8	14

Since θ is a ring isomorphism it restricts to an isomorphism on unit groups,

$$(\mathbb{Z}/M\mathbb{Z})^\times \cong (\mathbb{Z}/m_1\mathbb{Z})^\times \times \cdots \times (\mathbb{Z}/m_k\mathbb{Z})^\times,$$

and comparing sizes gives the following.

Corollary 36.3.8

If $m_1, \dots, m_k$ are pairwise coprime and $M = \prod_i m_i$, then $\phi(M) = \prod_i \phi(m_i)$.

Remark. A warning: one cannot in general split off prime powers further. For example $\mathbb{Z}/4\mathbb{Z}$ is *not* isomorphic to $(\mathbb{Z}/2\mathbb{Z})^2$.

§36.3.3 Multiplicative Functions

The totient function is the first of several arithmetic functions we will meet, all of which share a convenient property.

Definition 36.3.9

A function $f : \mathbb{N} \rightarrow \mathbb{C}$ is **multiplicative** if $f(mn) = f(m)f(n)$ whenever $(m, n) = 1$, and **totally multiplicative** if $f(mn) = f(m)f(n)$ for all m, n .

A multiplicative function with f not identically zero has $f(1) = 1$, and is determined by its values on prime powers. Standard examples are ϕ , the divisor count $\tau(n) = |\{d : d \mid n\}|$, and more generally $\sigma_k(n) = \sum_{d \mid n} d^k$ (so $\sigma_0 = \tau$ and $\sigma_1 = \sigma$, the sum of divisors). None of these is totally multiplicative: $\tau(4) = 3 \neq 4 = \tau(2)^2$.

That σ_k is multiplicative is not quite obvious, and it is worth isolating the reason.

Lemma 36.3.10

If f is multiplicative then so is $g(n) = \sum_{d \mid n} f(d)$.

Proof. If $(m, n) = 1$ then every divisor d of mn factors uniquely as $d = d_1 d_2$ with $d_1 \mid m$, $d_2 \mid n$, and automatically $(d_1, d_2) = 1$. So

$$g(mn) = \sum_{d \mid mn} f(d) = \sum_{d_1 \mid m} \sum_{d_2 \mid n} f(d_1 d_2) = \left(\sum_{d_1 \mid m} f(d_1) \right) \left(\sum_{d_2 \mid n} f(d_2) \right) = g(m)g(n). \quad \square$$

Taking $f(n) = n^k$, which is totally multiplicative, gives that σ_k is multiplicative.

Theorem 36.3.11

Let p be prime and $m, n \geq 1$. Then

- (i) $\phi(p^m) = p^m - p^{m-1} = p^m(1 - p^{-1})$;
- (ii) $\phi(n) = n \prod_{p \mid n} \left(1 - \frac{1}{p}\right)$;
- (iii) $\sum_{d \mid n} \phi(d) = n$.

Proof. (i) Among $1, \dots, p^m$ the integers not coprime to p^m are exactly the multiples of p , of which there are p^{m-1} .

(ii) Follows from (i) and [Corollary 36.3.8](#).

(iii) The function $g(n) = \sum_{d \mid n} \phi(d)$ is multiplicative by [Lemma 36.3.10](#), and $g(p^m) = 1 + (p-1) + \dots + (p^m - p^{m-1}) = p^m$ telescopes. So g and the identity agree on prime powers and are both multiplicative, hence agree everywhere. $\square$

An alternative proof of (iii) which is worth remembering: classify $1 \leq m \leq n$ by the value of (m, n) . There are exactly $\phi(n/d)$ integers m with $(m, n) = d$, namely d times those integers up to n/d coprime to n/d ; summing over $d \mid n$ gives $n = \sum_{d \mid n} \phi(n/d) = \sum_{d \mid n} \phi(d)$.

§36.3.4 Polynomial Congruences

Linear congruences we understand completely. What about higher degree? Here are three warnings.

- Example 36.3.12** (i) $x^2 + 2 \equiv 0 \pmod{5}$ has no solutions, since the squares mod 5 are 0, 1, 4.
 (ii) $x^3 + 1 \equiv 0 \pmod{7}$ has the three solutions $x \equiv 3, 5, 6$.
 (iii) $x^2 - 1 \equiv 0 \pmod{8}$ has the four solutions $x \equiv 1, 3, 5, 7$.

The last of these should be startling: a quadratic with four roots. The explanation is that $\mathbb{Z}/8\mathbb{Z}$ is not an integral domain, and the familiar bound ‘degree n implies at most n roots’ needs one.

Definition 36.3.13

For a commutative ring R , write $R[X]$ for the ring of polynomials $a_0 + a_1X + \cdots + a_nX^n$ with $a_i \in R$.

Remark. Polynomials are equal when their coefficients are equal, which is not the same as the induced functions being equal. Over $R = \mathbb{Z}/p\mathbb{Z}$ the polynomials $X^p - X$ and 0 are distinct elements of $R[X]$ but define the same function $R \rightarrow R$, by Fermat’s little theorem.

Proposition 36.3.14 (Division Algorithm for Polynomials)

Let $f, g \in R[X]$ with $\deg g = m > 0$ and the leading coefficient of g invertible in R . Then there are $q, r \in R[X]$ with $f = qg + r$ and $\deg r < m$.

Proof. Induct on $n = \deg f$. If $n < m$ take $q = 0$, $r = f$. Otherwise write $f = aX^n + \cdots$ and $g = bX^m + \cdots$; then $f' = f - ab^{-1}X^{n-m}g$ has degree strictly less than n , so by induction $f' = q'g + r$ with $\deg r < m$, and $f = (ab^{-1}X^{n-m} + q')g + r$. $\square$

Corollary 36.3.15 (Remainder Theorem)

If $f \in R[X]$ and $\alpha \in R$ then $f(X) = (X - \alpha)q(X) + f(\alpha)$ for some $q \in R[X]$.

Proof. Divide by $X - \alpha$, whose leading coefficient is 1; the remainder has degree 0, so is a constant r , and putting $X = \alpha$ gives $r = f(\alpha)$. $\square$

Theorem 36.3.16

Let R be an integral domain and let $f \in R[X]$ be nonzero of degree n . Then f has at most n distinct roots in R .

Proof. Induct on n . For $n = 0$ the polynomial is a nonzero constant and has no roots. For $n > 0$, if f has no roots we are done; otherwise let α be a root, so $f = (X - \alpha)q$ with $\deg q = n - 1$. Any root β of f satisfies $(\beta - \alpha)q(\beta) = 0$, and

since R is a domain either $\beta = \alpha$ or $q(\beta) = 0$. By induction q has at most $n - 1$ roots, so f has at most n . $\square$

Corollary 36.3.17 (Lagrange)

Let p be prime and let $f(X) = a_0 + a_1X + \cdots + a_nX^n$ be an integer polynomial with $p \nmid a_n$. Then $f(x) \equiv 0 \pmod{p}$ has at most n solutions modulo p .

Proof. $\mathbb{Z}/p\mathbb{Z}$ is a field, hence an integral domain, and the reduction of f has degree n there. $\square$

A pretty application:

Theorem 36.3.18 (Wilson)

If p is prime then $(p - 1)! \equiv -1 \pmod{p}$.

Proof. Consider $f(X) = X^{p-1} - 1 - \prod_{a=1}^{p-1} (X - a)$ over $\mathbb{Z}/p\mathbb{Z}$. Both terms are monic of degree $p - 1$, so $\deg f \leq p - 2$; but by Fermat's little theorem f vanishes at each of $1, \dots, p - 1$, which is $p - 1$ roots. By Theorem 36.3.16 we must have $f = 0$. Comparing constant terms, $-1 - (-1)^{p-1}(p - 1)! \equiv 0$, so $(p - 1)! \equiv -1 \pmod{p}$ for odd p , and directly for $p = 2$. $\square$

Remark. Alternatively, pair each $a \in \{1, \dots, p - 1\}$ with its inverse. The pairing is a genuine involution with no fixed points except where $a^2 \equiv 1$, i.e. $a \equiv \pm 1$, so the product collapses to $1 \times (p - 1) \equiv -1$.

§36.3.5 Primitive Roots

We now come to the real business of this section: understanding $(\mathbb{Z}/n\mathbb{Z})^\times$ as a group.

Definition 36.3.19

For $(a, n) = 1$, the **order** of a modulo n , written $\text{ord}_n(a)$, is the least $d \geq 1$ with $a^d \equiv 1 \pmod{n}$. We call a a **primitive root** modulo n if $\text{ord}_n(a) = \phi(n)$, that is, if a generates $(\mathbb{Z}/n\mathbb{Z})^\times$.

By Lagrange's theorem $\text{ord}_n(a) \mid \phi(n)$ always, and more generally $a^m \equiv 1 \pmod{n}$ if and only if $\text{ord}_n(a) \mid m$.

Theorem 36.3.20

If p is prime then $(\mathbb{Z}/p\mathbb{Z})^\times$ is cyclic.

Proof. Let $\psi(d)$ be the number of elements of $(\mathbb{Z}/p\mathbb{Z})^\times$ of order exactly d . Every element has some order dividing $p - 1$, so

$$\sum_{d \mid p-1} \psi(d) = p - 1.$$

We claim $\psi(d) \leq \phi(d)$ for each $d \mid p-1$. Indeed, if $\psi(d) = 0$ this is clear. Otherwise pick a of order d ; then $a, a^2, \dots, a^d$ are d distinct solutions of $X^d - 1 \equiv 0 \pmod{p}$, and by [Corollary 36.3.17](#) they are *all* of them. So every element of order d lies in $\langle a \rangle$, and a cyclic group of order d has exactly $\phi(d)$ generators. Hence $\psi(d) \leq \phi(d)$.

But $\sum_{d \mid p-1} \phi(d) = p-1$ by [Theorem 36.3.11](#)(iii), so the inequalities $\psi(d) \leq \phi(d)$ must all be equalities. In particular $\psi(p-1) = \phi(p-1) \geq 1$, so a primitive root exists. $\square$

Example 36.3.21

Take $p = 19$, so $\phi(19) = 18$. The order of 2 divides 18, so it is one of 1, 2, 3, 6, 9, 18. Now $2^9 = 512 = 26 \times 19 + 18 \equiv -1 \pmod{19}$, so the order does not divide 9; and $2^6 = 64 \equiv 7 \not\equiv 1$. So $\text{ord}_{19}(2) = 18$ and 2 is a primitive root modulo 19. There are $\phi(18) = 6$ primitive roots in all, namely 2, 3, 10, 13, 14, 15.

Remark. The proof of [Theorem 36.3.20](#) is thoroughly non-constructive: it tells us that $\phi(p-1)$ of the residues are primitive roots but gives us no way of finding one except by trial. It is a genuinely open problem how small the least primitive root modulo p must be. Unconditionally one can show it is $O(p^{1/4+\varepsilon})$; on the generalised Riemann hypothesis one gets $O(\log^6 p)$. Relatedly:

Conjecture 36.3.22 (Artin). For any integer g which is not a perfect square and not -1 , there are infinitely many primes p for which g is a primitive root.

This is open for every single g , though it is known that at least one of 2, 3, 5 works.

Let us now deal with prime powers. Powers of 2 are badly behaved.

Example 36.3.23

$(\mathbb{Z}/8\mathbb{Z})^\times = \{\pm 1, \pm 3\}$, and every element squares to 1: $3^2 = 9 \equiv 1$, $5^2 = 25 \equiv 1$, $7^2 = 49 \equiv 1$. So $(\mathbb{Z}/8\mathbb{Z})^\times$ has exponent 2 and cannot be cyclic (it is a Klein four-group). Since reduction gives a surjection $(\mathbb{Z}/2^k\mathbb{Z})^\times \rightarrow (\mathbb{Z}/8\mathbb{Z})^\times$ for $k \geq 3$, and a quotient of a cyclic group is cyclic, no $(\mathbb{Z}/2^k\mathbb{Z})^\times$ with $k \geq 3$ is cyclic either.

For odd primes the situation is much better, and rests on the following lifting computation.

Lemma 36.3.24

Let $p > 2$ be prime, $k \geq 1$ and $y \in \mathbb{Z}$. Then $(1 + p^k y)^p \equiv 1 + p^{k+1} y \pmod{p^{k+2}}$.

Proof. Expanding by the binomial theorem,

$$(1 + p^k y)^p = 1 + p^{k+1} y + \sum_{j=2}^{p-1} \binom{p}{j} (p^k y)^j + p^{kp} y^p.$$

For $2 \leq j \leq p-1$ we have $p \mid \binom{p}{j}$ and $kj \geq k+2$ (since $k \geq 1$, $j \geq 2$), so those terms are divisible by p^{k+2} comfortably. The last term has exponent $kp \geq 3k \geq k+2$ since $p \geq 3$ and $k \geq 1$. The claim follows. $\square$

Remark. It is exactly here that $p = 2$ fails: for $p = 2, k = 1$ we would need $kp = 2 \geq k + 2 = 3$, which is false, and indeed $(1 + 2)^2 = 9 \equiv 1 \not\equiv 1 + 4 \pmod{8}$. For $p = 2$ and $k \geq 2$ the same proof does work.

Lemma 36.3.25

Let $p > 2$ be prime and $k \geq 1$. If g is a primitive root modulo p with $g^{p-1} \not\equiv 1 \pmod{p^2}$, then g is a primitive root modulo p^k for every $k \geq 1$.

Proof. The case $k = 1$ is given, so assume $k \geq 2$. Let $d = \text{ord}_{p^k}(g)$, so $d \mid \phi(p^k) = p^{k-1}(p-1)$. Reducing modulo p , we see $g^d \equiv 1 \pmod{p}$, so $(p-1) \mid d$. Hence $d = p^j(p-1)$ for some $0 \leq j \leq k-1$, and it suffices to rule out $j \leq k-2$; equivalently to show $g^{p^{k-2}(p-1)} \not\equiv 1 \pmod{p^k}$.

Write $g^{p-1} = 1 + py$ with $p \nmid y$, which is exactly the hypothesis. Applying Lemma 36.3.24 repeatedly,

$$g^{p^i(p-1)} = (1 + py)^{p^i} \equiv 1 + p^{i+1}y \pmod{p^{i+2}},$$

by induction on i . Taking $i = k-2$ gives $g^{p^{k-2}(p-1)} \equiv 1 + p^{k-1}y \pmod{p^k}$, and $p \nmid y$ means this is not $1 \pmod{p^k}$. $\square$

Theorem 36.3.26

If $p > 2$ is prime then $(\mathbb{Z}/p^k\mathbb{Z})^\times$ is cyclic for every $k \geq 1$.

Proof. Let g be a primitive root modulo p . If $g^{p-1} \not\equiv 1 \pmod{p^2}$ we are done by Lemma 36.3.25. Otherwise set $h = (1+p)g$, which is still a primitive root modulo p since $h \equiv g \pmod{p}$. Now

$$h^{p-1} = (1+p)^{p-1}g^{p-1} \equiv (1+p)^{p-1} \equiv 1 + (p-1)p \equiv 1 - p \pmod{p^2},$$

which is not 1 modulo p^2 . So h satisfies the hypothesis of Lemma 36.3.25. $\square$

Example 36.3.27

We saw that 3 is a primitive root modulo 7. Now $3^6 - 1 = 728 = 7 \times 104$, and 104 is not divisible by 7, so $3^6 \not\equiv 1 \pmod{49}$. Hence 3 is a primitive root modulo 7^k for every k .

We can now settle the question completely.

Theorem 36.3.28

There is a primitive root modulo n if and only if $n = 1, 2, 4, p^k$ or $2p^k$, where p is an odd prime.

Proof. For $n = 1, 2, 4$ one checks directly (1, 1 and 3 respectively). The case $n = p^k$ is Theorem 36.3.26. For $n = 2p^k$, note $\phi(2p^k) = \phi(p^k)$, and if g is a primitive root

modulo p^k then whichever of g and $g + p^k$ is odd is coprime to $2p^k$ and still has order $\phi(p^k)$ modulo p^k , hence modulo $2p^k$.

Conversely, suppose n is none of these. If $n = 2^k$ with $k \geq 3$ we have seen that $(\mathbb{Z}/n\mathbb{Z})^\times$ is not cyclic. Otherwise n has at least two coprime factors $n = rs$ with $r, s > 2$ and $(r, s) = 1$, so $\phi(r)$ and $\phi(s)$ are both even. Then for any a coprime to n ,

$$a^{\phi(n)/2} = a^{\phi(r)\phi(s)/2} = (a^{\phi(r)})^{\phi(s)/2} \equiv 1 \pmod{r},$$

and symmetrically modulo s , so $a^{\phi(n)/2} \equiv 1 \pmod{n}$ and no element has order $\phi(n)$. $\square$

For completeness, here is the structure in the remaining case.

Proposition 36.3.29

For $k \geq 3$ we have $(\mathbb{Z}/2^k\mathbb{Z})^\times \cong \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2^{k-2}\mathbb{Z}$, generated by -1 and 5 .

Proof. The version of Lemma 36.3.24 valid for $p = 2, k \geq 2$ gives $(1 + 4y)^{2^i} \equiv 1 + 2^{i+2}y \pmod{2^{i+3}}$, and applying this with $y = 1$ shows $5^{2^{k-3}} \equiv 1 + 2^{k-1} \not\equiv 1 \pmod{2^k}$, whereas $5^{2^{k-2}} \equiv 1 \pmod{2^k}$. So 5 has order 2^{k-2} . Also $-1 \notin \langle 5 \rangle$, since every power of 5 is $1 \pmod{4}$. Hence $\langle -1 \rangle \times \langle 5 \rangle$ has order $2^{k-1} = \phi(2^k)$ and is everything. $\square$

Combining with the Chinese remainder theorem, we have a complete description of $(\mathbb{Z}/n\mathbb{Z})^\times$ for every n : it is a product of cyclic groups, one for each prime power in the factorisation of n (with the powers of 2 contributing a $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2^{k-2}\mathbb{Z}$).

§36.4 Quadratic Residues

Having dealt with linear congruences, the next case is quadratic. When is $x^2 \equiv a \pmod{n}$ soluble? By the Chinese remainder theorem it is enough to answer this for prime powers, and by a lifting argument much like Lemma 36.3.24 it is essentially enough to answer it for primes. So we fix an odd prime p and ask which a are squares modulo p . The answer, quadratic reciprocity, is one of the great theorems of the subject, and is genuinely surprising: whether q is a square mod p turns out to be almost the same question as whether p is a square mod q , and there is no obvious reason why the two should have anything to do with one another.

§36.4.1 Euler's Criterion and Gauss's Lemma

Definition 36.4.1

Let p be an odd prime and $a \in \mathbb{Z}$ with $p \nmid a$. We say a is a **quadratic residue** modulo p if $x^2 \equiv a \pmod{p}$ for some x , and a **quadratic non-residue** otherwise.

Lemma 36.4.2

Let p be an odd prime. There are exactly $(p-1)/2$ quadratic residues modulo p .

Proof. Consider $\sigma : (\mathbb{Z}/p\mathbb{Z})^\times \rightarrow (\mathbb{Z}/p\mathbb{Z})^\times$, $x \mapsto x^2$. This is two-to-one, since $x^2 \equiv y^2$ if and only if $p \mid (x+y)(x-y)$ if and only if $x \equiv \pm y$, and $y \not\equiv -y$ as p is odd. The residues are the image of σ , which therefore has size $(p-1)/2$. $\square$

Remark. Equivalently, taking a primitive root g , the residues are exactly the even powers $\{g^{2n}\}$, of which there are $(p-1)/2$. So the squares form the unique index-two subgroup of the cyclic group $(\mathbb{Z}/p\mathbb{Z})^\times$.

Definition 36.4.3 (Legendre Symbol)

Let p be an odd prime and $a \in \mathbb{Z}$. The **Legendre symbol** is

$$\left(\frac{a}{p}\right) = \begin{cases} 0 & \text{if } p \mid a, \\ 1 & \text{if } a \text{ is a quadratic residue modulo } p, \\ -1 & \text{if } a \text{ is a quadratic non-residue modulo } p. \end{cases}$$

Here is a picture of the situation modulo 17: the residues 1, 2, 4, 8, 9, 13, 15, 16 are shown as filled dots and the non-residues 3, 5, 6, 7, 10, 11, 12, 14 as open ones.

Notice that the picture is symmetric about the vertical axis, which reflects the fact that -1 is a residue mod 17 (so a and $-a$ are residues together). We will prove that shortly. Notice also that there is no visible pattern in which dots are filled – and indeed finding the least non-residue $n(p)$ quickly is an open problem, the best unconditional bound being $n(p) = O(p^\theta)$ for any $\theta > 1/(4\sqrt{e})$.

The first serious tool is the following.

Theorem 36.4.4 (Euler's Criterion)

Let p be an odd prime and $a \in \mathbb{Z}$. Then

$$\left(\frac{a}{p}\right) \equiv a^{(p-1)/2} \pmod{p}.$$

Proof. If $p \mid a$ both sides are 0, so assume $p \nmid a$. By Fermat's little theorem $(a^{(p-1)/2})^2 = a^{p-1} \equiv 1$, so $a^{(p-1)/2} \equiv \pm 1 \pmod{p}$.

If $a \equiv x^2$ is a residue then $a^{(p-1)/2} \equiv x^{p-1} \equiv 1$. So all $(p-1)/2$ residues are roots of $X^{(p-1)/2} - 1$; but by [Corollary 36.3.17](#) this polynomial has at most $(p-1)/2$ roots, so they are exactly the residues. Hence if a is a non-residue then $a^{(p-1)/2} \equiv -1$. $\square$

Since p is odd, $0, 1, -1$ are distinct modulo p , so this congruence really does determine the symbol. Two immediate consequences:

Corollary 36.4.5

For an odd prime p and $a, b \in \mathbb{Z}$,

$$\left(\frac{ab}{p}\right) = \left(\frac{a}{p}\right) \left(\frac{b}{p}\right).$$

In other words $a \mapsto \left(\frac{a}{p}\right)$ is a homomorphism $(\mathbb{Z}/p\mathbb{Z})^\times \rightarrow \{\pm 1\}$. In particular the product of two non-residues is a residue, which is not obvious from the definition.

Corollary 36.4.6

For an odd prime p ,

$$\left(\frac{-1}{p}\right) = (-1)^{(p-1)/2} = \begin{cases} 1 & \text{if } p \equiv 1 \pmod{4}, \\ -1 & \text{if } p \equiv 3 \pmod{4}. \end{cases}$$

Euler's criterion is already an algorithm: computing $a^{(p-1)/2} \pmod{p}$ by repeated squaring (write $(p-1)/2$ in binary and multiply together the relevant a^{2^i}) takes $O(\log p)$ multiplications, so the Legendre symbol is computable in polynomial time. We will find something better still, but first we need a more refined counting statement.

Definition 36.4.7

The **numerically least residue** of a modulo n is the unique a' with $a' \equiv a \pmod{n}$ and $-n/2 < a' \leq n/2$.

Theorem 36.4.8 (Gauss's Lemma)

Let p be an odd prime and a with $p \nmid a$. For $1 \leq j \leq (p-1)/2$, let a_j be the numerically least residue of aj modulo p . Then

$$\left(\frac{a}{p}\right) = (-1)^\mu, \quad \mu = \left| \left\{ 1 \leq j \leq \frac{p-1}{2} : a_j < 0 \right\} \right|.$$

Proof. Write $a_j = \varepsilon_j c_j$ with $\varepsilon_j \in \{\pm 1\}$ and $1 \leq c_j \leq (p-1)/2$; then $\mu = |\{j : \varepsilon_j = -1\}|$. We claim the c_j are distinct. If $c_j = c_k$ then $aj \equiv \pm ak \pmod{p}$, so $j \equiv \pm k$; but $j, k \in \{1, \dots, (p-1)/2\}$, so $j \equiv -k$ is impossible and $j = k$.

Hence $\{c_1, \dots, c_{(p-1)/2}\} = \{1, \dots, (p-1)/2\}$ and

$$a^{(p-1)/2} \left(\frac{p-1}{2}\right)! \equiv \prod_{j=1}^{(p-1)/2} (a_j) \equiv \prod_{j=1}^{(p-1)/2} \varepsilon_j c_j \equiv (-1)^\mu \left(\frac{p-1}{2}\right)! \pmod{p}.$$

Cancelling the factorial, which is coprime to p , gives $a^{(p-1)/2} \equiv (-1)^\mu$, and Euler's criterion finishes the job. $\square$

Let us use it.

Example 36.4.9

Take $a = 2$. Then $2j$ for $1 \leq j \leq (p-1)/2$ runs over the even numbers $2, 4, \dots, p-1$, and $2j$ has negative least residue exactly when $2j > p/2$, i.e. $j > p/4$. So

$$\mu = \left| \left\{ \frac{p}{4} < j \leq \frac{p-1}{2} \right\} \right| = \frac{p-1}{2} - \left\lfloor \frac{p}{4} \right\rfloor.$$

Checking the four cases $p \equiv 1, 3, 5, 7 \pmod{8}$ gives μ even, odd, odd, even respectively, so

$$\left(\frac{2}{p} \right) = (-1)^{(p^2-1)/8} = \begin{cases} 1 & \text{if } p \equiv \pm 1 \pmod{8}, \\ -1 & \text{if } p \equiv \pm 3 \pmod{8}. \end{cases}$$

For instance $\left(\frac{2}{17} \right) = 1$, consistent with $6^2 = 36 \equiv 2 \pmod{17}$.

Example 36.4.10

Taking $a = -1$, every $-j$ has negative least residue, so $\mu = (p-1)/2$ and we recover [Corollary 36.4.6](#).

§36.4.2 Quadratic Reciprocity**Theorem 36.4.11** (Law of Quadratic Reciprocity)

Let p and q be distinct odd primes. Then

$$\left(\frac{p}{q} \right) \left(\frac{q}{p} \right) = (-1)^{\frac{p-1}{2} \cdot \frac{q-1}{2}}.$$

Equivalently, $\left(\frac{p}{q} \right) = \left(\frac{q}{p} \right)$ unless $p \equiv q \equiv 3 \pmod{4}$, in which case $\left(\frac{p}{q} \right) = -\left(\frac{q}{p} \right)$.

Before the proof, let us set up the counting. Consider the rectangle of lattice points

$$S = \left\{ (j, m) \in \mathbb{Z}^2 : 1 \leq j \leq \frac{p-1}{2}, 1 \leq m \leq \frac{q-1}{2} \right\},$$

so that $|S| = \frac{p-1}{2} \cdot \frac{q-1}{2}$. By Gauss's lemma, $\left(\frac{q}{p} \right) = (-1)^\mu$ where μ counts those j with qj having negative least residue mod p , that is, those j for which there exists m with

$$(m - \tfrac{1}{2})p < qj < mp, \quad \text{i.e.} \quad 0 < mp - qj < \tfrac{p}{2}.$$

Such an m is unique, and satisfies $1 \leq m \leq (q-1)/2$: indeed $mp < qj + p/2 \leq q(p-1)/2 + p/2 < qp/2$, so $m < q/2$. So $\mu = |\{(j, m) \in S : 0 < mp - qj < p/2\}|$, and symmetrically $\left(\frac{p}{q} \right) = (-1)^\nu$ with $\nu = |\{(j, m) \in S : 0 < qj - mp < q/2\}|$.

Note that $mp - qj$ is never zero on S , since $p \nmid qj$. So S is partitioned into four pieces: the two 'bands' counted by μ and ν , together with

$$A = \left\{ (j, m) \in S : mp - qj > \tfrac{p}{2} \right\}, \quad B = \left\{ (j, m) \in S : qj - mp > \tfrac{q}{2} \right\}.$$

The picture for $p = 11$, $q = 7$ looks as follows, with the fifteen points of S drawn and the three lines $mp = qj$, $mp - qj = p/2$ and $qj - mp = q/2$ marked. The filled points are those counted by μ and ν ; the open points make up A (above) and B (below).

Here $\mu = 3$ (the points $(1, 1), (3, 2), (4, 3)$) and $\nu = 2$ (the points $(2, 1), (5, 3)$), while $|A| = |B| = 5$. The grey arrow indicates the symmetry which pairs A with B ; it takes $(2, 3)$ to $(4, 1)$.

Proof of Theorem 36.4.11. With the notation above, S is the disjoint union of the μ -set, the ν -set, A and B , so

$$\frac{p-1}{2} \cdot \frac{q-1}{2} = |S| = \mu + \nu + |A| + |B|.$$

We claim $|A| = |B|$. Consider the map

$$(j, m) \mapsto (j', m') = \left(\frac{p+1}{2} - j, \frac{q+1}{2} - m \right),$$

which is an involution of S . A short computation gives

$$qj' - m'p = q \left(\frac{p+1}{2} - j \right) - p \left(\frac{q+1}{2} - m \right) = \frac{q-p}{2} - (qj - mp) = (mp - qj) - \frac{p-q}{2}.$$

So if $(j, m) \in A$, meaning $mp - qj > p/2$, then $qj' - m'p > p/2 - (p-q)/2 = q/2$ and $(j', m') \in B$. By symmetry the involution maps B into A , so it restricts to a bijection $A \rightarrow B$ and $|A| = |B|$.

Therefore $\mu + \nu \equiv |S| = \frac{p-1}{2} \cdot \frac{q-1}{2} \pmod{2}$, and

$$\left(\frac{p}{q} \right) \left(\frac{q}{p} \right) = (-1)^\nu (-1)^\mu = (-1)^{\frac{p-1}{2} \cdot \frac{q-1}{2}}. \quad \square$$

The practical content is that $\left(\frac{p}{q} \right)$ is determined by $q \pmod{p}$ together with $p, q \pmod{4}$, and that we may flip symbols upside down at the cost of a sign. Combined with [Corollary 36.4.5](#), [Corollary 36.4.6](#) and [Example 36.4.9](#), this gives a fast way to evaluate symbols.

Example 36.4.12 (i) For a prime $p \geq 5$, reciprocity gives $\left(\frac{3}{p} \right) = (-1)^{(p-1)/2} \left(\frac{p}{3} \right)$, and unwinding the four cases modulo 12,

$$\left(\frac{3}{p} \right) = \begin{cases} 1 & \text{if } p \equiv \pm 1 \pmod{12}, \\ -1 & \text{if } p \equiv \pm 5 \pmod{12}. \end{cases}$$

(ii) Since $73 \equiv 1 \pmod{4}$ we may flip freely:

$$\left(\frac{19}{73}\right) = \left(\frac{73}{19}\right) = \left(\frac{16}{19}\right) = 1,$$

so 19 is a quadratic residue modulo 73. (Indeed $26^2 = 676 = 9 \times 73 + 19$.)

(iii) A longer one:

$$\begin{aligned} \left(\frac{34}{97}\right) &= \left(\frac{2}{97}\right) \left(\frac{17}{97}\right) = \left(\frac{17}{97}\right) = \left(\frac{97}{17}\right) \\ &= \left(\frac{12}{17}\right) = \left(\frac{3}{17}\right) \left(\frac{2}{17}\right)^2 = \left(\frac{3}{17}\right) = -1, \end{aligned}$$

using $97 \equiv 1 \pmod{8}$ for the second symbol and $17 \equiv 5 \pmod{12}$ at the end. So 34 is a non-residue modulo 97.

There is a catch. To apply reciprocity to $\left(\frac{a}{n}\right)$ we must first factorise a into primes, and factorisation is expensive. The fix is to extend the symbol so that it makes sense for composite ‘denominators’ too, and to check that reciprocity survives.

§36.4.3 The Jacobi Symbol

Definition 36.4.13 (Jacobi Symbol)

Let $n \geq 1$ be odd with $n = p_1 \cdots p_k$ a factorisation into (not necessarily distinct) primes, and let $a \in \mathbb{Z}$. The **Jacobi symbol** is

$$\left(\frac{a}{n}\right) = \prod_{i=1}^k \left(\frac{a}{p_i}\right),$$

a product of Legendre symbols, with the convention $\left(\frac{a}{1}\right) = 1$.

Note $\left(\frac{a}{n}\right) = 0$ exactly when $(a, n) \neq 1$.

Proposition 36.4.14

Let $m, n \geq 1$ be odd and $a, b \in \mathbb{Z}$. Then

- (i) $a \equiv b \pmod{n}$ implies $\left(\frac{a}{n}\right) = \left(\frac{b}{n}\right)$;
- (ii) $\left(\frac{ab}{n}\right) = \left(\frac{a}{n}\right) \left(\frac{b}{n}\right)$ and $\left(\frac{a}{mn}\right) = \left(\frac{a}{m}\right) \left(\frac{a}{n}\right)$;
- (iii) $\left(\frac{-1}{n}\right) = (-1)^{(n-1)/2}$ and $\left(\frac{2}{n}\right) = (-1)^{(n^2-1)/8}$.

Proof. (i) and (ii) are immediate from the definition and the corresponding facts for the Legendre symbol. For (iii) one needs the elementary identities

$$\frac{x-1}{2} + \frac{y-1}{2} \equiv \frac{xy-1}{2} \pmod{2}, \quad \frac{x^2-1}{8} + \frac{y^2-1}{8} \equiv \frac{(xy)^2-1}{8} \pmod{2}$$

for odd x, y ; the first because $(x-1)(y-1) \equiv 0 \pmod{4}$, the second because $(x^2-1)(y^2-1) \equiv 0 \pmod{16}$. Writing $n = p_1 \cdots p_k$ and summing the identity over

the factors gives the result. $\square$

Theorem 36.4.15 (Reciprocity for the Jacobi Symbol)

Let $m, n \geq 1$ be odd. Then

$$\left(\frac{m}{n}\right) \left(\frac{n}{m}\right) = (-1)^{\frac{m-1}{2} \cdot \frac{n-1}{2}}.$$

Proof. If $(m, n) > 1$ both sides of $\left(\frac{m}{n}\right) \left(\frac{n}{m}\right)$ vanish, so assume $(m, n) = 1$ and write $m = p_1 \cdots p_k$, $n = q_1 \cdots q_l$ with $\{p_i\} \cap \{q_j\} = \emptyset$. By Theorem 36.4.11,

$$\left(\frac{m}{n}\right) = \prod_{i=1}^k \prod_{j=1}^l \left(\frac{p_i}{q_j}\right) = \prod_{i=1}^k \prod_{j=1}^l (-1)^{\frac{p_i-1}{2} \cdot \frac{q_j-1}{2}} \left(\frac{q_j}{p_i}\right).$$

Using the first identity in the proof of Proposition 36.4.14 repeatedly, $\sum_i \frac{p_i-1}{2} \equiv \frac{m-1}{2}$ and $\sum_j \frac{q_j-1}{2} \equiv \frac{n-1}{2} \pmod{2}$, so the accumulated sign is $(-1)^{\frac{m-1}{2} \cdot \frac{n-1}{2}}$, and the remaining product is $\left(\frac{n}{m}\right)$. $\square$

Remark. The Jacobi symbol is *not* a test for quadratic residuacity. If a is a square modulo n then certainly $\left(\frac{a}{n}\right) = 1$, but the converse fails: $\left(\frac{2}{15}\right) = \left(\frac{2}{3}\right) \left(\frac{2}{5}\right) = (-1)(-1) = 1$, yet 2 is not a square modulo 15. In general the symbol only records the *parity* of the number of prime factors modulo which a fails to be a square.

What the Jacobi symbol buys us is speed. To compute $\left(\frac{a}{n}\right)$ we may reduce a modulo n , pull out powers of 2 using Proposition 36.4.14(iii), and flip using Theorem 36.4.15 – and at no point do we need to factorise anything. The resulting algorithm is essentially Euclid’s, and runs in polynomial time.

Example 36.4.16

Let us evaluate $\left(\frac{7411}{9283}\right)$. Both are odd; $7411 \equiv 3$ and $9283 \equiv 3 \pmod{4}$, so flipping costs a sign:

$$\left(\frac{7411}{9283}\right) = -\left(\frac{9283}{7411}\right) = -\left(\frac{1872}{7411}\right) = -\left(\frac{2}{7411}\right)^4 \left(\frac{117}{7411}\right) = -\left(\frac{117}{7411}\right),$$

since $1872 = 2^4 \times 117$. Now $117 \equiv 1 \pmod{4}$, so

$$-\left(\frac{117}{7411}\right) = -\left(\frac{7411}{117}\right) = -\left(\frac{40}{117}\right) = -\left(\frac{2}{117}\right)^3 \left(\frac{5}{117}\right) = -\left(\frac{5}{117}\right),$$

as $117 \equiv 5 \pmod{8}$ gives $\left(\frac{2}{117}\right) = -1$ and $(-1)^3 = -1$ combines with $40 = 2^3 \times 5$. Finally $\left(\frac{5}{117}\right) = \left(\frac{117}{5}\right) = \left(\frac{2}{5}\right) = -1$, so

$$\left(\frac{7411}{9283}\right) = -(-1) \cdot (-1) = -1.$$

No factorisation was required at any stage. Note that $9283 = 9283$ is in fact prime, so this really does tell us that 7411 is a non-residue modulo 9283.

Remark. One may ask about higher powers. If $p \equiv 2 \pmod{3}$ then every element of $(\mathbb{Z}/p\mathbb{Z})^\times$ is a cube (the map $x \mapsto x^3$ is injective since $3 \nmid p-1$), so the question is only interesting for $p \equiv 1 \pmod{3}$, where one defines a cubic residue symbol taking values in the cube roots of unity. The ultimate generalisation of all such statements is Artin's reciprocity law, which describes how primes factorise in abelian extensions of number fields; that is a story for Part III.

§36.5 Binary Quadratic Forms

Here is a question which looks like it belongs to the previous section but does not quite fit there: which integers are a sum of two squares? Equivalently, which N are in the image of the function $f(x, y) = x^2 + y^2$? Fermat knew the answer.

Theorem 36.5.1 (Sums of Two Squares)

Let $N \in \mathbb{N}$. Then $N = x^2 + y^2$ for some $x, y \in \mathbb{Z}$ if and only if every prime $p \equiv 3 \pmod{4}$ divides N to an even power.

We can immediately do half of it.

Proof of the 'only if' direction. Suppose $N = x^2 + y^2$ and $p \equiv 3 \pmod{4}$ is a prime dividing N . If $p \nmid y$ then y is invertible mod p and $(xy^{-1})^2 \equiv -1 \pmod{p}$, contradicting [Corollary 36.4.6](#). So $p \mid y$, and then $p \mid x$ too, so $p^2 \mid N$ and $N/p^2 = (x/p)^2 + (y/p)^2$. Repeating, p divides N to an even power. $\square$

For the converse we may reduce a good deal. Writing $N = M^2K$ with K squarefree, we need only represent K ; and by the identity

$$(x^2 + y^2)(w^2 + z^2) = (xw + yz)^2 + (xz - yw)^2,$$

which says that the norm on $\mathbb{Z}[i]$ is multiplicative, it suffices to represent each prime factor of K . Since $2 = 1^2 + 1^2$, everything comes down to the following: *every prime $p \equiv 1 \pmod{4}$ is a sum of two squares*. This turns out to require a genuinely new idea, and the idea is to consider not just $x^2 + y^2$ but all quadratic forms at once.

§36.5.1 Equivalence and Discriminants

Definition 36.5.2

A **binary quadratic form** (BQF) is a polynomial $f(x, y) = ax^2 + bxy + cy^2$ with $a, b, c \in \mathbb{Z}$. We often write $f = (a, b, c)$ for short. We say f **represents** n if $n = f(x, y)$ for some $x, y \in \mathbb{Z}$.

It is helpful to record f as a matrix. Setting

$$M_f = \begin{pmatrix} a & b/2 \\ b/2 & c \end{pmatrix}, \quad f(x, y) = \begin{pmatrix} x & y \end{pmatrix} M_f \begin{pmatrix} x \\ y \end{pmatrix}.$$

The entries of M_f need not be integers, but its determinant is a quarter of an integer, which is all we shall need.

Definition 36.5.3

A **unimodular substitution** is a change of variables $(X, Y) = (x, y)A$ with $A \in \text{SL}_2(\mathbb{Z})$. Two BQFs f, g are **equivalent**, written $f \sim g$, if $g(x, y) = f(X, Y)$ for some such substitution.

Since $\text{SL}_2(\mathbb{Z})$ is a group, this is an equivalence relation; concretely, $\text{SL}_2(\mathbb{Z})$ acts on forms by $M_g = AM_fA^\top$. Because A and A^{-1} both have integer entries, equivalent forms represent exactly the same integers – which is the whole point of the definition.

Example 36.5.4

Let $f = (1, 0, 1)$ and $g = (4, 12, 10)$. Then

$$g(x, y) = 4x^2 + 12xy + 10y^2 = (2x + 3y)^2 + y^2 = f(2x + 3y, y),$$

so g is obtained from f by the substitution with matrix $\begin{pmatrix} 2 & 3 \\ 0 & 1 \end{pmatrix}$. But this matrix has determinant 2, not 1, and indeed f and g are *not* equivalent: f represents 1 and g does not. The inverse substitution does not have integer entries, so the argument above breaks down.

Definition 36.5.5

The **discriminant** of $f = (a, b, c)$ is $\text{disc}(f) = b^2 - 4ac = -4 \det M_f$.

The reason for the name is the completed square: for $a \neq 0$,

$$4af(x, y) = (2ax + by)^2 - dy^2, \quad d = \text{disc}(f),$$

which we shall use repeatedly.

Lemma 36.5.6

Equivalent forms have the same discriminant.

Proof. If $M_g = AM_fA^\top$ with $\det A = 1$ then $\det M_g = \det M_f$, so $\text{disc}(g) = -4 \det M_g = -4 \det M_f = \text{disc}(f)$. $\square$

The converse is false, and this failure is the entire subject: $x^2 + 6y^2$ and $2x^2 + 3y^2$ both have discriminant -24 , but the first represents 1 and the second does not, so they are inequivalent.

Lemma 36.5.7

There is a BQF of discriminant d if and only if $d \equiv 0$ or $1 \pmod{4}$.

Proof. If $d = b^2 - 4ac$ then $d \equiv b^2 \equiv 0, 1 \pmod{4}$. Conversely, if $d \equiv 0 \pmod{4}$ take $(1, 0, -d/4)$, and if $d \equiv 1 \pmod{4}$ take $(1, 1, (1-d)/4)$. $\square$

The form exhibited in each case is called the **principal form** of discriminant d .

Definition 36.5.8

A real quadratic form f in n variables is **positive definite** if $f(\underline{x}) > 0$ for all $\underline{x} \neq 0$, **negative definite** if $f(\underline{x}) < 0$ for all $\underline{x} \neq 0$, and **indefinite** if it takes both signs.

Lemma 36.5.9

Let $f = (a, b, c)$ be a BQF with $d = \text{disc}(f)$.

- (i) If $d < 0$ and $a > 0$, then f is positive definite (and $c > 0$).
- (ii) If $d < 0$ and $a < 0$, then f is negative definite.
- (iii) If $d > 0$, then f is indefinite.
- (iv) If $d = 0$, then $f = l(mx + ny)^2$ for some $l, m, n \in \mathbb{Z}$.

Proof. (i), (ii) From $4af(x, y) = (2ax + by)^2 - dy^2$ and $d < 0$, the right-hand side is positive unless $x = y = 0$. So f has the sign of a .

(iii) If $a = c = 0$ then $f(1, 1) = b$ and $f(1, -1) = -b$ have opposite signs (and $b \neq 0$ as $d > 0$). Otherwise assume $a \neq 0$; then $4af(1, 0) = 4a^2 > 0$ and $4af(-b, 2a) = (-2ab + 2ab)^2 - 4a^2d = -4a^2d < 0$, so $f(1, 0)$ and $f(-b, 2a)$ have opposite signs.

(iv) If $b^2 = 4ac$, write $a = lm^2$ with l squarefree. Then $b^2 = 4lm^2c$, so $l \mid (b/m)^2$. appropriately and one checks $2lm \mid b$; setting $n = b/(2lm)$ gives $f = l(mx + ny)^2$. $\square$

For the rest of this section we restrict to positive definite forms, so $d < 0$ and $a, c > 0$. Our aim is to pick a canonical representative in each equivalence class.

§36.5.2 Reduction

Two particular substitutions do all the work. With $A = \begin{pmatrix} 1 & 0 \\ \lambda & 1 \end{pmatrix}$, taking $\lambda = \pm 1$ gives

$$T_{\pm} : (a, b, c) \mapsto (a, b \pm 2a, a \pm b + c),$$

which changes b by $2a$ and leaves a alone. With $A = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$ we get

$$S : (a, b, c) \mapsto (c, -b, a),$$

which swaps the outer coefficients. Between them we can make a small and $|b|$ small.

Definition 36.5.10

A positive definite BQF (a, b, c) is **reduced** if either $-a < b \leq a < c$, or $0 \leq b \leq a = c$.

The awkward second clause is there purely to break ties on the boundary; morally the condition is $|b| \leq a \leq c$.

Proposition 36.5.11

Every positive definite BQF is equivalent to a reduced form.

Proof. If $a > c$, apply S to decrease a while leaving $|b|$ unchanged. If $a \leq c$ and $|b| > a$, apply T_+ or T_- (whichever decreases $|b|$) to replace b by $b \mp 2a$; this leaves a unchanged and strictly decreases $|b|$. Since $a + |b|$ is a nonnegative integer which strictly decreases at every step, the process terminates.

We end with a form satisfying $a \leq c$ and $|b| \leq a$. If $a < c$ then either $b > -a$, in which case the form is reduced, or $b = -a$, in which case T_+ gives (a, a, c) which is reduced. If $a = c$ then either $0 \leq b$, and the form is reduced, or $-a \leq b < 0$, and S gives $(a, -b, a)$ which is reduced. $\square$

Lemma 36.5.12

If $f = (a, b, c)$ is a reduced positive definite BQF of discriminant d , then $b \equiv d \pmod{2}$ and

$$|b| \leq a \leq \sqrt{\frac{|d|}{3}}.$$

Proof. Since $d = b^2 - 4ac$ we have $d \equiv b^2 \equiv b \pmod{2}$. For the inequality, reducedness gives $|b| \leq a \leq c$, so

$$|d| = 4ac - b^2 \geq 4a^2 - a^2 = 3a^2,$$

whence $a^2 \leq |d|/3$. $\square$

In particular there are only finitely many reduced forms of a given discriminant: a is bounded, then b is bounded by a and determined modulo 2, and then $c = (b^2 - d)/(4a)$ is determined. This is an entirely effective search.

The next result says that reduced forms are canonical, and the key is that we can read off a reduced form from the integers it represents.

Lemma 36.5.13

Let $f = (a, b, c)$ be a reduced positive definite BQF. Then the least integers properly represented by f – that is, values $f(x, y)$ with $(x, y) = 1$ – are a , c and $a - |b| + c$, in that order.

Proof. Certainly $f(\pm 1, 0) = a$ and $f(0, \pm 1) = c$, and $0 < a \leq c$. Suppose $(x, y) = 1$ with x, y both nonzero, and say $|x| \geq |y| > 0$. Then

$$f(x, y) \geq a|x|^2 - |b||x||y| + c|y|^2 \geq (a - |b|)|x|^2 + c|y|^2 \geq a - |b| + c,$$

using $|x| \geq |y|$ and $a \geq |b|$. The case $|y| \geq |x| > 0$ is symmetric, using $c \geq a \geq |b|$. Finally $f(1, -\text{sign}(b)) = a - |b| + c$, so the bound is attained. $\square$

Theorem 36.5.14

Every positive definite BQF is equivalent to a *unique* reduced form.

Proof. Suppose (a, b, c) and (a', b', c') are equivalent reduced forms. Equivalent forms properly represent the same integers (a unimodular substitution preserves coprimality of (x, y) , since its inverse is also integral), so by Lemma 36.5.13 we get $a = a'$ and $c = c'$; then equality of discriminants gives $b = \pm b'$.

If $b = 0$ or $b = b'$ we are done, so suppose $b > 0$ and $(a, b, c) \sim (a, -b, c)$ with both reduced. Reducedness of $(a, -b, c)$ forces $-a < -b$, so $|b| < a$, and then reducedness of (a, b, c) with $b > 0$ and $|b| < a$ forces $a < c$. So $a < c < a - |b| + c$ are three strictly increasing values, and by Lemma 36.5.13 each is properly represented in essentially one way: $f(x, y) = a$ only for $(x, y) = (\pm 1, 0)$, and $f(x, y) = c$ only for $(x, y) = (0, \pm 1)$.

So if $A \in \mathrm{SL}_2(\mathbb{Z})$ realises the equivalence, it must send $(\pm 1, 0)$ to $(\pm 1, 0)$ and $(0, \pm 1)$ to $(0, \pm 1)$, forcing $A = \pm I$. But $\pm I$ acts trivially on forms, so $(a, b, c) = (a, -b, c)$ and $b = 0$, a contradiction. $\square$

Definition 36.5.15

For $d < 0$ with $d \equiv 0, 1 \pmod{4}$, the **class number** $h(d)$ is the number of reduced positive definite BQFs of discriminant d ; equivalently, by Theorem 36.5.14, the number of equivalence classes of positive definite BQFs of discriminant d .

- Example 36.5.16** (i) $d = -4$. By Lemma 36.5.12, $a \leq \sqrt{4/3} < 2$, so $a = 1$, hence $|b| \leq 1$ and $b \equiv 0 \pmod{2}$, so $b = 0$ and $c = 1$. Thus $h(-4) = 1$ and $(1, 0, 1)$ is the only class: *every* positive definite form of discriminant -4 is equivalent to $x^2 + y^2$.
- (ii) $d = -24$. Now $a \leq \sqrt{8} < 3$ and b is even. If $a = 1$ then $b = 0$ and $c = 6$. If $a = 2$ then $b \in \{0, \pm 2\}$; $b = \pm 2$ gives $c = (4 + 24)/8 \notin \mathbb{Z}$, so $b = 0$ and $c = 3$. Hence $h(-24) = 2$, with classes $(1, 0, 6)$ and $(2, 0, 3)$.
- (iii) $d = -23$. Here $a \leq \sqrt{23/3} < 3$ and b is odd. If $a = 1$ then $b = 1$ and $c = 6$. If $a = 2$ then $b = \pm 1$ and $c = (1 + 23)/8 = 3$, and both $(2, 1, 3)$ and $(2, -1, 3)$ are reduced since $-2 < \pm 1 \leq 2 < 3$. So $h(-23) = 3$.

There is a geometric way to see all this which is worth knowing. To a positive definite $f = (a, b, c)$ of discriminant $d < 0$ associate the root

$$z_f = \frac{-b + i\sqrt{|d|}}{2a}$$

of $az^2 + bz + c$ lying in the upper half plane $\mathbb{H}$. Then $\mathrm{Re} z_f = -b/(2a)$ and $|z_f|^2 = c/a$, so the reducedness conditions $|b| \leq a$ and $a \leq c$ say exactly that

$$|\mathrm{Re} z_f| \leq \frac{1}{2} \quad \text{and} \quad |z_f| \geq 1,$$

which is the celebrated fundamental domain for the action of $\mathrm{SL}_2(\mathbb{Z})$ on $\mathbb{H}$. The two operations $T_\pm$ and S correspond to $z \mapsto z \pm 1$ and $z \mapsto -1/z$, and the reduction algorithm is the familiar business of translating into the strip and inverting whenever you fall inside the unit circle. Below is the region, with the three reduced forms of discriminant -23 marked.

Remark. The class number is a delicate object. Heilbronn (1934) showed $h(d) \rightarrow \infty$ as $d \rightarrow -\infty$, and Mertens showed that on average $\frac{1}{N} \sum_{3 \leq -d \leq N} h(d) \sim \frac{\pi}{18} \sqrt{N}$. Determining all d with $h(d) = 1$ was a famous problem finally settled by Baker, Heegner and Stark: the fundamental such discriminants are

$$-3, -4, -7, -8, -11, -19, -43, -67, -163,$$

and there are a handful of non-fundamental ones besides. (A discriminant is **fundamental** if it is not of the form $k^2 d'$ with $k > 1$ and $d' \equiv 0, 1 \pmod{4}$.) For fundamental $d < 0$, Gauss defined a composition law making the classes into a finite abelian group, which turns out to be the ideal class group of $\mathbb{Q}(\sqrt{d})$.

§36.5.3 Representations

We now connect forms back to congruences.

Definition 36.5.17

A BQF f **properly represents** n if $n = f(x, y)$ for some x, y with $(x, y) = 1$.

Lemma 36.5.18

A BQF f properly represents n if and only if $f \sim (n, b, c)$ for some $b, c \in \mathbb{Z}$.

Proof. If $f \sim g = (n, b, c)$ then $g(1, 0) = n$ is properly represented by g , hence by f (proper representation being preserved by unimodular substitutions).

Conversely, suppose $f(\alpha, \beta) = n$ with $(\alpha, \beta) = 1$. By Bézout there are γ, δ with $\alpha\delta - \beta\gamma = 1$, so $A = \begin{pmatrix} \alpha & \gamma \\ \beta & \delta \end{pmatrix} \in \text{SL}_2(\mathbb{Z})$. The form $g(x, y) = f(\alpha x + \gamma y, \beta x + \delta y)$ is equivalent to f and has $g(1, 0) = f(\alpha, \beta) = n$, so its leading coefficient is n . $\square$

Theorem 36.5.19

Let $n \in \mathbb{N}$ and $d \equiv 0, 1 \pmod{4}$. Then n is properly represented by *some* BQF of

discriminant d if and only if $x^2 \equiv d \pmod{4n}$ is soluble.

Proof. If n is properly represented by f with disc $f = d$, then by [Lemma 36.5.18](#) $f \sim (n, b, c)$, and $b^2 - 4nc = d$ gives $b^2 \equiv d \pmod{4n}$.

Conversely if $b^2 \equiv d \pmod{4n}$ then $b^2 = d + 4nc$ for some $c \in \mathbb{Z}$, and the form (n, b, c) has discriminant d and represents n properly at $(1, 0)$. $\square$

This is exactly what we need. When $h(d) = 1$ there is only one form to worry about, and the theorem becomes a complete criterion.

Proof of Theorem 36.5.1, completed. It remains to show that every prime $p \equiv 1 \pmod{4}$ is a sum of two squares. By [Corollary 36.4.6](#), $\left(\frac{-1}{p}\right) = 1$, so there is m with $m^2 \equiv -1 \pmod{p}$; replacing m by $m + p$ if necessary we may take m even, and then $(2m)^2 \equiv -4 \pmod{4p}$. So $x^2 \equiv -4 \pmod{4p}$ is soluble, and by [Theorem 36.5.19](#) some form of discriminant -4 properly represents p .

But $h(-4) = 1$ by [Example 36.5.16](#), so that form is equivalent to $(1, 0, 1)$, and equivalent forms represent the same integers. Hence $p = x^2 + y^2$ for some x, y . $\square$

Geometrically, asking whether N is a sum of two squares is asking whether the circle of radius $\sqrt{N}$ passes through a point of the integer lattice. Here is $N = 25$, where it passes through twelve of them, coming from the two essentially different representations $25 = 5^2 + 0^2 = 4^2 + 3^2$.

The method is not special to -4 . Let us run it for another discriminant with class number one.

Example 36.5.20

Which integers are properly represented by $f(x, y) = x^2 + xy + 2y^2$? We have disc $f = 1 - 8 = -7$, and f is positive definite. By [Lemma 36.5.12](#) a reduced form of discriminant -7 has $a \leq \sqrt{7/3} < 2$, so $a = 1$, and b odd with $|b| \leq 1$ gives $b = 1$, $c = 2$. So $h(-7) = 1$ and f is the only class.

By [Theorem 36.5.19](#), f properly represents n if and only if $x^2 \equiv -7 \pmod{4n}$ is soluble. Take $n = p$ an odd prime, $p \neq 7$. Then $x^2 \equiv -7 \pmod{4p}$ is soluble if and only if -7 is a square modulo 4 (always true, as $-7 \equiv 1$) and modulo p ; and by

reciprocity, using $\left(\frac{-1}{p}\right)\left(\frac{7}{p}\right) = \left(\frac{-7}{p}\right)$ and $-7 \equiv 1 \pmod{4}$,

$$\left(\frac{-7}{p}\right) = \left(\frac{p}{7}\right).$$

So f properly represents an odd prime $p \neq 7$ exactly when $p \equiv 1, 2, 4 \pmod{7}$, these being the quadratic residues mod 7. Adding in $f(0, 1) = 2$ and $f(1, -2) = 1 - 2 + 8 = 7$, we conclude that f properly represents a prime p if and only if $p \equiv 0, 1, 2, 4 \pmod{7}$.

To go from proper representations to all representations one notes that $f(kx, ky) = k^2 f(x, y)$, so the values of f are exactly $k^2 n$ with n properly represented; and to go from primes to general n one uses the following lifting lemma together with the Chinese remainder theorem.

Lemma 36.5.21

Let $a \in \mathbb{Z}$.

- (i) If $a \equiv 1 \pmod{8}$ then a is a square modulo 2^k for every $k \geq 1$.
- (ii) If $p > 2$ is prime and $\left(\frac{a}{p}\right) = 1$, then a is a square modulo p^k for every $k \geq 1$.

Proof. (ii) Induct on k . Given $x^2 \equiv a \pmod{p^k}$, say $x^2 = a + mp^k$, we look for a solution of the shape $x + tp^k$:

$$(x + tp^k)^2 = x^2 + 2xtp^k + t^2p^{2k} \equiv a + (m + 2xt)p^k \pmod{p^{k+1}}.$$

Since $p \nmid 2x$, we may choose t with $m + 2xt \equiv 0 \pmod{p}$, and then a is a square modulo p^{k+1} .

(i) The same idea, but $2x$ is now not invertible so one has to work slightly harder. Given $x^2 = a + m2^k$ with $k \geq 3$ and x odd: if m is even then $x^2 \equiv a \pmod{2^{k+1}}$ already. If m is odd, then

$$(x + 2^{k-1})^2 = x^2 + 2^k x + 2^{2k-2} \equiv a + 2^k(m + x) \pmod{2^{k+1}}$$

since $2k - 2 \geq k + 1$, and $m + x$ is even. The base case $k = 3$ is the hypothesis $a \equiv 1 \pmod{8}$. $\square$

Remark. If $h(d) > 1$ this analysis tells us which n are represented by *some* form of discriminant d , but not by which one. Sometimes extra congruence conditions separate the classes – for $d = -24$ one finds that $x^2 + 6y^2$ represents primes $p \equiv 1, 7 \pmod{24}$ while $2x^2 + 3y^2$ represents $p \equiv 5, 11 \pmod{24}$ – but in general no such separation exists, and one needs class field theory. The smallest failure is $d = -92$, where $x^2 + 23y^2$ and $3x^2 \pm 2xy + 8y^2$ cannot be told apart by congruences.

Remark. For indefinite forms everything changes: the number of representations of a given n is typically infinite. For instance $1 = x^2 - 2y^2$ has the solutions $(1, 0)$ and $(3, 2)$, and if (x, y) is a solution so is $(x^2 + 2y^2, 2xy)$, giving infinitely many. We will meet this again in §7 under the name of Pell's equation.

Finally, some context. Lagrange (1770) proved that every positive integer is a sum of

four squares, and Legendre (1797) that n is a sum of three squares if and only if n is not of the form $4^a(8b+7)$. Waring's problem asks for the least $s = g(k)$ such that every positive integer is a sum of s k -th powers; Hilbert (1909) showed $g(k)$ is finite for every k , and we know $g(2) = 4$, $g(3) = 9$, $g(4) = 19$, but the asymptotic behaviour of g remains open.

§36.6 The Distribution of Primes

The sequence $2, 3, 5, 7, 11, \dots$ is one of the most interesting objects in mathematics, and the obvious questions about it are hard. How fast does it grow? How regularly is it distributed? We know from §2 that it is infinite, and Euclid's proof gives the miserable bound $\pi(x) \gg \log \log x$; our first goal is to do considerably better.

Definition 36.6.1

The **prime counting function** is $\pi(x) = |\{p \leq x : p \text{ prime}\}|$.

The most convenient way to construct the primes up to x is the sieve of Eratosthenes: list $2, \dots, x$, and repeatedly take the smallest surviving number, declare it prime, and delete all of its proper multiples. Since any composite $n \leq x$ has a prime factor at most $\sqrt{x}$, we may stop once we pass $\sqrt{x}$. Here it is up to 60, where the primes are shown in blue and the numbers struck out are those deleted as multiples of 2, 3, 5 or 7.

1	2	3	4	5	6	7	8	9	10
11	12	13	14	15	16	17	18	19	20
21	22	23	24	25	26	27	28	29	30
31	32	33	34	35	36	37	38	39	40
41	42	43	44	45	46	47	48	49	50
51	52	53	54	55	56	57	58	59	60

§36.6.1 What is True

Before working, let us record the theorems we would like to have. The first is the central result of the subject.

Theorem 36.6.2 (Prime Number Theorem)

$$\pi(x) \sim \frac{x}{\log x} \text{ as } x \rightarrow \infty.$$

We will not prove this – the proof needs complex analysis of the Riemann zeta function, and belongs to a Part III course – but we will meet the main character, and we will prove the correct order of magnitude.

Remark. Recall the asymptotic notation. For $f, g : \mathbb{R}_{>0} \rightarrow \mathbb{R}$ we write $f = O(g)$ as $x \rightarrow \infty$ if there are $C > 0$ and x_0 with $|f(x)| \leq C|g(x)|$ for all $x \geq x_0$; and $f = o(g)$ if for every $\varepsilon > 0$ there is x_0 with $|f(x)| \leq \varepsilon|g(x)|$ for $x \geq x_0$. Finally $f \sim g$ means $f = (1 + o(1))g$.

A better approximation to $\pi(x)$ than $x/\log x$ is the logarithmic integral

$$\text{Li}(x) = \int_2^x \frac{dt}{\log t},$$

and the strongest known error term is of the following shape.

Theorem 36.6.3

There is a constant $C > 0$ such that

$$\pi(x) = \text{Li}(x) + O\left(x \exp\left(-C\sqrt{\log x}\right)\right).$$

The Riemann hypothesis is the assertion that the error is in fact $O(\sqrt{x} \log x)$, which is very much smaller. The following picture shows $\pi(x)$ against $x/\log x$ and against $x/(\log x - 1)$ for $x \leq 1000$; the last of these is a decent hands-on approximation, and gives a sense of just how good $\text{Li}(x)$ is.

A different flavour of question concerns primes in arithmetic progressions. In IA we saw that there are infinitely many primes congruent to 3 modulo 4; the general statement is much harder.

Theorem 36.6.4 (Dirichlet)

Let a, q be coprime positive integers. Then there are infinitely many primes $p \equiv a \pmod{q}$.

The coprimality is clearly necessary, since $(a, q) > 1$ divides every term of the progression. Quantitatively one expects the primes to be shared out equally among the $\phi(q)$ admissible residues, and this is true in a strong sense.

Theorem 36.6.5 (Siegel–Walfisz)

Let $(a, q) = 1$ and let $\pi(x; q, a)$ be the number of primes $p \leq x$ with $p \equiv a \pmod{q}$. For every $B > 0$ there is $C_B > 0$ such that

$$\pi(x; q, a) = \frac{x}{\phi(q) \log x} + O\left(x \exp\left(-C_B \sqrt{\log x}\right)\right)$$

uniformly for $q \leq (\log x)^B$.

Our own aim, which we will actually achieve, is the following.

Theorem 36.6.6 (Chebyshev)

For all $x \geq 4$,

$$\frac{\log 2}{2} \cdot \frac{x}{\log x} \leq \pi(x) \leq 6 \log 2 \cdot \frac{x}{\log x}.$$

That will take a while, so let us warm up.

§36.6.2 Elementary Bounds

Lemma 36.6.7

For $x \geq 1$ we have $\pi(x) \geq \frac{\log x}{2 \log 2}$.

Proof. Let $p_1, \dots, p_r$ be the primes up to x , so $r = \pi(x)$. Every $n \leq x$ can be written as $n = k^2 m$ with m squarefree, so $m = \prod_i p_i^{\alpha_i}$ with each $\alpha_i \in \{0, 1\}$ and $k \leq \sqrt{x}$. There are at most 2^r choices for m and at most $\sqrt{x}$ for k , so

$$x \leq \sqrt{x} \cdot 2^r = \sqrt{x} \cdot 2^{\pi(x)},$$

giving $\sqrt{x} \leq 2^{\pi(x)}$ and hence the claim. $\square$

This already beats Euclid handsomely: $\log x$ rather than $\log \log x$. It is still far from the truth, but the argument is worth remembering because the ‘squarefree times a square’ decomposition is genuinely useful.

Next we quantify the divergence of $\sum 1/p$. Euler’s observation that this series diverges is a much better proof that there are infinitely many primes than Euclid’s, because it says something about density.

Theorem 36.6.8 (Mertens) (i) For $x \geq 2$ we have $\prod_{p \leq x} \left(1 - \frac{1}{p}\right)^{-1} \geq \log x$; in particular the product diverges.

(ii) For $x \geq 5$ we have $\sum_{p \leq x} \frac{1}{p} \geq \log \log x - \frac{1}{2}$; in particular $\sum_p 1/p$ diverges.

Here and below, p ranges over primes.

Proof. (i) Expanding each factor as a geometric series,

$$\prod_{p \leq x} \left(1 - \frac{1}{p}\right)^{-1} = \prod_{p \leq x} \left(1 + \frac{1}{p} + \frac{1}{p^2} + \cdots\right) \geq \sum_{n \leq x} \frac{1}{n},$$

since every $n \leq x$ has all its prime factors at most x , so $1/n$ appears exactly once when the product is expanded. Finally $\sum_{n \leq x} 1/n \geq \int_1^{\lfloor x \rfloor + 1} dy/y \geq \log x$.

(ii) Take logarithms in (i) and compare with the sum. Using $-\log(1-t) = t + t^2/2 + t^3/3 + \dots$,

$$\begin{aligned} \log \left(\prod_{p \leq x} \left(1 - \frac{1}{p}\right)^{-1} \right) - \sum_{p \leq x} \frac{1}{p} &= \sum_{p \leq x} \left(\frac{1}{2p^2} + \frac{1}{3p^3} + \dots \right) \\ &\leq \sum_{p \leq x} \frac{1}{2p^2} \left(1 + \frac{1}{p} + \frac{1}{p^2} + \dots \right) \\ &= \sum_{p \leq x} \frac{1}{2p^2} \cdot \frac{1}{1 - p^{-1}} = \sum_{p \leq x} \frac{1}{2p(p-1)} \\ &\leq \sum_{2 \leq n \leq x} \frac{1}{2n(n-1)} = \frac{1}{2} \sum_{2 \leq n \leq x} \left(\frac{1}{n-1} - \frac{1}{n} \right) \leq \frac{1}{2}. \end{aligned}$$

Combining with (i) gives $\sum_{p \leq x} 1/p \geq \log \log x - 1/2$. $\square$

Remark. The truth is sharper: there are constants c and γ (the latter being Euler's constant, $\gamma \approx 0.5772$) with

$$\sum_{p \leq x} \frac{1}{p} = \log \log x + c + O\left(\frac{1}{\log x}\right), \quad \prod_{p \leq x} \left(1 - \frac{1}{p}\right)^{-1} = e^\gamma \log x + O(1).$$

For a sanity check, $\sum_{p \leq 100} 1/p \approx 1.803$ while $\log \log 100 \approx 1.527$.

§36.6.3 The Riemann Zeta Function

The expansion in the proof of [Theorem 36.6.8](#) is worth taking seriously. It is the case $s = 1$ of an identity which holds for all s with $\operatorname{Re} s > 1$, and which is the reason analysis has anything to say about primes at all.

Definition 36.6.9

For $s \in \mathbb{C}$ with $\operatorname{Re} s > 1$, the **Riemann zeta function** is

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}.$$

Conventionally one writes $s = \sigma + it$.

Lemma 36.6.10

The series converges absolutely for $\sigma > 1$, and uniformly on $\{\sigma \geq 1 + \delta\}$ for any $\delta > 0$. In particular ζ is analytic on $\sigma > 1$.

Proof. $|n^{-s}| = n^{-\sigma}$, and $\sum n^{-\sigma}$ converges for $\sigma > 1$. Uniform convergence on $\sigma \geq 1 + \delta$ follows from the Weierstrass M -test with $M_n = n^{-1-\delta}$, and a uniform limit of analytic functions is analytic. $\square$

Theorem 36.6.11 (Euler Product)

For $\sigma > 1$,

$$\zeta(s) = \prod_p \left(1 - \frac{1}{p^s}\right)^{-1}.$$

Proof. Fix s with $\sigma > 1$ and let $x \geq 2$. Expanding the finite product,

$$\prod_{p \leq x} (1 - p^{-s})^{-1} = \prod_{p \leq x} (1 + p^{-s} + p^{-2s} + \cdots) = \sum_{n \in \mathcal{N}_x} n^{-s},$$

where $\mathcal{N}_x$ is the set of positive integers all of whose prime factors are at most x ; the rearrangement is legitimate by absolute convergence, and each n occurs exactly once by unique factorisation. Hence

$$\left| \zeta(s) - \prod_{p \leq x} (1 - p^{-s})^{-1} \right| = \left| \sum_{n \notin \mathcal{N}_x} n^{-s} \right| \leq \sum_{n > x} n^{-\sigma} \rightarrow 0$$

as $x \rightarrow \infty$, since every $n \notin \mathcal{N}_x$ has a prime factor exceeding x and so satisfies $n > x$. $\square$

This identity is the analytic form of unique factorisation, and it is the bridge we need: the left-hand side is a smooth analytic object, the right-hand side knows about primes.

Corollary 36.6.12

$\zeta(s) \neq 0$ for $\sigma > 1$.

Proof. For $x \geq 2$ let $P_x = \prod_{p \leq x} (1 - p^{-s})$, which is a finite product of nonzero numbers. Expanding as above,

$$\zeta(s)P_x = 1 + \sum_{n \in \mathcal{N}'_x} n^{-s},$$

where $\mathcal{N}'_x$ consists of those $n > 1$ all of whose prime factors exceed x ; every such n is $> x$, so

$$|\zeta(s)P_x| \geq 1 - \sum_{n > x} n^{-\sigma} \rightarrow 1$$

as $x \rightarrow \infty$. So $\zeta(s)P_x \neq 0$ for large x , whence $\zeta(s) \neq 0$. $\square$

Remark. One can extend ζ meromorphically to all of $\mathbb{C}$. The recipe uses the gamma function $\Gamma(z) = \int_0^\infty e^{-t} t^{z-1} dt$, defined for $\operatorname{Re} z > 0$ and continued meromorphically with simple poles at $0, -1, -2, \dots$; setting

$$\Xi(s) = \pi^{-s/2} \Gamma(s/2) \zeta(s),$$

one shows the functional equation $\Xi(s) = \Xi(1-s)$, which continues Ξ and hence ζ everywhere. It turns out that ζ has a single simple pole, at $s = 1$ with residue 1, and ‘trivial’ zeros at $s = -2, -4, -6, \dots$ coming from the poles of $\Gamma(s/2)$. Since ζ does not vanish for $\sigma > 1$, the functional equation confines all other zeros to the **critical strip** $0 \leq \sigma \leq 1$. Non-vanishing on the line $\sigma = 1$ is already enough to prove the prime number

theorem; the Riemann hypothesis asserts that all the nontrivial zeros lie on $\sigma = \frac{1}{2}$.

Two more arithmetic functions, both of which have pleasant zeta-flavoured descriptions.

Definition 36.6.13 (Möbius Function)

Define $\mu : \mathbb{N} \rightarrow \{-1, 0, 1\}$ by $\mu(1) = 1$ and

$$\mu(n) = \begin{cases} (-1)^k & \text{if } n \text{ is a product of } k \text{ distinct primes,} \\ 0 & \text{if } n \text{ is not squarefree.} \end{cases}$$

Lemma 36.6.14

μ is multiplicative, and $\sum_{d|n} \mu(d) = \begin{cases} 1 & n = 1, \\ 0 & n > 1. \end{cases}$

Proof. Multiplicativity is immediate from the definition. Hence $\nu(n) = \sum_{d|n} \mu(d)$ is multiplicative by [Lemma 36.3.10](#), and $\nu(p^a) = \mu(1) + \mu(p) = 0$ for $a \geq 1$, while $\nu(1) = 1$. $\square$

This innocuous lemma is what makes inclusion–exclusion work in this setting, and it gives the Möbius inversion formula: if $g(n) = \sum_{d|n} f(d)$ for all n , then $f(n) = \sum_{e|n} \mu(e)g(n/e)$.

Definition 36.6.15

A **Dirichlet series** is a series of the form $\sum_{n \geq 1} a_n n^{-s}$ with $a_n \in \mathbb{C}$.

If $|a_n| \leq Cn^k$ then the series converges absolutely for $\sigma > k + 1$ and uniformly on $\sigma \geq k + 1 + \delta$. Multiplying two Dirichlet series gives a third, whose coefficients are a ‘Dirichlet convolution’:

$$\left(\sum_m \frac{a_m}{m^s} \right) \left(\sum_n \frac{b_n}{n^s} \right) = \sum_{N \geq 1} \frac{c_N}{N^s}, \quad c_N = \sum_{d|N} a_d b_{N/d}.$$

For instance for $\sigma > 2$,

$$\zeta(s-1)\zeta(s) = \left(\sum_m \frac{m}{m^s} \right) \left(\sum_n \frac{1}{n^s} \right) = \sum_{N \geq 1} \frac{1}{N^s} \sum_{d|N} d = \sum_{N \geq 1} \frac{\sigma(N)}{N^s},$$

and by [Lemma 36.6.14](#), $\zeta(s) \sum_n \mu(n)n^{-s} = 1$, i.e. $\sum_n \mu(n)n^{-s} = 1/\zeta(s)$.

Definition 36.6.16 (von Mangoldt Function)

Define $\Lambda : \mathbb{N} \rightarrow \mathbb{R}$ by

$$\Lambda(n) = \begin{cases} \log p & \text{if } n = p^k \text{ for some prime } p \text{ and } k \geq 1, \\ 0 & \text{otherwise.} \end{cases}$$

Proposition 36.6.17

For $\sigma > 1$,

$$-\frac{\zeta'(s)}{\zeta(s)} = \sum_{n=1}^{\infty} \frac{\Lambda(n)}{n^s}.$$

Proof. Taking logarithms in [Theorem 36.6.11](#), valid since ζ is nonvanishing on $\sigma > 1$,

$$\log \zeta(s) = - \sum_p \log(1 - p^{-s}).$$

Differentiating term by term (legitimate by local uniform convergence),

$$\frac{\zeta'(s)}{\zeta(s)} = - \sum_p \frac{p^{-s} \log p}{1 - p^{-s}} = - \sum_p (\log p) \sum_{k=1}^{\infty} p^{-ks} = - \sum_{n=1}^{\infty} \frac{\Lambda(n)}{n^s},$$

since the only n contributing are prime powers p^k , each with weight $\log p$. $\square$

So Λ is a weighted indicator function of the prime powers, packaged so as to be visible to ζ . Setting $\psi(x) = \sum_{n \leq x} \Lambda(n)$, one can show that the prime number theorem is equivalent to $\psi(x) \sim x$, and the analytic proof proceeds by writing

$$\psi(x) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \left(-\frac{\zeta'(s)}{\zeta(s)} \right) \frac{x^s}{s} ds$$

for $c > 1$ and moving the contour left, picking up x from the pole of $-\zeta'/\zeta$ at $s = 1$ and a term x^ρ/ρ from each nontrivial zero ρ . One sees very concretely why the location of the zeros controls the error term.

§36.6.4 Counting Primes

We now come back to earth and prove Chebyshev's bounds. First, the sieve of Eratosthenes made quantitative.

Proposition 36.6.18 (Legendre's Formula)

Let $x > 1$ and let $P = \prod_{p \leq \sqrt{x}} p$. Then

$$\pi(x) - \pi(\sqrt{x}) + 1 = |\{1 \leq n \leq x : (n, P) = 1\}| = \sum_{d|P} \mu(d) \left\lfloor \frac{x}{d} \right\rfloor.$$

Proof. For the first equality: an integer $1 \leq n \leq x$ is coprime to P if and only if it has no prime factor at most $\sqrt{x}$, which happens exactly when $n = 1$ or n is a prime in $(\sqrt{x}, x]$. There are $1 + \pi(x) - \pi(\sqrt{x})$ such n .

For the second, use [Lemma 36.6.14](#) to detect coprimality:

$$|\{n \leq x : (n, P) = 1\}| = \sum_{n \leq x} \sum_{d|(n, P)} \mu(d) = \sum_{d|P} \mu(d) |\{n \leq x : d | n\}|,$$

which is $\sum_{d|P} \mu(d) \lfloor x/d \rfloor$. □

Example 36.6.19

Take $x = 100$, so $P = 2 \cdot 3 \cdot 5 \cdot 7 = 210$. The formula reads

$$100 - (50 + 33 + 20 + 14) + (16 + 10 + 7 + 6 + 4 + 2) - (3 + 2 + 1 + 0) + 0 = 22,$$

where the bracketed groups come from d with one, two, three and four prime factors. And indeed $\pi(100) - \pi(10) + 1 = 25 - 4 + 1 = 22$.

This is inclusion–exclusion, and it is exact, but the number of terms is $2^{\pi(\sqrt{x})}$, which grows far too fast to be useful. The successful approach instead extracts information from binomial coefficients, and the following simple observations are the engine.

Lemma 36.6.20

Let $n \geq 5$ and $N = \binom{2n}{n}$.

- (i) If $2n/3 < p \leq n$ then $p \nmid N$.
- (ii) If $p^k \mid N$ for some $k \geq 1$, then $p^k \leq 2n$.

Proof. (i) Write $N = \frac{(2n)(2n-1)\cdots(n+1)}{n(n-1)\cdots 1}$. If $2n/3 < p \leq n$ then $2p \leq 2n < 3p$, so exactly one multiple of p (namely $2p$) lies in $(n, 2n]$ and exactly one (namely p) in $[1, n]$; and $p^2 > 4n^2/9 > 2n$ for $n \geq 5$, so no higher power intervenes. So numerator and denominator each contain exactly one factor of p , which therefore cancels.

(ii) By Legendre's formula for v_p ,

$$v_p(N) = v_p((2n)!) - 2v_p(n!) = \sum_{i \geq 1} \left(\left\lfloor \frac{2n}{p^i} \right\rfloor - 2 \left\lfloor \frac{n}{p^i} \right\rfloor \right).$$

Each summand is $\lfloor 2y \rfloor - 2\lfloor y \rfloor \in \{0, 1\}$, and the summand vanishes once $p^i > 2n$. So if $p^k \mid N$, i.e. $v_p(N) \geq k$, then at least k summands are nonzero and hence $p^k \leq 2n$. □

Proof of Theorem 36.6.6. Upper bound. We first show $\pi(2^k) \leq 3 \cdot 2^k/k$ for all $k \geq 1$ by induction. For $1 \leq k \leq 6$ this is clear, since for even $n \geq 4$ we have $\pi(n) \leq n/2$ and so $\pi(2^k) \leq 2^{k-1} \leq 3 \cdot 2^k/k$ whenever $k \leq 6$.

For the inductive step, note that every prime $p \in (n, 2n]$ divides $\binom{2n}{n}$ exactly once (it divides the numerator and not the denominator), so

$$2^{2n} > \binom{2n}{n} \geq \prod_{n < p \leq 2n} p \geq n^{\pi(2n) - \pi(n)},$$

giving $\pi(2n) - \pi(n) \leq 2n \log 2 / \log n$. Applying this with $n = 2^k$,

$$\pi(2^{k+1}) \leq \pi(2^k) + \frac{2^{k+1} \log 2}{\log 2^k} = \pi(2^k) + \frac{2^{k+1}}{k} \leq \frac{3 \cdot 2^k}{k} + \frac{2^{k+1}}{k} = \frac{5 \cdot 2^{k+1}}{2k} \leq \frac{3 \cdot 2^{k+1}}{k+1},$$

the last step because $5/(2k) \leq 3/(k+1)$ for $k \geq 5$. This completes the induction.

Now given $x \geq 4$, choose k with $2^k < x \leq 2^{k+1}$, so $k \geq 2$. Since $y/\log y$ is increasing for $y \geq e$,

$$\pi(x) \leq \pi(2^{k+1}) \leq \frac{6 \cdot 2^k}{k+1} < \frac{6 \cdot 2^k}{k} = 6 \log 2 \cdot \frac{2^k}{\log 2^k} \leq 6 \log 2 \cdot \frac{x}{\log x}.$$

Lower bound. By [Lemma 36.6.20\(ii\)](#), $p^{v_p(N)} \leq 2n$ for every prime p , where $N = \binom{2n}{n}$; and only primes $p \leq 2n$ divide N . So

$$\log N = \sum_{p \leq 2n} v_p(N) \log p \leq \sum_{p \leq 2n} \frac{\log 2n}{\log p} \log p = \pi(2n) \log 2n.$$

On the other hand N is the largest of the $2n+1$ binomial coefficients $\binom{2n}{j}$, and

$$2^{2n} = \sum_{j=0}^{2n} \binom{2n}{j} = 2 + \sum_{j=1}^{2n-1} \binom{2n}{j} \leq 2 + (2n-1)N \leq 2nN$$

for $n \geq 1$. Hence $\log N \geq 2n \log 2 - \log 2n$, and combining,

$$\pi(2n) \geq \frac{2n \log 2 - \log 2n}{\log 2n} = \log 2 \cdot \frac{2n}{\log 2n} - 1.$$

Finally, for $x \geq 4$ pick n with $2n \leq x \leq 2n+2$; then $2n \geq x-2$ and $\log 2n \leq \log x$, so

$$\pi(x) \geq \pi(2n) \geq \log 2 \cdot \frac{x-2}{\log x} - 1 \geq \frac{\log 2}{2} \cdot \frac{x}{\log x},$$

the last inequality being equivalent to $\frac{\log 2}{2}x \geq 2 \log 2 + \log x$, which holds for $x \geq 11$. For $4 \leq x < 11$ the claimed bound asserts $\pi(x) \geq 1.51$, and $\pi(x) \geq 2$ throughout that range. $\square$

So $\pi(x)$ is of order $x/\log x$, which is the qualitative content of the prime number theorem. It is worth appreciating that the constants $\log 2/2 \approx 0.347$ and $6 \log 2 \approx 4.16$ bracket the truth of 1, so there is still work to be done – but the shape is right, and it was got by hand.

§36.6.5 Bertrand's Postulate

A pleasant application of the same circle of ideas is the following, conjectured by Bertrand in 1845 and proved by Chebyshev.

Theorem 36.6.21 (Bertrand's Postulate)

For every integer $n \geq 2$ there is a prime p with $n \leq p < 2n$.

The key input is a bound on the product of all primes up to x , which is essentially the

statement $\theta(x) = O(x)$ for Chebyshev's θ function.

Lemma 36.6.22

For $x \geq 1$, $P(x) = \prod_{p \leq x} p \leq 4^x$.

Proof. Since P is a step function it suffices to prove this for integers $x = n$, and we induct. The cases $n = 1, 2, 3$ are clear. If n is even and $n \geq 4$ then n is not prime, so $P(n) = P(n-1) \leq 4^{n-1} < 4^n$. So we may assume n is odd, say $n = 2m+1$ with $m \geq 1$.

Every prime p with $m+2 \leq p \leq 2m+1$ divides $\binom{2m+1}{m}$, since it divides the numerator $(2m+1)!$ once and neither $m!$ nor $(m+1)!$. Hence

$$\prod_{m+2 \leq p \leq 2m+1} p \mid \binom{2m+1}{m}, \quad 2 \binom{2m+1}{m} = \binom{2m+1}{m} + \binom{2m+1}{m+1} \leq 2^{2m+1},$$

so $\binom{2m+1}{m} \leq 4^m$. Therefore

$$P(2m+1) = P(m+1) \prod_{m+2 \leq p \leq 2m+1} p \leq 4^{m+1} \cdot 4^m = 4^{2m+1},$$

using the inductive hypothesis for $P(m+1)$. □

Corollary 36.6.23

$\pi(x) \leq \frac{x \log 4}{\log x}$ for $x \geq 2$.

Proof. Every prime in $(\sqrt{x}, x]$ contributes a factor exceeding $\sqrt{x}$ to $P(x)$, so

$$x^{(\pi(x) - \pi(\sqrt{x}))/2} \leq P(x) \leq 4^x.$$

Taking logarithms and absorbing $\pi(\sqrt{x}) \leq \sqrt{x}$ gives the bound. □

Proof of Theorem 36.6.21. Suppose for contradiction that there is no prime in $[n, 2n)$, and set $N = \binom{2n}{n}$. Any prime $p \mid N$ satisfies $p \leq 2n$; and $p \neq 2n$ unless $n = 1$, while our assumption rules out $n \leq p < 2n$. So $p < n$, and then Lemma 36.6.20(i) forces $p \leq 2n/3$.

Split $N = N_1 N_2$ where $N_1 = \prod_{v_p(N)=1} p$ and $N_2 = \prod_{v_p(N) \geq 2} p^{v_p(N)}$. By Lemma 36.6.22,

$$N_1 \leq \prod_{p \leq 2n/3} p = P(2n/3) \leq 4^{2n/3}.$$

For N_2 : if $v_p(N) \geq 2$ then $p^2 \leq p^{v_p(N)} \leq 2n$ by Lemma 36.6.20(ii), so $p \leq \sqrt{2n}$, and

each such prime contributes at most $2n$. Hence

$$N_2 \leq \prod_{p \leq \sqrt{2n}} 2n \leq (2n)^{\sqrt{2n}}.$$

Also $N = \binom{2n}{n} \geq 4^n/(2n)$, as in the proof of [Theorem 36.6.6](#). Combining,

$$\frac{4^n}{2n} \leq N \leq 4^{2n/3}(2n)^{\sqrt{2n}},$$

and taking logarithms, $\frac{n \log 4}{3} \leq (1 + \sqrt{2n}) \log 2n$, i.e.

$$\frac{2 \log 2}{3} n \leq (1 + \sqrt{2n}) \log 2n.$$

The left side grows linearly and the right like $\sqrt{n} \log n$, so this fails for all large n ; a short computation shows it fails for $n \geq 2^9 = 512$.

For $n < 512$ we exhibit primes directly: the list

$$2, 3, 5, 7, 13, 23, 43, 83, 163, 317, 631$$

has each term less than twice its predecessor, so for any $n < 512$ some consecutive pair straddles n and provides a prime in $[n, 2n)$. $\square$

§36.7 Continued Fractions

Suppose we want to approximate π by a rational number. Decimals give

$$\left| \pi - \frac{314159}{100000} \right| < 3 \times 10^{-6},$$

which is respectable. But

$$\left| \pi - \frac{355}{113} \right| < 3 \times 10^{-7},$$

which is better by an order of magnitude with a denominator nearly a thousand times smaller. Where did $355/113$ come from, and can we do better still? The answer to both questions is continued fractions.

§36.7.1 Diophantine Approximation

First, how well *can* we approximate? A denominator q divides the line into intervals of length $1/q$, so the best we can hope for from a fixed q is $|\theta - p/q| \leq 1/(2q)$. The following says that some q does very much better than that.

Theorem 36.7.1 (Dirichlet)

Let $\theta \in \mathbb{R}$ and $N \in \mathbb{N}$. Then there are $p, q \in \mathbb{Z}$ with $1 \leq q \leq N$ and

$$\left| \theta - \frac{p}{q} \right| \leq \frac{1}{qN} \leq \frac{1}{q^2}.$$

Proof. Consider the $N+1$ numbers $\{0\}, \{\theta\}, \{2\theta\}, \dots, \{N\theta\}$ where $\{\cdot\}$ denotes fractional part, all lying in $[0, 1)$. Partition $[0, 1)$ into the N intervals $[j/N, (j+1)/N)$; by pigeonhole two of our numbers lie in the same interval, say $\{k\theta\}$ and $\{l\theta\}$ with $k < l$. Then with $q = l - k \in [1, N]$ we have $|q\theta - p| \leq 1/N$ for a suitable integer p , and dividing by q gives the result. $\square$

Corollary 36.7.2

If θ is irrational then $|\theta - p/q| < 1/q^2$ has infinitely many solutions $p/q \in \mathbb{Q}$.

Proof. Given any finite set of rationals p_i/q_i , choose N with $1/N < \min_i |\theta - p_i/q_i|$ (possible as θ is irrational, so the minimum is positive). The p/q produced by Theorem 36.7.1 satisfies $|\theta - p/q| \leq 1/(qN) \leq 1/N$, so it is not on our list. $\square$

§36.7.2 Complete and Partial Quotients

The construction is a greedy algorithm: peel off the integer part, invert what remains, and repeat.

Definition 36.7.3

Let $\theta \in \mathbb{R}$. Set $\theta_0 = \theta$ and $a_0 = \lfloor \theta_0 \rfloor$. If $\theta_0 = a_0$ we stop; otherwise set $\theta_1 = 1/(\theta_0 - a_0)$ and $a_1 = \lfloor \theta_1 \rfloor$, and continue. We call the θ_n the **complete quotients** and the a_n the **partial quotients** of θ , and write

$$\theta = a_0 + \frac{1}{a_1 + \frac{1}{a_2 + \dots}} = [a_0, a_1, a_2, \dots]$$

for the **continued fraction expansion** of θ .

Since $0 < \theta_n - a_n < 1$ whenever the process does not stop, we have $\theta_{n+1} > 1$ and hence $a_n \geq 1$ for all $n \geq 1$; only a_0 may be zero or negative. At every stage we have the exact identity

$$\theta = [a_0, a_1, \dots, a_{n-1}, \theta_n],$$

which is the statement that we have not thrown anything away.

Example 36.7.4

Take $\theta = 59/13$. Then

$$\frac{59}{13} = 4 + \frac{7}{13} = 4 + \frac{1}{\frac{13}{7}} = 4 + \frac{1}{1 + \frac{6}{7}} = 4 + \frac{1}{1 + \frac{1}{1 + \frac{1}{6}}},$$

so $59/13 = [4, 1, 1, 6]$.

Proposition 36.7.5

The continued fraction expansion of θ terminates if and only if $\theta \in \mathbb{Q}$.

Proof. If the expansion terminates then θ is built from integers by finitely many additions and divisions, hence rational. Conversely, if $\theta = a/b$ then the algorithm is Euclid's: writing $a = a_0b + r$ we get $\theta_1 = b/r$, and the numerators $b > r > \dots$ strictly decrease, so the process stops. $\square$

Example 36.7.6

Compare the expansion of $59/13$ above with Euclid's algorithm on $(59, 13)$:

$$59 = 4 \times 13 + 7,$$

$$13 = 1 \times 7 + 6,$$

$$7 = 1 \times 6 + 1,$$

$$6 = 6 \times 1 + 0,$$

whose quotients are $4, 1, 1, 6$ – exactly the partial quotients.

Remark. The expansion of a rational is not quite unique: if $a_n \geq 2$ is the last partial quotient then $[a_0, \dots, a_n] = [a_0, \dots, a_n - 1, 1]$. The algorithm above always produces the version with $a_n \geq 2$ (for $n \geq 1$), and we take that as the canonical one.

§36.7.3 Convergents

Truncating the expansion gives rational approximations, and remarkably they satisfy a simple recursion.

Definition 36.7.7

Given integers $a_0, a_1, a_2, \dots$ with $a_n \geq 1$ for $n \geq 1$, define the **convergents** p_n/q_n by

$$\begin{aligned} p_{-1} &= 1, & q_{-1} &= 0, & p_0 &= a_0, & q_0 &= 1, \\ p_n &= a_n p_{n-1} + p_{n-2}, & q_n &= a_n q_{n-1} + q_{n-2} \quad (n \geq 1). \end{aligned}$$

Note $1 = q_0 \leq q_1 < q_2 < q_3 < \dots$, so the denominators grow at least as fast as the Fibonacci numbers, and in particular $q_n \rightarrow \infty$. It is worth recording the recursion in matrix form,

$$\begin{pmatrix} p_n & p_{n-1} \\ q_n & q_{n-1} \end{pmatrix} = \begin{pmatrix} a_0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} a_1 & 1 \\ 1 & 0 \end{pmatrix} \cdots \begin{pmatrix} a_n & 1 \\ 1 & 0 \end{pmatrix},$$

which one verifies by induction and which makes the next proposition transparent. (A warning about notation: by ‘the convergent p_n/q_n ’ we really mean the *pair* (p_n, q_n) , not merely the rational number; the distinction matters, as (i) below shows the pair is already in lowest terms.)

Proposition 36.7.8

Let (p_n/q_n) be the convergents of $[a_0, a_1, \dots]$. Then

- (i) $p_n q_{n-1} - p_{n-1} q_n = (-1)^{n+1}$; in particular $(p_n, q_n) = 1$;
- (ii) $[a_0, \dots, a_n] = p_n/q_n$;
- (iii) if $\alpha = [a_0, \dots, a_n, \beta]$ for some real $\beta > 0$, then

$$\alpha = \frac{p_n \beta + p_{n-1}}{q_n \beta + q_{n-1}},$$

and α lies strictly between p_n/q_n and p_{n-1}/q_{n-1} .

Proof. (i) Take determinants in the matrix identity: the left side has determinant $p_n q_{n-1} - p_{n-1} q_n$ and the right has determinant $(-1)^{n+1}$.

(iii) Induct on n . For $n = 0$, $[a_0, \beta] = a_0 + 1/\beta = (a_0 \beta + 1)/\beta = (p_0 \beta + p_{-1})/(q_0 \beta + q_{-1})$. For $n \geq 1$, write $\gamma = a_n + 1/\beta$, so $\alpha = [a_0, \dots, a_{n-1}, \gamma]$ and by induction

$$\alpha = \frac{p_{n-1} \gamma + p_{n-2}}{q_{n-1} \gamma + q_{n-2}} = \frac{p_{n-1}(a_n \beta + 1) + \beta p_{n-2}}{q_{n-1}(a_n \beta + 1) + \beta q_{n-2}} = \frac{(a_n p_{n-1} + p_{n-2})\beta + p_{n-1}}{(a_n q_{n-1} + q_{n-2})\beta + q_{n-1}},$$

which is $(p_n \beta + p_{n-1})/(q_n \beta + q_{n-1})$ as claimed. For the last claim, if $x/y < x'/y'$ with $y, y' > 0$ then the *mediant* satisfies $x/y < (x + x')/(y + y') < x'/y'$; applying this with weights gives that $(p_n \beta + p_{n-1})/(q_n \beta + q_{n-1})$ lies strictly between p_n/q_n and p_{n-1}/q_{n-1} .

(ii) Take $\beta = a_n$ in (iii) applied to $n - 1$. □

Theorem 36.7.9

Let θ be irrational with continued fraction $[a_0, a_1, \dots]$. Then for every $n \geq 0$,

$$\left| \theta - \frac{p_n}{q_n} \right| < \frac{1}{q_n q_{n+1}} \leq \frac{1}{q_n^2}.$$

In particular $p_n/q_n \rightarrow \theta$.

Proof. We have $\theta = [a_0, \dots, a_n, \theta_{n+1}]$ exactly, so by [Proposition 36.7.8\(iii\)](#),

$$\theta - \frac{p_n}{q_n} = \frac{p_n \theta_{n+1} + p_{n-1}}{q_n \theta_{n+1} + q_{n-1}} - \frac{p_n}{q_n} = \frac{q_n p_{n-1} - p_n q_{n-1}}{q_n (q_n \theta_{n+1} + q_{n-1})} = \frac{(-1)^n}{q_n (q_n \theta_{n+1} + q_{n-1})}.$$

Since $\theta_{n+1} > a_{n+1}$ we get $q_n \theta_{n+1} + q_{n-1} > a_{n+1} q_n + q_{n-1} = q_{n+1}$, and the bound follows. As $q_n \rightarrow \infty$, the convergents converge to θ . □

Notice that the sign of $\theta - p_n/q_n$ alternates. So the convergents straddle θ , the even ones increasing up to it from below and the odd ones decreasing to it from above, giving a nested sequence of intervals each containing θ :

(The spacing here is schematic: in reality the intervals shrink far faster than the picture suggests.)

Example 36.7.10

The expansion of π begins $\pi = [3, 7, 15, 1, 292, \dots]$, with convergents

$$3, \quad \frac{22}{7}, \quad \frac{333}{106}, \quad \frac{355}{113}, \quad \frac{103993}{33102}, \quad \dots$$

So $355/113$ is the fourth convergent, which explains its quality: the next partial quotient is the enormous 292, and by [Theorem 36.7.9](#) the error is at most $1/(q_3q_4) = 1/(113 \times 33102) \approx 2.7 \times 10^{-7}$. Large partial quotients are exactly the places where continued fractions do unusually well.

§36.7.4 Best Approximation

The convergents are not merely good approximations; they are the best possible.

Theorem 36.7.11

Let θ be irrational with convergents p_n/q_n .

- (i) If $1 \leq q < q_{n+1}$ then $|q\theta - p| \geq |q_n\theta - p_n|$ for every $p \in \mathbb{Z}$.
- (ii) If $|\theta - p/q| < |\theta - p_n/q_n|$ with $q \geq 1$, then $q > q_n$.

Proof. (i) Fix q, p with $1 \leq q < q_{n+1}$ and solve

$$\begin{cases} p_n u + p_{n+1} v = p, \\ q_n u + q_{n+1} v = q. \end{cases}$$

The determinant of the system is $p_n q_{n+1} - p_{n+1} q_n = \pm 1$ by [Proposition 36.7.8\(i\)](#), so u, v are integers, not both zero. Then

$$q\theta - p = u(q_n\theta - p_n) + v(q_{n+1}\theta - p_{n+1}).$$

If $v = 0$ then $u \neq 0$ and $|q\theta - p| = |u||q_n\theta - p_n| \geq |q_n\theta - p_n|$, as required. So suppose $v \neq 0$. If $u = 0$ then $q = q_{n+1}v$, forcing $q \geq q_{n+1}$, contrary to hypothesis. So $u \neq 0$ too, and from $q_n u = q - q_{n+1}v$ with $0 < q < q_{n+1}$ we see u and v have opposite signs. But $\theta - p_n/q_n$ and $\theta - p_{n+1}/q_{n+1}$ also have opposite signs, so $u(q_n\theta - p_n)$ and $v(q_{n+1}\theta - p_{n+1})$ have the *same* sign, and there is no cancellation:

$$|q\theta - p| = |u||q_n\theta - p_n| + |v||q_{n+1}\theta - p_{n+1}| \geq |q_n\theta - p_n|.$$

(ii) If $q \leq q_n < q_{n+1}$ then by (i),

$$\left| \theta - \frac{p}{q} \right| = \frac{1}{q} |q\theta - p| \geq \frac{1}{q} |q_n\theta - p_n| \geq \frac{1}{q_n} |q_n\theta - p_n| = \left| \theta - \frac{p_n}{q_n} \right|,$$

contradicting the hypothesis. □

So among all fractions with denominator at most q_n , the convergent p_n/q_n is the closest

to θ . There is a converse, which is the practical tool: any sufficiently good approximation *must* be a convergent.

Theorem 36.7.12

Let θ be irrational.

- (i) At least one of any two consecutive convergents satisfies $|\theta - p/q| < 1/(2q^2)$.
- (ii) If $p/q \in \mathbb{Q}$ with $q \geq 1$ satisfies $|\theta - p/q| < 1/(2q^2)$, then p/q is a convergent of θ .

Proof. (i) Suppose $|\theta - p_n/q_n| \geq 1/(2q_n^2)$ and $|\theta - p_{n+1}/q_{n+1}| \geq 1/(2q_{n+1}^2)$. Since θ lies between the two convergents,

$$\frac{1}{2} \left(\frac{1}{q_n^2} + \frac{1}{q_{n+1}^2} \right) \leq \left| \theta - \frac{p_n}{q_n} \right| + \left| \theta - \frac{p_{n+1}}{q_{n+1}} \right| = \left| \frac{p_n}{q_n} - \frac{p_{n+1}}{q_{n+1}} \right| = \frac{1}{q_n q_{n+1}}.$$

This says $(1/q_n - 1/q_{n+1})^2 \leq 0$, so $q_n = q_{n+1}$, which happens only for $n = 0$ with $a_1 = 1$; and one checks directly there.

(ii) Suppose p/q is not a convergent, and choose n with $q_n \leq q < q_{n+1}$. Then $p/q \neq p_n/q_n$, so $|pq_n - p_nq| \geq 1$ and

$$\frac{1}{qq_n} \leq \left| \frac{p}{q} - \frac{p_n}{q_n} \right| \leq \left| \theta - \frac{p}{q} \right| + \left| \theta - \frac{p_n}{q_n} \right| = \frac{1}{q} |q\theta - p| + \frac{1}{q_n} |q_n\theta - p_n|.$$

By Theorem 36.7.11(i), $|q_n\theta - p_n| \leq |q\theta - p| < 1/(2q)$, so

$$\frac{1}{qq_n} < \left(\frac{1}{q} + \frac{1}{q_n} \right) \frac{1}{2q} = \frac{1}{2q^2} + \frac{1}{2qq_n},$$

giving $1/(2qq_n) < 1/(2q^2)$ and hence $q < q_n$, a contradiction. $\square$

Remark. The constant $1/2$ in (ii) cannot be improved to 1 : by Theorem 36.7.1 there are always infinitely many p/q with $|\theta - p/q| < 1/q^2$, and these need not be convergents. In the other direction, Hurwitz showed that $|\theta - p/q| < 1/(\sqrt{5}q^2)$ has infinitely many solutions for every irrational θ , and that $\sqrt{5}$ is optimal – the golden ratio $[1, 1, 1, \dots]$ being the worst-approximable number.

An application in the opposite direction: some numbers cannot be approximated well at all.

Definition 36.7.13

A number $\alpha \in \mathbb{C}$ is **algebraic** if $P(\alpha) = 0$ for some nonzero polynomial P with integer coefficients; the least degree of such a P is the **degree** of α . Numbers which are not algebraic are **transcendental**.

Theorem 36.7.14 (Liouville)

Let $\alpha \in \mathbb{R}$ be algebraic of degree $n > 1$. Then there is $c = c(\alpha) > 0$ with

$$\left| \alpha - \frac{p}{q} \right| > \frac{c}{q^n}$$

for all $p/q \in \mathbb{Q}$ with $q \geq 1$.

Proof. Let P be the minimal polynomial of α , of degree n . We may assume $|\alpha - p/q| < 1$, else take $c \leq 1$. Since P is irreducible of degree $n > 1$ it has no rational roots, so $P(p/q) \neq 0$; and $q^n P(p/q)$ is a nonzero integer, so $|P(p/q)| \geq 1/q^n$.

By the mean value theorem, $P(\alpha) - P(p/q) = (\alpha - p/q)P'(\xi)$ for some ξ between α and p/q , hence with $|\xi - \alpha| < 1$. Let $C = \sup_{|\xi - \alpha| \leq 1} |P'(\xi)|$, which is finite and nonzero. Since $P(\alpha) = 0$,

$$\left| \alpha - \frac{p}{q} \right| = \frac{|P(p/q)|}{|P'(\xi)|} \geq \frac{1}{Cq^n},$$

so $c = \min(1, 1/(2C))$ works, the case $|\alpha - p/q| \geq 1$ being trivial. $\square$

Corollary 36.7.15

The number $\alpha = \sum_{k=1}^{\infty} 10^{-k!}$ is transcendental.

Proof. Truncating at $k = m$ gives a rational p_m/q_m with $q_m = 10^{m!}$ and

$$\left| \alpha - \frac{p_m}{q_m} \right| = \sum_{k>m} 10^{-k!} < 2 \cdot 10^{-(m+1)!} = \frac{2}{q_m^{m+1}}.$$

If α were algebraic of degree n this would contradict Liouville's theorem for $m \geq n$ (and $\alpha \notin \mathbb{Q}$ since its decimal expansion is not eventually periodic). $\square$

§36.7.5 Periodic Continued Fractions

Definition 36.7.16

A continued fraction expansion is **eventually periodic** if it has the form

$$[a_0, \dots, a_{m-1}, \overline{a_m, \dots, a_{m+k-1}}],$$

the bar denoting infinite repetition of the block. It is **purely periodic** if we may take $m = 0$. The **period** is the least such k .

Example 36.7.17

Let us expand $\theta = \sqrt{6}$. Since $2 < \sqrt{6} < 3$ we have $a_0 = 2$, and

$$\theta_1 = \frac{1}{\sqrt{6} - 2} = \frac{\sqrt{6} + 2}{2} = 2 + \frac{\sqrt{6} - 2}{2}, \quad a_1 = 2,$$

$$\begin{aligned}\theta_2 &= \frac{2}{\sqrt{6}-2} = \sqrt{6} + 2 = 4 + (\sqrt{6} - 2), & a_2 &= 4, \\ \theta_3 &= \frac{1}{\sqrt{6}-2} = \theta_1.\end{aligned}$$

So the complete quotients repeat with period 2 and $\sqrt{6} = [2, \overline{2, 4}]$.

Definition 36.7.18

A **quadratic irrational** is an irrational $\theta \in \mathbb{R}$ satisfying $A\theta^2 + B\theta + C = 0$ for some $A, B, C \in \mathbb{Z}$ not all zero. Its **conjugate** θ' is the other root.

Theorem 36.7.19 (Lagrange)

The continued fraction expansion of an irrational θ is eventually periodic if and only if θ is a quadratic irrational.

Proof. ($\Leftarrow$) Suppose $A\theta^2 + B\theta + C = 0$ and consider the BQF $f = (A, B, C)$, so $f(\theta, 1) = 0$. For each $n \geq 0$ define

$$f_n(x, y) = f(p_n x + p_{n-1} y, q_n x + q_{n-1} y) = (A_n, B_n, C_n),$$

which is a unimodular substitution applied to f (up to sign of the determinant), so $\text{disc } f_n = \text{disc } f$ for all n . Since $\theta = (p_n \theta_{n+1} + p_{n-1}) / (q_n \theta_{n+1} + q_{n-1})$ by [Proposition 36.7.8\(iii\)](#), we get

$$f_n(\theta_{n+1}, 1) = (q_n \theta_{n+1} + q_{n-1})^2 f(\theta, 1) = 0,$$

so θ_{n+1} is a root of $A_n x^2 + B_n x + C_n$.

It remains to show the f_n take only finitely many values. Now $A_n = f_n(1, 0) = f(p_n, q_n)$, and writing $g(x) = Ax^2 + Bx + C$ so that $f(p, q) = q^2 g(p/q)$,

$$|A_n| = q_n^2 \left| g\left(\frac{p_n}{q_n}\right) \right| = q_n^2 |A| \left| \frac{p_n}{q_n} - \theta \right| \left| \frac{p_n}{q_n} - \theta' \right| \leq |A| \left| \frac{p_n}{q_n} - \theta' \right|$$

using $|\theta - p_n/q_n| \leq 1/q_n^2$. As $p_n/q_n \rightarrow \theta$, the right-hand side tends to $|A||\theta - \theta'|$, so the A_n are bounded. Similarly $C_n = f_n(0, 1) = f(p_{n-1}, q_{n-1}) = A_{n-1}$ is bounded, and then $B_n^2 = \text{disc } f + 4A_n C_n$ is bounded too. So the f_n take finitely many values, and hence so do the complete quotients θ_{n+1} , each being a root of one of finitely many quadratics. Two must coincide, and once $\theta_i = \theta_j$ the expansion repeats.

($\Rightarrow$) Suppose first that the expansion is purely periodic, say $\phi = [\overline{a_0, \dots, a_{k-1}}]$, so that $\phi = [a_0, \dots, a_{k-1}, \phi]$. By [Proposition 36.7.8\(iii\)](#),

$$\phi = \frac{p_{k-1}\phi + p_{k-2}}{q_{k-1}\phi + q_{k-2}}, \quad \text{i.e.} \quad q_{k-1}\phi^2 + (q_{k-2} - p_{k-1})\phi - p_{k-2} = 0,$$

a quadratic with integer coefficients and $q_{k-1} \neq 0$. In general $\theta = [a_0, \dots, a_{m-1}, \phi]$ for such a ϕ , so $\theta = (p_{m-1}\phi + p_{m-2}) / (q_{m-1}\phi + q_{m-2})$ is a rational function of ϕ with integer coefficients, hence also a quadratic irrational. $\square$

Theorem 36.7.20 (Galois)

Let θ be a quadratic irrational. The continued fraction of θ is purely periodic if and only if $\theta > 1$ and $-1 < \theta' < 0$.

We shall not prove this, but we will use the following consequence, which is what makes Pell's equation tractable.

Corollary 36.7.21

If $d \in \mathbb{N}$ is not a perfect square, then

$$\sqrt{d} = [a_0, \overline{a_1, \dots, a_n}]$$

for some n , with $a_0 = \lfloor \sqrt{d} \rfloor$.

Proof. Let $a_0 = \lfloor \sqrt{d} \rfloor$ and $\theta_1 = 1/(\sqrt{d} - a_0)$. Then $\theta_1 > 1$, and its conjugate is $1/(-\sqrt{d} - a_0) \in (-1, 0)$ since $\sqrt{d} + a_0 > 1$. By [Theorem 36.7.20](#), θ_1 is purely periodic, which is the claim. $\square$

Remark. In fact the periodic part is always a palindrome followed by $2a_0$, so $\sqrt{d} = [a_0, \overline{a_1, a_2, \dots, a_2, a_1, 2a_0}]$. For instance $\sqrt{6} = [2, \overline{2, 4}]$, $\sqrt{17} = [4, \overline{8}]$, $\sqrt{7} = [2, \overline{1, 1, 4}]$ and $\sqrt{23} = [4, \overline{1, 3, 1, 8}]$.

§36.7.6 Pell's Equation**Definition 36.7.22**

Let $d \in \mathbb{N}$ not be a perfect square. The equation

$$x^2 - dy^2 = 1$$

is called **Pell's equation**.

This is an indefinite binary quadratic form set equal to 1, and as we noted in §5 we should expect infinitely many solutions once there is one. Geometrically we are asking for lattice points on a hyperbola; here is $x^2 - 3y^2 = 1$, whose first few solutions are $(1, 0)$, $(2, \pm 1)$ and $(7, \pm 4)$.

The first observation is that solutions can only come from continued fractions.

Proposition 36.7.23

If (x, y) is a solution of $x^2 - dy^2 = 1$ with $x, y > 0$, then x/y is a convergent of $\sqrt{d}$.

Proof. From $(x - y\sqrt{d})(x + y\sqrt{d}) = 1$ we get $x > y\sqrt{d}$ and

$$x - y\sqrt{d} = \frac{1}{x + y\sqrt{d}} < \frac{1}{2y\sqrt{d}},$$

so $|\sqrt{d} - x/y| < 1/(2y^2\sqrt{d}) \leq 1/(2y^2)$. By [Theorem 36.7.12\(ii\)](#), x/y is a convergent of $\sqrt{d}$. $\square$

That there is a solution at all is where periodicity comes in.

Theorem 36.7.24 (Pell)

If $d \in \mathbb{N}$ is not a perfect square then $x^2 - dy^2 = 1$ has a solution with $y \neq 0$.

Proof. By [Corollary 36.7.21](#), $\sqrt{d} = [a_0, \overline{a_1, \dots, a_n}]$; replacing n by $2n$ if necessary we may assume n is even. Then $\theta_1 = \theta_{n+1} = [a_1, \dots, a_n]$, and $\sqrt{d} = a_0 + 1/\theta_1$, so $\theta_{n+1} = 1/(\sqrt{d} - a_0)$. By [Proposition 36.7.8\(iii\)](#),

$$\sqrt{d} = \frac{p_n\theta_{n+1} + p_{n-1}}{q_n\theta_{n+1} + q_{n-1}} = \frac{p_n + p_{n-1}(\sqrt{d} - a_0)}{q_n + q_{n-1}(\sqrt{d} - a_0)}.$$

Clearing denominators,

$$q_{n-1}d + (q_n - q_{n-1}a_0)\sqrt{d} = p_n - a_0p_{n-1} + p_{n-1}\sqrt{d}.$$

Since $\sqrt{d}$ is irrational we may equate ‘rational’ and ‘irrational’ parts: $p_{n-1} = q_n - a_0q_{n-1}$ and $q_{n-1}d = p_n - a_0p_{n-1}$. Hence

$$p_{n-1}^2 - dq_{n-1}^2 = p_{n-1}(q_n - a_0q_{n-1}) - q_{n-1}(p_n - a_0p_{n-1}) = p_{n-1}q_n - p_nq_{n-1},$$

which is $(-1)^n = 1$, using [Proposition 36.7.8\(i\)](#) and that n is even. So (p_{n-1}, q_{n-1}) is a solution. $\square$

Theorem 36.7.25

Let (x_1, y_1) be the solution of $x^2 - dy^2 = 1$ with $x_1, y_1 > 0$ and $\varepsilon = x_1 + y_1\sqrt{d}$ minimal. Then every solution with $x, y > 0$ is given by $x_n + y_n\sqrt{d} = \varepsilon^n$ for some $n \geq 1$.

Proof. Define the norm $N(a + b\sqrt{d}) = a^2 - db^2 = (a + b\sqrt{d})(a - b\sqrt{d})$, which is multiplicative since $\alpha \mapsto \alpha' = a - b\sqrt{d}$ is a ring homomorphism on $\mathbb{Z}[\sqrt{d}]$. So $N(\varepsilon) = 1$ implies $N(\varepsilon^n) = 1$, and every ε^n gives a solution.

Conversely, suppose $\alpha = a + b\sqrt{d}$ with $a, b > 0$ and $N(\alpha) = 1$. Then $\alpha \geq \varepsilon > 1$, so there is $k \geq 1$ with $\varepsilon^k \leq \alpha < \varepsilon^{k+1}$. Set $\beta = \alpha\varepsilon^{-k}$, so $N(\beta) = 1$ and $1 \leq \beta < \varepsilon$.

Writing $\beta = u + v\sqrt{d}$, from $\beta\beta' = 1$ and $\beta \geq 1$ we get $0 < \beta' \leq 1$, whence $2u = \beta + \beta' > 0$ and $2v\sqrt{d} = \beta - \beta' \geq 0$. So (u, v) is a nonnegative solution with $u + v\sqrt{d} < \varepsilon$, and minimality of ε forces $v = 0$, i.e. $\beta = 1$ and $\alpha = \varepsilon^k$. $\square$

Example 36.7.26

Take $d = 6$, so $\sqrt{6} = [2, \overline{2, 4}]$ with period 2. The convergents are

$$\frac{2}{1}, \frac{5}{2}, \frac{22}{9}, \frac{49}{20}, \frac{218}{89}, \frac{485}{198}, \dots$$

and evaluating $p^2 - 6q^2$ along them gives $-2, 1, -2, 1, -2, 1, \dots$. So the fundamental solution is $(5, 2)$: indeed $25 - 24 = 1$. The next is

$$(5 + 2\sqrt{6})^2 = 49 + 20\sqrt{6},$$

giving $(49, 20)$, and $49^2 - 6 \times 20^2 = 2401 - 2400 = 1$. These are precisely the convergents at odd index, as [Proposition 36.7.23](#) predicts.

Example 36.7.27

Take $d = 17$, so $\sqrt{17} = [4, \overline{8}]$ with period 1, which is odd. The convergent $p_0/q_0 = 4/1$ gives $16 - 17 = -1$, so $(4, 1)$ solves the *negative* Pell equation $x^2 - 17y^2 = -1$. Squaring, $(4 + \sqrt{17})^2 = 33 + 8\sqrt{17}$ gives the fundamental solution $(33, 8)$ of $x^2 - 17y^2 = 1$, and indeed $1089 - 1088 = 1$.

Remark. In general, $x^2 - dy^2 = -1$ is soluble if and only if the period of $\sqrt{d}$ is odd, and then the solutions of the two equations interlace along the convergents. For $d = 6$ the period is 2, and correspondingly $x^2 - 6y^2 = -1$ has no solutions – as one can also see modulo 3: $x^2 \equiv -1 \pmod{3}$ is insoluble.

§36.8 Primality Testing and Factorisation

Given a large integer N , we want to decide whether it is prime, and if not, to find a factor. These are different problems, and it is one of the pleasant discoveries of the last fifty years that the first is much easier than the second. Throughout we assume N is odd, since removing factors of 2 is free.

§36.8.1 Fermat Pseudoprimes

The obvious tool is Fermat's little theorem: if N is prime and $(b, N) = 1$ then $b^{N-1} \equiv 1 \pmod{N}$. Computing $b^{N-1} \pmod{N}$ by repeated squaring costs $O(\log N)$ multiplications, so this is a cheap test, and if it fails we have *proved* that N is composite – without finding a single factor.

Example 36.8.1

Take $N = 15$ and $b = 2$. Then $2^{14} = 16384 = 1092 \times 15 + 4$, so $2^{14} \equiv 4 \not\equiv 1 \pmod{15}$ and 15 is composite.

Unfortunately the converse fails.

Definition 36.8.2

Let $b \in \mathbb{N}$. An odd composite $N > 1$ is a **Fermat pseudoprime** to base b if $(b, N) = 1$ and $b^{N-1} \equiv 1 \pmod{N}$.

Example 36.8.3

$N = 91 = 7 \times 13$ is a Fermat pseudoprime to base 3: since $3^6 = 729 = 8 \times 91 + 1$, we have $3^{90} = (3^6)^{15} \equiv 1 \pmod{91}$. It is not one to base 2: $2^{90} \equiv 64 \pmod{91}$.

So a single base can fail us. How many bases can fail us at once?

Proposition 36.8.4

Let $N > 1$ be odd. If N is not a Fermat pseudoprime to some base b_0 coprime to N , then it fails to be one for at least half of the bases in $(\mathbb{Z}/N\mathbb{Z})^\times$.

Proof. The set $B = \{b \in (\mathbb{Z}/N\mathbb{Z})^\times : b^{N-1} \equiv 1\}$ is the kernel of the homomorphism $b \mapsto b^{N-1}$, hence a subgroup of $(\mathbb{Z}/N\mathbb{Z})^\times$. It is proper, since $b_0 \notin B$. So by Lagrange $|B| \leq |(\mathbb{Z}/N\mathbb{Z})^\times|/2$. $\square$

So if there is *any* witness, a handful of random guesses will find one with high probability. Sadly there need not be one.

Definition 36.8.5

An odd composite $N > 1$ is a **Carmichael number** if it is a Fermat pseudoprime to every base b with $(b, N) = 1$.

Example 36.8.6

$N = 561 = 3 \times 11 \times 17$ is the smallest Carmichael number. Indeed $560 = 2^4 \times 5 \times 7$ is divisible by each of $2 = 3 - 1$, $10 = 11 - 1$ and $16 = 17 - 1$, so for $(b, 561) = 1$ we have $b^{560} \equiv 1$ modulo each of 3, 11, 17 and hence modulo 561.

Proposition 36.8.7

An odd composite N is a Carmichael number if and only if N is squarefree and $p - 1 \mid N - 1$ for every prime $p \mid N$.

Proof. $(\Leftarrow)$ is the computation in the example. For $(\Rightarrow)$, suppose $p^2 \mid N$ for some prime p . Then $(\mathbb{Z}/N\mathbb{Z})^\times$ has an element of order p (take a generator of the cyclic factor $(\mathbb{Z}/p^k\mathbb{Z})^\times$ and raise it appropriately), and $p \nmid N - 1$ since $p \mid N$, so that element is not killed by $N - 1$. Hence N is squarefree. Now for $p \mid N$, take b with b a primitive root mod p and $b \equiv 1$ modulo N/p , possible by the Chinese remainder theorem; then $b^{N-1} \equiv 1 \pmod{p}$ forces $(p - 1) \mid N - 1$. $\square$

It was shown by Alford, Granville and Pomerance in 1994 that there are infinitely many

Carmichael numbers, so the Fermat test alone cannot be rescued. We need to ask for more.

§36.8.2 The Solovay–Strassen Test

The refinement is to use Euler’s criterion rather than Fermat’s theorem: if N is an odd prime then $b^{(N-1)/2} \equiv \left(\frac{b}{N}\right) \pmod{N}$, and the right-hand side is a Jacobi symbol which we can compute quickly for composite N too.

Definition 36.8.8

An odd composite $N > 1$ is an **Euler pseudoprime** to base b if $(b, N) = 1$ and

$$b^{(N-1)/2} \equiv \left(\frac{b}{N}\right) \pmod{N},$$

the symbol being Jacobi’s.

Squaring shows that an Euler pseudoprime to base b is also a Fermat pseudoprime to base b , so this is a genuinely stronger requirement. Exactly as in [Proposition 36.8.4](#), the set of bases witnessing Euler pseudoprimality is a subgroup, so if it is proper it has index at least 2. The point is that now it *is* always proper.

Theorem 36.8.9

Let $N > 1$ be odd and composite. Then there is $b \in (\mathbb{Z}/N\mathbb{Z})^\times$ such that N is not an Euler pseudoprime to base b .

Proof. Suppose first N is squarefree, say $N = pm$ with p prime, $p \nmid m$ and $m \geq 3$. Choose u with $\left(\frac{u}{p}\right) = -1$, and by the Chinese remainder theorem choose b with

$$b \equiv u \pmod{p}, \quad b \equiv 1 \pmod{m}.$$

Then $\left(\frac{b}{N}\right) = \left(\frac{b}{p}\right) \left(\frac{b}{m}\right) = (-1) \cdot 1 = -1$. But $b \equiv 1 \pmod{m}$ gives $b^{(N-1)/2} \equiv 1 \pmod{m}$, whereas $-1 \not\equiv 1 \pmod{m}$ as $m \geq 3$. So $b^{(N-1)/2} \not\equiv \left(\frac{b}{N}\right) \pmod{N}$.

Now suppose $p^2 \mid N$ for some prime p . By the Chinese remainder theorem choose b coprime to N with $b \equiv 1 + p \pmod{p^2}$ and $b \equiv 1$ modulo $N/p^{v_p(N)}$. Then

$$b^{N-1} \equiv (1 + p)^{N-1} \equiv 1 + (N-1)p \pmod{p^2},$$

and $p \nmid N-1$ since $p \mid N$, so $b^{N-1} \not\equiv 1 \pmod{p^2}$ and hence $b^{N-1} \not\equiv 1 \pmod{N}$. So $b^{(N-1)/2} \not\equiv \pm 1$, and in particular it is not the Jacobi symbol. $\square$

Corollary 36.8.10

If N is odd and composite, then N is an Euler pseudoprime to at most half of the bases in $(\mathbb{Z}/N\mathbb{Z})^\times$.

This gives the **Solovay–Strassen test**. Given odd $N > 1$, pick $1 < b < N$ at random.

- (1) Compute (b, N) by Euclid’s algorithm. If it is not 1, output COMPOSITE.

- (2) Compute $b^{(N-1)/2} \pmod N$ by repeated squaring, and $(\frac{b}{N})$ by reciprocity. If they differ, output COMPOSITE.
- (3) Otherwise output PROBABLY PRIME.

Every step is polynomial time. If N is prime the test never says COMPOSITE; if N is composite, each run catches it with probability at least $1/2$, so after k independent runs the probability of a composite slipping through is at most 2^{-k} .

§36.8.3 The Miller–Rabin Test

We can squeeze more out of the same idea. If N is an odd prime and $(b, N) = 1$, then $b^{(N-1)/2} \equiv \pm 1$. If it happens to be $+1$ and $(N-1)/2$ is still even, we may take a square root again, and so on. Since the only square roots of 1 modulo a prime are ± 1 , we get a rigid pattern.

Definition 36.8.11

Let $N > 1$ be odd and write $N - 1 = 2^s t$ with t odd and $s \geq 1$. Let $(b, N) = 1$. We say N passes the **strong test** to base b if either

$$b^t \equiv 1 \pmod N \quad \text{or} \quad b^{2^r t} \equiv -1 \pmod N \text{ for some } 0 \leq r < s.$$

An odd composite N passing the strong test to base b is called a **strong pseudo-prime** to base b .

Proposition 36.8.12

Every odd prime N passes the strong test to every base b with $(b, N) = 1$.

Proof. The sequence $b^t, b^{2t}, b^{4t}, \dots, b^{2^{s-1}t} = b^{N-1}$ ends at 1 and each term is the square of the previous one. Let r be least with $b^{2^r t} \equiv 1$. If $r = 0$ we are in the first case. Otherwise $b^{2^{r-1}t}$ is a square root of 1, hence ± 1 , and it is not 1 by minimality, so it is -1 . $\square$

Example 36.8.13

Take $N = 65$, so $N - 1 = 64 = 2^6$ and $s = 6$, $t = 1$.

- Base $b = 8$: we have $8^1 = 8 \not\equiv 1$, but $8^2 = 64 \equiv -1 \pmod{65}$. So 65 passes the strong test to base 8, and is a strong pseudoprime to that base.
- Base $b = 2$: the sequence 2^{2^r} for $r = 0, \dots, 5$ is $2, 4, 16, 61, 16, 61 \pmod{65}$. None of these is $-1 = 64$, and $2^t = 2^1 \not\equiv 1$. So 65 fails the strong test to base 2 and is composite.

Example 36.8.14

The Carmichael number $N = 561$ has $560 = 2^4 \times 35$, so $s = 4$, $t = 35$. To base 2 we find $2^{35} \equiv 263$, then squaring, $166, 67, 1 \pmod{561}$. Since $2^{35} \not\equiv 1$ and none of $263, 166, 67$ is $-1 = 560$, the number 561 fails the strong test to base 2. So the

strong test detects a Carmichael number that Fermat's test cannot.

Remark. One can show that a strong pseudoprime to base b is an Euler pseudoprime to base b , and hence a Fermat pseudoprime; so the strong test is the sharpest of the three. Rabin proved the quantitative statement we want: an odd composite N is a strong pseudoprime to at most a quarter of the bases in $(\mathbb{Z}/N\mathbb{Z})^\times$.

The **Miller–Rabin test** is then as follows.

Repeating k times, a composite N survives with probability at most 4^{-k} .

Remark. (i) On the generalised Riemann hypothesis, a composite N fails the strong test to some base $b < 2(\log N)^2$. Since the strong test is polynomial time, this would give a *deterministic* polynomial-time primality test.

(ii) Unconditionally, Agrawal, Kayal and Saxena found a deterministic polynomial-time primality test in 2002. In practice Miller–Rabin remains the algorithm of choice, being far faster.

§36.8.4 Fermat Factorisation

Now suppose we know N is composite and want a factor. If $N = ab$ with $a > b$ both odd, then setting

$$r = \frac{a+b}{2}, \quad s = \frac{a-b}{2}$$

we get $N = r^2 - s^2$ with $r > \sqrt{N}$. So we may try $r = \lfloor \sqrt{N} \rfloor + 1, \lfloor \sqrt{N} \rfloor + 2, \dots$ and test whether $r^2 - N$ is a perfect square. This is **Fermat factorisation**, and it is fast exactly when N has two factors of similar size.

Example 36.8.15

Let $N = 200819$. We have $\lfloor \sqrt{N} \rfloor = 448$, so we try $r = 449$, giving $449^2 - N = 201601 - 200819 = 782$, which is not a square; and then $r = 450$, giving

$$450^2 - N = 202500 - 200819 = 1681 = 41^2.$$

Hence $N = 450^2 - 41^2 = (450 + 41)(450 - 41) = 491 \times 409$.

The number of steps is about $(a-b)/2$, so this is hopeless when the factors are far apart. But the underlying idea generalises beautifully.

Proposition 36.8.16

Suppose $x^2 \equiv y^2 \pmod{N}$ with $x \not\equiv \pm y \pmod{N}$. Then $(N, x-y)$ and $(N, x+y)$ are nontrivial factors of N .

Proof. We have $N \mid (x+y)(x-y)$, so $(N, x+y) \neq 1$ or $(N, x-y) \neq 1$; in fact if $(N, x-y) = 1$ then $N \mid x+y$, contradicting $x \not\equiv -y$. Similarly $(N, x+y) \neq 1$. And $N \nmid x \pm y$ by hypothesis, so neither gcd is N . $\square$

So we want congruent squares. Finding them directly is no easier than Fermat factorisation; the trick is to build them out of many small pieces.

§36.8.5 The Factor Base Method

Lemma 36.8.17

Let $p_1, \dots, p_r$ be distinct primes and let $c_1, \dots, c_k$ be nonzero integers all of whose prime factors lie in $\{p_1, \dots, p_r\}$. If $k > r+1$ then there is a nonempty $I \subseteq \{1, \dots, k\}$ with $\prod_{i \in I} c_i$ a perfect square.

Proof. For $J \subseteq \{1, \dots, k\}$ write $c_J = \prod_{i \in J} c_i = (-1)^{\alpha_{J,0}} p_1^{\alpha_{J,1}} \dots p_r^{\alpha_{J,r}} m_J^2$ with each $\alpha_{J,i} \in \{0, 1\}$; that is, record the exponent parities together with the sign. This gives a vector $\underline{\alpha}_J \in \mathbb{F}_2^{r+1}$, and there are only 2^{r+1} possibilities but $2^k > 2^{r+1}$ subsets. So there are $J \neq K$ with $\underline{\alpha}_J = \underline{\alpha}_K$, and then $c_J c_K$ is a square. Taking $I = (J \setminus K) \cup (K \setminus J)$, the elements of $J \cap K$ contribute a square to $c_J c_K$, so c_I is a square too, and $I \neq \emptyset$ as $J \neq K$. $\square$

Definition 36.8.18

A **factor base** is a set $B = \{-1, p_1, \dots, p_r\}$ with the p_i distinct primes. A **B -number** for N is a positive integer x such that the representative $\langle x^2 \rangle$ of x^2 modulo N in $(-N/2, N/2]$ has all its prime factors in B .

The algorithm is now clear. Choose a factor base B , generate more than $|B|$ many B -numbers $x_1, x_2, \dots$, use Lemma 36.8.17 to find I with $\prod_{i \in I} \langle x_i^2 \rangle = y^2$ a square, and set $x = \prod_{i \in I} x_i$. Then $x^2 \equiv y^2 \pmod{N}$, and if we are lucky enough that $x \not\equiv \pm y$, Proposition 36.8.16 hands us a factor. Otherwise, generate more B -numbers and try again.

The obvious way to find B -numbers is to take $x_i = \lceil \sqrt{kN} \rceil$ for small $k \geq 1$, since then $\langle x_i^2 \rangle$ is small in absolute value and so more likely to be smooth.

Example 36.8.19

Let $N = 1829$ and take the factor base $B = \{-1, 2, 3, 5, 7, 11, 13, 19\}$. Now $\lfloor \sqrt{1829k} \rfloor$

equals 42, 60, 74, 85 for $k = 1, 2, 3, 4$, so we try values of x near these:

x	42	43	60	61	74	75	85
$\langle x^2 \rangle$	-65	20	-58	63	-11	138	-91
factorisation	$-5 \cdot 13$	$2^2 \cdot 5$	$-2 \cdot 29$	$3^2 \cdot 7$	-11	$2 \cdot 3 \cdot 23$	$-7 \cdot 13$
B -number?	yes	yes	no	yes	yes	no	yes

Taking I to correspond to $x \in \{42, 43, 61, 85\}$,

$$(-5 \cdot 13)(2^2 \cdot 5)(3^2 \cdot 7)(-7 \cdot 13) = (2 \cdot 3 \cdot 5 \cdot 7 \cdot 13)^2 = 2730^2,$$

while $42 \cdot 43 \cdot 61 \cdot 85 = 9364110 \equiv 1459 \pmod{1829}$ and $2730 \equiv 901 \pmod{1829}$. So

$$1459^2 \equiv 901^2 \equiv 1554 \pmod{1829},$$

and $1459 \not\equiv \pm 901$. Hence $(1829, 1459 - 901) = (1829, 558) = 31$ and $(1829, 1459 + 901) = (1829, 2360) = 59$, giving $1829 = 31 \times 59$.

Remark. Why should the method work? Heuristically, if $N = \prod_{i=1}^t p_i^{e_i}$ with $t \geq 2$ distinct primes, then $x^2 \equiv 1 \pmod{N}$ has 2^t solutions by the Chinese remainder theorem, of which only ± 1 are useless. So a ‘random’ pair (x, y) with $x^2 \equiv y^2 \pmod{N}$ succeeds with probability $1 - 2^{1-t} \geq 1/2$. The case $t = 1$, where N is a prime power, is easy to detect separately.

[Lemma 36.8.17](#) guarantees the subset I exists but the naive search for it is exponential; in practice one finds it by linear algebra over $\mathbb{F}_2$, which is polynomial.

§36.8.6 The Continued Fraction Method

Continued fractions supply an excellent source of B -numbers, because convergents to $\sqrt{N}$ have squares that are unusually close to multiples of N .

Lemma 36.8.20

Let p_n/q_n be a convergent of $\sqrt{N}$. Then $|p_n^2 - Nq_n^2| \leq 2\sqrt{N}$.

Proof. Using [Theorem 36.7.9](#),

$$|p_n^2 - Nq_n^2| = q_n^2 \left| \sqrt{N} - \frac{p_n}{q_n} \right| \left| \sqrt{N} + \frac{p_n}{q_n} \right| \leq \frac{q_n}{q_{n+1}} \left(2\sqrt{N} + \frac{1}{q_n q_{n+1}} \right) \leq 2\sqrt{N},$$

since $q_n \leq q_{n+1}$ and the correction term is tiny. $\square$

So $\langle p_n^2 \rangle = p_n^2 - Nq_n^2$ exactly (it already lies in $(-N/2, N/2]$ for $N > 16$), which makes p_n an excellent B -number candidate. Better still, the recursion $p_n = a_n p_{n-1} + p_{n-2}$ may be run modulo N throughout, since only $p_n \bmod N$ is needed.

Example 36.8.21

Let $N = 12403$. Then $\sqrt{N} = [111, 2, 1, 2, 2, 7, 1, \dots]$, and computing the convergents

modulo N :

n	0	1	2	3	4	5	6
$p_n \bmod N$	111	223	334	891	2116	3300	5416
$\langle p_n^2 \rangle$	-82	117	-71	89	-27	166	-39
factorisation	$-2 \cdot 41$	$3^2 \cdot 13$	-71	89	-3^3	$2 \cdot 83$	$-3 \cdot 13$

The factor base $B = \{-1, 3, 13\}$ picks out $p_1 = 223$, $p_4 = 2116$ and $p_6 = 5416$, and

$$(3^2 \cdot 13)(-3^3)(-3 \cdot 13) = 3^6 \cdot 13^2 = (27 \cdot 13)^2 = 351^2.$$

Meanwhile $223 \times 2116 \times 5416 \equiv 11341 \pmod{12403}$, so $11341^2 \equiv 351^2 \pmod{12403}$, and

$$(12403, 11341 - 351) = (12403, 10990) = 157, \quad (12403, 11341 + 351) = 79.$$

Indeed $12403 = 79 \times 157$.

Remark. A far-reaching refinement of these ideas is the [number field sieve](#), which is the best general-purpose factorisation algorithm known. It runs in time

$$O\left(\exp\left(c(\log N)^{1/3}(\log \log N)^{2/3}\right)\right),$$

which is subexponential but not polynomial. The current record is a 250-digit number, which took thousands of core-years.

§36.8.7 Pollard's $p - 1$ Method

Sometimes we can go faster by looking for factors of a particular shape. Suppose $N = pN_0$ with $(p, N_0) = 1$ and suppose that $p - 1$ happens to be a product of small primes. For any a coprime to N we have $a^{p-1} \equiv 1 \pmod{p}$, so $p \mid (a^{p-1} - 1, N)$; and unless we are unlucky, $N_0 \nmid a^{p-1} - 1$, so the gcd is a nontrivial factor.

We do not know p , so we cannot form a^{p-1} . But we do not need to: any multiple k of $p - 1$ will do, since then $a^k \equiv 1 \pmod{p}$ as well. And if $p - 1$ is a product of prime powers at most m , then

$$k = \text{lcm}(1, 2, \dots, m)$$

is such a multiple.

The algorithm is therefore: choose a bound m , set $k = \text{lcm}(1, \dots, m)$, choose a small $a \geq 2$, check $(a, N) = 1$ (if not we have already won), compute $a^k \bmod N$ by repeated squaring, and evaluate $(a^k - 1, N)$. If this is nontrivial we are done; otherwise increase m and try again.

Example 36.8.22

Let $N = 540143$ and take $m = 8$, so $k = \text{lcm}(1, \dots, 8) = 840$. With $a = 2$,

$$2^{840} \equiv 53047 \pmod{540143},$$

and $(53047 - 1, 540143) = 421$. Indeed $540143 = 421 \times 1283$, and the method worked because

$$421 - 1 = 420 = 2^2 \times 3 \times 5 \times 7$$

is a product of small prime powers, all at most 8. Note that the other factor is no help here: $1283 - 1 = 2 \times 641$, and 641 is far larger than m .

Remark. The running time is $O(m(\log m)(\log^2 N))$, so the method is efficient precisely when some prime factor p of N has $p-1$ smooth. This is why cryptographic applications insist on ‘safe’ primes, for which $(p-1)/2$ is also prime.

For factors of general shape but moderate size (say $N \approx 2^{1000}$ with a factor $p \approx 2^{100}$), the method of choice is Lenstra’s elliptic curve method, which replaces $(\mathbb{Z}/p\mathbb{Z})^\times$ by the group of points of an elliptic curve mod p and thereby gets to vary the group order. And if one is allowed a quantum computer, Shor’s algorithm factors in polynomial time – which is, for now, the only known route to the conjecture with which we began.

37 Principles of Quantum Mechanics

In the IB Quantum Mechanics course, quantum mechanics was a theory of *wavefunctions*: a particle is described by a complex function $\psi(\mathbf{x}, t)$, observables are differential operators acting on it, and everything is computed by doing integrals. That framework is perfectly correct, and it is how one actually solves the hydrogen atom. But it has an obvious defect – there are quantum systems, spin being the first and most important, that have nothing to do with functions on space at all, and for which no wavefunction exists.

The right response is to notice that the wavefunction was never the essential object. What mattered were the *structural* facts: that states form a complex vector space with an inner product, that observables are Hermitian operators on it, and that measurement is expansion in an eigenbasis. In this course we take those facts as the definition. States become abstract vectors $|\psi\rangle$ in a Hilbert space, written in Dirac’s marvellously efficient bra-ket notation; the wavefunction becomes the collection of components $\psi(\mathbf{x}) = \langle \mathbf{x} | \psi \rangle$ of the state in one particular basis, no more privileged than any other. Once the theory is set up this way, a great deal that looked like a series of miracles in IB – the harmonic oscillator spectrum, the quantisation of angular momentum, the existence of spin – becomes a consequence of a few commutation relations, and can be derived in a page of algebra with no differential equations in sight.

Along the way we will find that almost everything in the subject comes from symmetry. Momentum is what generates translations, angular momentum is what generates rotations, and energy is what generates time evolution; conservation laws and degeneracies are then automatic. We will also develop the approximation methods (perturbation theory, the variational principle, Fermi’s golden rule) without which the theory would be able to describe only a handful of exactly solvable toy systems, and we will end by looking hard at what quantum mechanics says about reality itself, via the EPR paradox and Bell’s inequality.

This article constitutes my notes for the ‘Principles of Quantum Mechanics’ course, held in Michaelmas 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§37.1 The Dirac Formalism

We begin by rebuilding the foundations of quantum mechanics in the abstract. Nothing here contradicts IB Quantum Mechanics – the wavefunction picture will drop out as a special case in §37.1.8 – but the emphasis shifts entirely, from the analysis of a particular differential equation to the linear algebra that underlies every quantum system.

§37.1.1 States and the Hilbert Space

The first postulate says what a quantum system *is*.

Axiom 37.1.1 (States)

The states of a quantum system are the non-zero vectors of a complex Hilbert space

$\mathcal{H}$, with two vectors describing the same physical state if and only if they differ by a non-zero complex scalar.

A **Hilbert space** is a complex vector space $\mathcal{H}$ equipped with an inner product $\langle \cdot | \cdot \rangle : \mathcal{H} \times \mathcal{H} \rightarrow \mathbb{C}$ which is

- (i) *conjugate symmetric*: $\langle \phi | \psi \rangle = \langle \psi | \phi \rangle^*$;
- (ii) *linear in the second slot*: $\langle \phi | (\lambda_1 |\psi_1\rangle + \lambda_2 |\psi_2\rangle) = \lambda_1 \langle \phi | \psi_1 \rangle + \lambda_2 \langle \phi | \psi_2 \rangle$ (and hence, by (i), *antilinear* in the first slot);
- (iii) *positive definite*: $\langle \psi | \psi \rangle \geq 0$, with equality iff $|\psi\rangle = 0$;

and which is *complete* in the associated norm $\|\psi\| = \langle \psi | \psi \rangle^{1/2}$, meaning every Cauchy sequence converges. We shall also always assume $\mathcal{H}$ is *separable*, i.e. has a countable orthonormal basis.

Two remarks on the postulate. First, since scalar multiples describe the same state, we may and usually will **normalise**, choosing a representative with $\langle \psi | \psi \rangle = 1$. This still leaves a phase ambiguity $|\psi\rangle \mapsto e^{i\alpha} |\psi\rangle$: an *overall* phase is physically meaningless. Second – and this is where all the interesting physics lives – a *relative* phase is not meaningless at all. The states

$$\frac{1}{\sqrt{2}} (|\psi_1\rangle + |\psi_2\rangle) \quad \text{and} \quad \frac{1}{\sqrt{2}} (|\psi_1\rangle - |\psi_2\rangle)$$

are physically different, and it is precisely their difference that produces interference. The technically correct statement of the postulate is that states are *rays* (one-dimensional subspaces) in $\mathcal{H}$; we will not fuss about this, but it is worth remembering when a phase seems to appear from nowhere.

The vector space structure is the **superposition principle**: any linear combination of states is a state. This is not a small assumption, and it is the single most counterintuitive thing about quantum mechanics.

Example 37.1.2 (Some Hilbert Spaces) (i) $\mathcal{H} = \mathbb{C}^n$, with $\langle \phi | \psi \rangle = \sum_i \phi_i^* \psi_i$. Finite-dimensional spaces are always complete, so this is a Hilbert space with nothing to check. The case $n = 2$ is the **qubit**, and is the state space of a spin- $\frac{1}{2}$ particle's spin degree of freedom.

(ii) $\mathcal{H} = L^2(\mathbb{R}^3)$, the square-integrable functions on $\mathbb{R}^3$, with

$$\langle \phi | \psi \rangle = \int_{\mathbb{R}^3} \phi(\mathbf{x})^* \psi(\mathbf{x}) d^3x.$$

This is the state space of a single spinless particle in three dimensions, and is the setting of IB Quantum Mechanics. (Completeness of L^2 is a theorem of measure theory; positive definiteness requires identifying functions that agree almost everywhere.)

(iii) A particle with spin, moving in space, has $\mathcal{H} = L^2(\mathbb{R}^3) \otimes \mathbb{C}^2$ – a *tensor product*, which we will meet properly in §37.5.1.

Almost all of the structure we need is already familiar from IB Linear Algebra; the only genuinely infinite-dimensional subtleties we shall meet are flagged as they arise, and we will treat them at the level of rigour of a physics course.

§37.1.2 Bras and Kets

Dirac's notation is a piece of notational engineering so good that it does a substantial part of the thinking for you. The idea is to split the inner product bracket $\langle\phi|\psi\rangle$ down the middle.

We write a vector of $\mathcal{H}$ as a **ket** $|\psi\rangle$, with the label inside the ket being whatever is convenient – a Greek letter, a list of quantum numbers $|n, \ell, m\rangle$, an eigenvalue $|\lambda\rangle$, or even an arrow $|\uparrow\rangle$. The labels are just names, and one must remember that (for example) $|\psi_1 + \psi_2\rangle$ is not automatically $|\psi_1\rangle + |\psi_2\rangle$ unless we say so.

Now consider the dual space $\mathcal{H}^*$ of continuous linear maps $\mathcal{H} \rightarrow \mathbb{C}$. Each $|\phi\rangle \in \mathcal{H}$ gives such a map, namely $|\psi\rangle \mapsto \langle\phi|\psi\rangle$, and the Riesz representation theorem (met in IB Analysis and Topology, and proved in Linear Analysis) says that *every* element of $\mathcal{H}^*$ arises this way, exactly once. So $\mathcal{H}^*$ is a faithful copy of $\mathcal{H}$, and we may write its elements as **bras** $\langle\phi|$, defined by

$$\langle\phi| : |\psi\rangle \mapsto \langle\phi|\psi\rangle.$$

The correspondence $|\phi\rangle \leftrightarrow \langle\phi|$ is antilinear:

$$\lambda_1 |\phi_1\rangle + \lambda_2 |\phi_2\rangle \longleftrightarrow \lambda_1^* \langle\phi_1| + \lambda_2^* \langle\phi_2|,$$

which is the notational shadow of conjugate symmetry, and the commonest source of slips. In $\mathbb{C}^n$, if $|\psi\rangle$ is a column vector then $\langle\psi|$ is the conjugate-transposed row vector, and $\langle\phi|\psi\rangle$ is literally the matrix product.

Notation. We will use $\langle\phi|\psi\rangle$ for the inner product throughout, dropping the IB notation $\langle\phi, \psi\rangle$. Both are linear in the second argument and antilinear in the first, matching the physicists' convention; be warned that many pure mathematics texts use the opposite convention.

An **orthonormal basis** of $\mathcal{H}$ is a family $\{|n\rangle\}_{n \in \mathbb{N}}$ with $\langle m|n\rangle = \delta_{mn}$ whose finite linear combinations are dense in $\mathcal{H}$. Given one, every state expands as

$$|\psi\rangle = \sum_n a_n |n\rangle, \quad a_n = \langle n|\psi\rangle,$$

where the coefficients are extracted by taking the inner product with $\langle m|$ and using orthonormality. Substituting the second formula into the first gives an identity worth displaying on its own:

$$|\psi\rangle = \sum_n |n\rangle \langle n|\psi\rangle \quad \text{for all } |\psi\rangle, \quad \text{i.e.} \quad \sum_n |n\rangle \langle n| = I.$$

This is the **completeness relation** (or *resolution of the identity*), and it is the workhorse of the whole formalism: whenever a calculation stalls, the answer is very often to insert a complete set of states in the middle of an expression. Here $|n\rangle \langle n|$ is an **outer product** – an operator, not a number – built by juxtaposing a ket and a bra the ‘wrong’ way round. Dirac's notation makes such objects, and the rule for reading them, completely automatic.

Two standard consequences of the inner product axioms, both proved exactly as in IB:

$$|\langle\phi|\psi\rangle| \leq \|\phi\| \|\psi\| \quad (\text{Cauchy-Schwarz}), \quad \|\phi + \psi\| \leq \|\phi\| + \|\psi\| \quad (\text{triangle inequality}),$$

and Parseval's identity $\|\psi\|^2 = \sum_n |a_n|^2$, which is what makes the Born rule below consistent.

§37.1.3 Operators and Adjoins

An **operator** is a linear map $A : \mathcal{H} \rightarrow \mathcal{H}$. Given an orthonormal basis $\{|n\rangle\}$, an operator is completely determined by its **matrix elements**

$$A_{mn} = \langle m|A|n\rangle,$$

since sandwiching A between two copies of the completeness relation gives

$$A = \left(\sum_m |m\rangle \langle m| \right) A \left(\sum_n |n\rangle \langle n| \right) = \sum_{m,n} A_{mn} |m\rangle \langle n|.$$

So an operator really is a (possibly infinite) matrix once a basis is chosen – and, pleasingly, the composition AB has matrix elements $\sum_k A_{mk} B_{kn}$, again by inserting the identity. All the linear algebra of IB carries over verbatim.

Notation. We will not decorate operators with hats, except occasionally where it aids clarity: whether a symbol denotes an operator or a number will always be clear from context. So the Hamiltonian is H , the position operator is x , and so on.

Definition 37.1.3 (Adjoint)

The **adjoint** (or Hermitian conjugate) of A is the unique operator $A^\dagger$ with

$$\langle \phi|A\psi\rangle = \langle A^\dagger\phi|\psi\rangle \quad \text{for all } |\phi\rangle, |\psi\rangle \in \mathcal{H}.$$

In terms of matrix elements this says $(A^\dagger)_{mn} = A_{nm}^*$ – the conjugate transpose, as expected. The notation is designed so that $A^\dagger$ is ‘ A acting leftwards on a bra’: the ket $A|\psi\rangle$ has as its bra $\langle\psi|A^\dagger$, and so

$$\langle\phi|A|\psi\rangle^* = \langle\psi|A^\dagger|\phi\rangle.$$

The algebraic rules are

$$(\lambda A + \mu B)^\dagger = \lambda^* A^\dagger + \mu^* B^\dagger, \quad (AB)^\dagger = B^\dagger A^\dagger, \quad (A^\dagger)^\dagger = A,$$

and $(|\phi\rangle\langle\psi|)^\dagger = |\psi\rangle\langle\phi|$. In practice one takes the dagger of any expression by reversing the order of everything and daggering each piece; kets become bras, bras become kets, and scalars get conjugated.

Definition 37.1.4 (Hermitian, Unitary, Projector)

An operator A is

- (i) **Hermitian** (or self-adjoint) if $A^\dagger = A$;
- (ii) **unitary** if $U^\dagger U = U U^\dagger = I$, equivalently if U is invertible with $U^{-1} = U^\dagger$;
- (iii) a **projector** if $P^2 = P = P^\dagger$.

Unitaries are exactly the operators preserving the inner product, $\langle U\phi|U\psi\rangle = \langle\phi|\psi\rangle$, so they are the symmetries of the Hilbert space – the quantum analogue of orthogonal transformations. They will describe time evolution, translations and rotations. Projectors are exactly the orthogonal projections onto closed subspaces: if $\{|i\rangle\}_{i \in I}$ is an orthonormal basis of a subspace V , then $P = \sum_{i \in I} |i\rangle\langle i|$ is the projector onto V , and $I - P$ is the projector onto $V^\perp$.

Finally, we will need the trace.

Definition 37.1.5 (Trace)

The **trace** of an operator A is $\text{tr } A = \sum_n \langle n|A|n\rangle$ for any orthonormal basis $\{|n\rangle\}$ (when the sum converges absolutely).

Proposition 37.1.6

The trace is independent of the basis used to compute it, and is cyclic: $\text{tr}(AB) = \text{tr}(BA)$.

Proof. For cyclicity, insert a complete set of states in the middle:

$$\text{tr}(AB) = \sum_n \langle n|AB|n\rangle = \sum_{n,m} \langle n|A|m\rangle \langle m|B|n\rangle = \sum_{m,n} B_{mn} A_{nm} = \sum_m \langle m|BA|m\rangle,$$

which is $\text{tr}(BA)$. Basis independence now follows: any other orthonormal basis is $|n'\rangle = U|n\rangle$ for some unitary U , and

$$\sum_n \langle n'|A|n'\rangle = \sum_n \langle n|U^\dagger A U|n\rangle = \text{tr}(U^\dagger A U) = \text{tr}(A U U^\dagger) = \text{tr } A. \quad \square$$

A useful special case: $\text{tr}(|\phi\rangle\langle\psi|) = \langle\psi|\phi\rangle$.

§37.1.4 Observables and Measurement**Axiom 37.1.7 (Observables)**

Every observable quantity of a quantum system is represented by a Hermitian operator on $\mathcal{H}$.

The reason Hermiticity is the right condition is the following, familiar from IB but worth re-proving in the new notation because the proof is three lines.

Proposition 37.1.8

Let A be Hermitian. Then all eigenvalues of A are real, and eigenvectors with distinct eigenvalues are orthogonal.

Proof. Suppose $A|\psi\rangle = \lambda|\psi\rangle$ with $|\psi\rangle \neq 0$. Then

$$\lambda \langle\psi|\psi\rangle = \langle\psi|A|\psi\rangle = \langle\psi|A^\dagger|\psi\rangle = \langle A\psi|\psi\rangle = \lambda^* \langle\psi|\psi\rangle,$$

and $\langle\psi|\psi\rangle \neq 0$, so $\lambda = \lambda^*$. If also $A|\phi\rangle = \mu|\phi\rangle$ then

$$\mu \langle\psi|\phi\rangle = \langle\psi|A|\phi\rangle = \langle A\psi|\phi\rangle = \lambda^* \langle\psi|\phi\rangle = \lambda \langle\psi|\phi\rangle,$$

so $(\lambda - \mu) \langle\psi|\phi\rangle = 0$, and $\lambda \neq \mu$ forces $\langle\psi|\phi\rangle = 0$. $\square$

We shall assume throughout, as physicists do, that the observables we meet have a complete set of eigenvectors – that is, that $\mathcal{H}$ has an orthonormal basis of eigenvectors of A . In finite dimensions this is the spectral theorem of IB Linear Algebra. In infinite dimensions it is true for a large and well-behaved class of operators, but genuinely fails for

others; the correct general statement is the spectral theorem for unbounded self-adjoint operators, which belongs to a different course. We shall also cheerfully use ‘eigenstates’ like $|x\rangle$ and $|p\rangle$ which are not in $\mathcal{H}$ at all (§37.1.8).

Axiom 37.1.9 (Measurement)

Let A be an observable with eigenvalues $\{\lambda_n\}$ (distinct) and let P_n be the orthogonal projector onto the eigenspace $\mathcal{H}_n = \{|\psi\rangle : A|\psi\rangle = \lambda_n|\psi\rangle\}$. Then a measurement of A in the normalised state $|\psi\rangle$

- (i) returns one of the eigenvalues λ_n ;
- (ii) returns λ_n with probability $\mathbb{P}(\lambda_n) = \|P_n|\psi\rangle\|^2 = \langle\psi|P_n|\psi\rangle$;
- (iii) leaves the system, immediately afterwards, in the state $P_n|\psi\rangle / \|P_n|\psi\rangle\|$.

This is the IB measurement postulate, restated so that degeneracy is handled without extra clauses. If the eigenvalue λ_n is non-degenerate with normalised eigenvector $|n\rangle$, then $P_n = |n\rangle\langle n|$ and the rules reduce to the familiar $\mathbb{P}(\lambda_n) = |\langle n|\psi\rangle|^2$ with collapse to $|n\rangle$. The probabilities sum to one because $\sum_n P_n = I$:

$$\sum_n \mathbb{P}(\lambda_n) = \langle\psi|\sum_n P_n|\psi\rangle = \langle\psi|\psi\rangle = 1.$$

Notice also that multiplying $|\psi\rangle$ by an overall phase changes nothing in (ii) or (iii), as it must.

Definition 37.1.10 (Expectation and Uncertainty)

For a normalised state $|\psi\rangle$ and observable A , the **expectation value** is

$$\langle A \rangle_\psi = \langle\psi|A|\psi\rangle,$$

and the **uncertainty** $(\Delta A)_\psi$ is the standard deviation,

$$(\Delta A)_\psi^2 = \langle (A - \langle A \rangle_\psi)^2 \rangle_\psi = \langle A^2 \rangle_\psi - \langle A \rangle_\psi^2.$$

That $\langle A \rangle_\psi$ is genuinely the mean of the measurement distribution is a one-line check: $\sum_n \lambda_n \langle\psi|P_n|\psi\rangle = \langle\psi|\sum_n \lambda_n P_n|\psi\rangle = \langle\psi|A|\psi\rangle$, using the spectral decomposition we prove next. Note that $(\Delta A)_\psi = 0$ if and only if $|\psi\rangle$ is an eigenstate of A : the uncertainty measures how far the state is from having a definite value of A .

§37.1.5 The Spectral Decomposition

Collecting the projectors of the measurement axiom gives the structural statement that we will use constantly.

Theorem 37.1.11 (Spectral Decomposition)

Let A be an observable with distinct eigenvalues $\{\lambda_n\}$ and eigenprojectors $\{P_n\}$. Then

$$P_n P_m = \delta_{nm} P_n, \quad \sum_n P_n = I, \quad A = \sum_n \lambda_n P_n.$$

Equivalently, in terms of an orthonormal eigenbasis $\{|n\rangle\}$ with $A|n\rangle = \lambda_n|n\rangle$ (repeats allowed),

$$A = \sum_n \lambda_n |n\rangle \langle n|.$$

Proof. Eigenspaces for distinct eigenvalues are orthogonal, giving $P_n P_m = 0$ for $n \neq m$, and $P_n^2 = P_n$ since P_n is a projector. Completeness of the eigenvectors is exactly $\sum_n P_n = I$. Finally, for any $|\psi\rangle$,

$$A|\psi\rangle = A \sum_n P_n |\psi\rangle = \sum_n \lambda_n P_n |\psi\rangle,$$

since $P_n |\psi\rangle$ lies in the λ_n -eigenspace. $\square$

This is more than a restatement of diagonalisability: it lets us *define functions of operators*. Given any function $f: \mathbb{R} \rightarrow \mathbb{C}$, set

$$f(A) = \sum_n f(\lambda_n) P_n.$$

When f is a polynomial this agrees with the obvious definition (check it on $f(\lambda) = \lambda^2$, using $P_n P_m = \delta_{nm} P_n$), and it extends the notion to functions where no power series is available. The most important instances are e^{iA} , which is unitary when A is Hermitian, and A^{-1} , which exists precisely when 0 is not an eigenvalue.

Example 37.1.12 (A Two-State System)

Take $\mathcal{H} = \mathbb{C}^2$ with basis $|\uparrow\rangle, |\downarrow\rangle$, and the observable

$$S_z = \frac{\hbar}{2} (|\uparrow\rangle \langle \uparrow| - |\downarrow\rangle \langle \downarrow|) = \frac{\hbar}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

already written in spectral form: eigenvalues $\pm\hbar/2$ with projectors $|\uparrow\rangle \langle \uparrow|$ and $|\downarrow\rangle \langle \downarrow|$. In the state $|\psi\rangle = \alpha|\uparrow\rangle + \beta|\downarrow\rangle$ (with $|\alpha|^2 + |\beta|^2 = 1$) a measurement gives $+\hbar/2$ with probability $|\alpha|^2$ and $-\hbar/2$ with probability $|\beta|^2$, so

$$\langle S_z \rangle = \frac{\hbar}{2} (|\alpha|^2 - |\beta|^2), \quad \langle S_z^2 \rangle = \frac{\hbar^2}{4},$$

the latter because $S_z^2 = \frac{\hbar^2}{4} I$ – every state is an eigenstate of S_z^2 . Hence

$$(\Delta S_z)^2 = \frac{\hbar^2}{4} (1 - (|\alpha|^2 - |\beta|^2)^2) = \hbar^2 |\alpha|^2 |\beta|^2,$$

which vanishes exactly when α or β is zero, and is maximal for the equal superpositions $|\alpha| = |\beta| = 1/\sqrt{2}$. Also $e^{i\theta S_z/\hbar} = e^{i\theta/2} |\uparrow\rangle \langle \uparrow| + e^{-i\theta/2} |\downarrow\rangle \langle \downarrow|$, which is our first glimpse of the peculiar fact that a spin- $\frac{1}{2}$ state returns to itself only after a 4π rotation.

§37.1.6 Compatible Observables and Complete Sets

Two observables can be measured simultaneously exactly when they commute. This was proved in IB; we restate it here because the language of *complete sets of commuting*

observables organises everything that follows.

Definition 37.1.13 (Commutator)

The **commutator** of A and B is $[A, B] = AB - BA$.

The commutator is bilinear and antisymmetric, satisfies the Leibniz rules

$$[A, BC] = [A, B]C + B[A, C], \quad [AB, C] = A[B, C] + [A, C]B,$$

and the Jacobi identity $[A, [B, C]] + [B, [C, A]] + [C, [A, B]] = 0$. If A, B are Hermitian then $[A, B]$ is *anti*-Hermitian, so $i[A, B]$ is Hermitian – a fact we use immediately below.

Theorem 37.1.14 (Compatibility)

Two observables A, B admit a complete orthonormal basis of joint eigenvectors if and only if $[A, B] = 0$.

Proof. ($\Rightarrow$) On a joint eigenvector $|i\rangle$ with $A|i\rangle = \lambda_i|i\rangle$, $B|i\rangle = \mu_i|i\rangle$, we have $[A, B]|i\rangle = (\lambda_i\mu_i - \mu_i\lambda_i)|i\rangle = 0$; by completeness $[A, B] = 0$.

($\Leftarrow$) Let $\mathcal{H}_\lambda$ be an eigenspace of A . For $|\psi\rangle \in \mathcal{H}_\lambda$ we have $A(B|\psi\rangle) = B(A|\psi\rangle) = \lambda B|\psi\rangle$, so B maps $\mathcal{H}_\lambda$ to itself. The restriction $B|_{\mathcal{H}_\lambda}$ is Hermitian, hence diagonalisable within $\mathcal{H}_\lambda$; choosing such a basis for each λ and taking the union gives a complete joint eigenbasis. $\square$

Observables with $[A, B] = 0$ are called **compatible**. The proof shows exactly what commuting buys us: B acts *within* each eigenspace of A , so measuring B does not disturb the value of A .

Definition 37.1.15 (Complete Set of Commuting Observables)

A set $\{A_1, \dots, A_k\}$ of pairwise commuting observables is a **complete set of commuting observables** (CSCO) if their joint eigenspaces are all one-dimensional; equivalently, if the list of eigenvalues $(\lambda_1, \dots, \lambda_k)$ determines the state uniquely up to phase.

A CSCO gives an unambiguous labelling $|\lambda_1, \dots, \lambda_k\rangle$ of a basis of $\mathcal{H}$, and the eigenvalues are the **quantum numbers** of the state. This is where the familiar labels come from: for the hydrogen atom $\{H, L^2, L_z\}$ gives $|n, \ell, m\rangle$, and adding spin gives the four quantum numbers behind the periodic table. Conversely, a degeneracy is precisely a failure of some set to be complete, and – as we shall see in §37.6 – degeneracies are almost always caused by a symmetry.

§37.1.7 The Uncertainty Principle

If two operators do not commute, we cannot expect to measure both exactly. This is quantified in an *uncertainty principle*. Let A, B be Hermitian. Then taking $C = A + i\lambda B$ with $\lambda \in \mathbb{R}$,

$$C^\dagger C = A^2 + \lambda^2 B^2 + \lambda i[A, B].$$

The first three are Hermitian, so $i[A, B]$ is also Hermitian. We have

$$\begin{aligned} 0 &\leq \langle C\psi | C\psi \rangle = \langle \psi | C^\dagger C | \psi \rangle \\ &= \langle A^2 \rangle_\psi + \lambda^2 \langle B^2 \rangle_\psi + \lambda \langle i[A, B] \rangle_\psi. \end{aligned}$$

For this to always be nonnegative, the quadratic in λ can have at most one real root, so the discriminant gives

$$\langle A^2 \rangle_\psi \langle B^2 \rangle_\psi \geq \frac{1}{4} (\langle i[A, B] \rangle_\psi)^2.$$

This works for any A, B , so if we apply it to $\tilde{A} = A - \langle A \rangle_\psi$ and $\tilde{B} = B - \langle B \rangle_\psi$, we find $[\tilde{A}, \tilde{B}] = [A, B]$ and hence the following.

Theorem 37.1.16 (Generalised Uncertainty Principle)

For any Hermitian A, B and any normalised state $|\psi\rangle$,

$$(\Delta A)_\psi (\Delta B)_\psi \geq \frac{1}{2} |\langle [A, B] \rangle_\psi|.$$

Most famous is Heisenberg's uncertainty principle, from applying this to the canonical commutation relation $[x, p] = i\hbar$:

$$(\Delta x)(\Delta p) \geq \frac{1}{2}\hbar.$$

It is worth being precise about what this does and does not say. It is *not* a statement that measurement is clumsy, or that our apparatus is imperfect. It says that no state exists in which both spreads are small: prepare a million identical copies, measure x on half of them and p on the other half, and the two sample standard deviations obey the inequality. The bound is also *state-dependent* in general – for spin, $[S_x, S_y] = i\hbar S_z$ gives $\Delta S_x \Delta S_y \geq \frac{\hbar}{2} |\langle S_z \rangle|$, whose right-hand side vanishes for states with $\langle S_z \rangle = 0$.

Tracing through the proof tells us when equality holds: we need $\langle C\psi | C\psi \rangle = 0$ for the optimal λ , that is

$$(\tilde{A} + i\lambda\tilde{B})|\psi\rangle = 0$$

for some real λ . States achieving equality are called **minimum uncertainty states**; for x and p we will find in §37.1.9 that they are exactly the Gaussian wavepackets.

§37.1.8 Position and Momentum Representations

We now recover the wavefunction. The subtlety is that the position operator x (in one dimension, for simplicity) has a *continuous* spectrum, and its ‘eigenstates’ are not normalisable – they do not live in $\mathcal{H}$. Physicists handle this by treating them as a limiting case of an orthonormal basis, replacing sums by integrals and Kronecker deltas by Dirac deltas. Every formula below can be justified rigorously, but doing so properly requires the theory of rigged Hilbert spaces, which we shall not need.

So we postulate a family of states $|x\rangle$, $x \in \mathbb{R}$, with

$$x|x\rangle = x|x\rangle, \quad \langle x|x'\rangle = \delta(x-x'), \quad \int_{-\infty}^{\infty} |x\rangle \langle x| dx = I,$$

the last being the continuum completeness relation. Applying it to a state $|\psi\rangle$,

$$|\psi\rangle = \int |x\rangle \langle x|\psi\rangle dx,$$

so $|\psi\rangle$ is determined by the function

$$\psi(x) := \langle x|\psi\rangle,$$

which is precisely the **wavefunction** of IB. It is the component of the abstract state $|\psi\rangle$ along the ‘basis vector’ $|x\rangle$, exactly as $a_n = \langle n|\psi\rangle$ was in the discrete case. Inner products become the familiar integrals,

$$\langle \phi|\psi\rangle = \int \langle \phi|x\rangle \langle x|\psi\rangle dx = \int \phi(x)^* \psi(x) dx,$$

and $|\psi(x)|^2 dx$ is the probability of finding the particle in $[x, x+dx]$ – the Born rule, now a special case of the measurement axiom.

How do operators act? Position is immediate: $\langle x|X|\psi\rangle = x\psi(x)$, writing X for the operator to distinguish it from the number. For momentum, we *define* the momentum operator by its action in this representation,

$$\langle x|P|\psi\rangle = -i\hbar \frac{d\psi}{dx}(x),$$

and then the canonical commutation relation follows in one line, acting on an arbitrary ψ :

$$[X, P]\psi = x(-i\hbar\psi') - (-i\hbar)(x\psi)' = i\hbar\psi, \quad \text{so} \quad [X, P] = i\hbar.$$

(In three dimensions, $[X_i, P_j] = i\hbar\delta_{ij}$ and $[X_i, X_j] = [P_i, P_j] = 0$.)

There is nothing special about position. The eigenstates $|p\rangle$ of P give an equally good basis, and we can find their wavefunctions immediately: $\langle x|p\rangle$ must satisfy $-i\hbar\partial_x \langle x|p\rangle = p \langle x|p\rangle$, so $\langle x|p\rangle \propto e^{ipx/\hbar}$. Fixing the constant by demanding $\langle p|p'\rangle = \delta(p-p')$ and using $\int e^{i(p-p')x/\hbar} dx = 2\pi\hbar \delta(p-p')$, we get

$$\langle x|p\rangle = \frac{1}{\sqrt{2\pi\hbar}} e^{ipx/\hbar}, \quad \int |p\rangle \langle p| dp = I.$$

The **momentum-space wavefunction** is $\tilde{\psi}(p) = \langle p|\psi\rangle$, and inserting the position completeness relation relates the two:

$$\tilde{\psi}(p) = \int \langle p|x\rangle \langle x|\psi\rangle dx = \frac{1}{\sqrt{2\pi\hbar}} \int \psi(x) e^{-ipx/\hbar} dx.$$

This is the Fourier transform, and it is worth appreciating what has just happened: the deep-looking fact that position and momentum wavefunctions are Fourier transforms of each other is nothing but a change of basis, of exactly the same nature as rotating coordinate axes in $\mathbb{R}^3$. In the momentum representation the roles are swapped,

$$\langle p|P|\psi\rangle = p\tilde{\psi}(p), \quad \langle p|X|\psi\rangle = i\hbar \frac{d\tilde{\psi}}{dp}(p),$$

(the sign change coming from the conjugate in $\langle p|x\rangle$), and the theory is perfectly symmetric between the two.

Remark. This is the real payoff of the abstract formalism. In IB the wavefunction *was* the state, and momentum space felt like a trick. Here neither representation is preferred: $|\psi\rangle$ is the state, and $\psi(x)$, $\tilde{\psi}(p)$, or the coefficients in any other basis are just different ways of writing down the same thing. For systems like spin, no position representation exists at all, and we simply use a different basis.

§37.1.9 Wavepackets

Let us see the uncertainty principle in action, and identify the states that saturate it. Take the **Gaussian wavepacket**

$$\psi(x) = \left(\frac{1}{\pi\sigma^2}\right)^{1/4} \exp\left(-\frac{x^2}{2\sigma^2} + \frac{ip_0x}{\hbar}\right),$$

normalised so that $\int |\psi|^2 = 1$. Since $|\psi(x)|^2$ is an even Gaussian of variance $\sigma^2/2$, we read off

$$\langle X \rangle = 0, \quad (\Delta X)^2 = \frac{\sigma^2}{2}.$$

Its Fourier transform is another Gaussian (completing the square in the exponent),

$$\tilde{\psi}(p) = \left(\frac{\sigma^2}{\pi\hbar^2}\right)^{1/4} \exp\left(-\frac{\sigma^2(p-p_0)^2}{2\hbar^2}\right),$$

so $\langle P \rangle = p_0$ and $(\Delta P)^2 = \hbar^2/2\sigma^2$. Multiplying,

$$\Delta X \Delta P = \frac{\sigma}{\sqrt{2}} \cdot \frac{\hbar}{\sqrt{2}\sigma} = \frac{\hbar}{2},$$

exactly the minimum. Indeed the equality condition of the previous section, $(X - \langle X \rangle + i\lambda(P - \langle P \rangle))|\psi\rangle = 0$, becomes the first-order ODE $x\psi + i\lambda(-i\hbar\psi' - p_0\psi) = 0$, whose solutions are precisely the Gaussians above with $\sigma^2 = \lambda\hbar$.

Squeezing the packet in position necessarily broadens it in momentum, and vice versa – which, given that the two are Fourier transforms of each other, is a theorem about Fourier analysis quite as much as about physics. In the limits $\sigma \rightarrow 0$ and $\sigma \rightarrow \infty$ we approach the (non-normalisable) states $|x\rangle$ and $|p\rangle$ respectively, with one uncertainty going to zero and the other diverging.

§37.2 Time Evolution

So far the formalism is entirely kinematic: it describes states at one instant. We now add dynamics, and in doing so we will meet a theme that runs through the rest of the course – that a continuous symmetry is implemented by a family of unitary operators, and is ‘generated’ by a Hermitian observable.

§37.2.1 The Evolution Operator

Axiom 37.2.1 (Time Evolution)

The state of an isolated system evolves according to the **Schrödinger equation**

$$i\hbar \frac{d}{dt} |\psi(t)\rangle = H |\psi(t)\rangle,$$

where the Hamiltonian H is the observable corresponding to the energy of the system.

Since the equation is first order in t and linear, the state at time t is determined by the state at time 0 by a linear operator:

$$|\psi(t)\rangle = U(t) |\psi(0)\rangle.$$

$U(t)$ is the **time evolution operator**. Substituting into the Schrödinger equation, and demanding it hold for all initial states, gives the operator equation

$$i\hbar \frac{dU}{dt} = HU(t), \quad U(0) = I,$$

which for a time-independent H has the solution

$$U(t) = \exp\left(-\frac{iHt}{\hbar}\right),$$

where the exponential is defined by the spectral decomposition (or, equivalently here, by its power series). The key property is the following.

Proposition 37.2.2

$U(t)$ is unitary, and $U(s)U(t) = U(s+t)$, $U(t)^{-1} = U(-t)$.

Proof. The group property is immediate from the exponential form (the exponents commute). For unitarity, note that $H^\dagger = H$ gives $U(t)^\dagger = \exp(+iHt/\hbar) = U(-t)$, so $U(t)^\dagger U(t) = U(0) = I$. Alternatively, and more instructively, one can prove it without solving anything: for any $|\psi(t)\rangle$ obeying the Schrödinger equation,

$$\frac{d}{dt} \langle \psi | \psi \rangle = \langle \dot{\psi} | \psi \rangle + \langle \psi | \dot{\psi} \rangle = \frac{i}{\hbar} \langle \psi | H^\dagger | \psi \rangle - \frac{i}{\hbar} \langle \psi | H | \psi \rangle = 0$$

exactly because H is Hermitian. So the norm – total probability – is conserved. $\square$

This is the first instance of a pattern we will see repeatedly. A one-parameter family of unitaries $U(t) = e^{-iHt/\hbar}$ with $U(0) = I$ is determined by its derivative at the identity,

$$H = i\hbar \left. \frac{dU}{dt} \right|_{t=0},$$

and this derivative is Hermitian precisely because the $U(t)$ are unitary. We say H **generates** time translations. In §37.6 momentum will generate spatial translations and angular momentum will generate rotations, by exactly the same argument.

Solving the dynamics is now a matter of diagonalising H . If $H|n\rangle = E_n|n\rangle$ with $\{|n\rangle\}$ an orthonormal basis, then expanding $|\psi(0)\rangle = \sum_n a_n |n\rangle$,

$$|\psi(t)\rangle = \sum_n a_n e^{-iE_n t/\hbar} |n\rangle, \quad a_n = \langle n | \psi(0) \rangle.$$

Time evolution simply attaches a phase to each energy eigenstate. In particular a state which starts as an energy eigenstate stays one, acquiring only an overall phase – these are the **stationary states**, physically unchanging.

Remark (Time-Dependent Hamiltonians). If $H = H(t)$, the formula

$$U(t) = \exp\left(-\frac{i}{\hbar} \int_0^t H(t') dt'\right)$$

is *wrong* in general, because $H(t_1)$ and $H(t_2)$ need not commute. The correct expression is a time-ordered exponential, obtained by iterating the integral equation $U(t) = I - \frac{i}{\hbar} \int_0^t H(t') U(t') dt'$. We will construct the first two terms of this series when we do time-dependent perturbation theory in §37.9. Unitarity of $U(t)$, however, holds regardless, by the norm-conservation argument above.

§37.2.2 The Heisenberg Picture

There is a redundancy in the formalism: all physical predictions are matrix elements $\langle \phi(t) | A | \psi(t) \rangle$, and we can move the time dependence between the states and the operators at will. Writing the evolution out,

$$\langle \phi(t) | A | \psi(t) \rangle = \langle \phi(0) | U(t)^\dagger A U(t) | \psi(0) \rangle,$$

we may either regard the states as evolving with A fixed – the **Schrödinger picture**, which is what we have been doing – or regard the states as fixed and the operators as evolving.

Definition 37.2.3 (Heisenberg Picture)

In the **Heisenberg picture** the states are the fixed vectors $|\psi\rangle_H = |\psi(0)\rangle$, and observables carry the time dependence:

$$A_H(t) = U(t)^\dagger A U(t).$$

By construction the two pictures agree on every matrix element, hence on every physical prediction, and they agree at $t = 0$. Note that $A_H(t)$ is Hermitian if A is, that the transformation preserves all algebraic relations,

$$(AB)_H = U^\dagger AB U = U^\dagger A U U^\dagger B U = A_H B_H, \quad [A, B]_H = [A_H, B_H],$$

and that $H_H = H$ when H is time-independent (it commutes with U). Differentiating the definition gives the dynamical law.

Theorem 37.2.4 (Heisenberg's Equation of Motion)

For a time-independent Hamiltonian and a Schrödinger-picture operator A which may itself depend explicitly on t ,

$$\frac{dA_H}{dt} = \frac{i}{\hbar} [H, A_H] + \left(\frac{\partial A}{\partial t} \right)_H.$$

Proof. Using $dU/dt = -\frac{i}{\hbar}HU$ and $dU^\dagger/dt = \frac{i}{\hbar}U^\dagger H$,

$$\frac{d}{dt}(U^\dagger AU) = \frac{i}{\hbar}U^\dagger HAU - \frac{i}{\hbar}U^\dagger AHU + U^\dagger \frac{\partial A}{\partial t}U = \frac{i}{\hbar}U^\dagger [H, A]U + \left(\frac{\partial A}{\partial t}\right)_H,$$

and $U^\dagger [H, A]U = [H_H, A_H] = [H, A_H]$. $\square$

This is a beautiful result, because it is *formally identical to Hamilton's equations of classical mechanics*, with the Poisson bracket replaced by $\frac{1}{i\hbar}$ times the commutator:

$$\frac{df}{dt} = \{f, H\}_{\text{PB}} + \frac{\partial f}{\partial t} \quad \rightsquigarrow \quad \frac{dA_H}{dt} = \frac{1}{i\hbar}[A_H, H] + \left(\frac{\partial A}{\partial t}\right)_H.$$

Taking expectation values in any fixed state recovers, in the Schrödinger picture, **Ehrenfest's theorem**:

$$\frac{d}{dt}\langle A \rangle_{\psi(t)} = \frac{i}{\hbar}\langle [H, A] \rangle_{\psi(t)} + \left\langle \frac{\partial A}{\partial t} \right\rangle_{\psi(t)}.$$

Corollary 37.2.5 (Conserved Quantities)

If A has no explicit time dependence and $[A, H] = 0$, then A_H is constant, and $\langle A \rangle$ and indeed the whole probability distribution of A are constant in time.

The last claim follows because the eigenprojectors of A also commute with H , so $\langle \psi(t) | P_n | \psi(t) \rangle = \langle \psi(0) | U^\dagger P_n U | \psi(0) \rangle = \langle \psi(0) | P_n | \psi(0) \rangle$. Conservation laws in quantum mechanics are therefore exactly statements that observables commute with the Hamiltonian – and, since the eigenvalues of H label energies, they are also statements that the observable can be simultaneously diagonalised with the energy. This is the tight link between symmetry, conservation and degeneracy that §37.6 makes systematic.

Example 37.2.6 (The Free Particle)

For $H = P^2/2m$ we have $[H, P] = 0$, so $P_H(t) = P$: momentum is conserved, as classically. For position, $[H, X] = \frac{1}{2m}[P^2, X] = \frac{1}{2m}(P[P, X] + [P, X]P) = -\frac{i\hbar}{m}P$, so

$$\frac{dX_H}{dt} = \frac{i}{\hbar}\left(-\frac{i\hbar P}{m}\right) = \frac{P}{m}, \quad \text{hence} \quad X_H(t) = X + \frac{Pt}{m}.$$

This is exactly the classical solution, now as an operator identity. It has genuine content: for instance

$$[X_H(t), X_H(0)] = \frac{t}{m}[P, X] = -\frac{i\hbar t}{m},$$

so positions at different times are *incompatible* observables, and we recover the spreading of a free wavepacket,

$$(\Delta X)_t^2 = \langle X_H(t)^2 \rangle - \langle X_H(t) \rangle^2 = (\Delta X)_0^2 + \frac{t}{m} \langle XP + PX \rangle_c + \frac{t^2}{m^2} (\Delta P)^2,$$

where the middle term is the connected correlator $\langle XP + PX \rangle - 2\langle X \rangle \langle P \rangle$. For large t the packet spreads linearly with rate $\Delta P/m$, which is just the classical statement that a spread of velocities produces a spread of positions.

Remark (Time-Energy Uncertainty). There is no time operator in quantum mechanics – t is a parameter, not an observable – so ‘ $\Delta E \Delta t \geq \hbar/2$ ’ cannot be an instance of the generalised uncertainty principle. It can, however, be given a precise meaning. For any observable A with no explicit time dependence, Ehrenfest plus the uncertainty relation give

$$\Delta E \Delta A \geq \frac{1}{2} |\langle [H, A] \rangle| = \frac{\hbar}{2} \left| \frac{d \langle A \rangle}{dt} \right|,$$

so defining $\tau_A = \Delta A / |d \langle A \rangle / dt|$ – the time needed for $\langle A \rangle$ to shift by one standard deviation, i.e. the timescale on which the change is detectable – we get $\Delta E \tau_A \geq \hbar/2$. A state of sharp energy is stationary and nothing ever happens in it; things can only change on a timescale set by the energy spread.

§37.3 The Harmonic Oscillator

Every quantum system that oscillates is, near equilibrium, a harmonic oscillator, and in IB we solved it by grinding through Hermite’s equation. We now solve it again in three-quarters of a page, using nothing but the commutator $[X, P] = i\hbar$. This is not merely a labour-saving trick: the method – find operators that step between eigenstates, then bound the spectrum below – is exactly the method we will use for angular momentum, and the operators we build are the foundation of quantum field theory.

§37.3.1 Creation and Annihilation Operators

The Hamiltonian is

$$H = \frac{P^2}{2m} + \frac{1}{2} m \omega^2 X^2.$$

If X and P were numbers we would factorise this as a product of $(\cdot + i\cdot)$ and $(\cdot - i\cdot)$. They are not, but let us try anyway.

Definition 37.3.1 (Annihilation and Creation Operators)

Set

$$a = \sqrt{\frac{m\omega}{2\hbar}} \left(X + \frac{iP}{m\omega} \right), \quad a^\dagger = \sqrt{\frac{m\omega}{2\hbar}} \left(X - \frac{iP}{m\omega} \right),$$

the **annihilation** and **creation** operators. (The normalisation is chosen to make them dimensionless.)

These are adjoints of one another, as the notation says, since X and P are Hermitian; they are not themselves Hermitian, and are the first non-Hermitian operators we have found a use for. Inverting,

$$X = \sqrt{\frac{\hbar}{2m\omega}} (a + a^\dagger), \quad P = -i\sqrt{\frac{m\hbar\omega}{2}} (a - a^\dagger),$$

which we will use constantly – almost every harmonic-oscillator computation in the rest of the course is done by substituting these and reading off the answer.

The single fact we need is:

$$[a, a^\dagger] = \frac{m\omega}{2\hbar} \left(\left[X + \frac{iP}{m\omega}, X - \frac{iP}{m\omega} \right] \right) = \frac{m\omega}{2\hbar} \cdot \frac{-2i}{m\omega} [X, P] = \frac{m\omega}{2\hbar} \cdot \frac{-2i}{m\omega} \cdot i\hbar = 1.$$

Now compute the product:

$$a^\dagger a = \frac{m\omega}{2\hbar} \left(X^2 + \frac{P^2}{m^2\omega^2} + \frac{i}{m\omega} [X, P] \right) = \frac{H}{\hbar\omega} - \frac{1}{2}.$$

Definition 37.3.2 (Number Operator)

$N = a^\dagger a$, so that $H = \hbar\omega (N + \frac{1}{2})$.

N is Hermitian, and finding the spectrum of H is now the same as finding the spectrum of N . The Leibniz rule and $[a, a^\dagger] = 1$ give the two commutators that do all the work:

$$[N, a] = [a^\dagger a, a] = [a^\dagger, a]a = -a, \quad [N, a^\dagger] = a^\dagger[a, a^\dagger] = a^\dagger.$$

§37.3.2 The Spectrum

Theorem 37.3.3 (Spectrum of the Harmonic Oscillator)

The eigenvalues of N are exactly $n = 0, 1, 2, \dots$, each non-degenerate, so

$$E_n = \left(n + \frac{1}{2}\right) \hbar\omega, \quad n \in \mathbb{Z}_{\geq 0}.$$

Writing $|n\rangle$ for the normalised eigenstate of N with eigenvalue n ,

$$a|n\rangle = \sqrt{n}|n-1\rangle, \quad a^\dagger|n\rangle = \sqrt{n+1}|n+1\rangle, \quad |n\rangle = \frac{(a^\dagger)^n}{\sqrt{n!}}|0\rangle.$$

Proof. Suppose $N|\nu\rangle = \nu|\nu\rangle$ with $|\nu\rangle$ normalised. First,

$$\nu = \langle \nu | a^\dagger a | \nu \rangle = \|a|\nu\rangle\|^2 \geq 0,$$

so all eigenvalues are non-negative, with $\nu = 0$ if and only if $a|\nu\rangle = 0$. Next, using $[N, a] = -a$,

$$N(a|\nu\rangle) = (aN - a)|\nu\rangle = (\nu - 1)a|\nu\rangle,$$

so $a|\nu\rangle$ is either zero or an eigenvector with eigenvalue $\nu - 1$; similarly $N(a^\dagger|\nu\rangle) = (\nu + 1)a^\dagger|\nu\rangle$, with $\|a^\dagger|\nu\rangle\|^2 = \langle \nu | aa^\dagger | \nu \rangle = \nu + 1 > 0$, so $a^\dagger|\nu\rangle$ is never zero.

Now suppose ν is not a non-negative integer. Then applying a repeatedly produces eigenvectors with eigenvalues $\nu - 1, \nu - 2, \dots$, and none of them can ever be zero (a vector is zero only if its eigenvalue was 0, which never occurs in this sequence). But eventually the eigenvalues become negative, contradicting $\nu \geq 0$. Hence $\nu = n \in \mathbb{Z}_{\geq 0}$, and the descending sequence terminates cleanly at $|0\rangle$ with $a|0\rangle = 0$.

Conversely such states exist: $|0\rangle$ exists (we exhibit it in the next subsection), and $(a^\dagger)^n|0\rangle$ is a non-zero eigenvector with eigenvalue n . The normalisations follow from $\|a|n\rangle\|^2 = n$ and $\|a^\dagger|n\rangle\|^2 = n + 1$, choosing phases so that both constants are positive; iterating $a^\dagger|n\rangle = \sqrt{n+1}|n+1\rangle$ gives $|n\rangle = (a^\dagger)^n|0\rangle / \sqrt{n!}$.

Finally, non-degeneracy. In the position representation $a|0\rangle = 0$ reads

$$\left(x + \frac{\hbar}{m\omega} \frac{d}{dx}\right) \psi_0(x) = 0,$$

a first-order linear ODE with a one-dimensional solution space. So the ground state is unique, and since every $|n\rangle$ is obtained from it by $(a^\dagger)^n$ – and conversely any eigenvector of eigenvalue n is mapped by a^n into the $\nu = 0$ eigenspace – every level is non-degenerate. $\square$

So the spectrum is an evenly spaced ladder, with $a^\dagger$ climbing it and a descending it. It is worth drawing.

The operators are named for what the picture shows: $a^\dagger$ creates a quantum of energy $\hbar\omega$ and a annihilates one. The state $|n\rangle$ is naturally thought of not as ‘the n th excited state of one oscillator’ but as ‘ n identical quanta’, with N counting them and $|0\rangle$ the **vacuum**. Applied to the modes of the electromagnetic field, those quanta are photons; this reinterpretation is the beginning of quantum field theory, and it is why this small piece of algebra is so important.

§37.3.3 Wavefunctions and Matrix Elements

We can now recover the IB results with no differential equations beyond the first-order one above. Solving $\psi'_0 = -(m\omega/\hbar)x\psi_0$ and normalising,

$$\psi_0(x) = \langle x|0\rangle = \left(\frac{m\omega}{\pi\hbar}\right)^{1/4} \exp\left(-\frac{m\omega x^2}{2\hbar}\right),$$

a Gaussian – and, by §37.1.9, a minimum uncertainty state. The excited states follow by applying

$$a^\dagger = \sqrt{\frac{m\omega}{2\hbar}} \left(x - \frac{\hbar}{m\omega} \frac{d}{dx}\right)$$

repeatedly, which manufactures a Hermite polynomial times the Gaussian at each step; for instance

$$\psi_1(x) \propto \left(x - \frac{\hbar}{m\omega} \frac{d}{dx}\right) e^{-m\omega x^2/2\hbar} = 2x e^{-m\omega x^2/2\hbar},$$

matching $H_1(\xi) = 2\xi$. Orthonormality of the $|n\rangle$ is automatic (eigenvectors of a Hermitian operator with distinct eigenvalues), which saves proving any Hermite polynomial identities at all.

More useful in practice are matrix elements. From $X = \sqrt{\hbar/2m\omega}(a + a^\dagger)$,

$$\langle m|X|n\rangle = \sqrt{\frac{\hbar}{2m\omega}} \left(\sqrt{n} \delta_{m,n-1} + \sqrt{n+1} \delta_{m,n+1} \right),$$

so X connects only neighbouring levels – a selection rule which we will use in perturbation theory. Similarly

$$\langle m|P|n\rangle = i\sqrt{\frac{m\hbar\omega}{2}} \left(\sqrt{n+1} \delta_{m,n+1} - \sqrt{n} \delta_{m,n-1} \right).$$

Example 37.3.4 (Uncertainties in the Level $|n\rangle$)

Since $\langle n|X|n\rangle = \langle n|P|n\rangle = 0$, we need only the squares. Expanding,

$$X^2 = \frac{\hbar}{2m\omega} \left(a^2 + (a^\dagger)^2 + aa^\dagger + a^\dagger a \right),$$

and $\langle n|a^2|n\rangle = \langle n|(a^\dagger)^2|n\rangle = 0$ (they change the level by two), while $a^\dagger a = N$ and $aa^\dagger = N + 1$. Hence

$$\langle X^2 \rangle_n = \frac{\hbar}{2m\omega} (2n + 1) = \frac{\hbar}{m\omega} \left(n + \frac{1}{2} \right),$$

and identically $\langle P^2 \rangle_n = m\hbar\omega \left(n + \frac{1}{2} \right)$. Therefore

$$\Delta X \Delta P = \left(n + \frac{1}{2} \right) \hbar,$$

saturating the uncertainty bound only in the ground state, as expected. Note also that $\langle P^2/2m \rangle_n = \langle \frac{1}{2}m\omega^2 X^2 \rangle_n = \frac{1}{2}E_n$: kinetic and potential energy contribute equally, which is the quantum virial theorem for a quadratic potential.

Example 37.3.5 (The Oscillator in the Heisenberg Picture)

The Heisenberg equation for a is especially clean. Since $[H, a] = \hbar\omega[N, a] = -\hbar\omega a$,

$$\frac{da_H}{dt} = \frac{i}{\hbar}[H, a_H] = -i\omega a_H \quad \implies \quad a_H(t) = a e^{-i\omega t},$$

and taking adjoints $a_H^\dagger(t) = a^\dagger e^{i\omega t}$. Substituting into $X = \sqrt{\hbar/2m\omega}(a + a^\dagger)$ gives

$$X_H(t) = X \cos \omega t + \frac{P}{m\omega} \sin \omega t, \quad P_H(t) = P \cos \omega t - m\omega X \sin \omega t,$$

which is precisely the classical solution, holding now as an operator identity. This is Ehrenfest's theorem in its most satisfying form: for a quadratic Hamiltonian the expectation values follow the classical trajectory *exactly*, for every state.

Remark (Coherent States). Since a is not Hermitian its eigenvalues need not be real, and in fact a has an eigenstate for *every* complex number α :

$$|\alpha\rangle = e^{-|\alpha|^2/2} \sum_{n \geq 0} \frac{\alpha^n}{\sqrt{n!}} |n\rangle, \quad a |\alpha\rangle = \alpha |\alpha\rangle,$$

as one checks by applying a term by term. These **coherent states** are minimum-uncertainty Gaussians displaced from the origin, and under time evolution $|\alpha\rangle \mapsto |\alpha e^{-i\omega t}\rangle$ – a wavepacket that oscillates back and forth without ever spreading, tracing out the classical motion. They are the closest thing quantum mechanics has to a classical oscillator, and are the states produced by a laser.

Example 37.3.6 (The Three-Dimensional Isotropic Oscillator)

For $H = \frac{\mathbf{P}^2}{2m} + \frac{1}{2}m\omega^2\mathbf{X}^2$ the three directions decouple: with a_i built from X_i, P_i we have $[a_i, a_j^\dagger] = \delta_{ij}$ and

$$H = \hbar\omega \left(N_1 + N_2 + N_3 + \frac{3}{2} \right),$$

so $E = (n + \frac{3}{2})\hbar\omega$ with $n = n_1 + n_2 + n_3$. The degeneracy of the level n is the number of ways to write n as an ordered sum of three non-negative integers, namely $\binom{n+2}{2} = \frac{1}{2}(n+1)(n+2)$: so 1, 3, 6, 10, ... Some of this is explained by rotational symmetry (§37.6), but not all of it – the isotropic oscillator, like the hydrogen atom, has a ‘hidden’ symmetry larger than rotations.

§37.4 Angular Momentum

In IB we found that the orbital angular momentum operators $L_i = \epsilon_{ijk}X_jP_k$ satisfy

$$[L_i, L_j] = i\hbar \epsilon_{ijk}L_k,$$

and that solving the associated differential equations gives the spherical harmonics, with ℓ a non-negative integer. We now run the harmonic-oscillator strategy on this problem: forget where the operators came from, keep only the commutation relations, and see what the algebra forces. The answer will turn out to be strictly richer than what the differential equations gave us – half-integer values appear, and they are realised in nature as *spin*, an angular momentum with no classical or orbital counterpart at all.

§37.4.1 The Algebra

Definition 37.4.1 (Angular Momentum)

An **angular momentum** is a triple of Hermitian operators J_1, J_2, J_3 on $\mathcal{H}$ satisfying

$$[J_i, J_j] = i\hbar \epsilon_{ijk}J_k.$$

We write $J^2 = J_1^2 + J_2^2 + J_3^2$, and usually J_z for J_3 .

Written out, the relations are $[J_1, J_2] = i\hbar J_3$ and its cyclic images. The first thing to check is that although no two components are compatible, the total is compatible with each one.

Proposition 37.4.2

$[J^2, J_i] = 0$ for each i .

Proof. Take $i = 3$; the rest follow by relabelling. Using $[A, B^2] = B[A, B] + [A, B]B$,

$$[J_1^2, J_3] = J_1[J_1, J_3] + [J_1, J_3]J_1 = -i\hbar(J_1J_2 + J_2J_1),$$

$$[J_2^2, J_3] = J_2[J_2, J_3] + [J_2, J_3]J_2 = i\hbar(J_2J_1 + J_1J_2),$$

and $[J_3^2, J_3] = 0$. The two non-zero pieces cancel. $\square$

So $\{J^2, J_z\}$ is a commuting pair, and we look for their simultaneous eigenstates. This is the best we can do – the length of the angular momentum vector and one of its components – and the choice of z is pure convention.

Definition 37.4.3 (Ladder Operators)

$J_{\pm} = J_1 \pm iJ_2$, so that $J_{\pm}^{\dagger} = J_{\mp}$.

The relations we need are all immediate:

$$[J_z, J_{\pm}] = \pm\hbar J_{\pm}, \quad [J_+, J_-] = 2\hbar J_z, \quad [J^2, J_{\pm}] = 0,$$

and, expanding the products and using $[J_1, J_2] = i\hbar J_3$,

$$J_-J_+ = (J_1 - iJ_2)(J_1 + iJ_2) = J_1^2 + J_2^2 + i[J_1, J_2] = J^2 - J_z^2 - \hbar J_z,$$

and, changing the sign of i throughout, $J_+J_- = J^2 - J_z^2 + \hbar J_z$. The first of these commutators, $[J_z, J_{\pm}] = \pm\hbar J_{\pm}$, is exactly the relation $[N, a^{\dagger}] = a^{\dagger}$ that made the oscillator work, and it does the same job here.

§37.4.2 The Spectrum

Theorem 37.4.4 (Spectrum of Angular Momentum)

Let $|\psi\rangle$ be a simultaneous eigenstate of J^2 and J_z . Then the eigenvalues take the form

$$J^2 |j m\rangle = \hbar^2 j(j+1) |j m\rangle, \quad J_z |j m\rangle = \hbar m |j m\rangle,$$

where

$$j \in \{0, \frac{1}{2}, 1, \frac{3}{2}, 2, \dots\}, \quad m \in \{-j, -j+1, \dots, j-1, j\}.$$

Moreover, with a suitable choice of phases,

$$J_{\pm} |j m\rangle = \hbar \sqrt{j(j+1) - m(m \pm 1)} |j m \pm 1\rangle.$$

Proof. Write the eigenvalues as $J^2 |\psi\rangle = \hbar^2 \lambda |\psi\rangle$ and $J_z |\psi\rangle = \hbar m |\psi\rangle$ with $|\psi\rangle$ normalised.

Step 1: a bound. Since $J^2 - J_z^2 = J_1^2 + J_2^2$ and each J_i is Hermitian,

$$\hbar^2(\lambda - m^2) = \langle \psi | J_1^2 + J_2^2 | \psi \rangle = \|J_1 |\psi\rangle\|^2 + \|J_2 |\psi\rangle\|^2 \geq 0,$$

so $\lambda \geq m^2$: for fixed λ the possible m are bounded above and below.

Step 2: the ladder. Since $[J^2, J_{\pm}] = 0$ and $[J_z, J_{\pm}] = \pm\hbar J_{\pm}$,

$$J^2 (J_{\pm} |\psi\rangle) = \hbar^2 \lambda (J_{\pm} |\psi\rangle), \quad J_z (J_{\pm} |\psi\rangle) = \hbar(m \pm 1) (J_{\pm} |\psi\rangle),$$

so $J_{\pm}$ moves m by one while preserving λ – unless it gives zero. And its norm is computable:

$$\|J_{\pm}|\psi\rangle\|^2 = \langle\psi|J_{\mp}J_{\pm}|\psi\rangle = \langle\psi|J^2 - J_z^2 \mp \hbar J_z|\psi\rangle = \hbar^2(\lambda - m(m \pm 1)).$$

Step 3: termination. By Step 1 the sequence $|\psi\rangle, J_+|\psi\rangle, J_+^2|\psi\rangle, \dots$ cannot continue for ever, so there is a top state with J_z eigenvalue $\hbar j$ (say) killed by J_+ ; by Step 2, $\lambda = j(j+1)$. Likewise there is a bottom state with eigenvalue $\hbar m_{\min}$ killed by J_- , giving $\lambda = m_{\min}(m_{\min} - 1)$. Setting the two equal,

$$j(j+1) = m_{\min}(m_{\min} - 1) \implies m_{\min} = -j$$

(the other root, $m_{\min} = j+1$, is impossible since $m_{\min} \leq j$).

Step 4: quantisation. The bottom state is reached from the top by applying J_- some non-negative integer number of times, so $j - (-j) = 2j \in \mathbb{Z}_{\geq 0}$: that is, j is a non-negative integer or half-integer, and m runs over $-j, -j+1, \dots, j$ in unit steps, giving $2j+1$ values. The normalisation constants come from Step 2, choosing all phases positive. $\square$

Compare this with the IB derivation. There, integrality of ℓ came from demanding that $e^{im\phi}$ be single-valued on the sphere; here, quantisation comes from the algebra alone, and it permits half-integers. Both answers are correct: half-integer j cannot occur for *orbital* angular momentum (§37.4.5), but nothing forbids it in general, and electrons, protons and neutrons all have $j = \frac{1}{2}$.

the multiplet $j = 2$: five states, all with $J^2 = 6\hbar^2$

For each allowed j the $2j+1$ states $|j, m\rangle$ form a **multiplet**, closed under the action of all three J_i (since J_1, J_2 are combinations of $J_{\pm}$). In the language of Representation Theory, a multiplet is an irreducible representation of the Lie algebra $\mathfrak{su}(2)$, and we have just classified them all. Nothing in the argument says which j actually occur in a given physical system, or how many times – that depends on the system.

§37.4.3 Matrix Representations and Spin

Within a single multiplet the operators are finite matrices, which we can write down explicitly.

Example 37.4.5 ($j = 0$)

A single state $|00\rangle$ with $J_i = 0$: no angular momentum at all.

Example 37.4.6 ($j = \frac{1}{2}$)

Two states, $|\frac{1}{2} \frac{1}{2}\rangle =: |\uparrow\rangle$ and $|\frac{1}{2} -\frac{1}{2}\rangle =: |\downarrow\rangle$, spanning $\mathbb{C}^2$. From the theorem, $J_z = \frac{\hbar}{2}\text{diag}(1, -1)$, and

$$J_+ |\downarrow\rangle = \hbar |\uparrow\rangle, \quad J_+ |\uparrow\rangle = 0, \quad J_- |\uparrow\rangle = \hbar |\downarrow\rangle, \quad J_- |\downarrow\rangle = 0,$$

so in the basis $(|\uparrow\rangle, |\downarrow\rangle)$,

$$J_+ = \hbar \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad J_- = \hbar \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \quad \text{hence} \quad J_1 = \frac{J_+ + J_-}{2}, \quad J_2 = \frac{J_+ - J_-}{2i}.$$

Writing $\mathbf{S} = \frac{\hbar}{2}\boldsymbol{\sigma}$ (the traditional notation for spin), this gives the **Pauli matrices**

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

Example 37.4.7 ($j = 1$)

Three states; in the basis $|11\rangle, |10\rangle, |1-1\rangle$, the coefficients $\sqrt{j(j+1) - m(m \pm 1)}$ are all $\sqrt{2}$, so

$$J_z = \hbar \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \quad J_+ = \sqrt{2}\hbar \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}, \quad J_- = \frac{\hbar}{\sqrt{2}} \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}.$$

One can check $J^2 = 2\hbar^2 I$, as it must be.

The Pauli matrices deserve their own list of properties, since spin- $\frac{1}{2}$ is by far the most important case.

Proposition 37.4.8 (Pauli Algebra)

The Pauli matrices are Hermitian and traceless, with $\sigma_i^2 = I$, and

$$\sigma_i \sigma_j = \delta_{ij} I + i\epsilon_{ijk} \sigma_k.$$

Consequently $[\sigma_i, \sigma_j] = 2i\epsilon_{ijk} \sigma_k$ and $\{\sigma_i, \sigma_j\} = 2\delta_{ij} I$, and for any unit vector $\mathbf{n}$,

$$(\mathbf{n} \cdot \boldsymbol{\sigma})^2 = I, \quad \exp\left(-\frac{i\theta}{2} \mathbf{n} \cdot \boldsymbol{\sigma}\right) = \cos \frac{\theta}{2} I - i \sin \frac{\theta}{2} \mathbf{n} \cdot \boldsymbol{\sigma}.$$

Proof. The product rule is verified by multiplying the matrices out (or by noting that the symmetric part must be $\delta_{ij} I$ since $\sigma_i^2 = I$, and the antisymmetric part is

$\frac{1}{2}[\sigma_i, \sigma_j]$, which is the angular momentum relation). Then

$$(\mathbf{n} \cdot \boldsymbol{\sigma})^2 = n_i n_j \sigma_i \sigma_j = n_i n_j \delta_{ij} I + i \epsilon_{ijk} n_i n_j \sigma_k = |\mathbf{n}|^2 I = I,$$

the ϵ term dying by symmetry. The exponential then follows by splitting the power series into even and odd parts, exactly as for $e^{i\theta}$. $\square$

Since $(\mathbf{n} \cdot \boldsymbol{\sigma})^2 = I$, the operator $\mathbf{n} \cdot \mathbf{S} = \frac{\hbar}{2} \mathbf{n} \cdot \boldsymbol{\sigma}$ has eigenvalues $\pm \frac{\hbar}{2}$ for *every* direction $\mathbf{n}$: a spin- $\frac{1}{2}$ measurement along any axis gives one of two answers. Writing $\mathbf{n} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$, one finds the eigenstates

$$|\mathbf{n} \uparrow\rangle = \cos \frac{\theta}{2} |\uparrow\rangle + e^{i\phi} \sin \frac{\theta}{2} |\downarrow\rangle, \quad |\mathbf{n} \downarrow\rangle = -e^{-i\phi} \sin \frac{\theta}{2} |\uparrow\rangle + \cos \frac{\theta}{2} |\downarrow\rangle.$$

This is a bijection (up to phase) between unit vectors in $\mathbb{R}^3$ and states of a qubit, and gives the standard picture of the spin- $\frac{1}{2}$ state space as a sphere.

This is the **Bloch sphere**. Antipodal points are orthogonal states (note $\theta \mapsto \pi - \theta$, $\phi \mapsto \phi + \pi$ sends $|\mathbf{n} \uparrow\rangle$ to $|\mathbf{n} \downarrow\rangle$ up to phase), so the angle on the sphere is *twice* the angle in Hilbert space – another manifestation of the factor of $\frac{1}{2}$ that pervades spin- $\frac{1}{2}$.

Example 37.4.9 (Measuring Spin in a Rotated Basis)

Prepare a particle in $|\uparrow\rangle$ and measure $\mathbf{n} \cdot \mathbf{S}$. The probability of $+\frac{\hbar}{2}$ is

$$|\langle \mathbf{n} \uparrow | \uparrow \rangle|^2 = \cos^2 \frac{\theta}{2} = \frac{1 + \cos \theta}{2},$$

and of $-\frac{\hbar}{2}$ is $\sin^2 \frac{\theta}{2}$. So $\langle \mathbf{n} \cdot \mathbf{S} \rangle_{\uparrow} = \frac{\hbar}{2} \cos \theta$: the expectation behaves like the projection of a classical vector of length $\frac{\hbar}{2}$ onto $\mathbf{n}$, even though every individual measurement returns $\pm \frac{\hbar}{2}$. For $\theta = \pi/2$ the two outcomes are equally likely – a state with definite S_z is maximally uncertain in S_x .

§37.4.4 The Stern–Gerlach Experiment

Spin is not a mathematical curiosity: it was forced on physics by experiment. A neutral particle with spin has a magnetic moment proportional to it,

$$\boldsymbol{\mu} = \gamma \mathbf{S},$$

with γ the **gyromagnetic ratio**, and in a magnetic field it acquires an energy $H = -\boldsymbol{\mu} \cdot \mathbf{B}$. In a field with a gradient the particle also feels a force $\nabla(\boldsymbol{\mu} \cdot \mathbf{B})$, so a beam

passing through an inhomogeneous field is deflected by an amount proportional to μ_z – which is a direct measurement of S_z . Classically, an unpolarised beam has μ_z uniformly distributed and one expects a continuous smear on the screen. What Stern and Gerlach (1922) saw with silver atoms was two discrete spots.

Two spots means two values of S_z , i.e. $2j + 1 = 2$, i.e. $j = \frac{1}{2}$ – a value impossible for orbital angular momentum. The apparatus is also the cleanest illustration of the measurement postulate: block the lower beam, and the surviving atoms are all in $|\uparrow\rangle$; pass them through a second identical magnet and they all go up, but pass them through a magnet oriented along x and they split 50–50, in agreement with the example above. Recombining the two beams coherently, on the other hand, restores the original state entirely – so long as no measurement records which path was taken.

Example 37.4.10 (Larmor Precession)

Put a spin in a uniform field $\mathbf{B} = B\mathbf{e}_3$. Then $H = -\gamma BS_z$, and using $[S_3, S_1] = i\hbar S_2$, $[S_3, S_2] = -i\hbar S_1$, the Heisenberg equations give

$$\frac{dS_1}{dt} = -\gamma B \frac{i}{\hbar} [S_3, S_1] = \omega_L S_2, \quad \frac{dS_2}{dt} = -\omega_L S_1, \quad \frac{dS_3}{dt} = 0,$$

where $\omega_L = \gamma B$. So $\langle \mathbf{S} \rangle$ precesses about the field at the **Larmor frequency** ω_L , exactly like a classical gyroscope. In the Schrödinger picture the same statement is that $|\uparrow\rangle$ and $|\downarrow\rangle$ acquire phases $e^{\pm i\omega_L t/2}$, so a state initially along $\mathbf{e}_1$ becomes

$$\frac{1}{\sqrt{2}} \left(e^{i\omega_L t/2} |\uparrow\rangle + e^{-i\omega_L t/2} |\downarrow\rangle \right),$$

which is the spin pointing along $(\cos \omega_L t, -\sin \omega_L t, 0)$. Note that after a time $2\pi/\omega_L$ the *spin direction* has returned but the *state vector* has acquired a factor of -1 ; only after 4π of rotation does the state itself return.

§37.4.5 Orbital Angular Momentum

Return now to $\mathbf{L} = \mathbf{X} \times \mathbf{P}$. One checks (as in IB, using $[X_i, P_j] = i\hbar \delta_{ij}$) that this satisfies the angular momentum algebra, so all of the above applies with $j = \ell$. The question is which ℓ occur.

In spherical polar coordinates $L_z = -i\hbar \partial_\phi$, and a slightly longer computation gives

$$L_\pm = \hbar e^{\pm i\phi} \left(\pm \frac{\partial}{\partial \theta} + i \cot \theta \frac{\partial}{\partial \phi} \right).$$

An eigenfunction of L_z with eigenvalue $\hbar m$ has ϕ -dependence $e^{im\phi}$, and single-valuedness on the sphere forces $m \in \mathbb{Z}$; hence $\ell \in \mathbb{Z}_{\geq 0}$. *Half-integer values are excluded for orbital angular momentum, but only by this topological input, which has no analogue for an intrinsic degree of freedom.* That is the precise sense in which spin is ‘not orbital’.

The ladder operators give a pleasant way to construct the spherical harmonics without touching Legendre's equation. The top state of the multiplet satisfies $L_+ Y_{\ell\ell} = 0$, i.e.

$$\left(\frac{\partial}{\partial \theta} - \ell \cot \theta \right) f(\theta) = 0 \quad \text{for } Y_{\ell\ell} = f(\theta) e^{i\ell\phi},$$

whose solution is $f \propto \sin^\ell \theta$. So

$$Y_{\ell\ell}(\theta, \phi) \propto \sin^\ell \theta e^{i\ell\phi},$$

and every other $Y_{\ell m}$ follows by applying L_- repeatedly, with the normalisations supplied by the theorem. For $\ell = 1$ this gives $Y_{11} \propto \sin \theta e^{i\phi}$, then L_- produces $Y_{10} \propto \cos \theta$ and $Y_{1,-1} \propto \sin \theta e^{-i\phi}$, matching IB.

Remark. Notice how much less work this is than the differential equation route, and how much more it explains. The mysterious constraint $|m| \leq \ell$ and the eigenvalue $\hbar^2 \ell(\ell+1)$ (rather than $\hbar^2 \ell^2$) are now consequences of the commutation relations, and the same algebra will hand us the whole theory of spin and of adding angular momenta.

For a particle with spin moving in space, the total angular momentum is

$$\mathbf{J} = \mathbf{L} + \mathbf{S},$$

where $\mathbf{L}$ acts on the spatial factor of $\mathcal{H} = L^2(\mathbb{R}^3) \otimes \mathbb{C}^2$ and $\mathbf{S}$ on the spin factor. Since they act on different factors they commute, and one checks immediately that $\mathbf{J}$ satisfies the angular momentum algebra. Understanding the multiplet structure of such a sum is the subject of the next section.

§37.5 Composite Systems and Addition of Angular Momentum

§37.5.1 Tensor Products

If a system is built from two subsystems – two particles, or the position and spin of one particle – how do their Hilbert spaces combine? The answer is not a direct sum but a tensor product, and this innocuous-looking choice is the source of essentially everything strange about quantum mechanics.

Definition 37.5.1 (Tensor Product)

Let $\mathcal{H}_1, \mathcal{H}_2$ be Hilbert spaces with orthonormal bases $\{|i\rangle_1\}, \{|a\rangle_2\}$. Their **tensor product** $\mathcal{H}_1 \otimes \mathcal{H}_2$ is the Hilbert space with orthonormal basis $\{|i\rangle_1 \otimes |a\rangle_2\}$, and inner product determined by

$$(\langle \phi |_1 \otimes \langle \chi |_2) (|\psi \rangle_1 \otimes |\omega \rangle_2) = \langle \phi | \psi \rangle_1 \langle \chi | \omega \rangle_2.$$

The map $(|\psi \rangle_1, |\omega \rangle_2) \mapsto |\psi \rangle_1 \otimes |\omega \rangle_2$ is bilinear.

Axiom 37.5.2 (Composite Systems)

The state space of a system composed of two subsystems with state spaces $\mathcal{H}_1$ and $\mathcal{H}_2$ is $\mathcal{H}_1 \otimes \mathcal{H}_2$.

In particular $\dim(\mathcal{H}_1 \otimes \mathcal{H}_2) = \dim \mathcal{H}_1 \cdot \dim \mathcal{H}_2$ – dimensions multiply, they do not add. We will freely abbreviate $|\psi\rangle \otimes |\omega\rangle$ as $|\psi\rangle |\omega\rangle$ or $|\psi\omega\rangle$ when no confusion can arise. An operator A on $\mathcal{H}_1$ acts on the product as $A \otimes I$, and

$$(A \otimes B)(|\psi\rangle \otimes |\omega\rangle) = A|\psi\rangle \otimes B|\omega\rangle, \quad (A \otimes B)(C \otimes D) = AC \otimes BD.$$

Operators belonging to different factors always commute: $[A \otimes I, I \otimes B] = 0$. This is the formal statement that measurements on subsystem 1 are compatible with measurements on subsystem 2.

Example 37.5.3 (Two Spins)

For two spin- $\frac{1}{2}$ particles, $\mathcal{H} = \mathbb{C}^2 \otimes \mathbb{C}^2$ is four-dimensional with basis

$$|\uparrow\uparrow\rangle, \quad |\uparrow\downarrow\rangle, \quad |\downarrow\uparrow\rangle, \quad |\downarrow\downarrow\rangle.$$

A single spin- $\frac{1}{2}$ particle in three dimensions has $\mathcal{H} = L^2(\mathbb{R}^3) \otimes \mathbb{C}^2$; a general state is $|\Psi\rangle = |\psi_\uparrow\rangle \otimes |\uparrow\rangle + |\psi_\downarrow\rangle \otimes |\downarrow\rangle$, conveniently written as a two-component **spinor** wavefunction

$$\Psi(\mathbf{x}) = \begin{pmatrix} \psi_\uparrow(\mathbf{x}) \\ \psi_\downarrow(\mathbf{x}) \end{pmatrix},$$

with $|\psi_\uparrow(\mathbf{x})|^2$ the probability density for finding the particle at $\mathbf{x}$ with spin up.

Definition 37.5.4 (Entanglement)

A state of $\mathcal{H}_1 \otimes \mathcal{H}_2$ is a **product state** if it can be written as $|\psi\rangle \otimes |\omega\rangle$, and is **entangled** otherwise.

Most states are entangled: a general state $\sum_{i,a} c_{ia} |i\rangle |a\rangle$ is a product exactly when the matrix (c_{ia}) has rank one. For example,

$$\frac{1}{\sqrt{2}} (|\uparrow\uparrow\rangle + |\uparrow\downarrow\rangle) = |\uparrow\rangle \otimes \frac{|\uparrow\rangle + |\downarrow\rangle}{\sqrt{2}} \quad \text{is a product,}$$

whereas

$$\frac{1}{\sqrt{2}} (|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle) \quad \text{is not}$$

(its coefficient matrix is $\frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$, which is invertible). In an entangled state neither subsystem has a state of its own, yet the pair does – a situation with no classical analogue whatsoever, and the crux of the EPR argument in §37.11.

§37.5.2 Adding Angular Momenta

Suppose subsystems 1 and 2 carry angular momenta $\mathbf{J}^{(1)}$ and $\mathbf{J}^{(2)}$. The total angular momentum of the composite system is

$$\mathbf{J} = \mathbf{J}^{(1)} \otimes I + I \otimes \mathbf{J}^{(2)},$$

which we will write simply as $\mathbf{J} = \mathbf{J}^{(1)} + \mathbf{J}^{(2)}$. Since the two pieces commute, $\mathbf{J}$ satisfies the angular momentum algebra:

$$[J_i, J_j] = [J_i^{(1)}, J_j^{(1)}] + [J_i^{(2)}, J_j^{(2)}] = i\hbar\epsilon_{ijk} (J_k^{(1)} + J_k^{(2)}) = i\hbar\epsilon_{ijk} J_k.$$

So the results of §37.4 apply, and the question is: given multiplets j_1 and j_2 , how does the $(2j_1 + 1)(2j_2 + 1)$ -dimensional product space decompose into multiplets of $\mathbf{J}$?

There are two natural bases. The **uncoupled basis**

$$|j_1 m_1\rangle |j_2 m_2\rangle, \quad m_1 = -j_1, \dots, j_1, \quad m_2 = -j_2, \dots, j_2,$$

diagonalises the CSCO $\{(J^{(1)})^2, J_z^{(1)}, (J^{(2)})^2, J_z^{(2)}\}$; the **coupled basis**

$$|J M\rangle, \quad M = -J, \dots, J,$$

diagonalises $\{(J^{(1)})^2, (J^{(2)})^2, J^2, J_z\}$. Both are legitimate: one checks that J^2 commutes with $(J^{(1)})^2$ and $(J^{(2)})^2$ (each $\mathbf{J}^{(a)}$ commutes with its own square) and with J_z , but that

$$[J^2, J_z^{(1)}] \neq 0,$$

which is why we must give up m_1 and m_2 individually to gain J . Indeed $J^2 = (J^{(1)})^2 + (J^{(2)})^2 + 2\mathbf{J}^{(1)} \cdot \mathbf{J}^{(2)}$, and the cross term does not commute with $J_z^{(1)}$.

Theorem 37.5.5 (Decomposition of a Tensor Product)

The product of multiplets j_1 and j_2 decomposes as

$$j_1 \otimes j_2 = (j_1 + j_2) \oplus (j_1 + j_2 - 1) \oplus \dots \oplus |j_1 - j_2|,$$

each value of J occurring exactly once.

Proof. Since $J_z = J_z^{(1)} + J_z^{(2)}$, the uncoupled basis vectors are already J_z eigenstates with $M = m_1 + m_2$. Let $d(M)$ be the number of uncoupled basis states with that value of M ; assume without loss of generality $j_1 \geq j_2$. Counting lattice points on the line $m_1 + m_2 = M$ inside the rectangle,

$$d(M) = \begin{cases} 0 & |M| > j_1 + j_2, \\ j_1 + j_2 - |M| + 1 & j_1 - j_2 \leq |M| \leq j_1 + j_2, \\ 2j_2 + 1 & |M| \leq j_1 - j_2. \end{cases}$$

On the other hand, a multiplet of total J contributes exactly one state to each M with $|M| \leq J$. So if $n(J)$ is the number of times J occurs,

$$d(M) = \sum_{J \geq |M|} n(J), \quad \text{hence} \quad n(J) = d(J) - d(J+1).$$

Reading off from the formula for d : $n(J) = 1$ for $|j_1 - j_2| \leq J \leq j_1 + j_2$ and $n(J) = 0$ otherwise. $\square$

As a check on the arithmetic, the dimensions must agree, and they do:

$$\sum_{J=|j_1-j_2|}^{j_1+j_2} (2J+1) = (2j_1+1)(2j_2+1),$$

which is an easy sum of an arithmetic progression. Note also that the parity of $j_1 + j_2 - J$ organises the answer, and that if j_1 and j_2 are both half-integers then all the resulting

J are integers – so a system of two fermions has integer total angular momentum, and behaves like a boson.

The counting is best seen as a picture. Here is the lattice of uncoupled states for $j_1 = 1$, $j_2 = \frac{1}{2}$, with the lines of constant $M = m_1 + m_2$ drawn in.

The picture makes the counting argument transparent: the multiplicities $d(M)$ along the diagonals are 1, 2, 2, 1 for $M = \frac{3}{2}, \frac{1}{2}, -\frac{1}{2}, -\frac{3}{2}$, so $n(\frac{3}{2}) = 1$ and $n(\frac{1}{2}) = 2 - 1 = 1$, giving $1 \otimes \frac{1}{2} = \frac{3}{2} \oplus \frac{1}{2}$, of dimension $4 + 2 = 6$.

§37.5.3 Clebsch–Gordan Coefficients

The two bases are related by a change of basis, whose matrix elements have a name.

Definition 37.5.6 (Clebsch–Gordan Coefficients)

Inserting the completeness relation for the uncoupled basis,

$$|J M\rangle = \sum_{m_1, m_2} |j_1 m_1\rangle |j_2 m_2\rangle \langle j_1 m_1; j_2 m_2 | J M \rangle,$$

and the numbers $\langle j_1 m_1; j_2 m_2 | J M \rangle$ are the **Clebsch–Gordan coefficients**.

They vanish unless $M = m_1 + m_2$ and $|j_1 - j_2| \leq J \leq j_1 + j_2$; by convention they are taken real, so the transformation matrix is orthogonal and the inverse expansion uses the same numbers. In practice one computes them by the following recipe, which needs no tables:

- (i) The state of maximal M is unambiguous: $|J=j_1+j_2, M=j_1+j_2\rangle = |j_1 j_1\rangle |j_2 j_2\rangle$.
- (ii) Apply $J_- = J_-^{(1)} + J_-^{(2)}$ repeatedly to descend the top multiplet, using the known action of J_- on each factor.
- (iii) The top state of the next multiplet, $|J=j_1+j_2-1, M=J\rangle$, is the (unique up to phase) normalised state with $M = j_1 + j_2 - 1$ orthogonal to the one found in (ii). Then descend again, and repeat.

§37.5.4 Two Spins: Singlet and Triplet

Let us run the recipe on the most important case, $j_1 = j_2 = \frac{1}{2}$. The theorem says

$$\frac{1}{2} \otimes \frac{1}{2} = 1 \oplus 0,$$

so the four-dimensional space splits into a three-dimensional $J = 1$ multiplet and a one-dimensional $J = 0$ multiplet. Explicitly, the top state is $|1 1\rangle = |\uparrow\uparrow\rangle$, and applying

$J_- = S_-^{(1)} + S_-^{(2)}$, using $S_- |\uparrow\rangle = \hbar |\downarrow\rangle$ and $S_- |\downarrow\rangle = 0$:

$$J_- |\uparrow\uparrow\rangle = \hbar (|\downarrow\uparrow\rangle + |\uparrow\downarrow\rangle), \quad \text{while} \quad J_- |1\,1\rangle = \hbar\sqrt{2} |1\,0\rangle,$$

so $|1\,0\rangle = \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)$; one more application gives $|1\,-1\rangle = |\downarrow\downarrow\rangle$. The remaining state is the normalised combination with $M = 0$ orthogonal to $|1\,0\rangle$.

Proposition 37.5.7 (Singlet and Triplet)

The $J = 1$ **triplet** states are

$$|1\,1\rangle = |\uparrow\uparrow\rangle, \quad |1\,0\rangle = \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle), \quad |1\,-1\rangle = |\downarrow\downarrow\rangle,$$

and the $J = 0$ **singlet** state is

$$|0\,0\rangle = \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle).$$

The triplet is symmetric under exchange of the two particles, the singlet antisymmetric.

The names come from spectroscopy: in a magnetic field the $J = 1$ states have distinct energies and produce three lines, while the $J = 0$ state gives one. The energy splitting between the two families is already visible without a field, because

$$\mathbf{S}^{(1)} \cdot \mathbf{S}^{(2)} = \frac{1}{2} (J^2 - (S^{(1)})^2 - (S^{(2)})^2) = \frac{\hbar^2}{2} \left(J(J+1) - \frac{3}{4} - \frac{3}{4} \right) = \begin{cases} +\frac{\hbar^2}{4} & \text{triplet,} \\ -\frac{3\hbar^2}{4} & \text{singlet,} \end{cases}$$

so any interaction of the form $\lambda \mathbf{S}^{(1)} \cdot \mathbf{S}^{(2)}$ splits them. (This identity is the standard trick for evaluating dot products of angular momenta: rewrite them in terms of squares, which are diagonal in the coupled basis.) It is worth recording that the singlet is rotationally invariant – being a $J = 0$ state, it is annihilated by every J_i and so looks the same along every axis. This innocuous fact is exactly what makes it the star of the EPR discussion.

Example 37.5.8 (Spin–Orbit Coupling)

An electron in an atomic orbital with $\ell = 1$ has $\mathbf{J} = \mathbf{L} + \mathbf{S}$ with $j_1 = 1$, $j_2 = \frac{1}{2}$, so by the theorem $J = \frac{3}{2}$ or $\frac{1}{2}$: six states in all, splitting $4 + 2$. Relativistic effects generate a term

$$H_{\text{SO}} = \xi(r) \mathbf{L} \cdot \mathbf{S} = \frac{\xi(r)}{2} (J^2 - L^2 - S^2),$$

whose expectation value is $\frac{\hbar^2}{2} \langle \xi \rangle (j(j+1) - \ell(\ell+1) - \frac{3}{4})$, that is $+\frac{\hbar^2}{2} \langle \xi \rangle$ for $j = \frac{3}{2}$ and $-\frac{\hbar^2}{2} \langle \xi \rangle$ for $j = \frac{1}{2}$. This is the origin of the *fine structure* doublet in the sodium spectrum (the famous yellow D lines), and shows why the coupled basis, not the

uncoupled one, is the useful one whenever such a term is present.

§37.6 Transformations and Symmetries

We have already seen the key idea twice: time evolution is a one-parameter family of unitaries generated by the Hermitian operator H , and (in the Larmor example) rotation about the z -axis is generated by S_z . We now make this systematic. The pattern will be that every continuous symmetry of a quantum system is implemented by unitaries $U(\alpha) = \exp(-i\alpha Q/\hbar)$, that the generator Q is an observable, and that Q is conserved precisely when the symmetry is a symmetry of the Hamiltonian. This is Noether's theorem, and in quantum mechanics it is almost a triviality.

§37.6.1 Translations

Consider translating a state of a particle in one dimension by a . In terms of wavefunctions this should send $\psi(x)$ to $\psi(x - a)$ – a bump at the origin moves to a bump at a . Define $U(a)$ by

$$\langle x|U(a)|\psi\rangle = \psi(x - a).$$

For infinitesimal a , Taylor expansion gives $\psi(x - a) = \psi(x) - a\psi'(x) + O(a^2)$, and since $-i\hbar\partial_x$ is the momentum operator,

$$U(a) = I - \frac{iaP}{\hbar} + O(a^2).$$

Composing n translations by a/n and letting $n \rightarrow \infty$ (or simply solving $dU/da = -\frac{i}{\hbar}PU$),

$$U(a) = \exp\left(-\frac{iaP}{\hbar}\right),$$

and in three dimensions $U(\mathbf{a}) = \exp(-i\mathbf{a} \cdot \mathbf{P}/\hbar)$, which makes sense because the components of $\mathbf{P}$ commute with each other. So:

Proposition 37.6.1

Momentum generates translations. The translation operators are unitary and form an abelian group, $U(\mathbf{a})U(\mathbf{b}) = U(\mathbf{a} + \mathbf{b})$.

It is worth checking the effect on operators. Since translating the state and translating the observable should be inverse operations,

$$U(a)^\dagger XU(a) = X + a, \quad U(a)^\dagger PU(a) = P,$$

the first of which one can verify directly from $e^B A e^{-B} = A + [B, A] + \frac{1}{2!}[B, [B, A]] + \dots$ (the *Baker–Campbell–Hausdorff* lemma, proved by differentiating $f(s) = e^{sB} A e^{-sB}$) with $B = iaP/\hbar$: the series terminates after one term since $[P, X] = -i\hbar$ is a constant.

Remark. The canonical commutation relation is thus *equivalent* to the statement that P generates translations of X . Read this way, $[X, P] = i\hbar$ stops looking like an arbitrary postulate.

§37.6.2 Rotations

The same logic applies to rotations, with two differences: the group is non-abelian, and the answer knows about spin. A rotation by angle θ about the axis $\mathbf{n}$ should be implemented by

$$U(\theta, \mathbf{n}) = \exp\left(-\frac{i\theta \mathbf{n} \cdot \mathbf{J}}{\hbar}\right),$$

where $\mathbf{J}$ is the total angular momentum. For a spinless particle we can check this directly: taking $\mathbf{n} = \mathbf{e}_3$ and using $L_z = -i\hbar\partial_\phi$,

$$\exp\left(-\frac{i\theta L_z}{\hbar}\right) = \exp\left(-\theta \frac{\partial}{\partial \phi}\right),$$

which is precisely the Taylor-series operator sending $\psi(r, \theta', \phi)$ to $\psi(r, \theta', \phi - \theta)$: a rotation. The failure of rotations about different axes to commute is encoded in $[J_i, J_j] = i\hbar\epsilon_{ijk}J_k$; indeed expanding both sides of $U(\alpha, \mathbf{e}_1)U(\beta, \mathbf{e}_2)U(\alpha, \mathbf{e}_1)^{-1}U(\beta, \mathbf{e}_2)^{-1}$ to second order reproduces exactly the commutator.

Under a rotation, a **vector operator** $\mathbf{V}$ – one which transforms like $\mathbf{X}$ or $\mathbf{P}$ – satisfies

$$U^\dagger V_i U = R_{ij} V_j, \quad \text{equivalently} \quad [J_i, V_j] = i\hbar\epsilon_{ijk} V_k,$$

where R is the corresponding 3×3 rotation matrix. A **scalar operator** S satisfies $[J_i, S] = 0$; examples are r , P^2 , L^2 and $\mathbf{L} \cdot \mathbf{S}$.

Remark (Spin and the Double Cover). For spin- $\frac{1}{2}$, $U(\theta, \mathbf{n}) = \exp(-\frac{i\theta}{2}\mathbf{n} \cdot \boldsymbol{\sigma}) = \cos \frac{\theta}{2} I - i \sin \frac{\theta}{2} \mathbf{n} \cdot \boldsymbol{\sigma}$,

$$U(2\pi, \mathbf{n}) = -I.$$

A rotation by 2π – which is no rotation at all – acts as -1 on the state. This is consistent, because states are rays and an overall sign is unobservable; but it means the map from rotations to unitaries is only defined up to sign. What we really have is a representation of $SU(2)$, which is a double cover of $SO(3)$. Half-integer j gives genuine $SU(2)$ representations that are not representations of $SO(3)$ – another way of seeing why orbital angular momentum, which acts on honest functions on space, must have integer ℓ . And the sign is not entirely unobservable: in an interference experiment where one arm rotates a neutron by 2π and the other does not, the relative sign is real and measurable, and has been measured.

§37.6.3 Symmetries, Conservation and Degeneracy

Definition 37.6.2 (Symmetry)

A unitary operator U is a **symmetry** of a system with Hamiltonian H if

$$U^\dagger H U = H, \quad \text{equivalently} \quad [U, H] = 0.$$

For a continuous family $U(\alpha) = e^{-i\alpha Q/\hbar}$, differentiating at $\alpha = 0$ shows this is equivalent to $[Q, H] = 0$. The consequences are immediate and important.

Theorem 37.6.3 (Symmetry and Conservation)

If Q generates a symmetry of H then Q is a conserved quantity: $\langle Q \rangle$ and the whole

probability distribution of Q are constant in time.

Proof. This is the corollary of §2.2: $[Q, H] = 0$ and Q has no explicit time dependence, so $dQ_H/dt = 0$. $\square$

Theorem 37.6.4 (Symmetry and Degeneracy)

If U is a symmetry and $|\psi\rangle$ is an energy eigenstate with $H|\psi\rangle = E|\psi\rangle$, then $U|\psi\rangle$ is also an energy eigenstate with the same E . Consequently, if the set $\{U|\psi\rangle\}$ over all symmetries U spans a space of dimension $d > 1$, the level E is at least d -fold degenerate.

Proof. $H(U|\psi\rangle) = UH|\psi\rangle = EU|\psi\rangle$. $\square$

This is the deepest structural fact in the subject, and answers a question left dangling in IB: *why* do energy levels come with degeneracies? Because the eigenspaces of H are invariant under the symmetry group, and therefore carry representations of it. For a rotationally invariant Hamiltonian, $[H, J_i] = 0$, so each energy eigenspace is a sum of angular momentum multiplets, and every level automatically has degeneracy $2j + 1$ for some j : the $(2\ell + 1)$ -fold degeneracy of the hydrogen levels in m is a theorem about $SO(3)$, not an accident of the Coulomb potential.

Example 37.6.5 (Accidental Degeneracy)

Hydrogen has a larger degeneracy than rotational symmetry demands: the level E_n has degeneracy n^2 , with all $\ell < n$ appearing, whereas rotational symmetry alone would allow the different ℓ to have different energies (as they do in every other atom). This is not an accident: the Coulomb problem has an extra conserved vector, the quantum *Runge–Lenz vector*

$$\mathbf{A} = \frac{1}{2m} (\mathbf{P} \times \mathbf{L} - \mathbf{L} \times \mathbf{P}) - \frac{e^2}{4\pi\epsilon_0} \frac{\mathbf{X}}{r},$$

which commutes with H and enlarges the symmetry from $SO(3)$ to $SO(4)$. The whole hydrogen spectrum can be derived from this algebra without solving a differential equation, exactly as we did for the oscillator. The three-dimensional isotropic oscillator has a similar story with symmetry group $SU(3)$.

§37.6.4 Parity

Not all symmetries are continuous. The most important discrete one is spatial inversion.

Definition 37.6.6 (Parity)

The **parity operator** Π acts on wavefunctions by $(\Pi\psi)(\mathbf{x}) = \psi(-\mathbf{x})$.

Proposition 37.6.7

Π is Hermitian and unitary with $\Pi^2 = I$, so its eigenvalues are ± 1 . Moreover

$$\Pi \mathbf{X} \Pi = -\mathbf{X}, \quad \Pi \mathbf{P} \Pi = -\mathbf{P}, \quad \Pi \mathbf{L} \Pi = +\mathbf{L}, \quad \Pi \mathbf{S} \Pi = +\mathbf{S}.$$

Proof. Hermiticity is a change of variables in the integral $\int \phi^*(\mathbf{x})\psi(-\mathbf{x})d^3x$, and $\Pi^2 = I$ is clear; together these give unitarity. The action on $\mathbf{X}$ and $\mathbf{P}$ follows from $\Pi\psi(\mathbf{x}) = \psi(-\mathbf{x})$ and the chain rule, and then $\mathbf{L} = \mathbf{X} \times \mathbf{P}$ picks up two signs, so is unchanged. Spin, being an angular momentum, transforms the same way as $\mathbf{L}$. $\square$

Quantities like $\mathbf{L}$ and $\mathbf{S}$ that are *even* under parity are called **axial** (or pseudo-) vectors, while $\mathbf{X}, \mathbf{P}$ are **polar** vectors – the same distinction as in classical mechanics. Since Π commutes with L^2 and $\mathbf{L}$, it acts as a constant on each multiplet, and one finds that constant by evaluating on $Y_{\ell\ell} \propto \sin^\ell \theta e^{i\ell\phi}$: inversion sends $(\theta, \phi) \mapsto (\pi - \theta, \phi + \pi)$, which multiplies this by $(-1)^\ell$. So

$$\Pi Y_{\ell m} = (-1)^\ell Y_{\ell m}.$$

If $[\Pi, H] = 0$ – which holds whenever the potential is even, $U(-\mathbf{x}) = U(\mathbf{x})$ – then parity is conserved and we may choose energy eigenstates of definite parity. The most useful consequence is a *selection rule*.

Proposition 37.6.8 (Parity Selection Rule)

Let $|\psi\rangle$ and $|\phi\rangle$ have definite parities $\eta_\psi, \eta_\phi = \pm 1$, and let V be an operator with $\Pi V \Pi = \eta_V V$. Then

$$\langle \phi | V | \psi \rangle = 0 \quad \text{unless} \quad \eta_\phi \eta_V \eta_\psi = +1.$$

Proof. Insert $\Pi^2 = I$ twice: $\langle \phi | V | \psi \rangle = \langle \phi | \Pi \Pi V \Pi | \psi \rangle = \eta_\phi \eta_V \eta_\psi \langle \phi | V | \psi \rangle$. $\square$

For instance $\mathbf{X}$ is parity-odd, so $\langle \phi | \mathbf{X} | \psi \rangle$ vanishes between states of the same parity. Since the leading interaction of an atom with light is the electric dipole term $\propto \mathbf{E} \cdot \mathbf{X}$, this is exactly the rule that atomic transitions must change parity – so, using $\Pi Y_{\ell m} = (-1)^\ell Y_{\ell m}$, they must change ℓ by an odd number, and a more refined argument using rotational symmetry sharpens this to $\Delta\ell = \pm 1$. Selection rules of this kind are why atomic spectra contain far fewer lines than the number of pairs of levels would suggest.

Remark (Time Reversal). The other classic discrete symmetry is time reversal, which should send $\mathbf{X} \mapsto \mathbf{X}$ and $\mathbf{P} \mapsto -\mathbf{P}$ (and $\mathbf{J} \mapsto -\mathbf{J}$). No unitary can do this: it would preserve $[X, P] = i\hbar$ while flipping the sign of the right-hand side. The resolution, due to Wigner, is that time reversal is implemented by an *antiunitary* operator Θ – one that is antilinear, $\Theta(\lambda|\psi\rangle) = \lambda^* \Theta|\psi\rangle$, and satisfies $\langle \Theta\phi | \Theta\psi \rangle = \langle \phi | \psi \rangle^*$. For a spinless particle Θ is simply complex conjugation of the wavefunction, and indeed if $\psi(\mathbf{x}, t)$ solves the Schrödinger equation with real potential then so does $\psi^*(\mathbf{x}, -t)$. Because Θ is not linear it has no eigenvalues in the usual sense and generates no conservation law; its main structural consequence is *Kramers' degeneracy*, that a time-reversal-invariant system with half-integer total angular momentum has all its energy levels degenerate to even order.

§37.7 Time-Independent Perturbation Theory

The list of quantum systems we can solve exactly is embarrassingly short: the free particle, the square well, the oscillator, the hydrogen atom, and a handful of others. Almost every real problem is one of these with something extra added – an electric field, a magnetic field, a second electron, a slight anharmonicity. Perturbation theory is the systematic way of getting approximate answers by treating the extra piece as small.

The setup throughout is

$$H = H_0 + \lambda V,$$

where the **unperturbed** Hamiltonian H_0 is solved,

$$H_0 |n^{(0)}\rangle = E_n^{(0)} |n^{(0)}\rangle,$$

with $\{|n^{(0)}\rangle\}$ a complete orthonormal set, and λ is a small dimensionless parameter that we use to organise the expansion (and often set to 1 at the end). We write $V_{mn} = \langle m^{(0)} | V | n^{(0)} \rangle$.

§37.7.1 The Non-Degenerate Case

Assume first that the level $E_n^{(0)}$ we are interested in is non-degenerate, and posit power series

$$E_n = E_n^{(0)} + \lambda E_n^{(1)} + \lambda^2 E_n^{(2)} + \dots, \quad |n\rangle = |n^{(0)}\rangle + \lambda |n^{(1)}\rangle + \lambda^2 |n^{(2)}\rangle + \dots.$$

We may normalise the expansion by choosing $\langle n^{(0)} | n^{(k)} \rangle = 0$ for $k \geq 1$ – the component of the correction along the original state is pure rescaling, and can be removed at the end. Substituting into $H |n\rangle = E_n |n\rangle$ and collecting powers of λ :

$$\begin{aligned} \lambda^0 : \quad & (H_0 - E_n^{(0)}) |n^{(0)}\rangle = 0, \\ \lambda^1 : \quad & (H_0 - E_n^{(0)}) |n^{(1)}\rangle = (E_n^{(1)} - V) |n^{(0)}\rangle, \\ \lambda^2 : \quad & (H_0 - E_n^{(0)}) |n^{(2)}\rangle = (E_n^{(1)} - V) |n^{(1)}\rangle + E_n^{(2)} |n^{(0)}\rangle. \end{aligned}$$

Now project each equation onto the unperturbed basis. Taking $\langle n^{(0)} |$ of the λ^1 equation, the left-hand side vanishes (as H_0 is Hermitian and acts leftwards as $E_n^{(0)}$), giving at once

$$E_n^{(1)} = V_{nn} = \langle n^{(0)} | V | n^{(0)} \rangle.$$

Taking $\langle m^{(0)} |$ with $m \neq n$ gives $(E_m^{(0)} - E_n^{(0)}) \langle m^{(0)} | n^{(1)} \rangle = -V_{mn}$, so

$$|n^{(1)}\rangle = \sum_{m \neq n} \frac{V_{mn}}{E_n^{(0)} - E_m^{(0)}} |m^{(0)}\rangle.$$

Finally, taking $\langle n^{(0)} |$ of the λ^2 equation and using $\langle n^{(0)} | n^{(1)} \rangle = 0$,

$$0 = -\langle n^{(0)} | V | n^{(1)} \rangle + E_n^{(2)}, \quad \text{so} \quad E_n^{(2)} = \sum_{m \neq n} \frac{|V_{mn}|^2}{E_n^{(0)} - E_m^{(0)}}.$$

Theorem 37.7.1 (Rayleigh–Schrödinger Perturbation Theory)

To second order, and setting $\lambda = 1$,

$$E_n = E_n^{(0)} + V_{nn} + \sum_{m \neq n} \frac{|V_{mn}|^2}{E_n^{(0)} - E_m^{(0)}} + O(V^3),$$

with corresponding state $|n\rangle = |n^{(0)}\rangle + \sum_{m \neq n} \frac{V_{mn}}{E_n^{(0)} - E_m^{(0)}} |m^{(0)}\rangle + O(V^2)$.

Several things are worth noticing. The first-order shift is just the expectation value of the perturbation in the unperturbed state – entirely intuitive. The second-order shift for the *ground state* is always negative, since every denominator $E_0^{(0)} - E_m^{(0)}$ is negative: mixing in other states can only push the ground state down. More generally levels ‘repel’: a pair of levels contributes to each other’s shift with opposite signs, pushing the higher one up and the lower one down. And the whole thing is an asymptotic expansion in $V/\Delta E$, where ΔE is the typical level spacing; it fails badly if any denominator is small, which is exactly the situation of degeneracy.

**Example 37.7.2** (The Anharmonic Oscillator)

Take $H = \frac{P^2}{2m} + \frac{1}{2}m\omega^2 X^2 + \lambda X^4$. The first-order shift of the level n is $\lambda \langle n|X^4|n\rangle$, which is easy with creation and annihilation operators. Writing $X = \alpha(a + a^\dagger)$ with $\alpha = \sqrt{\hbar/2m\omega}$, we need the terms of $(a + a^\dagger)^4$ with equal numbers of a and $a^\dagger$; keeping track of the orderings,

$$\langle n|X^4|n\rangle = \alpha^4 (3 + 6n + 6n^2) = 3 \left(\frac{\hbar}{2m\omega} \right)^2 (2n^2 + 2n + 1).$$

(A quick check: for $n = 0$ this is $3\alpha^4 = 3 \langle X^2 \rangle_0^2$, as it should be for a Gaussian.) So

$$E_n \approx \left(n + \frac{1}{2} \right) \hbar\omega + \frac{3\lambda\hbar^2}{4m^2\omega^2} (2n^2 + 2n + 1).$$

The correction grows like n^2 , so the expansion is only good for $n \ll m^2\omega^3/\lambda\hbar$: perturbation theory in a fixed λ eventually fails for high levels, which is physically obvious since a highly excited state explores large x where λx^4 dominates $\frac{1}{2}m\omega^2 x^2$.

Example 37.7.3 (A Two-State System, Exactly and Perturbatively)

Let $H = \begin{pmatrix} E_1 & v \\ v & E_2 \end{pmatrix}$ with $E_1 < E_2$ and v real. The exact eigenvalues are

$$E_{\pm} = \frac{E_1 + E_2}{2} \pm \sqrt{\left(\frac{E_2 - E_1}{2}\right)^2 + v^2},$$

and expanding the square root for $v \ll E_2 - E_1$ gives

$$E_- = E_1 - \frac{v^2}{E_2 - E_1} + O(v^4), \quad E_+ = E_2 + \frac{v^2}{E_2 - E_1} + O(v^4),$$

exactly matching the second-order formula (the first-order shifts vanish since the diagonal of V is zero). Note the level repulsion, and note also what happens as $E_2 \rightarrow E_1$: the perturbative answer diverges but the exact one does not – it becomes $E_{\pm} = E_1 \pm v$, a splitting *linear* in v . This is the degenerate case, and it needs different treatment.

§37.7.2 The Degenerate Case

Suppose now that $E^{(0)}$ is an eigenvalue of H_0 with a d -dimensional eigenspace $\mathcal{H}_0$, spanned by orthonormal $|1\rangle, \dots, |d\rangle$. The non-degenerate formulae break down because of the vanishing denominators; but the two-state example above shows what is really going on. *Any* basis of $\mathcal{H}_0$ diagonalises H_0 , so at zeroth order we do not know which states to expand around, and we must let the perturbation tell us.

Write the true eigenstate as $|\psi\rangle = |\psi^{(0)}\rangle + \lambda |\psi^{(1)}\rangle + \dots$ with $|\psi^{(0)}\rangle = \sum_{i=1}^d c_i |i\rangle \in \mathcal{H}_0$ unknown. The order- λ equation is as before,

$$(H_0 - E^{(0)}) |\psi^{(1)}\rangle = (E^{(1)} - V) |\psi^{(0)}\rangle,$$

and projecting onto $\langle j|$ for $j = 1, \dots, d$ kills the left-hand side, leaving

$$\sum_i \langle j|V|i\rangle c_i = E^{(1)} c_j.$$

Theorem 37.7.4 (Degenerate Perturbation Theory)

The first-order energy shifts of a degenerate level are the eigenvalues of the $d \times d$ Hermitian matrix

$$\mathcal{V}_{ji} = \langle j|V|i\rangle, \quad i, j = 1, \dots, d,$$

and the correct zeroth-order states are the corresponding eigenvectors.

So the recipe is: restrict the perturbation to the degenerate subspace and diagonalise it. If the eigenvalues of $\mathcal{V}$ are distinct, the degeneracy is completely lifted at first order and one may then continue with non-degenerate perturbation theory in the new basis. If some remain equal, the degeneracy survives to first order and one must go further – often it is protected by a symmetry that V does not break, in which case it survives to all orders.

§37.7.3 Atoms in Fields: Fine Structure, Zeeman and Stark

The classic applications of perturbation theory are all to hydrogen, and they are all degenerate. The spectrum found in IB, $E_n = -\text{Ry}/n^2$ with $\text{Ry} = 13.6 \text{ eV}$, is spectacularly degenerate – the level n has n^2 orbital states, and $2n^2$ once spin is counted – so *everything* we have so far neglected perturbs a degenerate level. Happily, the recipe of the previous subsection is usually easier to apply than it looks, because of the principle of §37.6: if the perturbation commutes with certain observables, we should choose the zeroth-order basis to diagonalise those, and then $\mathcal{V}$ is diagonal (or at worst block diagonal) with no work at all.

Three neglected effects, all of the same relative size $\alpha^2 \approx 5 \times 10^{-5}$, where

$$\alpha = \frac{e^2}{4\pi\epsilon_0\hbar c} \approx \frac{1}{137}$$

is the **fine structure constant**, make up the **fine structure** of the spectrum.

- (i) *The relativistic correction to the kinetic energy.* Expanding the exact expression,

$$\sqrt{p^2c^2 + m^2c^4} - mc^2 = \frac{p^2}{2m} - \frac{p^4}{8m^3c^2} + \cdots,$$

so the leading correction is $V_{\text{rel}} = -P^4/8m^3c^2$.

- (ii) *Spin-orbit coupling.* In the electron's instantaneous rest frame the proton orbits it, producing a magnetic field which couples to the electron's magnetic moment. Including the relativistic factor of $\frac{1}{2}$ from Thomas precession, this gives

$$V_{\text{SO}} = \frac{1}{2m^2c^2} \frac{1}{r} \frac{dU}{dr} \mathbf{L} \cdot \mathbf{S} = \frac{e^2}{8\pi\epsilon_0 m^2 c^2} \frac{\mathbf{L} \cdot \mathbf{S}}{r^3},$$

the operator we already met in §5.4.

- (iii) *The Darwin term,* $V_D = \frac{\hbar^2}{8m^2c^2} \nabla^2 U = \frac{\hbar^2 e^2}{8\epsilon_0 m^2 c^2} \delta^{(3)}(\mathbf{x})$, a relativistic smearing of the electron over a Compton wavelength which affects only the states with $\ell = 0$, the only ones with $\psi(0) \neq 0$.

Now, which basis? The terms V_{rel} and V_D are scalars: they are built from P^2 and r , and commute with every component of $\mathbf{L}$ and of $\mathbf{S}$. The spin-orbit term does not commute with L_z or S_z separately, but writing it as

$$\mathbf{L} \cdot \mathbf{S} = \frac{1}{2} (J^2 - L^2 - S^2)$$

shows that it commutes with L^2, S^2, J^2 and J_z . Hence all three perturbations are simultaneously diagonal in the *coupled* basis $|n \ell j m_j\rangle$, and the correct zeroth-order states are those of definite total angular momentum. Not a single matrix has to be diagonalised.

Evaluating the shifts then needs the radial expectation values $\langle r^{-2} \rangle$ and $\langle r^{-3} \rangle$ in hydrogen. That algebra is unedifying and we shall not reproduce it; what is worth knowing is that the three contributions conspire into something startlingly simple.

Theorem 37.7.5 (Fine Structure of Hydrogen)

To first order in α^2 , the energy levels of hydrogen are

$$E_{nj} = -\frac{\text{Ry}}{n^2} \left[1 + \frac{\alpha^2}{n^2} \left(\frac{n}{j + \frac{1}{2}} - \frac{3}{4} \right) \right],$$

depending on n and on the total angular momentum j , but not on ℓ .

The shift is always negative, and it lifts the degeneracy in ℓ only partially: states with the same j but different ℓ – such as $2s_{1/2}$ and $2p_{1/2}$, in the spectroscopic notation $n\ell_j$ – remain exactly degenerate. This is a peculiarity of the Coulomb potential, and it survives an exact treatment: solving the Dirac equation for hydrogen gives a spectrum depending only on n and j . The degeneracy is finally broken by quantum electrodynamics, producing the tiny **Lamb shift** of about 4×10^{-6} eV between $2s_{1/2}$ and $2p_{1/2}$ – whose measurement in 1947 was one of the founding experiments of QED.

With the internal structure understood, we can put the atom into an external field.

Example 37.7.6 (The Normal Zeeman Effect)

Put a hydrogen atom in a uniform magnetic field $\mathbf{B} = B\mathbf{e}_3$. The orbital motion of the electron gives a magnetic moment $\mu = -\frac{e}{2m_e}\mathbf{L}$, so (ignoring spin for the moment)

$$V = -\mu \cdot \mathbf{B} = \frac{eB}{2m_e}L_z = \frac{\mu_B B}{\hbar}L_z,$$

where $\mu_B = e\hbar/2m_e$ is the **Bohr magneton**. The unperturbed level E_n is n^2 -fold degenerate, so we should diagonalise V on that subspace – but it is already diagonal in the basis $|n\ell m\rangle$, with eigenvalues $\mu_B B m$. Hence

$$E_{n\ell m} = E_n + \mu_B B m, \quad m = -\ell, \dots, \ell,$$

and each ℓ -multiplet splits into $2\ell + 1$ equally spaced levels. This is exactly the degeneracy-versus-symmetry story of §37.6 run in reverse: the field picks out an axis, breaking $SO(3)$ down to rotations about $\mathbf{e}_3$, and the degeneracy protected by the larger group is destroyed.

The splitting is linear in B , and it is easiest to picture by plotting the levels against the field strength.

Remark (The Anomalous Zeeman Effect). Including spin, the moment is $\mu = -\frac{e}{2m_e}(\mathbf{L} + 2\mathbf{S})$ – the factor of 2 being the electron’s g -factor, a prediction of the Dirac equation – so

$$V = \frac{\mu_B B}{\hbar} (L_z + 2S_z) = \frac{\mu_B B}{\hbar} (J_z + S_z).$$

If the field is weak compared with the spin–orbit coupling, one must work in the coupled basis $|j m_j\rangle$, where S_z is not diagonal but its restriction to fixed j turns out to be proportional to J_z ; the shift is $\mu_B B g_J m_j$ with the **Landé g -factor**

$$g_J = 1 + \frac{j(j+1) + s(s+1) - \ell(\ell+1)}{2j(j+1)}.$$

In a strong field the spin–orbit term is instead the perturbation, and one works in the uncoupled basis; the two regimes give different-looking spectra, and the crossover between them (the Paschen–Back effect) is a nice illustration of why choosing the right zeroth-order basis is the whole art of degenerate perturbation theory.

Example 37.7.7 (The Linear Stark Effect)

Put hydrogen in a uniform electric field $\mathcal{E} = \mathcal{E}\mathbf{e}_3$, so $V = e\mathcal{E}Z$. For the ground state $|100\rangle$, the first-order shift vanishes by parity (Z is odd, $|100\rangle$ has definite parity), so the effect is quadratic in $\mathcal{E}$ – the atom has no permanent dipole moment.

The $n = 2$ level is different. It is four-fold degenerate (ignoring spin), spanned by $|200\rangle, |210\rangle, |21\pm 1\rangle$, and we must diagonalise the 4×4 matrix of V . Almost all entries vanish: $\langle 2\ell m | Z | 2\ell' m' \rangle = 0$ unless $m = m'$ (since Z commutes with L_z) and unless ℓ, ℓ' have opposite parity (since Z is parity-odd). The only surviving matrix element is between $|200\rangle$ and $|210\rangle$, and an explicit integral gives $\langle 200 | Z | 210 \rangle = -3a_0$ with a_0 the Bohr radius. So in the basis $(|200\rangle, |210\rangle, |211\rangle, |21-1\rangle)$,

$$\mathcal{V} = -3ea_0\mathcal{E} \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

with eigenvalues $\mp 3ea_0\mathcal{E}$ and 0 (twice). The level splits into three, with the outer two shifting *linearly* in the field – so an excited hydrogen atom does behave as though it has a permanent dipole moment of size $3ea_0$. The reason it can is precisely the accidental degeneracy between the $2s$ and $2p$ states, which lets the field mix states of opposite parity at no energy cost.

§37.7.4 The Variational Principle

Perturbation theory needs a nearby solvable problem. When there is none, the following gives a completely different handle, and in particular a rigorous *bound*.

Theorem 37.7.8 (Variational Principle)

Let H have ground state energy E_0 . Then for every normalised $|\psi\rangle \in \mathcal{H}$,

$$\langle\psi|H|\psi\rangle \geq E_0,$$

with equality if and only if $|\psi\rangle$ is a ground state.

Proof. Expand in an orthonormal basis of energy eigenstates, so that $|\psi\rangle = \sum_n a_n |n\rangle$ with coefficients satisfying $\sum_n |a_n|^2 = 1$. Then

$$\langle\psi|H|\psi\rangle = \sum_n E_n |a_n|^2 \geq E_0 \sum_n |a_n|^2 = E_0,$$

with equality iff $a_n = 0$ whenever $E_n > E_0$. □

The proof is trivial; the power comes from what one does with it. Choose a family of **trial states** $|\psi_\alpha\rangle$ depending on parameters α , compute

$$\mathcal{E}(\alpha) = \frac{\langle\psi_\alpha|H|\psi_\alpha\rangle}{\langle\psi_\alpha|\psi_\alpha\rangle},$$

and minimise over α . Whatever family we pick, the result is a genuine upper bound on E_0 , and if the family happens to contain a good approximation to the true ground state the bound will be tight. Even a crude family usually does well, because $\mathcal{E}$ is *stationary* at the true ground state: an error of size ϵ in the state produces an error of size ϵ^2 in the energy.

Example 37.7.9 (The Quartic Oscillator)

Take $H = \frac{P^2}{2m} + \lambda X^4$, which has no exact solution and no small parameter to perturb in (there is no quadratic term at all). Use the Gaussian family

$$\psi_a(x) = \left(\frac{a}{\pi}\right)^{1/4} e^{-ax^2/2},$$

for which $\langle X^2 \rangle = \frac{1}{2a}$, $\langle X^4 \rangle = 3 \langle X^2 \rangle^2 = \frac{3}{4a^2}$ and $\langle P^2 \rangle = \frac{\hbar^2 a}{2}$. Hence

$$\mathcal{E}(a) = \frac{\hbar^2 a}{4m} + \frac{3\lambda}{4a^2}.$$

Setting $\mathcal{E}'(a) = 0$ gives $a_*^3 = 6m\lambda/\hbar^2$, and substituting back,

$$E_0 \leq \mathcal{E}(a_*) \approx 0.681 \left(\frac{\hbar^2}{m} \right)^{2/3} \lambda^{1/3}.$$

Note first that the $\lambda^{1/3}$ scaling is exact – it follows from dimensional analysis, since $\hbar^2/m$ and λ can be combined into an energy in only one way. Numerical solution of the Schrödinger equation gives the true coefficient as 0.668, so our one-parameter guess is within 2%.

Remark (Excited States). The principle extends: if $|\psi\rangle$ is orthogonal to the exact ground state, then $\langle H \rangle_\psi \geq E_1$, and so on up the spectrum. In practice we rarely know the exact ground state, but symmetry often does the job for free – any odd trial function is automatically orthogonal to an even ground state, so minimising over odd trial functions bounds the first excited state of a symmetric potential.

Remark. A pleasant corollary: *any* attractive potential well in one dimension, however shallow, has at least one bound state. Take a trial Gaussian of width σ ; the kinetic energy costs $O(\hbar^2/m\sigma^2)$ while the potential energy gains $O(-\int U/\sigma)$ for large σ , and the latter wins as $\sigma \rightarrow \infty$, giving $\mathcal{E} < 0$ for some trial state and hence a bound state. The same argument fails in three dimensions, where the kinetic cost scales the same way but the potential gain is weaker – and indeed shallow three-dimensional wells have no bound states.

§37.8 Identical Particles

Classically, two identical billiard balls are still two *different* balls: we can paint one red, or simply follow their trajectories. In quantum mechanics neither option is available – there are no trajectories, and identical particles really are identical. This is not a philosophical nicety; it changes the state space, and its consequences include the structure of the periodic table, the stability of matter, and the existence of lasers.

§37.8.1 Exchange Symmetry

Take two identical particles, each with state space $\mathcal{H}_1$, so the pair lives in $\mathcal{H}_1 \otimes \mathcal{H}_1$.

Definition 37.8.1 (Exchange Operator)

The **exchange** (or swap) operator P is defined on $\mathcal{H}_1 \otimes \mathcal{H}_1$ by

$$P(|\psi\rangle \otimes |\phi\rangle) = |\phi\rangle \otimes |\psi\rangle,$$

extended linearly.

Clearly $P^2 = I$, and P is unitary and Hermitian, so its eigenvalues are ± 1 ; the corresponding eigenspaces are the **symmetric** and **antisymmetric** subspaces. If the par-

ticles are genuinely identical then the Hamiltonian must be unchanged by relabelling them, $[P, H] = 0$, so these subspaces are preserved by time evolution.

Axiom 37.8.2 (Symmetrisation Postulate)

The states of a system of identical particles are either totally symmetric under exchange of any two of them (such particles are **bosons**) or totally antisymmetric (**fermions**). Which of the two holds is a fixed property of the species.

The postulate is stronger than the observation that $[P, H] = 0$: it says the other states simply do not exist in nature. Empirically, particles with integer spin are bosons (photons, pions, helium-4 atoms) and particles with half-integer spin are fermions (electrons, protons, neutrons, helium-3 atoms). That this is forced – the **spin–statistics theorem** – is a genuine theorem, but only within relativistic quantum field theory; here we take it as given.

For N particles, ‘totally symmetric’ means invariant under every transposition (hence under every permutation), and ‘totally antisymmetric’ means picking up $\text{sign}(\sigma)$ under the permutation σ . Given single-particle states $|\chi_1\rangle, \dots, |\chi_N\rangle$ one builds

$$|\Psi_B\rangle \propto \sum_{\sigma \in S_N} |\chi_{\sigma(1)}\rangle \otimes \cdots \otimes |\chi_{\sigma(N)}\rangle, \quad |\Psi_F\rangle \propto \sum_{\sigma \in S_N} \text{sign}(\sigma) |\chi_{\sigma(1)}\rangle \otimes \cdots \otimes |\chi_{\sigma(N)}\rangle.$$

The fermionic expression is a determinant – the **Slater determinant** – of the matrix whose (i, j) entry is the i th state occupied by the j th particle, and this observation gives the fundamental result of the section for free.

Theorem 37.8.3 (Pauli Exclusion Principle)

No two identical fermions can occupy the same single-particle state.

Proof. If $|\chi_i\rangle = |\chi_j\rangle$ for some $i \neq j$, the determinant has two equal rows and vanishes. Directly, for two particles, $|\Psi_F\rangle \propto |\chi\rangle \otimes |\chi\rangle - |\chi\rangle \otimes |\chi\rangle = 0$: there is no antisymmetric state built from two copies of the same state. $\square$

There is no corresponding restriction on bosons – indeed they positively prefer to pile into the same state, which is what a laser and a Bose–Einstein condensate exploit.

§37.8.2 Exchange Forces

Symmetry has consequences even in the absence of any interaction. Suppose two particles occupy orthonormal single-particle states $|\chi_a\rangle, |\chi_b\rangle$, and consider the normalised combinations

$$|\Psi_{\pm}\rangle = \frac{1}{\sqrt{2}} (|\chi_a\rangle |\chi_b\rangle \pm |\chi_b\rangle |\chi_a\rangle).$$

Working in one dimension for brevity, let us compute the mean square separation of the two particles. A short calculation using orthonormality gives

$$\langle (X_1 - X_2)^2 \rangle_{\pm} = \langle X^2 \rangle_a + \langle X^2 \rangle_b - 2 \langle X \rangle_a \langle X \rangle_b \mp 2 |\langle \chi_a | X | \chi_b \rangle|^2,$$

where the first three terms are exactly what one would get for distinguishable particles. The last term is the **exchange term**. So symmetric (bosonic) states are on average

closer together, and antisymmetric (fermionic) states *further apart*, than distinguishable particles in the same orbitals.

The pictures show the probability density for the separation: bosons show a peak at zero separation ('bunching'), fermions a zero there. It looks like an attractive force between bosons and a repulsive one between fermions, and the effect can be large; but no force is involved at all, only the symmetry of the state. This **exchange force** is what holds covalent bonds together and, in the guise of the Pauli principle, what stops matter collapsing.

For particles with spin, the antisymmetry requirement applies to the *whole* state, space and spin together. For two spin- $\frac{1}{2}$ fermions, $\mathcal{H} = (L^2 \otimes L^2) \otimes (\mathbb{C}^2 \otimes \mathbb{C}^2)$, and using the singlet/triplet decomposition of §5.4 the allowed states are

$$\underbrace{\Psi_{\text{sym}}(\mathbf{x}_1, \mathbf{x}_2)}_{\text{symmetric space}} \otimes \underbrace{|00\rangle}_{\text{singlet}} \quad \text{or} \quad \underbrace{\Psi_{\text{anti}}(\mathbf{x}_1, \mathbf{x}_2)}_{\text{antisymmetric space}} \otimes \underbrace{|1m\rangle}_{\text{triplet}}.$$

So the spins and the spatial wavefunction are correlated even when the Hamiltonian contains no spin-dependent term whatsoever: *the total spin determines the spatial symmetry, and hence the energy*. This is the mechanism behind magnetism, and behind the structure of the helium spectrum, to which we now turn.

§37.8.3 The Helium Atom

Helium is two electrons bound to a nucleus of charge $Z = 2$. Ignoring spin-dependent forces and treating the nucleus as fixed,

$$H = \underbrace{\frac{\mathbf{P}_1^2}{2m} - \frac{Ze^2}{4\pi\epsilon_0 r_1} + \frac{\mathbf{P}_2^2}{2m} - \frac{Ze^2}{4\pi\epsilon_0 r_2}}_{H_0} + \underbrace{\frac{e^2}{4\pi\epsilon_0 |\mathbf{x}_1 - \mathbf{x}_2|}}_V.$$

Without V the problem separates into two hydrogen-like atoms with $Z = 2$, whose energies are $E_n = -Z^2 \text{Ry}/n^2$ with $\text{Ry} = 13.6 \text{ eV}$. The trouble is that V is not small – it is of the same order as the terms we kept – so we should not expect miracles. Let us see how badly it does.

Example 37.8.4 (The Ground State)

Both electrons in the 1s orbital: the spatial state $\psi_{100}(\mathbf{x}_1)\psi_{100}(\mathbf{x}_2)$ is symmetric, so the spin state must be the singlet, and the Pauli principle is satisfied. The unperturbed energy is

$$E^{(0)} = 2 \times (-Z^2 \text{Ry}) = -8 \text{ Ry} = -108.8 \text{ eV}.$$

The first-order correction is $\langle \Psi | V | \Psi \rangle$, a six-dimensional integral which evaluates to

$$E^{(1)} = \frac{5Z}{8} \cdot \frac{e^2}{4\pi\epsilon_0 a_0} = \frac{5Z}{4} \text{ Ry} = 34.0 \text{ eV},$$

giving $E \approx -74.8 \text{ eV}$ against the measured -79.0 eV . An error of 5% from a perturbation that is not small at all – better than we deserve.

The variational principle does better, and is more illuminating. Take the trial state to be two $1s$ orbitals with an *effective* nuclear charge Z_* treated as a parameter – physically, each electron partially screens the nucleus from the other. Computing $\langle H \rangle$ and minimising gives $Z_* = Z - \frac{5}{16} = 1.6875$ and

$$E_0 \leq -2 \left(Z - \frac{5}{16} \right)^2 \text{ Ry} = -77.5 \text{ eV},$$

within 2% – and with a transparent physical interpretation of the parameter.

Example 37.8.5 (Excited States: Para- and Orthohelium)

Now put one electron in $1s$ and one in some $n\ell$ orbital. The spatial state can be either

$$\Psi_{\pm}(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\sqrt{2}} (\psi_{1s}(\mathbf{x}_1)\psi_{n\ell}(\mathbf{x}_2) \pm \psi_{n\ell}(\mathbf{x}_1)\psi_{1s}(\mathbf{x}_2)),$$

with Ψ_+ (symmetric) paired with the spin singlet and Ψ_- (antisymmetric) with the spin triplet. Historically these two families were thought to be different substances and were named **parahelium** ($S = 0$) and **orthohelium** ($S = 1$).

Their energies differ at first order:

$$\langle \Psi_{\pm} | V | \Psi_{\pm} \rangle = I \pm J,$$

where the *direct* integral I is the ordinary electrostatic repulsion of the two charge clouds and the *exchange* integral is

$$J = \frac{e^2}{4\pi\epsilon_0} \int \frac{\psi_{1s}^*(\mathbf{x}_1)\psi_{n\ell}^*(\mathbf{x}_2)\psi_{n\ell}(\mathbf{x}_1)\psi_{1s}(\mathbf{x}_2)}{|\mathbf{x}_1 - \mathbf{x}_2|} d^3x_1 d^3x_2,$$

which turns out to be positive. So the triplet (orthohelium) lies *below* the singlet (parahelium), by $2J$: aligning the spins lowers the energy, even though the Hamiltonian does not mention spin. The reason is precisely the exchange force of the previous subsection – the antisymmetric spatial state keeps the electrons apart, reducing their repulsion.

Note the striking absence at the bottom right: there is no orthohelium ground state, because a $1s^2$ triplet would need an antisymmetric spatial function built from two identical orbitals, which is zero. The Pauli principle removes a state from the spectrum entirely.

§37.8.4 The Periodic Table

The same principle, applied to heavier atoms, produces chemistry. Model an atom of atomic number Z by Z electrons in hydrogen-like orbitals $|n\ell m\rangle \otimes |m_s\rangle$, and fill them from the bottom, respecting exclusion. Each (n, ℓ) **subshell** holds $2(2\ell + 1)$ electrons – the factor of 2 from spin – and the crucial point is that in a many-electron atom the degeneracy in ℓ is broken (the inner electrons screen the nucleus, and low- ℓ orbitals penetrate the screening cloud more effectively), so subshells fill in the order

$$1s, 2s, 2p, 3s, 3p, 4s, 3d, 4p, \dots$$

Filling $1s$ and then $2s, 2p$ gives the first two rows of the periodic table, of lengths 2 and 8; the closed-shell configurations $Z = 2, 10, 18$ are the noble gases, chemically inert because promoting an electron across the gap to the next shell is expensive. One electron more (lithium, sodium) or one fewer (fluorine, chlorine) than a closed shell gives the alkali metals and halogens, and the whole familiar periodicity follows. Within a subshell, the residual electron–electron interaction is handled by Hund’s rules, of which the first – *maximise the total spin* – is exactly the orthohelium effect above, and the reason that iron is magnetic.

Remark. It is worth pausing on how much rests on the antisymmetry postulate. Were electrons bosons, every atom would have all its electrons in the $1s$ orbital; there would be no chemistry, no periodic table, and no structure to matter. And white dwarf and neutron stars are held up against gravity by *degeneracy pressure*, the purely quantum-statistical resistance of a fermion gas to compression, which is again just exclusion in disguise.

§37.9 Time-Dependent Perturbation Theory

Time-independent perturbation theory answers ‘how are the energy levels shifted?’. But many of the questions we actually want to ask are about *transitions*: an atom in an excited state emits a photon and drops to the ground state; a beam of particles scatters off a target; a system is shaken by an oscillating field and absorbs energy. For these we need a perturbation that depends on time, and a different technology.

The setup is

$$H(t) = H_0 + V(t),$$

with H_0 time-independent and solved, $H_0 |n\rangle = E_n |n\rangle$, and $V(t)$ small.

§37.9.1 The Interaction Picture

The Schrödinger picture puts all the time dependence in the states, the Heisenberg picture all of it in the operators. When the Hamiltonian splits into a big solvable piece and a small piece, the useful compromise is to let H_0 evolve the operators and V evolve the states.

Definition 37.9.1 (Interaction Picture)

Define

$$|\psi(t)\rangle_I = e^{iH_0 t/\hbar} |\psi(t)\rangle_S, \quad A_I(t) = e^{iH_0 t/\hbar} A e^{-iH_0 t/\hbar}.$$

Matrix elements are unchanged, as always, since we have conjugated by a unitary. The point is the equation of motion:

$$i\hbar \frac{d}{dt} |\psi\rangle_I = -H_0 e^{iH_0 t/\hbar} |\psi\rangle_S + e^{iH_0 t/\hbar} (H_0 + V) |\psi\rangle_S = V_I(t) |\psi(t)\rangle_I,$$

where $V_I(t) = e^{iH_0 t/\hbar} V(t) e^{-iH_0 t/\hbar}$. So in the interaction picture the states evolve *only* under the perturbation – the fast, uninteresting evolution due to H_0 has been transformed away. If $V = 0$ then $|\psi\rangle_I$ is constant, and in general it moves slowly, on a timescale set by the size of V . To summarise the three pictures:

Schrödinger:	states move with H ,	operators fixed;
Heisenberg:	states fixed,	operators move with H ;
Interaction:	states move with V_I ,	operators move with H_0 .

§37.9.2 Transition Amplitudes

Suppose the system starts in the eigenstate $|i\rangle$ of H_0 at $t = 0$, and we ask for the probability of finding it in a different eigenstate $|f\rangle$ at time t . Expanding the interaction-picture state in the unperturbed basis,

$$|\psi(t)\rangle_I = \sum_n c_n(t) |n\rangle, \quad c_n(0) = \delta_{ni},$$

and substituting into $i\hbar \frac{d}{dt} |\psi\rangle_I = V_I |\psi\rangle_I$, then projecting onto $\langle f|$:

$$i\hbar \dot{c}_f(t) = \sum_n \langle f|V_I(t)|n\rangle c_n(t) = \sum_n e^{i\omega_{fn}t} V_{fn}(t) c_n(t), \quad \omega_{fn} := \frac{E_f - E_n}{\hbar}.$$

This is exact. To solve it perturbatively, integrate and iterate, starting from the zeroth-order guess $c_n(t) = \delta_{ni}$:

$$c_f(t) = \delta_{fi} - \frac{i}{\hbar} \int_0^t e^{i\omega_{fi}t'} V_{fi}(t') dt' + O(V^2).$$

(Continuing the iteration produces the **Dyson series**, whose k th term is a k -fold time-ordered integral; we shall only need the first.)

Theorem 37.9.2 (First-Order Transition Probability)

For $f \neq i$, the probability of a transition from $|i\rangle$ to $|f\rangle$ after time t is

$$P_{i \rightarrow f}(t) = |c_f(t)|^2 = \frac{1}{\hbar^2} \left| \int_0^t e^{i\omega_{fi}t'} V_{fi}(t') dt' \right|^2 + O(V^3).$$

The structure of this formula rewards a moment's thought: the amplitude is the Fourier component of the perturbation's matrix element at exactly the Bohr frequency ω_{fi} of the transition. A perturbation which contains no frequency component at ω_{fi} causes no transition; and a perturbation acting for a long time is sharply selective in frequency, while a sudden kick contains all frequencies and can excite anything.

§37.9.3 A Constant Perturbation

Take the simplest case: V is switched on at $t = 0$, held constant, and we ask for the transition probability at time t . Then

$$\int_0^t e^{i\omega_{fi}t'} dt' = \frac{e^{i\omega_{fi}t} - 1}{i\omega_{fi}},$$

so, writing $\omega = \omega_{fi}$,

$$P_{i \rightarrow f}(t) = \frac{|V_{fi}|^2}{\hbar^2} \cdot \frac{4 \sin^2(\omega t/2)}{\omega^2} = \frac{|V_{fi}|^2 t^2}{\hbar^2} \text{sinc}^2\left(\frac{\omega t}{2}\right),$$

where $\text{sinc } u = \sin u/u$.

The function is sharply peaked at $\omega_{fi} = 0$, that is at $E_f = E_i$: transitions overwhelmingly conserve energy. But the peak has a finite width $\sim 2\pi/t$ and a finite height $\sim t^2$, so at short times energy need not be conserved exactly – the time–energy uncertainty relation again. The two scalings are important:

- (i) the peak height grows like t^2 , so a transition to a single, exactly resonant final state has a probability growing quadratically – which must eventually fail, since probabilities are bounded by 1;
- (ii) the area under the curve grows like t , since height $\times$ width $\sim t^2 \times t^{-1}$.

It is the second scaling that survives when the final state is not a single level but a continuum, and it gives the linear-in-time behaviour we expect of a decay rate.

§37.9.4 Fermi's Golden Rule

Suppose the final states form a continuum – the ejected electron in the photoelectric effect, the emitted photon in atomic decay, the scattered particle in a collision – described by a **density of states** $\rho(E)$, so that the number of final states with energy in $[E, E+dE]$ is $\rho(E)dE$. Assume the matrix element V_{fi} varies slowly over the narrow band that contributes. Then the total transition probability is

$$P(t) = \int \rho(E_f) \frac{|V_{fi}|^2}{\hbar^2} \cdot \frac{4 \sin^2((E_f - E_i)t/2\hbar)}{((E_f - E_i)/\hbar)^2} dE_f.$$

For large t the sharply peaked factor picks out $E_f = E_i$, and using the standard integral $\int_{-\infty}^{\infty} \frac{\sin^2 au}{u^2} du = \pi|a|$ with $a = t/2\hbar$,

$$\int_{-\infty}^{\infty} \frac{4 \sin^2(\Delta t/2\hbar)}{\Delta^2} d\Delta = \frac{2\pi t}{\hbar},$$

so

$$P(t) = \frac{2\pi t}{\hbar} |V_{fi}|^2 \rho(E_i).$$

Theorem 37.9.3 (Fermi's Golden Rule)

The transition rate from $|i\rangle$ into a continuum of final states at the same energy is

$$\Gamma = \frac{dP}{dt} = \frac{2\pi}{\hbar} |V_{fi}|^2 \rho(E_f) \Big|_{E_f=E_i}.$$

The probability now grows *linearly* in time, at a constant rate – exactly the behaviour of an exponential decay $P_{\text{survive}} = e^{-\Gamma t}$ in its early stages. Note the conditions hiding behind the derivation: t must be long enough for the peak to be narrower than the scale on which ρ and V_{fi} vary, and short enough that $P \ll 1$ so that first-order perturbation theory is valid. There is usually a wide window in which both hold.

Example 37.9.4 (A Harmonic Perturbation)

Most perturbations of interest oscillate – an atom in a light wave feels $V(t) = V e^{-i\omega t} + V^\dagger e^{i\omega t}$. Repeating the calculation, the time integral becomes

$$\int_0^t \left(e^{i(\omega_{fi}-\omega)t'} V_{fi} + e^{i(\omega_{fi}+\omega)t'} (V^\dagger)_{fi} \right) dt',$$

which is large only when $\omega_{fi} = \pm\omega$, that is when

$$E_f = E_i + \hbar\omega \quad (\text{absorption}) \quad \text{or} \quad E_f = E_i - \hbar\omega \quad (\text{stimulated emission}).$$

The golden rule becomes $\Gamma = \frac{2\pi}{\hbar} |V_{fi}|^2 \rho(E_i \pm \hbar\omega)$. So a system absorbs energy from a driving field only in quanta of $\hbar\omega$, and only when a level exists at the right height

– this is the theoretical content of a spectrum, and of Einstein’s B coefficients. Note that the two terms describe processes whose rates are equal: absorption and stimulated emission are equally likely, which is why a population inversion is needed to make a laser.

Remark (Selection Rules Again). Everything is controlled by $V_{fi} = \langle f|V|i\rangle$, and this is where the symmetry arguments of §37.6 pay off. For light interacting with an atom the leading term is the electric dipole $V \propto \mathcal{E} \cdot \mathbf{X}$, so transitions are forbidden unless $\langle f|\mathbf{X}|i\rangle \neq 0$, which by parity and rotational symmetry requires

$$\Delta\ell = \pm 1, \quad \Delta m \in \{0, \pm 1\}.$$

Transitions violating these are not strictly impossible – higher multipole terms in the expansion can allow them – but they are enormously slower, and the corresponding excited states are ‘metastable’. This is why orthohelium, which cannot decay to the parahelium ground state without flipping a spin, is long-lived enough to have been mistaken for a separate substance.

§37.10 Density Operators and Mixed States

Everything so far has assumed that we know which state the system is in. It may be a superposition, but it is a definite vector $|\psi\rangle$. Yet there are two quite different reasons one might be unable to predict the result of a measurement, and only one of them is described by a vector.

The first is intrinsic. A spin in $\frac{1}{\sqrt{2}}(|\uparrow\rangle + |\downarrow\rangle)$ has no definite value of S_z , and no further information about it exists: this is a complete description, and the state *is* an eigenstate of S_x . The second is ordinary classical ignorance. Suppose the laboratory tossed a fair coin and prepared $|\uparrow\rangle$ or $|\downarrow\rangle$ accordingly, without telling us. Measuring S_z now also gives $\pm\frac{\hbar}{2}$ with equal probabilities; but measuring S_x gives $\pm\frac{\hbar}{2}$ with equal probabilities too, whereas in the superposition it gives $+\frac{\hbar}{2}$ with certainty. The two situations are physically different, and no vector in $\mathcal{H}$ describes the second one.

The fix is to enlarge the notion of state slightly, replacing vectors by operators.

§37.10.1 The Density Operator

Definition 37.10.1 (Density Operator)

Suppose a system is prepared in the normalised state $|\psi_i\rangle$ with probability p_i , where $p_i \geq 0$ and $\sum_i p_i = 1$. Such an **ensemble** is described by the **density operator**

$$\rho = \sum_i p_i |\psi_i\rangle \langle \psi_i|.$$

A density operator of the form $\rho = |\psi\rangle \langle \psi|$ is called **pure**; any other is **mixed**.

Note carefully that the $|\psi_i\rangle$ are *not* required to be orthogonal, and that the sum is a sum of *operators*, weighted by classical probabilities – not a superposition of states. A pure state $|\psi\rangle$ is recovered as the ensemble in which one outcome has probability 1, and the projector $|\psi\rangle \langle \psi|$ carries exactly the same information as $|\psi\rangle$ except for the (unphysical) overall phase, which is a small bonus.

Proposition 37.10.2

A density operator satisfies

$$\rho^\dagger = \rho, \quad \rho \geq 0 \text{ (i.e. } \langle \phi | \rho | \phi \rangle \geq 0 \text{ for all } |\phi\rangle), \quad \text{tr } \rho = 1.$$

Conversely, every operator with these three properties is the density operator of some ensemble.

Proof. Each $|\psi_i\rangle \langle \psi_i|$ is Hermitian and positive, with trace $\langle \psi_i | \psi_i \rangle = 1$; the properties follow since the p_i are non-negative reals summing to 1. Conversely, given such a ρ , the spectral decomposition gives $\rho = \sum_n \lambda_n |n\rangle \langle n|$ with $\{|n\rangle\}$ orthonormal, $\lambda_n = \langle n | \rho | n \rangle \geq 0$ and $\sum_n \lambda_n = \text{tr } \rho = 1$: an ensemble. $\square$

So the density operators form a convex set – any probabilistic mixture $t\rho_1 + (1-t)\rho_2$ of density operators is one – whose extreme points, as we are about to see, are exactly the pure states. Everything we can measure is computed from ρ by taking a trace.

Proposition 37.10.3

In the ensemble described by ρ , the expectation value of an observable A is

$$\langle A \rangle_\rho = \text{tr}(\rho A),$$

and a measurement of A returns the eigenvalue λ_n with probability $\text{tr}(\rho P_n)$.

Proof. Using $\text{tr}(|\phi\rangle \langle \psi| A) = \langle \psi | A | \phi \rangle$,

$$\text{tr}(\rho A) = \sum_i p_i \text{tr}(|\psi_i\rangle \langle \psi_i| A) = \sum_i p_i \langle \psi_i | A | \psi_i \rangle,$$

which is the average over the ensemble of the quantum expectation values – exactly what the two layers of uncertainty demand. The second claim is the case $A = P_n$. $\square$

This has an immediate and slightly unsettling consequence: *two ensembles with the same density operator are indistinguishable by any experiment whatsoever*. The decomposition $\rho = \sum_i p_i |\psi_i\rangle \langle \psi_i|$ is therefore not physical data; only ρ is.

Example 37.10.4 (The Same Mixture Twice Over)

Toss a fair coin and prepare $|\uparrow\rangle$ or $|\downarrow\rangle$. Then

$$\rho = \frac{1}{2} |\uparrow\rangle \langle \uparrow| + \frac{1}{2} |\downarrow\rangle \langle \downarrow| = \frac{1}{2} I.$$

Now instead toss a fair coin and prepare $|\rightarrow\rangle = \frac{1}{\sqrt{2}}(|\uparrow\rangle + |\downarrow\rangle)$ or $|\leftarrow\rangle = \frac{1}{\sqrt{2}}(|\uparrow\rangle - |\downarrow\rangle)$. Then

$$\rho' = \frac{1}{2} |\rightarrow\rangle \langle \rightarrow| + \frac{1}{2} |\leftarrow\rangle \langle \leftarrow| = \frac{1}{2} I$$

as well, since the cross terms cancel. The two preparation procedures are completely different, and yet no measurement can tell them apart. This $\rho = \frac{1}{2} I$ is the **maxi-**

mally mixed state of a qubit: every observable has expectation $\frac{1}{2} \text{tr } A$, and every measurement is a fair coin toss.

Proposition 37.10.5 (Purity)

For any density operator $\text{tr}(\rho^2) \leq 1$, with equality if and only if ρ is pure.

Proof. Diagonalise, $\rho = \sum_n \lambda_n |n\rangle \langle n|$. Then $\text{tr} \rho^2 = \sum_n \lambda_n^2 \leq (\sum_n \lambda_n)^2 = 1$, since the λ_n are non-negative and the cross terms are non-negative. Equality forces all but one λ_n to vanish, so $\rho = |n\rangle \langle n|$ for a single n . $\square$

The number $\text{tr} \rho^2$ is called the **purity**, and runs from 1 (pure) down to $1/\dim \mathcal{H}$ (maximally mixed). Equivalently, ρ is pure iff $\rho^2 = \rho$, that is iff ρ is a projector.

Finally, dynamics. If each member of the ensemble evolves by the Schrödinger equation, $|\psi_i(t)\rangle = U(t) |\psi_i(0)\rangle$, then $\rho(t) = U(t)\rho(0)U(t)^\dagger$, and differentiating:

Proposition 37.10.6 (Von Neumann Equation)

$$i\hbar \frac{d\rho}{dt} = [H, \rho].$$

Note the sign, which is *opposite* to Heisenberg's equation of motion $i\hbar \dot{A}_H = [A_H, H]$. There is no contradiction: ρ is a state, not an observable, and it evolves like one. A stationary ρ is one commuting with H – for instance any function of H , which is why the thermal state $\rho \propto e^{-\beta H}$ of Statistical Physics is an equilibrium state.

Measurement is described just as before. If A is measured and the outcome λ_n is observed, then

$$\rho \mapsto \frac{P_n \rho P_n}{\text{tr}(\rho P_n)};$$

and if the measurement is made but the result is discarded – a very natural thing to happen when the ‘apparatus’ is the surrounding environment – then averaging over outcomes with their probabilities gives

$$\rho \mapsto \sum_n P_n \rho P_n,$$

which simply deletes all the off-diagonal blocks of ρ in the eigenbasis of A . This is **decoherence**: an unobserved interaction with the environment turns a superposition into a mixture, destroying the relative phases that produce interference, and it is the reason that large objects are never seen in superpositions of macroscopically distinct states.

Example 37.10.7 (The Qubit and the Bloch Ball)

Any Hermitian 2×2 matrix is a real combination of I and the Pauli matrices, and $\text{tr} \sigma_i = 0$, so the trace condition fixes the coefficient of I :

$$\rho = \frac{1}{2} (I + \mathbf{n} \cdot \boldsymbol{\sigma}), \quad \mathbf{n} \in \mathbb{R}^3.$$

The eigenvalues of $\mathbf{n} \cdot \sigma$ are $\pm|\mathbf{n}|$, so those of ρ are $\frac{1}{2}(1 \pm |\mathbf{n}|)$, and positivity holds exactly when $|\mathbf{n}| \leq 1$. Moreover

$$\langle \mathbf{S} \rangle_\rho = \frac{\hbar}{2} \text{tr}(\rho \sigma) = \frac{\hbar}{2} \mathbf{n}, \quad \text{tr} \rho^2 = \frac{1}{2} (1 + |\mathbf{n}|^2),$$

so $\mathbf{n}$ – the **Bloch vector** – is just the mean spin direction, and ρ is pure precisely when $|\mathbf{n}| = 1$. The states of a qubit therefore fill a solid ball of radius 1, with the pure states of §4.3 on its surface (the Bloch sphere) and the maximally mixed state $\frac{1}{2}I$ at its centre.

§37.10.2 Subsystems and the Reduced Density Operator

The second, and more important, reason density operators are unavoidable is that *a subsystem of a system in a pure state need not itself have a pure state*. This is where the tensor product of §37.5.1 takes its revenge.

Suppose the composite system $\mathcal{H}_1 \otimes \mathcal{H}_2$ is in the state ρ , and we have access only to subsystem 1. The observables available to us are those of the form $A \otimes I$, and we would like a ρ_1 on $\mathcal{H}_1$ reproducing all their expectation values.

Definition 37.10.8 (Partial Trace)

Let $\{|a\rangle_2\}$ be an orthonormal basis of $\mathcal{H}_2$. The **reduced density operator** of subsystem 1 is

$$\rho_1 = \text{tr}_2 \rho := \sum_a (I \otimes \langle a|_2) \rho (I \otimes |a\rangle_2),$$

an operator on $\mathcal{H}_1$, and similarly for $\rho_2 = \text{tr}_1 \rho$.

Proposition 37.10.9

ρ_1 is a density operator on $\mathcal{H}_1$, independent of the basis chosen, and

$$\text{tr}(\rho(A \otimes I)) = \text{tr}(\rho_1 A) \quad \text{for every observable } A \text{ on } \mathcal{H}_1.$$

Proof. Hermiticity and positivity are inherited termwise, and $\text{tr} \rho_1 = \text{tr} \rho = 1$ because tracing over $\mathcal{H}_1$ and then $\mathcal{H}_2$ is the same as tracing over the product. For the

displayed identity, evaluate the full trace in a product basis $|i\rangle_1 |a\rangle_2$:

$$\mathrm{tr}(\rho(A \otimes I)) = \sum_{i,a} \langle i, a | \rho(A \otimes I) | i, a \rangle = \sum_i \langle i | \left(\sum_a \langle a | \rho | a \rangle \right) A | i \rangle = \mathrm{tr}(\rho_1 A).$$

Basis independence follows, since the left-hand side does not mention the basis of $\mathcal{H}_2$. $\square$

Example 37.10.10 (The Singlet)

Let the pair of spins be in the pure singlet state $|00\rangle = \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)$, so

$$\rho = \frac{1}{2} \left(|\uparrow\downarrow\rangle \langle\uparrow\downarrow| - |\uparrow\downarrow\rangle \langle\downarrow\uparrow| - |\downarrow\uparrow\rangle \langle\uparrow\downarrow| + |\downarrow\uparrow\rangle \langle\downarrow\uparrow| \right).$$

Tracing out the second spin with the basis $|\uparrow\rangle_2, |\downarrow\rangle_2$, the two cross terms die (they have orthogonal states in slot 2), and

$$\rho_1 = \frac{1}{2} |\uparrow\rangle \langle\uparrow| + \frac{1}{2} |\downarrow\rangle \langle\downarrow| = \frac{1}{2} I.$$

The first spin is in the *maximally mixed* state: we know everything there is to know about the pair, and nothing whatsoever about either member of it. Its purity is $\frac{1}{2}$, the smallest possible.

This is the sharpest statement of what entanglement is, and it is worth recording.

Proposition 37.10.11

Let $|\Psi\rangle \in \mathcal{H}_1 \otimes \mathcal{H}_2$ be a pure state. Then $|\Psi\rangle$ is a product state if and only if $\rho_1 = \mathrm{tr}_2 |\Psi\rangle \langle\Psi|$ is pure.

Proof. If $|\Psi\rangle = |\psi\rangle \otimes |\omega\rangle$ then $\rho = |\psi\rangle \langle\psi| \otimes |\omega\rangle \langle\omega|$ and $\rho_1 = |\psi\rangle \langle\psi|$, which is pure. Conversely, if $\rho_1 = |\psi\rangle \langle\psi|$ is pure then, expanding $|\Psi\rangle = \sum_i |i\rangle_1 |\chi_i\rangle_2$ in an orthonormal basis of $\mathcal{H}_1$ containing $|\psi\rangle$, one computes $\rho_1 = \sum_{ij} \langle\chi_j|\chi_i\rangle |i\rangle \langle j|$; purity forces every $|\chi_i\rangle$ with $|i\rangle \neq |\psi\rangle$ to vanish, leaving $|\Psi\rangle = |\psi\rangle \otimes |\chi_\psi\rangle$. $\square$

So the mixedness of ρ_1 measures how entangled the pair is, and one can turn this into a number (the *entropy of entanglement*, $-\mathrm{tr} \rho_1 \log \rho_1$), which is the starting point of quantum information theory. For us the important corollary is about signalling.

Proposition 37.10.12 (No Signalling)

Suppose Bob, who holds subsystem 2, applies any unitary to it, or measures any observable on it and does not tell Alice the outcome. Then Alice's reduced state ρ_1 is unchanged.

Proof. For a unitary, $\rho \mapsto (I \otimes U)\rho(I \otimes U^\dagger)$, and taking the partial trace over $\mathcal{H}_2$ we may cycle $U^\dagger$ round to meet U within that factor, giving ρ_1 again. For an unrecorded measurement, $\rho \mapsto \sum_n (I \otimes P_n)\rho(I \otimes P_n)$; cycling in the same way turns this into $\mathrm{tr}_2 [(I \otimes \sum_n P_n)\rho] = \mathrm{tr}_2 \rho = \rho_1$. $\square$

This modest-looking result is what reconciles the rest of this course with special relativity: however strongly two separated systems are correlated, nothing Bob does can alter the statistics of *any* measurement Alice makes. Correlation is not communication. Keep it in mind, because in the next section the correlations are going to look very much like communication indeed.

§37.11 The EPR Paradox and Bell's Inequality

We close by asking what quantum mechanics says about the world, rather than about the outcomes of experiments. The formalism is fixed by now and nothing in it will change; what is at stake is whether it can be regarded as a complete description of reality, or merely as a statistical summary of some deeper theory. Remarkably, this apparently metaphysical question turns out to have an experimental answer.

§37.11.1 The EPR Argument

Prepare two spin- $\frac{1}{2}$ particles in the singlet state

$$|00\rangle = \frac{1}{\sqrt{2}} (|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle),$$

and let them fly apart – to Alice on the left and Bob on the right, arbitrarily far away. Alice measures S_z on her particle. She gets $\pm\frac{\hbar}{2}$ with equal probability; but whatever she gets, she knows with *certainty* that Bob will get the opposite, since the state contains no $|\uparrow\uparrow\rangle$ or $|\downarrow\downarrow\rangle$ term.

Now recall from §5.4 that the singlet is rotationally invariant. Consequently the same argument works along *any* axis: Alice may equally measure S_x , and then predict Bob's S_x with certainty. This is the observation of Einstein, Podolsky and Rosen (1935). Their argument runs as follows.

- (i) *Locality*. Alice's measurement cannot physically affect Bob's distant particle. (The two events can be arranged to be spacelike separated.)
- (ii) *Reality*. 'If, without in any way disturbing a system, we can predict with certainty the value of a physical quantity, then there exists an element of physical reality corresponding to that quantity.'
- (iii) Alice can predict Bob's S_z with certainty, so Bob's S_z has a definite value. She could instead have chosen to predict his S_x , so his S_x has a definite value too. By locality, which choice she makes cannot matter to Bob's particle; so *both* values are real.
- (iv) But no quantum state assigns definite values to both S_x and S_z , since $[S_x, S_z] \neq 0$.

The conclusion EPR drew is that quantum mechanics, while correct as far as it goes, is *incomplete*: there must be additional variables – traditionally written λ and called **hidden variables** – which fix the outcomes of all measurements in advance, and of which the quantum state is only a coarse-grained average. On this view the randomness of quantum mechanics is like the randomness of a coin toss, a statement about our ignorance rather than about the coin.

It is a good argument. Bohr's reply at the time amounted to rejecting (ii), and for thirty years the matter was regarded as a question of taste. What nobody noticed until Bell (1964) was that the two views make *different experimental predictions*.

§37.11.2 Local Hidden Variables and the CHSH Inequality

Let us say exactly what a hidden-variable theory is. Alice chooses a direction $\mathbf{a}$ and measures $\mathbf{a} \cdot \sigma$, getting ± 1 ; Bob chooses $\mathbf{b}$ and gets ± 1 . A **local hidden variable** (LHV) theory posits

- (i) a hidden variable λ , distributed according to some probability density $p(\lambda)$ fixed by the preparation;
- (ii) functions $A(\mathbf{a}, \lambda) = \pm 1$ and $B(\mathbf{b}, \lambda) = \pm 1$ giving the outcomes.

The locality assumption is buried in the notation, and is the whole content of the theorem: A does not depend on $\mathbf{b}$, and B does not depend on $\mathbf{a}$. Alice's outcome is not allowed to know what Bob chose to measure.

The measurable quantity is the **correlation**

$$E(\mathbf{a}, \mathbf{b}) = \int A(\mathbf{a}, \lambda) B(\mathbf{b}, \lambda) p(\lambda) d\lambda,$$

the average of the product of the two outcomes, which is $+1$ for perfect correlation and -1 for perfect anticorrelation.

Theorem 37.11.1 (CHSH Inequality)

In any local hidden variable theory, and for any four directions $\mathbf{a}, \mathbf{a}', \mathbf{b}, \mathbf{b}'$,

$$S := E(\mathbf{a}, \mathbf{b}) - E(\mathbf{a}, \mathbf{b}') + E(\mathbf{a}', \mathbf{b}) + E(\mathbf{a}', \mathbf{b}') \quad \text{satisfies} \quad |S| \leq 2.$$

Proof. Fix λ and abbreviate $A = A(\mathbf{a}, \lambda)$, $A' = A(\mathbf{a}', \lambda)$, $B = B(\mathbf{b}, \lambda)$, $B' = B(\mathbf{b}', \lambda)$, each of which is ± 1 . Then

$$AB - AB' + A'B + A'B' = A(B - B') + A'(B + B').$$

Since $B, B' \in \{\pm 1\}$, either $B = B'$, in which case the first bracket vanishes and the second is ± 2 ; or $B = -B'$, in which case the second vanishes and the first is ± 2 . Either way the whole expression is ± 2 . Averaging over λ with the probability density p , which has total mass 1, gives $|S| \leq 2$. $\square$

The proof is three lines and uses nothing about quantum mechanics – indeed nothing about physics. It says only that if each particle carries with it a predetermined answer to every question it might be asked, then four particular correlations cannot all be large at once. It is very hard to see how any theory of the EPR type could evade it.

§37.11.3 The Quantum Prediction

Now compute the same four numbers in quantum mechanics, in the singlet state.

Proposition 37.11.2

In the singlet state of two spin- $\frac{1}{2}$ particles,

$$E(\mathbf{a}, \mathbf{b}) = \langle (\mathbf{a} \cdot \boldsymbol{\sigma}^{(1)}) (\mathbf{b} \cdot \boldsymbol{\sigma}^{(2)}) \rangle = -\mathbf{a} \cdot \mathbf{b} = -\cos \theta_{ab},$$

where θ_{ab} is the angle between the two directions.

Proof. Write $C_{ij} = \langle \sigma_i^{(1)} \sigma_j^{(2)} \rangle$. The singlet is annihilated by every component of $\mathbf{J} = \mathbf{S}^{(1)} + \mathbf{S}^{(2)}$, so it is invariant under simultaneous rotations of both spins, under which C_{ij} transforms as a rank-two tensor; the only rotationally invariant such tensor is a multiple of δ_{ij} , so $C_{ij} = c \delta_{ij}$. To find c , use $J^2 = 0$:

$$0 = (\mathbf{S}^{(1)} + \mathbf{S}^{(2)})^2 = \frac{3\hbar^2}{4} + \frac{3\hbar^2}{4} + 2\mathbf{S}^{(1)} \cdot \mathbf{S}^{(2)} \implies \mathbf{S}^{(1)} \cdot \mathbf{S}^{(2)} = -\frac{3\hbar^2}{4},$$

that is $\langle \sigma^{(1)} \cdot \sigma^{(2)} \rangle = -3$, so $3c = -3$ and $c = -1$. Hence $E(\mathbf{a}, \mathbf{b}) = a_i b_j C_{ij} = -\mathbf{a} \cdot \mathbf{b}$. $\square$

For those who prefer to see the arithmetic, the joint probabilities are

$$\mathbb{P}(\pm, \pm) = \frac{1}{2} \sin^2 \frac{\theta_{ab}}{2}, \quad \mathbb{P}(\pm, \mp) = \frac{1}{2} \cos^2 \frac{\theta_{ab}}{2},$$

whose difference is $\sin^2 \frac{\theta}{2} - \cos^2 \frac{\theta}{2} = -\cos \theta$, as claimed. At $\theta = 0$ the outcomes are perfectly anticorrelated (the EPR observation), and at $\theta = \pi$ perfectly correlated.

Corollary 37.11.3 (Bell's Theorem)

Quantum mechanics violates the CHSH inequality, and therefore no local hidden variable theory can reproduce its predictions.

Proof. Take all four directions in a plane, at angles $0, \frac{\pi}{2}, \frac{\pi}{4}, \frac{3\pi}{4}$ for $\mathbf{a}, \mathbf{a}', \mathbf{b}, \mathbf{b}'$ respectively. Then $\mathbf{a}$ makes an angle $\frac{\pi}{4}$ with $\mathbf{b}$ and $\frac{3\pi}{4}$ with $\mathbf{b}'$, while $\mathbf{a}'$ makes an angle $\frac{\pi}{4}$ with each of $\mathbf{b}, \mathbf{b}'$. So

$$S = -\cos \frac{\pi}{4} + \cos \frac{3\pi}{4} - \cos \frac{\pi}{4} - \cos \frac{\pi}{4} = -\frac{4}{\sqrt{2}} = -2\sqrt{2},$$

and $|S| = 2\sqrt{2} \approx 2.83 > 2$.

$\square$

The two Stern–Gerlach analysers may be light years apart, and the settings $\mathbf{a}, \mathbf{b}$ chosen at the last moment, so that no signal travelling at or below the speed of light can carry Alice's choice to Bob's apparatus. Yet the correlations between the two columns of ± 1 s are stronger than any pre-agreed strategy could produce. The following picture, of

the correlation as a function of the angle between the settings, shows where the extra strength comes from.

The straight line is the correlation produced by the most obvious hidden-variable model – each pair carries a random direction λ , and each particle answers according to which side of the plane perpendicular to its analyser λ falls on. It agrees with quantum mechanics at $\theta = 0, \frac{\pi}{2}, \pi$ and is wrong in between; and the CHSH combination is precisely designed to probe the region where the cosine bulges away from the line.

§37.11.4 What the Experiments Say

Everything above is theory. The experiment has been done, repeatedly and with increasing care: by Freedman and Clauser (1972), decisively by Aspect and collaborators in the early 1980s using rapidly switched analysers, and in ‘loophole-free’ form in 2015 with the detector settings chosen by fast random number generators at spacelike separation and essentially every photon detected. The answer is unambiguous, and it is $2\sqrt{2}$. Nature violates the CHSH inequality, in quantitative agreement with quantum mechanics; the 2022 Nobel Prize was awarded for this work.

So one of the assumptions of Bell’s theorem is false. Since the derivation used only realism (outcomes determined by λ) and locality (Alice’s outcome does not depend on Bob’s setting), at least one of these must be abandoned. The overwhelmingly standard view is to abandon realism: the outcome of Alice’s measurement simply does not exist before she makes it, and the perfect anticorrelation of the singlet is not explained by a pre-arranged agreement, because there is nothing to arrange. Quantum mechanics is not a statistical approximation to a deeper deterministic theory of the EPR kind.

Three remarks are worth making, to guard against over-interpretation.

Remark (No Signalling, Again). It is tempting to read the violation as instantaneous influence, and thus as a conflict with relativity. It is not, and the reason is the proposition of §37.10: Bob’s reduced density operator is $\frac{1}{2}I$ whatever Alice does, so the statistics he sees are the statistics of a fair coin no matter what she measures or whether she measures at all. The correlations only become visible when the two lists of outcomes are brought together and compared, which requires a classical channel and therefore takes time. Quantum mechanics is *non-local* in the sense that no local hidden variable theory can reproduce it, and yet perfectly *causal*.

Remark (Tsirelson’s Bound). Quantum mechanics does not violate CHSH as much as it logically could: a hypothetical theory with $\mathbb{P}(\text{same}) = 1$ or 0 chosen at will would give $|S| = 4$ while still forbidding signalling. That quantum mechanics stops at $|S| \leq 2\sqrt{2}$ – Tsirelson’s bound, which follows from $(\mathbf{a} \cdot \boldsymbol{\sigma})^2 = I$ and a short calculation – is a genuine and somewhat mysterious feature of the theory.

Remark (Entanglement as a Resource). Modern quantum information theory takes exactly the correlations that troubled Einstein and puts them to work: they are what makes quantum key distribution secure, and what makes teleportation and superdense coding possible. This is the subject of the Part II course Quantum Information and Computation, and it is a fine advertisement for taking the formalism seriously rather than apologising for it.

It is a good place to stop. We began by throwing away the wavefunction in favour of a vector in a Hilbert space, and found that almost everything – the oscillator spectrum, the quantisation of angular momentum, the existence of spin, conservation laws, degeneracies, selection rules – follows from a handful of commutators and the representation theory they generate. We end with the discovery that this abstract structure is not merely a convenient calculus but a statement about the world, and one which the world has been measured to obey.

38 Probability and Measure

Measure theory is the machinery that makes ‘size’ – length, area, volume, probability – into something we can actually do analysis with. The Riemann integral of Analysis I is a perfectly serviceable tool for integrating continuous functions on a closed interval, but it is fragile: it does not interact well with limits, the space of Riemann integrable functions is not complete, and it has nothing whatsoever to say about integration over abstract spaces. Lebesgue’s insight was that if one is willing to work harder at the front end – assigning a measure to sets before integrating functions – then the integral one gets at the back end is enormously more robust.

Probability theory is where this pays off most spectacularly. Kolmogorov’s observation, in 1933, was that a probability is nothing more than a measure of total mass one, a random variable is nothing more than a measurable function, and an expectation is nothing more than an integral. Once one accepts this dictionary, the great limit theorems of probability – the strong law of large numbers, the central limit theorem – become theorems about the convergence of integrals, and the tools of measure theory apply directly. In this course we will build the theory from the ground up and then spend the second half cashing it in.

This article constitutes my notes for the ‘Probability and Measure’ course, held in Michaelmas 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§38.1 Introduction

Let us begin by seeing what goes wrong with the integral we already have, because the shape of the fix is visible in the shape of the failure.

Recall from Analysis I that a bounded function $f : [a, b] \rightarrow \mathbb{R}$ is Riemann integrable if the supremum of the lower sums equals the infimum of the upper sums, where the sums are taken over partitions of $[a, b]$ into finitely many intervals. The essential move is to *chop up the domain* into small intervals and, on each one, to pretend that f is constant. That is a good idea when f is continuous, since then f really is nearly constant on small intervals. It is a terrible idea otherwise.

Example 38.1.1 (The indicator of the rationals)

Let $f = \mathbb{1}_{\mathbb{Q} \cap [0, 1]}$, so $f(x) = 1$ if x is rational and 0 otherwise. On every subinterval of $[0, 1]$, however small, f takes both the value 0 and the value 1. So every lower sum is 0 and every upper sum is 1, and f is not Riemann integrable.

But morally the answer ought to be 0: the rationals are a countable set, they are ‘negligible’ in $[0, 1]$, and f is zero off a negligible set. The Riemann integral has no way to express this thought.

The deeper problem is that the Riemann integral behaves badly under limits. Enumerate $\mathbb{Q} \cap [0, 1]$ as $q_1, q_2, \dots$ and let $f_n = \mathbb{1}_{\{q_1, \dots, q_n\}}$. Each f_n is Riemann integrable with integral

0, and $f_n \uparrow f$ pointwise, and yet the limit is not integrable at all. Any theorem of the form ‘if $f_n \rightarrow f$ then $\int f_n \rightarrow \int f$ ’ must, for the Riemann integral, carry hypotheses strong enough (uniform convergence, say) to rule out most of the situations one actually meets.

Lebesgue’s alternative is to *chop up the range* instead. If $f \geq 0$, then instead of asking ‘how much does f vary on $[x_i, x_{i+1}]$?’ we ask ‘how big is the set on which f exceeds y ?’.

Writing μ for ‘size’, we would like to say something like

$$\int f \approx \sum_j y_j \mu(\{x : y_j \leq f(x) < y_{j+1}\}),$$

approximating f from below by functions taking finitely many values. The point is that the sets $\{y_j \leq f < y_{j+1}\}$ are allowed to be horrible – they need not be intervals, or finite unions of intervals, or anything one can draw – provided only that we can assign them a size.

So the plan for the first third of the course is forced upon us. We must decide which sets get a size (§2), we must decide which functions are compatible with that assignment (§3), and only then can we build the integral (§4). It is worth saying at the outset that the first of these steps is the hard one, and that it cannot be done perfectly: we will prove in §2 that there is no way to assign a length to *every* subset of $\mathbb{R}$ in a translation-invariant, countably additive way. Some sets must be left out. Deciding exactly which ones is the content of the Carathéodory extension theorem, and it will occupy us for a while.

§38.2 Measures

§38.2.1 Set systems

Throughout, E is a non-empty set, and we write $\mathcal{P}(E)$ for its power set. We want to specify a family of subsets of E – the sets to which we are prepared to assign a size – and we want that family to be closed under the operations we expect to perform. The right notion is the following.

Definition 38.2.1 (σ -algebra)

A collection $\mathcal{E} \subseteq \mathcal{P}(E)$ is a **σ -algebra** on E if

- (i) $\emptyset \in \mathcal{E}$;
- (ii) $A \in \mathcal{E}$ implies $A^c = E \setminus A \in \mathcal{E}$;
- (iii) if $(A_n)_{n \in \mathbb{N}}$ is a sequence in $\mathcal{E}$ then $\bigcup_n A_n \in \mathcal{E}$.

The pair $(E, \mathcal{E})$ is then called a **measurable space**, and the elements of $\mathcal{E}$ are called **measurable sets**.

Note that $E = \emptyset^c \in \mathcal{E}$, and that by De Morgan

$$\bigcap_n A_n = \left(\bigcup_n A_n^c \right)^c \in \mathcal{E},$$

so σ -algebras are closed under countable intersections as well as countable unions; and $B \setminus A = B \cap A^c \in \mathcal{E}$, so they are closed under set difference too. The prefix σ is there to record the fact that we allow *countable* unions, and this is exactly the right amount of infinity: finite unions are too weak to say anything about limits, and uncountable unions would be far too strong (every subset of $\mathbb{R}$ is an uncountable union of singletons).

Example 38.2.2 (Two extreme examples)

The collection $\{\emptyset, E\}$ is a σ -algebra, the smallest one. The power set $\mathcal{P}(E)$ is a σ -algebra, the largest one. Neither is very useful on its own: the first is too coarse to distinguish anything, and we will see that the second is too fine to admit a sensible notion of length on $\mathbb{R}$.

In practice one rarely writes down a σ -algebra explicitly. Instead one specifies a handful of sets one certainly wants to be measurable, and takes the smallest σ -algebra containing them.

Definition 38.2.3 (Generated σ -algebra)

Let $\mathcal{A} \subseteq \mathcal{P}(E)$. The **σ -algebra generated by $\mathcal{A}$** is

$$\sigma(\mathcal{A}) = \bigcap \{ \mathcal{E} : \mathcal{E} \text{ is a } \sigma\text{-algebra on } E, \mathcal{A} \subseteq \mathcal{E} \}.$$

This is well defined because $\mathcal{P}(E)$ is a σ -algebra containing $\mathcal{A}$, so the intersection is over a non-empty family; and an arbitrary intersection of σ -algebras is easily checked to be a σ -algebra. By construction $\sigma(\mathcal{A})$ is the smallest σ -algebra containing $\mathcal{A}$.

Definition 38.2.4 (Borel σ -algebra)

Let (E, τ) be a topological space. The **Borel σ -algebra** on E is $\mathcal{B}(E) = \sigma(\tau)$, the σ -algebra generated by the open sets. Its elements are the **Borel sets**. We abbreviate $\mathcal{B} = \mathcal{B}(\mathbb{R})$.

The Borel σ -algebra on $\mathbb{R}$ contains every open set, every closed set, every countable intersection of open sets, every countable union of those, and so on – one really does have to work to write down a subset of $\mathbb{R}$ that is not Borel. (We will manage it, with the help of the axiom of choice, in §2.7.)

Example 38.2.5 (Generators of $\mathcal{B}$)

Each of the following families generates $\mathcal{B}$:

$$\{(a, b) : a < b\}, \quad \{(a, b] : a < b\}, \quad \{(-\infty, y] : y \in \mathbb{R}\}, \quad \{(q, r) : q < r, q, r \in \mathbb{Q}\}.$$

For the last of these: every open subset of $\mathbb{R}$ is a countable union of rational intervals,

so $\sigma(\{(q, r)\}) \supseteq \tau$ and hence contains $\mathcal{B}$; and each (q, r) is open, so the reverse containment holds too. For the third, $(-\infty, y] = \bigcap_n (-\infty, y + 1/n)$ is Borel, and conversely $(a, b) = \bigcup_n ((-\infty, b - 1/n] \setminus (-\infty, a])$.

Working directly with σ -algebras is unpleasant, because the countable operations make it hard to verify anything by hand. It is much more comfortable to work with systems closed only under finitary operations, and then to bootstrap. The following two definitions give the finitary systems that we will use as generators.

Definition 38.2.6 (Ring and algebra)

A collection $\mathcal{A} \subseteq \mathcal{P}(E)$ is a **ring** on E if $\emptyset \in \mathcal{A}$ and, for all $A, B \in \mathcal{A}$, both $B \setminus A \in \mathcal{A}$ and $A \cup B \in \mathcal{A}$.

It is an **algebra** on E if $\emptyset \in \mathcal{A}$ and, for all $A, B \in \mathcal{A}$, both $A^c \in \mathcal{A}$ and $A \cup B \in \mathcal{A}$.

Remark. Every algebra is a ring, since $B \setminus A = (B^c \cup A)^c$. The converse fails: a ring need not contain E itself. For instance the finite unions of bounded intervals of the form $(a, b]$ form a ring on $\mathbb{R}$ but not an algebra. Rings are closed under intersection, because $A \cap B = (A \cup B) \setminus ((A \setminus B) \cup (B \setminus A))$, and hence under symmetric difference as well.

The following triviality gets used so often that it deserves a name.

Proposition 38.2.7 (Disjointification)

Let $\mathcal{A}$ be a ring and let $A_1, A_2, \dots \in \mathcal{A}$. Then there are pairwise disjoint $B_1, B_2, \dots \in \mathcal{A}$ with $B_n \subseteq A_n$ and

$$\bigcup_{n \leq N} A_n = \bigcup_{n \leq N} B_n \quad \text{for every } N,$$

and consequently $\bigcup_n A_n = \bigcup_n B_n$.

Proof. Set $B_1 = A_1$ and $B_{n+1} = A_{n+1} \setminus (A_1 \cup \dots \cup A_n)$, which lies in $\mathcal{A}$ since rings are closed under finite unions and differences. These are disjoint, and an easy induction gives the displayed identity. $\square$

§38.2.2 Measures

We can now say what a size function is.

Definition 38.2.8 (Measure)

Let $(E, \mathcal{E})$ be a measurable space. A **measure** on $(E, \mathcal{E})$ is a function $\mu : \mathcal{E} \rightarrow [0, \infty]$ such that $\mu(\emptyset) = 0$ and, for every sequence $(A_n)_{n \in \mathbb{N}}$ of *pairwise disjoint* sets in $\mathcal{E}$,

$$\mu\left(\bigcup_{n \in \mathbb{N}} A_n\right) = \sum_{n \in \mathbb{N}} \mu(A_n).$$

This last property is **countable additivity**. The triple $(E, \mathcal{E}, \mu)$ is a **measure space**.

We allow the value $+\infty$; the sum on the right is a sum of non-negative terms, so it converges in $[0, \infty]$ regardless of order, and there is no ambiguity. A measure is **finite** if $\mu(E) < \infty$, and **σ -finite** if $E = \bigcup_n E_n$ for some $E_n \in \mathcal{E}$ with $\mu(E_n) < \infty$. It is a **probability measure** if $\mu(E) = 1$.

Example 38.2.9 (Counting measure and Dirac measure)

On $(E, \mathcal{P}(E))$, define $\mu(A) = |A|$ if A is finite and ∞ otherwise. This is the **counting measure**. Fix $x \in E$ and define $\delta_x(A) = 1$ if $x \in A$ and 0 otherwise; this is the **Dirac measure** at x , a probability measure.

Remark. If E is countable and $\mathcal{E} = \mathcal{P}(E)$, then any measure is determined by its values on singletons: $\mu(A) = \sum_{x \in A} \mu(\{x\})$ by countable additivity. This is exactly the notion of a probability mass function from IA Probability. It is the uncountable case that requires all the machinery.

Countable additivity is a strong assumption, and it immediately gives us the properties we would expect of a notion of size.

Proposition 38.2.10 (Basic properties of measures)

Let $(E, \mathcal{E}, \mu)$ be a measure space and let $A, B, A_n \in \mathcal{E}$.

- (i) (Monotonicity) If $A \subseteq B$ then $\mu(A) \leq \mu(B)$.
- (ii) (Countable subadditivity) $\mu(\bigcup_n A_n) \leq \sum_n \mu(A_n)$.
- (iii) (Continuity from below) If $A_n \uparrow A$, meaning $A_1 \subseteq A_2 \subseteq \dots$ and $A = \bigcup_n A_n$, then $\mu(A_n) \rightarrow \mu(A)$.
- (iv) (Continuity from above) If $A_n \downarrow A$ and $\mu(A_1) < \infty$, then $\mu(A_n) \rightarrow \mu(A)$.

Proof. (i) Write $B = A \sqcup (B \setminus A)$; then $\mu(B) = \mu(A) + \mu(B \setminus A) \geq \mu(A)$.

(ii) Disjointify as in Proposition 38.2.7 to get disjoint $B_n \subseteq A_n$ with the same union. Then

$$\mu\left(\bigcup_n A_n\right) = \mu\left(\bigsqcup_n B_n\right) = \sum_n \mu(B_n) \leq \sum_n \mu(A_n)$$

using monotonicity in the last step.

(iii) Set $B_1 = A_1$ and $B_{n+1} = A_{n+1} \setminus A_n$; these are disjoint with $\bigcup_{n \leq N} B_n = A_N$ and $\bigcup_n B_n = A$. So

$$\mu(A) = \sum_{n=1}^{\infty} \mu(B_n) = \lim_{N \rightarrow \infty} \sum_{n=1}^N \mu(B_n) = \lim_{N \rightarrow \infty} \mu(A_N).$$

(iv) Apply (iii) to $A_1 \setminus A_n \uparrow A_1 \setminus A$. This gives $\mu(A_1) - \mu(A_n) \rightarrow \mu(A_1) - \mu(A)$, and since $\mu(A_1) < \infty$ we may cancel. $\square$

The finiteness hypothesis in (iv) is genuinely needed: with μ the counting measure on $\mathbb{N}$ and $A_n = \{n, n+1, \dots\}$ we have $A_n \downarrow \emptyset$ but $\mu(A_n) = \infty$ for every n .

We will eventually want to build measures by prescribing them on some convenient family of sets and extending. For that we need to talk about functions defined on families that

are not σ -algebras.

Definition 38.2.11 (Set function)

Let $\mathcal{A} \subseteq \mathcal{P}(E)$ with $\emptyset \in \mathcal{A}$. A **set function** on $\mathcal{A}$ is a map $\mu : \mathcal{A} \rightarrow [0, \infty]$ with $\mu(\emptyset) = 0$. We call μ

- (i) **increasing** if $\mu(A) \leq \mu(B)$ whenever $A \subseteq B$ with $A, B \in \mathcal{A}$;
- (ii) **additive** if $\mu(A \cup B) = \mu(A) + \mu(B)$ whenever $A, B \in \mathcal{A}$ are disjoint and $A \cup B \in \mathcal{A}$;
- (iii) **countably additive** if $\mu(\bigcup_n A_n) = \sum_n \mu(A_n)$ whenever the $A_n \in \mathcal{A}$ are pairwise disjoint and $\bigcup_n A_n \in \mathcal{A}$;
- (iv) **countably subadditive** if $\mu(\bigcup_n A_n) \leq \sum_n \mu(A_n)$ whenever $A_n \in \mathcal{A}$ and $\bigcup_n A_n \in \mathcal{A}$.

On a ring, countable additivity implies all of the others, by exactly the arguments of Proposition 38.2.10. A measure is precisely a countably additive set function on a σ -algebra.

§38.2.3 π -systems, d -systems and Dynkin's lemma

Here is the difficulty we are about to face repeatedly. We will want to prove that two measures agree on a σ -algebra $\mathcal{E}$, knowing only that they agree on some generating family $\mathcal{A}$. The natural strategy is to consider $\mathcal{D} = \{A : \mu_1(A) = \mu_2(A)\}$ and show it is a σ -algebra containing $\mathcal{A}$. Unfortunately $\mathcal{D}$ is *not* obviously a σ -algebra: additivity gives us nothing about $\mu_i(A \cup B)$ when A and B overlap. What $\mathcal{D}$ is closed under is proper differences and increasing limits. This motivates the following.

Definition 38.2.12 (π -system)

A collection $\mathcal{A} \subseteq \mathcal{P}(E)$ is a **π -system** if $\emptyset \in \mathcal{A}$ and $A, B \in \mathcal{A}$ implies $A \cap B \in \mathcal{A}$.

Definition 38.2.13 (d -system)

A collection $\mathcal{D} \subseteq \mathcal{P}(E)$ is a **d -system** (or Dynkin system) if

- (i) $E \in \mathcal{D}$;
- (ii) if $B_1, B_2 \in \mathcal{D}$ with $B_1 \subseteq B_2$, then $B_2 \setminus B_1 \in \mathcal{D}$;
- (iii) if $A_n \in \mathcal{D}$ with $A_n \uparrow A$, then $A \in \mathcal{D}$.

The point of the pair of definitions is that they are complementary: neither alone is a σ -algebra, but together they are.

**Proposition 38.2.14**

A collection which is both a π -system and a d -system is a σ -algebra.

Proof. Let $\mathcal{D}$ be both. Then $E \in \mathcal{D}$, and taking $B_1 = A$, $B_2 = E$ in (ii) gives $A^c \in \mathcal{D}$; in particular $\emptyset = E^c \in \mathcal{D}$. For countable unions, let $A_n \in \mathcal{D}$. Since $\mathcal{D}$ is a π -system and is closed under complements, it is closed under finite unions:

$$A \cup B = (A^c \cap B^c)^c \in \mathcal{D}.$$

So $\tilde{A}_N = A_1 \cup \dots \cup A_N \in \mathcal{D}$, and $\tilde{A}_N \uparrow \bigcup_n A_n$, whence $\bigcup_n A_n \in \mathcal{D}$ by (iii). $\square$

The engine of the whole subject is now the following lemma, which says that to check a property holds on $\sigma(\mathcal{A})$ it is enough to check that the class of sets with that property is a d -system, provided $\mathcal{A}$ is a π -system.

Lemma 38.2.15 (Dynkin's lemma)

Let $\mathcal{A}$ be a π -system. Then any d -system containing $\mathcal{A}$ contains $\sigma(\mathcal{A})$.

Proof. Let $\mathcal{D}$ be the intersection of all d -systems containing $\mathcal{A}$; one checks immediately that an intersection of d -systems is a d -system, so $\mathcal{D}$ is the smallest d -system containing $\mathcal{A}$, and it suffices to show $\sigma(\mathcal{A}) \subseteq \mathcal{D}$. By Proposition 38.2.14 it is enough to show that $\mathcal{D}$ is a π -system, for then $\mathcal{D}$ is a σ -algebra containing $\mathcal{A}$ and hence contains $\sigma(\mathcal{A})$.

The trick is to do this in two steps. First set

$$\mathcal{D}' = \{B \in \mathcal{D} : B \cap A \in \mathcal{D} \text{ for all } A \in \mathcal{A}\}.$$

We claim $\mathcal{D}'$ is a d -system. Certainly $E \in \mathcal{D}'$, since $E \cap A = A \in \mathcal{A} \subseteq \mathcal{D}$. If $B_1 \subseteq B_2$ both lie in $\mathcal{D}'$ then for $A \in \mathcal{A}$,

$$(B_2 \setminus B_1) \cap A = (B_2 \cap A) \setminus (B_1 \cap A),$$

a proper difference of elements of $\mathcal{D}$, hence in $\mathcal{D}$; so $B_2 \setminus B_1 \in \mathcal{D}'$. If $B_n \uparrow B$ with $B_n \in \mathcal{D}'$ then $B_n \cap A \uparrow B \cap A$, so $B \cap A \in \mathcal{D}$ and $B \in \mathcal{D}'$. Finally $\mathcal{A} \subseteq \mathcal{D}'$, precisely because $\mathcal{A}$ is a π -system. By minimality of $\mathcal{D}$ we get $\mathcal{D} \subseteq \mathcal{D}'$, and the reverse inclusion is by definition, so $\mathcal{D}' = \mathcal{D}$.

Now set

$$\mathcal{D}'' = \{B \in \mathcal{D} : B \cap A \in \mathcal{D} \text{ for all } A \in \mathcal{D}\}.$$

Exactly the same three verifications show $\mathcal{D}''$ is a d -system. And $\mathcal{A} \subseteq \mathcal{D}''$: for $A \in \mathcal{A}$ and $B \in \mathcal{D} = \mathcal{D}'$ we have $B \cap A \in \mathcal{D}$, which is what membership of A in $\mathcal{D}''$ requires. So again $\mathcal{D}'' = \mathcal{D}$ by minimality, and this says exactly that $\mathcal{D}$ is closed under intersections. $\square$

The first payoff is immediate.

Theorem 38.2.16 (Uniqueness of extension)

Let $(E, \mathcal{E})$ be a measurable space and let μ_1, μ_2 be measures on it. Suppose $\mathcal{A} \subseteq \mathcal{E}$ is a π -system with $\sigma(\mathcal{A}) = \mathcal{E}$, that $\mu_1 = \mu_2$ on $\mathcal{A}$, and that $E \in \mathcal{A}$ with $\mu_1(E) = \mu_2(E) < \infty$. Then $\mu_1 = \mu_2$ on $\mathcal{E}$.

Proof. Let $\mathcal{D} = \{A \in \mathcal{E} : \mu_1(A) = \mu_2(A)\}$. By hypothesis $\mathcal{A} \subseteq \mathcal{D}$, so by Dynkin's lemma it suffices to show $\mathcal{D}$ is a d -system.

We have $E \in \mathcal{D}$ by assumption. If $B_1 \subseteq B_2$ lie in $\mathcal{D}$ then, using additivity and the finiteness of $\mu_i(B_1) \leq \mu_i(E) < \infty$ to justify the subtraction,

$$\mu_1(B_2 \setminus B_1) = \mu_1(B_2) - \mu_1(B_1) = \mu_2(B_2) - \mu_2(B_1) = \mu_2(B_2 \setminus B_1),$$

so $B_2 \setminus B_1 \in \mathcal{D}$. Finally if $A_n \uparrow A$ with $A_n \in \mathcal{D}$, then by continuity from below

$$\mu_1(A) = \lim_n \mu_1(A_n) = \lim_n \mu_2(A_n) = \mu_2(A),$$

so $A \in \mathcal{D}$. $\square$

Remark. The finiteness assumption cannot be dropped outright – take μ_1 counting measure and $\mu_2 = 2\mu_1$ on $(\mathbb{R}, \mathcal{B})$, which agree (both being ∞) on the π -system of non-empty open intervals. But it can be relaxed to σ -finiteness: if $E = \bigcup_n E_n$ with $E_n \in \mathcal{A}$ increasing and $\mu_1(E_n) = \mu_2(E_n) < \infty$, apply the theorem to $A \mapsto \mu_i(A \cap E_n)$ for each n and let $n \rightarrow \infty$. We will use it in this form for Lebesgue measure.

§38.2.4 The Carathéodory extension theorem

We now come to the existence half of the story. The situation we have in mind is this: on the ring $\mathcal{A}$ of finite unions of half-open intervals $(a, b] \subseteq \mathbb{R}$, there is an obvious candidate for length, namely the sum of the lengths of the intervals. We would like to promote it to a measure on $\sigma(\mathcal{A}) = \mathcal{B}$. Carathéodory's theorem says that this is always possible, provided the candidate is countably additive on the ring to begin with.

Theorem 38.2.17 (Carathéodory extension theorem)

Let $\mathcal{A}$ be a ring on E and let μ be a countably additive set function on $\mathcal{A}$. Then μ extends to a measure on $\sigma(\mathcal{A})$.

The proof is long but the idea is simple and worth stating first. We define an *outer measure* μ^* on *all* subsets of E by covering them as efficiently as possible with sets from $\mathcal{A}$. This μ^* is defined everywhere but is only subadditive, not additive. We then cut down to the class $\mathcal{M}$ of sets which ‘split every set additively’, and show that on this class μ^* is a genuine measure and that $\mathcal{M} \supseteq \mathcal{A}$ – hence $\mathcal{M} \supseteq \sigma(\mathcal{A})$, and we are done.

Proof. For $B \subseteq E$ define the **outer measure**

$$\mu^*(B) = \inf \left\{ \sum_{n \in \mathbb{N}} \mu(A_n) : A_n \in \mathcal{A}, B \subseteq \bigcup_{n \in \mathbb{N}} A_n \right\},$$

with the convention $\mu^*(B) = \infty$ if no such countable cover exists. Note $\mu^*(\emptyset) = 0$ and μ^* is increasing. Define the **μ^* -measurable sets**

$$\mathcal{M} = \{A \subseteq E : \mu^*(B) = \mu^*(B \cap A) + \mu^*(B \cap A^c) \text{ for all } B \subseteq E\}.$$

We proceed in five steps.

Step 1: μ^* is countably subadditive on $\mathcal{P}(E)$. Let $B \subseteq \bigcup_n B_n$; we must show

$$\mu^*(B) \leq \sum_n \mu^*(B_n). \quad (\dagger)$$

We may assume every $\mu^*(B_n) < \infty$. Fix $\varepsilon > 0$. For each n , choose $A_{n,m} \in \mathcal{A}$ with $B_n \subseteq \bigcup_m A_{n,m}$ and

$$\sum_m \mu(A_{n,m}) \leq \mu^*(B_n) + \varepsilon 2^{-n}.$$

Then $\{A_{n,m}\}_{n,m}$ is a countable cover of B by elements of $\mathcal{A}$, so

$$\mu^*(B) \leq \sum_{n,m} \mu(A_{n,m}) \leq \sum_n \mu^*(B_n) + \varepsilon.$$

As $\varepsilon > 0$ was arbitrary, $(\dagger)$ holds.

Step 2: μ^* extends μ . Let $A \in \mathcal{A}$. Covering A by $A, \emptyset, \emptyset, \dots$ gives $\mu^*(A) \leq \mu(A)$. Conversely, suppose $A \subseteq \bigcup_n A_n$ with $A_n \in \mathcal{A}$. Then $A = \bigcup_n (A \cap A_n)$ is a countable union of elements of $\mathcal{A}$; since μ is countably additive on the ring $\mathcal{A}$ it is countably subadditive there, so

$$\mu(A) \leq \sum_n \mu(A \cap A_n) \leq \sum_n \mu(A_n).$$

Taking the infimum over covers, $\mu(A) \leq \mu^*(A)$.

Step 3: $\mathcal{A} \subseteq \mathcal{M}$. Let $A \in \mathcal{A}$ and $B \subseteq E$. The inequality $\mu^*(B) \leq \mu^*(B \cap A) + \mu^*(B \cap A^c)$ is immediate from $(\dagger)$. For the reverse, we may assume $\mu^*(B) < \infty$. Fix $\varepsilon > 0$ and choose $A_n \in \mathcal{A}$ with $B \subseteq \bigcup_n A_n$ and $\sum_n \mu(A_n) \leq \mu^*(B) + \varepsilon$. Now $B \cap A \subseteq \bigcup_n (A_n \cap A)$ and $B \cap A^c \subseteq \bigcup_n (A_n \setminus A)$, and both $A_n \cap A$ and $A_n \setminus A$ lie in the ring $\mathcal{A}$. Hence

$$\begin{aligned} \mu^*(B \cap A) + \mu^*(B \cap A^c) &\leq \sum_n \mu(A_n \cap A) + \sum_n \mu(A_n \setminus A) \\ &= \sum_n [\mu(A_n \cap A) + \mu(A_n \setminus A)] = \sum_n \mu(A_n) \leq \mu^*(B) + \varepsilon, \end{aligned}$$

using additivity of μ on $\mathcal{A}$. Let $\varepsilon \rightarrow 0$.

Step 4: $\mathcal{M}$ is an algebra. That $\emptyset \in \mathcal{M}$ is clear, and the definition of $\mathcal{M}$ is symmetric in A and A^c , so $\mathcal{M}$ is closed under complements. For intersections, let

$A_1, A_2 \in \mathcal{M}$ and $B \subseteq E$. Applying the defining identity for A_1 and then for A_2 (with test set $B \cap A_1$),

$$\mu^*(B) = \mu^*(B \cap A_1 \cap A_2) + \mu^*(B \cap A_1 \cap A_2^c) + \mu^*(B \cap A_1^c).$$

Now observe $A_1 \cap A_2^c = (A_1 \cap A_2)^c \cap A_1$ and $A_1^c = (A_1 \cap A_2)^c \cap A_1^c$, so the last two terms are

$$\mu^*(B \cap (A_1 \cap A_2)^c \cap A_1) + \mu^*(B \cap (A_1 \cap A_2)^c \cap A_1^c) = \mu^*(B \cap (A_1 \cap A_2)^c),$$

using that $A_1 \in \mathcal{M}$ with test set $B \cap (A_1 \cap A_2)^c$. Hence

$$\mu^*(B) = \mu^*(B \cap (A_1 \cap A_2)) + \mu^*(B \cap (A_1 \cap A_2)^c),$$

so $A_1 \cap A_2 \in \mathcal{M}$.

Step 5: $\mathcal{M}$ is a σ -algebra and μ^* is a measure on it. Let $A = \bigcup_n A_n$ with $A_n \in \mathcal{M}$; by Step 4 and disjointification we may assume the A_n are disjoint. Let $B \subseteq E$. Applying the defining identity repeatedly and using disjointness (so that $B \cap A_1^c \cap A_2 = B \cap A_2$, and so on),

$$\begin{aligned} \mu^*(B) &= \mu^*(B \cap A_1) + \mu^*(B \cap A_1^c) \\ &= \mu^*(B \cap A_1) + \mu^*(B \cap A_2) + \mu^*(B \cap A_1^c \cap A_2^c) \\ &= \cdots = \sum_{n \leq N} \mu^*(B \cap A_n) + \mu^*\left(B \cap \bigcap_{n \leq N} A_n^c\right). \end{aligned}$$

Since $\bigcap_{n \leq N} A_n^c \supseteq A^c$ and μ^* is increasing, the last term is at least $\mu^*(B \cap A^c)$. Letting $N \rightarrow \infty$,

$$\mu^*(B) \geq \sum_{n=1}^{\infty} \mu^*(B \cap A_n) + \mu^*(B \cap A^c) \geq \mu^*(B \cap A) + \mu^*(B \cap A^c),$$

the last step by (†). The reverse inequality is (†) again, so $A \in \mathcal{M}$ and $\mathcal{M}$ is a σ -algebra. Moreover, taking $B = A$ in the display above gives

$$\mu^*(A) \geq \sum_{n=1}^{\infty} \mu^*(A_n),$$

and the reverse holds by subadditivity, so μ^* is countably additive on $\mathcal{M}$.

Combining Steps 3 and 5, $\mathcal{M}$ is a σ -algebra containing $\mathcal{A}$, so $\sigma(\mathcal{A}) \subseteq \mathcal{M}$; and by Step 2 the measure $\mu^*|_{\sigma(\mathcal{A})}$ extends μ . $\square$

Remark. The class $\mathcal{M}$ is generally strictly larger than $\sigma(\mathcal{A})$. In the case of Lebesgue measure on $\mathbb{R}$ it is the class of **Lebesgue measurable** sets, and one can show

$$\mathcal{M} = \{A \cup N : A \in \mathcal{B}, N \subseteq B \text{ for some } B \in \mathcal{B} \text{ with } \mu(B) = 0\} \supsetneq \mathcal{B}.$$

In words, $\mathcal{M}$ is obtained from $\mathcal{B}$ by throwing in all subsets of null sets; it is the **completion** of $\mathcal{B}$. There is no harm in working with $\mathcal{B}$ throughout, and it is more convenient, so we shall.

§38.2.5 Lebesgue measure

We can now build the measure that started it all. The construction on $\mathbb{R}$ is the substantial one; higher dimensions will follow painlessly from the theory of product measures in §5.

Theorem 38.2.18 (Lebesgue measure on $\mathbb{R}$)

There is a unique Borel measure μ on $\mathbb{R}$ with

$$\mu((a, b]) = b - a \quad \text{for all } a < b.$$

We call μ **Lebesgue measure**.

Proof. Let $\mathcal{A}$ consist of $\emptyset$ together with all sets of the form

$$A = (a_1, b_1] \cup \cdots \cup (a_n, b_n]$$

with the intervals disjoint and $-\infty < a_i < b_i < \infty$. This $\mathcal{A}$ is a ring: the difference and union of two such sets is again such a set. It is also a π -system, and $\sigma(\mathcal{A}) = \mathcal{B}$, since every open interval $(a, b) = \bigcup_n (a, b - 1/n]$ lies in $\sigma(\mathcal{A})$ and the open intervals generate $\mathcal{B}$.

Define $\mu(A) = \sum_{i=1}^n (b_i - a_i)$ for A as above. This is well defined: if $A = \bigsqcup_j C_j = \bigsqcup_k D_k$ are two such representations then, writing $C_j = \bigsqcup_k (C_j \cap D_k)$ and $D_k = \bigsqcup_j (C_j \cap D_k)$ and using additivity of length on intervals,

$$\sum_j \text{len}(C_j) = \sum_j \sum_k \text{len}(C_j \cap D_k) = \sum_k \sum_j \text{len}(C_j \cap D_k) = \sum_k \text{len}(D_k).$$

Additivity of μ on $\mathcal{A}$ is then clear.

To apply Carathéodory we must upgrade additivity to *countable* additivity on $\mathcal{A}$. For a finitely additive set function on a ring, countable additivity is equivalent to the statement that $\mu(A_n) \rightarrow 0$ whenever $A_n \in \mathcal{A}$ with $A_n \downarrow \emptyset$. (Indeed, if $\bigsqcup_n B_n = B \in \mathcal{A}$ then $A_N = B \setminus \bigsqcup_{n \leq N} B_n \downarrow \emptyset$ and $\mu(B) = \sum_{n \leq N} \mu(B_n) + \mu(A_N)$.) So suppose for contradiction that $B_n \in \mathcal{A}$ with $B_n \downarrow \emptyset$ but $\mu(B_n) \geq 2\varepsilon$ for all n , for some $\varepsilon > 0$.

The idea is to shrink each B_n slightly to a set whose closure is still inside B_n , and then use compactness. Write $B_n = \bigsqcup_{i=1}^{N_n} (a_{ni}, b_{ni}]$ and put

$$C_n = \bigsqcup_{i=1}^{N_n} \left(a_{ni} + \frac{2^{-n}\varepsilon}{N_n}, b_{ni} \right] \in \mathcal{A},$$

so that $\overline{C_n} \subseteq B_n$ and $\mu(B_n \setminus C_n) \leq 2^{-n}\varepsilon$. Since the B_n decrease, $B_N = \bigcap_{n \leq N} B_n$, and so

$$B_N \setminus (C_1 \cap \cdots \cap C_N) = \bigcup_{n \leq N} (B_N \setminus C_n) \subseteq \bigcup_{n \leq N} (B_n \setminus C_n),$$

giving $\mu(B_N \setminus (C_1 \cap \cdots \cap C_N)) \leq \sum_{n \leq N} 2^{-n}\varepsilon \leq \varepsilon$. As $\mu(B_N) \geq 2\varepsilon$, additivity forces

$$\mu(C_1 \cap \cdots \cap C_N) \geq \varepsilon > 0,$$

so in particular $C_1 \cap \cdots \cap C_N \neq \emptyset$ for every N . Setting $K_N = \overline{C_1} \cap \cdots \cap \overline{C_N}$, we obtain a decreasing sequence of non-empty compact subsets of $\mathbb{R}$, so by the finite intersection property there is $x \in \bigcap_N K_N$. But $K_N \subseteq \overline{C_N} \subseteq B_N$, so $x \in \bigcap_N B_N = \emptyset$, a contradiction. Hence μ is countably additive on $\mathcal{A}$, and Carathéodory gives a measure on $\sigma(\mathcal{A}) = \mathcal{B}$ extending it.

For uniqueness, suppose μ, λ are two Borel measures assigning length $b - a$ to $(a, b]$. For each $n \in \mathbb{Z}$ the measures $A \mapsto \mu(A \cap (n, n+1])$ and $A \mapsto \lambda(A \cap (n, n+1])$ are finite measures of total mass 1 agreeing on the π -system $\mathcal{A}$, so they agree on $\mathcal{B}$ by Theorem 38.2.16. Summing over $n \in \mathbb{Z}$ and using countable additivity, $\mu = \lambda$. $\square$

Definition 38.2.19 (Null set)

A set $N \in \mathcal{E}$ with $\mu(N) = 0$ is called **μ -null**. A property is said to hold **μ -almost everywhere** (abbreviated a.e.) if the set where it fails is contained in a null set.

Example 38.2.20 (Countable sets are Lebesgue null)

For $x \in \mathbb{R}$ we have $\{x\} = \bigcap_n (x - 1/n, x]$, a decreasing intersection of sets of finite measure, so by continuity from above $\mu(\{x\}) = \lim_n 1/n = 0$. Hence any countable set is null, being a countable union of null sets. In particular $\mu(\mathbb{Q}) = 0$, and

$$\mu((a, b)) = \mu([a, b]) = \mu((a, b]) = b - a.$$

Not every null set is countable: the Cantor middle-thirds set is uncountable and has measure $\lim_n (2/3)^n = 0$.

Proposition 38.2.21 (Translation invariance)

For $x \in \mathbb{R}$ and $B \in \mathcal{B}$ we have $B + x \in \mathcal{B}$ and $\mu(B + x) = \mu(B)$.

Proof. The map $y \mapsto y - x$ is a homeomorphism of $\mathbb{R}$, so $B \mapsto B + x$ preserves $\mathcal{B}$. Define $\mu_x(B) = \mu(B + x)$. This is a Borel measure and $\mu_x((a, b]) = \mu((a + x, b + x]) = b - a$. By the uniqueness in Theorem 38.2.18, $\mu_x = \mu$. $\square$

Since Lebesgue measure is the unique translation-invariant Borel measure normalised by $\mu((0, 1]) = 1$, translation invariance is really the defining property, and it is what we will exploit in the next subsection to show that not every set can be measured.

§38.2.6 Measures from distribution functions

Before that, it is worth recording that essentially the same construction gives every reasonable measure on $\mathbb{R}$ at once. Recall that a Borel measure μ on a Hausdorff space E is called a **Radon measure** if $\mu(K)$ is finite for every compact set $K \subseteq E$. Note that compact subsets of a Hausdorff space are closed, and hence Borel.

Lemma 38.2.22 (Generalised inverse)

Let $g : \mathbb{R} \rightarrow \mathbb{R}$ be non-decreasing and right-continuous, and put

$$g(-\infty) = \lim_{y \rightarrow -\infty} g(y), \quad g(+\infty) = \lim_{y \rightarrow \infty} g(y).$$

On the open interval $I = (g(-\infty), g(+\infty))$ define

$$f(x) = \inf\{y \in \mathbb{R} : x \leq g(y)\}.$$

Then f is non-decreasing and left-continuous, and for $x \in I$, $y \in \mathbb{R}$,

$$f(x) \leq y \iff x \leq g(y).$$

Proof. Let $J_x = \{y \in \mathbb{R} : x \leq g(y)\}$. Since $x > g(-\infty)$ the set J_x is bounded below, and since $x < g(+\infty)$ it is non-empty; so $f(x) \in \mathbb{R}$. If $y \in J_x$ and $y' \geq y$ then $y' \in J_x$ as g is non-decreasing, so J_x is an up-set. If $y_n \downarrow y$ with $y_n \in J_x$, then $x \leq g(y_n) \rightarrow g(y)$ by right-continuity, so $y \in J_x$. Hence J_x is closed and $J_x = [f(x), \infty)$, which is exactly the stated equivalence.

If $x \leq x'$ then $J_x \supseteq J_{x'}$, so $f(x) \leq f(x')$. If $x_n \uparrow x$ then $J_x = \bigcap_n J_{x_n}$, so $f(x_n) \uparrow f(x)$, giving left-continuity. $\square$

Theorem 38.2.23 (Lebesgue–Stieltjes measures)

Let $g : \mathbb{R} \rightarrow \mathbb{R}$ be non-decreasing and right-continuous. Then there is a unique Radon measure μ_g on $\mathbb{R}$ with

$$\mu_g((a, b]) = g(b) - g(a) \quad (a < b),$$

and every Radon measure on $\mathbb{R}$ arises this way.

Proof. The construction of Theorem 38.2.18 goes through verbatim with $b - a$ replaced by $g(b) - g(a)$, right-continuity of g being exactly what is needed to make the shrinking argument work. Alternatively – and this is the slicker route – let f be the generalised inverse of Lemma 38.2.22. For $z \in \mathbb{R}$,

$$f^{-1}((-\infty, z]) = \{x \in I : f(x) \leq z\} = \{x \in I : x \leq g(z)\} = I \cap (-\infty, g(z)],$$

which is Borel; since the sets $(-\infty, z]$ generate $\mathcal{B}$, the map f is measurable (see §3.1). Let μ be Lebesgue measure restricted to I and set $\mu_g = \mu \circ f^{-1}$. This is a measure, and

$$\mu_g((a, b]) = \mu(\{x : a < f(x) \leq b\}) = \mu(\{x : g(a) < x \leq g(b)\}) = g(b) - g(a).$$

Uniqueness follows as before. Any compact set lies in some $[a, b]$, whose measure $g(b) - g(a)$ is finite, so μ_g is Radon.

Conversely, given a Radon measure ν on $\mathbb{R}$, define $g(y) = \nu((0, y])$ for $y \geq 0$ and $g(y) = -\nu((y, 0])$ for $y < 0$. Then g is non-decreasing, right-continuous by continuity from above, and $\nu((a, b]) = g(b) - g(a)$ by additivity; uniqueness gives $\nu = \mu_g$. $\square$

We call g the **Stieltjes distribution function** of μ_g . Taking $g(y) = y$ recovers Lebesgue measure; taking $g = \mathbb{1}_{[x, \infty)}$ recovers the Dirac measure δ_x . When μ_g is a probability

measure this g is exactly the distribution function of a random variable, as we will see in §3.

§38.2.7 A non-measurable set

We now show that our caution was justified: one cannot extend Lebesgue measure to all of $\mathcal{P}(\mathbb{R})$. The construction is due to Vitali and uses the axiom of choice in an essential way.

Work on $E = (0, 1]$ with addition modulo 1; concretely, identify E with the circle $\mathbb{R}/\mathbb{Z}$. Lebesgue measure restricted to E is invariant under this addition: for $B \subseteq E$ Borel and $x \in E$, the set $B \oplus x$ is a translate of $B \cap (0, 1 - x]$ union a translate of $B \cap (1 - x, 1]$, and both pieces keep their measure.

Let $Q = E \cap \mathbb{Q}$, a countable subgroup of $(E, \oplus)$. Define $x \sim y$ iff $x - y \in Q$; this is an equivalence relation, whose classes are the cosets $x \oplus Q$. By the axiom of choice, pick one representative from each class and let S be the resulting set. Then

$$E = \bigsqcup_{q \in Q} (S \oplus q),$$

a *disjoint* union: every $x \in E$ lies in the class of exactly one representative, and if $S \oplus q$ met $S \oplus q'$ with $q \neq q'$ then S would contain two representatives of the same class.

Theorem 38.2.24 (Vitali)

The set S is not Lebesgue measurable. Consequently there is no translation-invariant measure defined on all of $\mathcal{P}((0, 1])$ giving the whole space measure 1.

Proof. Suppose S were measurable with $\mu(S) = c$. Each translate $S \oplus q$ is then measurable with the same measure c , and by countable additivity

$$1 = \mu(E) = \sum_{q \in Q} \mu(S \oplus q) = \sum_{q \in Q} c.$$

If $c = 0$ the sum is 0; if $c > 0$ the sum is ∞ (as Q is infinite). Either way we cannot get 1, a contradiction. $\square$

Remark. One can go further. Assuming the continuum hypothesis, a theorem of Banach and Kuratowski says that there is *no* measure at all on $\mathcal{P}((0, 1])$ with $\mu((0, 1]) = 1$ and $\mu(\{x\}) = 0$ for every x – translation invariance is not even needed. So the restriction to a σ -algebra is not an artefact of our construction; it is unavoidable.

§38.2.8 Probability spaces and independence

Everything we have done so far specialises to probability by the simple device of normalising the total mass.

Definition 38.2.25 (Probability space)

A measure space $(E, \mathcal{E}, \mu)$ with $\mu(E) = 1$ is a **probability space**. We change notation to $(\Omega, \mathcal{F}, \mathbb{P})$ and call Ω the **sample space**, elements of $\mathcal{F}$ **events**, and $\mathbb{P}$ the **probability measure**.

Kolmogorov's axioms of probability, as laid down in 1933, say precisely that $\mathbb{P}(\Omega) = 1$, that $0 \leq \mathbb{P}(A) \leq 1$, and that $\mathbb{P}$ is countably additive. So a probability space is nothing more than a measure space of total mass one – there is no new content, only new vocabulary. The reader who recalls the continuity properties of $\mathbb{P}$ from IA Probability will recognise Proposition 38.2.10 as the general form of those results.

Definition 38.2.26 (Independence)

Events $(A_i)_{i \in I}$ in $\mathcal{F}$ are **independent** if for every finite $J \subseteq I$,

$$\mathbb{P}\left(\bigcap_{j \in J} A_j\right) = \prod_{j \in J} \mathbb{P}(A_j).$$

Sub- σ -algebras $(\mathcal{A}_i)_{i \in I}$ of $\mathcal{F}$ are **independent** if, whenever $J \subseteq I$ is finite and $A_j \in \mathcal{A}_j$ for $j \in J$, the events $(A_j)_{j \in J}$ are independent.

Checking independence of σ -algebras directly is hopeless, but Dynkin's lemma reduces it to a check on generators.

Proposition 38.2.27

Let $\mathcal{A}_1, \mathcal{A}_2$ be π -systems contained in $\mathcal{F}$ with $\Omega \in \mathcal{A}_1 \cap \mathcal{A}_2$. Suppose

$$\mathbb{P}(A_1 \cap A_2) = \mathbb{P}(A_1)\mathbb{P}(A_2) \quad \text{for all } A_1 \in \mathcal{A}_1, A_2 \in \mathcal{A}_2.$$

Then $\sigma(\mathcal{A}_1)$ and $\sigma(\mathcal{A}_2)$ are independent.

Proof. Fix $A_2 \in \mathcal{A}_2$ and consider the two finite measures $B \mapsto \mathbb{P}(B \cap A_2)$ and $B \mapsto \mathbb{P}(B)\mathbb{P}(A_2)$ on $\sigma(\mathcal{A}_1)$. They agree on the π -system $\mathcal{A}_1$ and have the same total mass $\mathbb{P}(A_2)$, so by Theorem 38.2.16 they agree on $\sigma(\mathcal{A}_1)$. Now fix $B \in \sigma(\mathcal{A}_1)$ and repeat the argument in the second coordinate: the measures $C \mapsto \mathbb{P}(B \cap C)$ and $C \mapsto \mathbb{P}(B)\mathbb{P}(C)$ agree on the π -system $\mathcal{A}_2$, hence on $\sigma(\mathcal{A}_2)$. $\square$

§38.2.9 The Borel–Cantelli lemmas

Given a sequence of events (A_n) , two sets naturally record its asymptotic behaviour.

Definition 38.2.28 (Limsup and liminf of events)

For $A_n \in \mathcal{F}$ we define

$$\limsup_n A_n = \bigcap_n \bigcup_{m \geq n} A_m = \{A_n \text{ i.o.}\}, \quad \liminf_n A_n = \bigcup_n \bigcap_{m \geq n} A_m = \{A_n \text{ ev.}\}.$$

Unwinding the quantifiers: $\omega \in \limsup_n A_n$ iff for every n there is some $m \geq n$ with $\omega \in A_m$, that is, iff ω lies in infinitely many of the A_n . Similarly $\omega \in \liminf_n A_n$ iff ω lies in all but finitely many. Both sets are in $\mathcal{F}$.

The picture to keep in mind is the one above: draw Ω horizontally, draw each A_n at height n , and a point ω belongs to $\limsup_n A_n$ exactly when the vertical line through ω meets infinitely many of the segments. The two Borel–Cantelli lemmas give complementary criteria for whether this happens.

Lemma 38.2.29 (First Borel–Cantelli lemma)

Let (A_n) be events with $\sum_n \mathbb{P}(A_n) < \infty$. Then $\mathbb{P}(A_n \text{ i.o.}) = 0$.

Proof. For every n ,

$$\mathbb{P}\left(\bigcap_k \bigcup_{m \geq k} A_m\right) \leq \mathbb{P}\left(\bigcup_{m \geq n} A_m\right) \leq \sum_{m \geq n} \mathbb{P}(A_m),$$

and the right-hand side is the tail of a convergent series, so tends to 0 as $n \rightarrow \infty$. $\square$

Note that this proof never used $\mathbb{P}(\Omega) = 1$; the lemma holds for an arbitrary measure μ in place of $\mathbb{P}$, and we will use it in that generality.

Lemma 38.2.30 (Second Borel–Cantelli lemma)

Let (A_n) be *independent* events with $\sum_n \mathbb{P}(A_n) = \infty$. Then $\mathbb{P}(A_n \text{ i.o.}) = 1$.

Proof. Fix n . By independence and the elementary inequality $1 - a \leq e^{-a}$,

$$\mathbb{P}\left(\bigcap_{m=n}^N A_m^c\right) = \prod_{m=n}^N (1 - \mathbb{P}(A_m)) \leq \exp\left(-\sum_{m=n}^N \mathbb{P}(A_m)\right) \rightarrow 0$$

as $N \rightarrow \infty$, since the series diverges. The sets $\bigcap_{m=n}^N A_m^c$ decrease to $\bigcap_{m \geq n} A_m^c$ as

$N \rightarrow \infty$, so $\mathbb{P}(\bigcap_{m \geq n} A_m^c) = 0$ for every n . Hence

$$\mathbb{P}((A_n \text{ i.o.})^c) = \mathbb{P}\left(\bigcup_n \bigcap_{m \geq n} A_m^c\right) \leq \sum_n \mathbb{P}\left(\bigcap_{m \geq n} A_m^c\right) = 0. \quad \square$$

The two lemmas together are a remarkably sharp tool: for independent events, $\mathbb{P}(A_n \text{ i.o.})$ is 0 or 1 according to whether $\sum_n \mathbb{P}(A_n)$ converges or diverges, with no intermediate case. Here is a typical application, which we can state now and will be able to re-derive later.

Example 38.2.31 (Records of exponential variables)

Let (X_n) be independent with $\mathbb{P}(X_1 > x) = e^{-x}$ for $x \geq 0$, and let $\alpha > 0$. Put $A_n = \{X_n \geq \alpha \log n\}$, so $\mathbb{P}(A_n) = n^{-\alpha}$. Then $\sum_n \mathbb{P}(A_n) < \infty$ iff $\alpha > 1$. By the two lemmas, for every $\varepsilon > 0$,

$$\mathbb{P}\left(\frac{X_n}{\log n} \geq 1 \text{ i.o.}\right) = 1, \quad \mathbb{P}\left(\frac{X_n}{\log n} \geq 1 + \varepsilon \text{ i.o.}\right) = 0.$$

Combining, $\limsup_n X_n / \log n = 1$ almost surely. So the record values of an i.i.d. exponential sequence grow exactly logarithmically.

§38.3 Measurable Functions and Random Variables

§38.3.1 Measurable functions

Having decided which sets we can measure, we must decide which functions respect that structure. As always in mathematics, the right notion of morphism is the one that pulls structure back.

Definition 38.3.1 (Measurable function)

Let $(E, \mathcal{E})$ and $(G, \mathcal{G})$ be measurable spaces. A function $f : E \rightarrow G$ is **$\mathcal{E}$ - $\mathcal{G}$ measurable** (or just **measurable**) if

$$f^{-1}(A) \in \mathcal{E} \quad \text{for every } A \in \mathcal{G}.$$

When $G = \mathbb{R}$ with $\mathcal{G} = \mathcal{B}$, we simply say f is measurable; when in addition E is a topological space and $\mathcal{E} = \mathcal{B}(E)$, we say f is **Borel measurable**. Note the analogy with continuity, which is the statement that preimages of open sets are open.

The saving grace is that measurability can be checked on generators, because preimages commute with all the set operations: $f^{-1}(A^c) = f^{-1}(A)^c$ and $f^{-1}(\bigcup_n A_n) = \bigcup_n f^{-1}(A_n)$.

Lemma 38.3.2 (Measurability on generators)

Let $\mathcal{G} = \sigma(\mathcal{A})$. If $f^{-1}(A) \in \mathcal{E}$ for every $A \in \mathcal{A}$, then f is measurable.

Proof. The collection $\{A \subseteq G : f^{-1}(A) \in \mathcal{E}\}$ is a σ -algebra on G , by the displayed identities. It contains $\mathcal{A}$ by hypothesis, hence contains $\sigma(\mathcal{A}) = \mathcal{G}$. $\square$

Example 38.3.3 (Useful special cases) (i) A function $f : (E, \mathcal{E}) \rightarrow \mathbb{R}$ is measurable if and only if $\{x : f(x) \leq y\} \in \mathcal{E}$ for every $y \in \mathbb{R}$, since the sets $(-\infty, y]$ generate $\mathcal{B}$.

(ii) If E is a topological space with $\mathcal{E} = \mathcal{B}(E)$ and $f : E \rightarrow \mathbb{R}$ is continuous, then f is measurable: preimages of open sets are open, hence Borel, and open sets generate $\mathcal{B}$.

(iii) The indicator $\mathbb{1}_A$ is measurable if and only if $A \in \mathcal{E}$, since $\mathbb{1}_A^{-1}(\{1\}) = A$.

Proposition 38.3.4 (Stability of measurability)

Let $f, g, f_n : (E, \mathcal{E}) \rightarrow \mathbb{R}$ be measurable and $\lambda \in \mathbb{R}$. Then the following are measurable:

$$f+g, \quad fg, \quad \lambda f, \quad \max(f, g), \quad \min(f, g), \quad \inf_n f_n, \quad \sup_n f_n, \quad \liminf_n f_n, \quad \limsup_n f_n,$$

the last four taking values in $[-\infty, \infty]$. Moreover the composition of measurable functions is measurable.

Proof. Composition is immediate: $(g \circ f)^{-1}(A) = f^{-1}(g^{-1}(A))$.

For the supremum, $\{\sup_n f_n \leq y\} = \bigcap_n \{f_n \leq y\} \in \mathcal{E}$; for the infimum, $\{\inf_n f_n < y\} = \bigcup_n \{f_n < y\} \in \mathcal{E}$. Then $\liminf_n f_n = \sup_n \inf_{m \geq n} f_m$ and $\limsup_n f_n = \inf_n \sup_{m \geq n} f_m$ are measurable, and $\max, \min$ of two functions are special cases.

For sums, note $\{f + g > y\} = \bigcup_{q \in \mathbb{Q}} (\{f > q\} \cap \{g > y - q\}) \in \mathcal{E}$. For products, $fg = \frac{1}{4}[(f + g)^2 - (f - g)^2]$, so it suffices to know h^2 is measurable when h is, and this follows from $\{h^2 \leq y\} = \{-\sqrt{y} \leq h \leq \sqrt{y}\}$ for $y \geq 0$. $\square$

That last proposition is worth pausing over. It says that measurability – unlike continuity, or differentiability, or Riemann integrability – is preserved under *pointwise limits*. This is exactly the robustness we were missing, and it is the reason the Lebesgue theory has the convergence theorems it does.

We single out the functions which will serve as building blocks.

Definition 38.3.5 (Simple function)

A function $f : (E, \mathcal{E}) \rightarrow \mathbb{R}$ is **simple** if it can be written as

$$f = \sum_{k=1}^m a_k \mathbb{1}_{A_k}, \quad a_k \geq 0, \quad A_k \in \mathcal{E}, \quad m \in \mathbb{N}.$$

Equivalently, f is measurable, non-negative, and takes only finitely many values.

The following approximation is the single most used construction in the course; we will refer to it as *the standard approximation*.

Proposition 38.3.6 (Approximation by simple functions)

Let $f : (E, \mathcal{E}) \rightarrow [0, \infty]$ be measurable. Define

$$f_n = 2^{-n} \lfloor 2^n f \rfloor \wedge n = \sum_{j=0}^{n2^n-1} \frac{j}{2^n} \mathbb{1}_{A_{n,j}} + n \mathbb{1}_{\{f \geq n\}}, \quad A_{n,j} = f^{-1} \left(\left[\frac{j}{2^n}, \frac{j+1}{2^n} \right) \right).$$

Then each f_n is simple, $0 \leq f_n \leq f_{n+1} \leq f$, and $f_n \rightarrow f$ pointwise. If f is bounded the convergence is uniform, with $\|f - f_n\|_\infty \leq 2^{-n}$ once $n > \|f\|_\infty$.

Proof. Each $A_{n,j}$ lies in $\mathcal{E}$ by measurability of f , so f_n is simple. Monotonicity in n holds because refining the mesh from 2^{-n} to $2^{-(n+1)}$ can only increase the value of $\lfloor \cdot \rfloor$ -rounding downwards, and because the truncation level n increases. If $f(x) < \infty$ then for $n > f(x)$ we have $0 \leq f(x) - f_n(x) \leq 2^{-n}$, and if $f(x) = \infty$ then $f_n(x) = n \rightarrow \infty$. $\square$

The picture shows the staircase f_n sitting underneath f . Everything we prove about the integral will be proved first for simple functions, where it is a finite computation, and then transported to general non-negative f along this staircase using the monotone convergence theorem.

§38.3.2 The monotone class theorem

Dynkin's lemma has a functional analogue which will let us prove statements about all bounded measurable functions by checking them only on indicators of a π -system.

Theorem 38.3.7 (Monotone class theorem)

Let $\mathcal{A}$ be a π -system generating $\mathcal{E}$, with $E \in \mathcal{A}$. Let $\mathcal{V}$ be a vector space of bounded functions $E \rightarrow \mathbb{R}$ such that

- (i) $\mathbb{1}_E \in \mathcal{V}$ and $\mathbb{1}_A \in \mathcal{V}$ for all $A \in \mathcal{A}$;
- (ii) if $f_n \in \mathcal{V}$ are non-negative with $f_n \uparrow f$ pointwise and f is bounded, then $f \in \mathcal{V}$.

Then $\mathcal{V}$ contains every bounded measurable function $f : (E, \mathcal{E}) \rightarrow \mathbb{R}$.

Proof. Let $\mathcal{D} = \{A \in \mathcal{E} : \mathbb{1}_A \in \mathcal{V}\}$. Then $E \in \mathcal{D}$ and $\mathcal{A} \subseteq \mathcal{D}$. If $A \subseteq B$ with $A, B \in \mathcal{D}$ then $\mathbb{1}_{B \setminus A} = \mathbb{1}_B - \mathbb{1}_A \in \mathcal{V}$ since $\mathcal{V}$ is a vector space. If $A_n \uparrow A$ with $A_n \in \mathcal{D}$ then $\mathbb{1}_{A_n} \uparrow \mathbb{1}_A$, which is bounded, so $\mathbb{1}_A \in \mathcal{V}$ by (ii). Hence $\mathcal{D}$ is a d -system containing the π -system $\mathcal{A}$, and Dynkin's lemma gives $\mathcal{D} = \mathcal{E}$.

Now let f be bounded, measurable and non-negative, and let f_n be its standard approximation from Proposition 38.3.6. Each f_n is a finite non-negative linear

combination of indicators of sets in $\mathcal{E} = \mathcal{D}$, hence lies in $\mathcal{V}$; and $f_n \uparrow f$ with f bounded, so $f \in \mathcal{V}$ by (ii). For general bounded measurable f , write $f = f^+ - f^-$ with $f^\pm = \max(\pm f, 0)$ bounded, measurable and non-negative; both lie in $\mathcal{V}$, hence so does f . $\square$

§38.3.3 Image measures and random variables

A measurable function transports a measure forwards.

Definition 38.3.8 (Image measure)

Let $f : (E, \mathcal{E}) \rightarrow (G, \mathcal{G})$ be measurable and μ a measure on $(E, \mathcal{E})$. The **image measure** (or pushforward) is

$$(\mu \circ f^{-1})(A) = \mu(f^{-1}(A)), \quad A \in \mathcal{G}.$$

That this is a measure is immediate: preimages preserve disjointness and commute with countable unions.

Definition 38.3.9 (Random variable)

Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space and $(E, \mathcal{E})$ a measurable space. An **E -valued random variable** is a measurable map $X : (\Omega, \mathcal{F}) \rightarrow (E, \mathcal{E})$. When $E = \mathbb{R}$ (or $\mathbb{R}^d$) with the Borel σ -algebra we simply say **random variable** (or random vector).

The **law** or **distribution** of X is the image measure $\mu_X = \mathbb{P} \circ X^{-1}$, a probability measure on $(E, \mathcal{E})$.

We also write $\sigma(X) = \{X^{-1}(A) : A \in \mathcal{E}\}$, the σ -algebra *generated by* X ; it is the smallest σ -algebra on Ω making X measurable, and morally it encodes exactly the information one learns by observing X .

Definition 38.3.10 (Distribution function)

For a real-valued random variable X , the **distribution function** is

$$F_X(z) = \mu_X((-\infty, z]) = \mathbb{P}(X \leq z).$$

Since the intervals $(-\infty, z]$ form a π -system generating $\mathcal{B}$, and μ_X is a probability measure, Theorem 38.2.16 tells us that F_X determines μ_X completely. From the properties of measures we read off that F_X is non-decreasing, right-continuous (by continuity from above), with $F_X(z) \rightarrow 0$ as $z \rightarrow -\infty$ and $F_X(z) \rightarrow 1$ as $z \rightarrow \infty$. Conversely, given any such F , Lemma 38.2.22 produces a random variable with that distribution function: take $(\Omega, \mathcal{F}, \mathbb{P}) = ((0, 1), \mathcal{B}((0, 1)), \mu)$ and $X(\omega) = \inf\{x : \omega \leq F(x)\}$, so that $\mathbb{P}(X \leq z) = \mu(\{\omega : \omega \leq F(z)\}) = F(z)$. This is the *inverse transform* construction familiar from simulation.

Definition 38.3.11 (Independent random variables)

A family $(X_i)_{i \in I}$ of random variables on $(\Omega, \mathcal{F}, \mathbb{P})$ is **independent** if the σ -algebras $\sigma(X_i)$ are independent.

For real-valued X_i the sets $\{X_i \leq x\}$ form a π -system generating $\sigma(X_i)$, so by Proposition 38.2.27 (extended to finitely many systems in the obvious way) independence is equivalent to

$$\mathbb{P}(X_1 \leq x_1, \dots, X_n \leq x_n) = \prod_{i=1}^n \mathbb{P}(X_i \leq x_i)$$

for all finite subfamilies and all $x_i \in \mathbb{R}$. This is the criterion one actually uses.

§38.3.4 Constructing independent random variables

It is not obvious that an infinite sequence of independent random variables with prescribed laws exists at all. Happily, one probability space suffices for everything: the unit interval with Lebesgue measure.

Take $(\Omega, \mathcal{F}, \mathbb{P}) = ((0, 1), \mathcal{B}((0, 1)), \mu)$. Every $\omega \in (0, 1)$ has a binary expansion $\omega = \sum_{n \geq 1} \omega_n 2^{-n}$, unique if we forbid expansions ending in all 1s. Define the **Rademacher functions**

$$R_n(\omega) = \omega_n \in \{0, 1\}.$$

Each R_n is a finite sum of indicators of dyadic intervals, hence measurable, and $\mathbb{P}(R_n = 1) = \mathbb{P}(R_n = 0) = 1/2$. For any $x_1, \dots, x_n \in \{0, 1\}$, the event $\{R_1 = x_1, \dots, R_n = x_n\}$ is a single dyadic interval of length 2^{-n} , so

$$\mathbb{P}(R_1 = x_1, \dots, R_n = x_n) = 2^{-n} = \prod_{i=1}^n \mathbb{P}(R_i = x_i),$$

and the R_n are independent Bernoulli(1/2) variables.

Now take a bijection $m : \mathbb{N}^2 \rightarrow \mathbb{N}$ and set $Y_{n,k} = R_{m(n,k)}$; these are again independent. Define

$$Y_n = \sum_{k=1}^{\infty} 2^{-k} Y_{n,k},$$

which converges everywhere. The Y_n are independent, being functions of disjoint subfamilies of the R_m . Moreover each Y_n is uniform on $(0, 1)$: for the dyadic intervals $(i2^{-m}, (i+1)2^{-m}]$, which form a π -system generating $\mathcal{B}((0, 1))$,

$$\mathbb{P}(Y_n \in (i2^{-m}, (i+1)2^{-m}]) = 2^{-m},$$

since this event prescribes the first m binary digits of Y_n . By uniqueness of extension, $Y_n \sim U(0, 1)$.

Finally, given any sequence (F_n) of distribution functions, let g_n be the generalised inverse of F_n from Lemma 38.2.22. Then $X_n = g_n(Y_n)$ is a sequence of independent random variables with $\mathbb{P}(X_n \leq x) = \mathbb{P}(Y_n \leq F_n(x)) = F_n(x)$. So:

Theorem 38.3.12

Given any sequence (F_n) of distribution functions there is a probability space carrying a sequence of independent random variables (X_n) with X_n having distribution function F_n . In particular i.i.d. sequences of any prescribed law exist.

§38.3.5 Convergence of measurable functions

Two notions of convergence make sense at this level of generality.

Definition 38.3.13 (Almost everywhere and in measure)

Let f_n, f be measurable functions on $(E, \mathcal{E}, \mu)$. We say $f_n \rightarrow f$ **almost everywhere** if $\mu(\{x : f_n(x) \not\rightarrow f(x)\}) = 0$, and $f_n \rightarrow f$ **in measure** if for every $\varepsilon > 0$,

$$\mu(\{x : |f_n(x) - f(x)| > \varepsilon\}) \rightarrow 0 \quad \text{as } n \rightarrow \infty.$$

On a probability space these are called convergence **almost surely** and **in probability**, and we write $X_n \rightarrow X$ a.s. and $X_n \xrightarrow{\mathbb{P}} X$.

Theorem 38.3.14 (Relations between the two)

Let f_n be measurable on $(E, \mathcal{E}, \mu)$.

- (i) If $\mu(E) < \infty$ and $f_n \rightarrow 0$ a.e., then $f_n \rightarrow 0$ in measure.
- (ii) If $f_n \rightarrow 0$ in measure, then $f_{n_k} \rightarrow 0$ a.e. along some subsequence (n_k) .

Proof. (i) Fix $\varepsilon > 0$. The sets $B_n = \bigcap_{m \geq n} \{|f_m| \leq \varepsilon\}$ increase, with

$$\bigcup_n B_n = \{|f_n| \leq \varepsilon \text{ eventually}\} \supseteq \{f_n \rightarrow 0\},$$

a set of full measure. By continuity from below, $\mu(B_n) \rightarrow \mu(E)$. Since $\mu(\{|f_n| \leq \varepsilon\}) \geq \mu(B_n)$ and $\mu(E) < \infty$, we may subtract to get $\mu(\{|f_n| > \varepsilon\}) \leq \mu(E) - \mu(B_n) \rightarrow 0$.

(ii) For each k , convergence in measure with $\varepsilon = 1/k$ lets us choose n_k (increasing) with

$$\mu(|f_{n_k}| > 1/k) \leq 2^{-k}.$$

Then $\sum_k \mu(|f_{n_k}| > 1/k) < \infty$, so by the first Borel–Cantelli lemma (valid for any measure) the set where $|f_{n_k}| > 1/k$ infinitely often is null. Off that set, $|f_{n_k}| \leq 1/k$ eventually, so $f_{n_k} \rightarrow 0$. $\square$

Both hypotheses are needed, as the following show.

Example 38.3.15 (Two counterexamples) (i) On $(\mathbb{R}, \mathcal{B}, \mu)$ let $f_n = \mathbb{1}_{(n, \infty)}$. Then $f_n \rightarrow 0$ pointwise, but $\mu(|f_n| > 1/2) = \infty$ for every n . So (i) genuinely needs $\mu(E) < \infty$.

(ii) Let (A_n) be independent events with $\mathbb{P}(A_n) = 1/n$. Then $\mathbb{1}_{A_n} \rightarrow 0$ in probability, since $\mathbb{P}(\mathbb{1}_{A_n} > \varepsilon) = 1/n \rightarrow 0$. But $\sum_n \mathbb{P}(A_n) = \infty$, so by the second Borel–Cantelli lemma $\mathbb{P}(A_n \text{ i.o.}) = 1$ and $\mathbb{1}_{A_n} \not\rightarrow 0$ almost surely. So (ii) genuinely needs a subsequence.

§38.3.6 Tail events and Kolmogorov's zero-one law

Let $(X_n)_{n \in \mathbb{N}}$ be a sequence of random variables. Define

$$\mathcal{T}_n = \sigma(X_{n+1}, X_{n+2}, \dots), \quad \mathcal{T} = \bigcap_{n \in \mathbb{N}} \mathcal{T}_n.$$

We call $\mathcal{T}$ the **tail σ -algebra**. An event in $\mathcal{T}$ is one whose occurrence is unaffected by changing any finite number of the X_n – for instance $\{X_n \rightarrow 0\}$, or $\{\sum_n X_n \text{ converges}\}$, or $\{\limsup_n \frac{1}{n} \sum_{i \leq n} X_i > c\}$. Kolmogorov's theorem says that for independent X_n such events are deterministic.

Theorem 38.3.16 (Kolmogorov's zero-one law)

Let (X_n) be independent random variables and let $A \in \mathcal{T}$. Then $\mathbb{P}(A) \in \{0, 1\}$. Moreover any $\mathcal{T}$ -measurable random variable Y is almost surely constant.

Proof. Let $\mathcal{F}_n = \sigma(X_1, \dots, X_n)$, which is generated by the π -system of events of the form $\{X_1 \leq x_1, \dots, X_n \leq x_n\}$; and note that $\mathcal{T}_n$ is generated by the π -system of events of the form $\{X_{n+1} \leq x_{n+1}, \dots, X_{n+k} \leq x_{n+k}\}$, for $k \in \mathbb{N}$. By independence of the X_i these two π -systems satisfy the product rule, so by Proposition 38.2.27 the σ -algebras $\mathcal{F}_n$ and $\mathcal{T}_n$ are independent.

Let $\mathcal{F}_\infty = \sigma(X_1, X_2, \dots)$. Then $\bigcup_n \mathcal{F}_n$ is a π -system (the $\mathcal{F}_n$ increase) generating $\mathcal{F}_\infty$. Any $A \in \bigcup_n \mathcal{F}_n$ lies in some $\mathcal{F}_n$, hence is independent of $\mathcal{T}_n \supseteq \mathcal{T}$. So $\bigcup_n \mathcal{F}_n$ and $\mathcal{T}$ satisfy the product rule, and by Proposition 38.2.27 again, $\mathcal{F}_\infty$ is independent of $\mathcal{T}$.

But $\mathcal{T} \subseteq \mathcal{F}_\infty$. So if $A \in \mathcal{T}$ then A is independent of itself:

$$\mathbb{P}(A) = \mathbb{P}(A \cap A) = \mathbb{P}(A)^2,$$

forcing $\mathbb{P}(A) \in \{0, 1\}$.

For the last statement, $F_Y(y) = \mathbb{P}(Y \leq y)$ takes only the values 0 and 1, is non-decreasing and right-continuous with limits 0 and 1 at $\mp\infty$; so $c = \inf\{y : F_Y(y) = 1\}$ is finite and $Y = c$ almost surely. $\square$

Example 38.3.17

If (X_n) are independent then the event that $\sum_n X_n$ converges has probability 0 or 1, and $\limsup_n \frac{1}{n} \sum_{i=1}^n X_i$ is an almost surely constant element of $[-\infty, \infty]$. The zero-one law does not tell us *which* constant – that is the work of the laws of large numbers – but it does tell us that there is no randomness left to speak of.

§38.4 Integration

§38.4.1 Defining the integral

We now carry out the plan of §1. Throughout $(E, \mathcal{E}, \mu)$ is a measure space. We will write the integral of f interchangeably as

$$\mu(f) = \int_E f \, d\mu = \int_E f(x) \, d\mu(x),$$

and when $(\Omega, \mathcal{F}, \mathbb{P})$ is a probability space and X a random variable, we write $\mathbb{E}[X] = \int_{\Omega} X \, d\mathbb{P}$ for its **expectation**. The notation $\mu(f)$ is compact and emphasises that integration is a functional; we will use it freely.

The construction proceeds in three stages: simple functions, non-negative functions, then general functions.

Definition 38.4.1 (Integral of a simple function)

For a simple function $f = \sum_{k=1}^m a_k \mathbb{1}_{A_k}$ with $a_k \geq 0$ and $A_k \in \mathcal{E}$, set

$$\mu(f) = \sum_{k=1}^m a_k \mu(A_k) \in [0, \infty].$$

This requires a check: the representation of f is not unique. Suppose $\sum_k a_k \mathbb{1}_{A_k} = \sum_{\ell} b_{\ell} \mathbb{1}_{B_{\ell}}$. Refining both into the common refinement generated by the A_k and B_{ℓ} (finitely many sets, so this is a finite disjoint partition) and using finite additivity of μ on each piece shows both expressions equal the same number. We omit the routine bookkeeping.

Proposition 38.4.2 (The integral on simple functions)

For simple f, g and $\alpha, \beta \geq 0$:

$$\mu(\alpha f + \beta g) = \alpha \mu(f) + \beta \mu(g), \quad f \leq g \implies \mu(f) \leq \mu(g),$$

$$f = 0 \text{ a.e.} \implies \mu(f) = 0.$$

Proof. Linearity is immediate from the definition once one notes that $\alpha f + \beta g$ is again simple with an obvious representation. Monotonicity: if $f \leq g$ then $g - f$ is a non-negative simple function (take a common refinement), so $\mu(g) = \mu(f) + \mu(g - f) \geq \mu(f)$. For the last part, in a representation with the A_k disjoint and $a_k > 0$, we must have $\mu(A_k) = 0$. $\square$

Definition 38.4.3 (Integral of a non-negative function)

For measurable $f : E \rightarrow [0, \infty]$, define

$$\mu(f) = \sup\{\mu(g) : g \text{ simple, } g \leq f\} \in [0, \infty].$$

By monotonicity on simple functions this is consistent with the previous definition when f is itself simple. It also makes monotonicity for non-negative $f \leq h$ obvious, since the supremum on the left is over a smaller family.

Definition 38.4.4 (Integrable functions)

For measurable $f : E \rightarrow \mathbb{R}$ write $f^+ = \max(f, 0)$ and $f^- = \max(-f, 0)$, so $f = f^+ - f^-$ and $|f| = f^+ + f^-$. We say f is **μ -integrable** if $\mu(|f|) < \infty$, and then set

$$\mu(f) = \mu(f^+) - \mu(f^-),$$

a well-defined real number. We write $L^1(\mu)$ for the set of integrable functions.

Note the asymmetry with the Riemann theory: a function is Lebesgue integrable if and only if its absolute value is. There is no analogue of a conditionally convergent improper integral here; $\int_0^\infty \frac{\sin x}{x} dx$ exists as an improper Riemann integral but $\frac{\sin x}{x}$ is not Lebesgue integrable on $(0, \infty)$.

§38.4.2 The monotone convergence theorem

Everything now hinges on the following theorem, which is the reason the whole edifice works.

Theorem 38.4.5 (Monotone convergence theorem)

Let f_n, f be measurable and non-negative with $f_n \uparrow f$ pointwise. Then $\mu(f_n) \uparrow \mu(f)$.

Proof. Since $f_n \leq f_{n+1} \leq f$, the sequence $\mu(f_n)$ is non-decreasing and bounded above by $\mu(f)$; let $M = \lim_n \mu(f_n) = \sup_n \mu(f_n) \leq \mu(f)$. It remains to prove $\mu(f) \leq M$, i.e. that $\mu(g) \leq M$ for every simple $g \leq f$.

Fix such a $g = \sum_{k=1}^m a_k \mathbb{1}_{A_k}$ with the $A_k \in \mathcal{E}$ disjoint and $a_k > 0$, and fix $\varepsilon \in (0, 1)$. Put

$$A_k(n) = \{x \in A_k : f_n(x) \geq (1 - \varepsilon)a_k\} \in \mathcal{E}.$$

Since $f_n \uparrow f \geq g = a_k$ on A_k , every $x \in A_k$ eventually satisfies $f_n(x) \geq (1 - \varepsilon)a_k$; so $A_k(n) \uparrow A_k$ and, by continuity from below, $\mu(A_k(n)) \uparrow \mu(A_k)$.

Because the A_k are disjoint,

$$f_n \geq \sum_{k=1}^m f_n \mathbb{1}_{A_k(n)} \geq (1 - \varepsilon) \sum_{k=1}^m a_k \mathbb{1}_{A_k(n)},$$

and the right-hand side is simple, so

$$\mu(f_n) \geq (1 - \varepsilon) \sum_{k=1}^m a_k \mu(A_k(n)).$$

Letting $n \rightarrow \infty$, the right-hand side tends to $(1 - \varepsilon) \sum_k a_k \mu(A_k) = (1 - \varepsilon)\mu(g)$. Hence $M \geq (1 - \varepsilon)\mu(g)$, and letting $\varepsilon \downarrow 0$ gives $M \geq \mu(g)$ as required. $\square$

Remark. Three comments. First, this is a theorem about interchanging limits:

$$\mu\left(\lim_n f_n\right) = \lim_n \mu(f_n),$$

something the Riemann integral cannot deliver without uniform convergence. Second, it suffices that $f_n \uparrow f$ almost everywhere – alter the functions on a null set, which changes no integral. Third, non-negativity is only used to get started; if f_0 is integrable and $f_n \uparrow f$ then applying the theorem to $f_n - f_0$ gives the same conclusion.

Applying the theorem to the standard approximation of Proposition 38.3.6 we get, for measurable $f \geq 0$,

$$\mu(f) = \lim_n \mu(2^{-n} \lfloor 2^n f \rfloor \wedge n),$$

which is a completely explicit recipe: the integral is the limit of the horizontal-slab sums from §1. It also delivers linearity for free.

Theorem 38.4.6 (Properties of the integral, non-negative case)

Let $f, g : E \rightarrow [0, \infty]$ be measurable and $\alpha, \beta \geq 0$. Then

- (i) $\mu(\alpha f + \beta g) = \alpha\mu(f) + \beta\mu(g)$;
- (ii) if $f \leq g$ then $\mu(f) \leq \mu(g)$;
- (iii) $\mu(f) = 0$ if and only if $f = 0$ almost everywhere;
- (iv) if $g_n \geq 0$ are measurable then $\mu(\sum_n g_n) = \sum_n \mu(g_n)$.

Proof. (i) Let $\tilde{f}_n \uparrow f$ and $\tilde{g}_n \uparrow g$ be the standard approximations. Then $\alpha\tilde{f}_n + \beta\tilde{g}_n \uparrow \alpha f + \beta g$, and by linearity on simple functions together with the monotone convergence theorem applied three times,

$$\mu(\alpha f + \beta g) = \lim_n [\alpha\mu(\tilde{f}_n) + \beta\mu(\tilde{g}_n)] = \alpha\mu(f) + \beta\mu(g).$$

(ii) Already noted.

(iii) If $f = 0$ a.e. then every simple $g \leq f$ vanishes a.e., so $\mu(g) = 0$ and hence $\mu(f) = 0$. Conversely suppose $\mu(f) = 0$ and let $A_n = \{f > 1/n\}$. Then $\frac{1}{n}\mathbb{1}_{A_n} \leq f$, so $\mu(A_n) \leq n\mu(f) = 0$; and $\{f > 0\} = \bigcup_n A_n$ is null.

(iv) Apply the monotone convergence theorem to the partial sums, using (i) for finite sums. $\square$

Theorem 38.4.7 (Properties of the integral, general case)

Let $f, g \in L^1(\mu)$ and $\alpha, \beta \in \mathbb{R}$. Then $\alpha f + \beta g \in L^1(\mu)$ with $\mu(\alpha f + \beta g) = \alpha\mu(f) + \beta\mu(g)$; if $f \leq g$ then $\mu(f) \leq \mu(g)$; and $|\mu(f)| \leq \mu(|f|)$.

Proof. For $\alpha \geq 0$, $(\alpha f)^\pm = \alpha f^\pm$ so $\mu(\alpha f) = \alpha\mu(f)$; and $(-f)^\pm = f^\mp$ so $\mu(-f) = -\mu(f)$. For sums, put $h = f + g$. Then $h^+ - h^- = f^+ - f^- + g^+ - g^-$, so rearranging to avoid subtraction of infinities,

$$h^+ + f^- + g^- = h^- + f^+ + g^+.$$

Both sides are non-negative measurable, so Theorem 38.4.6(i) applies to give

$$\mu(h^+) + \mu(f^-) + \mu(g^-) = \mu(h^-) + \mu(f^+) + \mu(g^+),$$

and all terms are finite, so rearranging gives $\mu(h) = \mu(f) + \mu(g)$. Monotonicity follows since $g - f \geq 0$ has non-negative integral. Finally $|\mu(f)| = |\mu(f^+) - \mu(f^-)| \leq \mu(f^+) + \mu(f^-) = \mu(|f|)$. $\square$

Remark. Part (iii) of Theorem 38.4.6 says that the integral cannot distinguish functions agreeing almost everywhere. So $\mathbb{1}_{\mathbb{Q}}$ is integrable with $\mu(\mathbb{1}_{\mathbb{Q}}) = 0$ – exactly the answer we wanted in §1 and could not get from Riemann. It also means that $\mu(\cdot)$ is not quite a norm on L^1 , a point we return to in §6.

§38.4.3 Fatou's lemma and dominated convergence

Monotone convergence needs monotonicity. Fatou's lemma is what survives without it.

Lemma 38.4.8 (Fatou)

Let $f_n : E \rightarrow [0, \infty]$ be measurable. Then

$$\mu\left(\liminf_n f_n\right) \leq \liminf_n \mu(f_n).$$

Proof. Put $g_n = \inf_{m \geq n} f_m$, so g_n is measurable, non-negative, and $g_n \uparrow \liminf_n f_n$. For every $k \geq n$ we have $g_n \leq f_k$, so $\mu(g_n) \leq \mu(f_k)$ and hence

$$\mu(g_n) \leq \inf_{k \geq n} \mu(f_k) \leq \liminf_n \mu(f_n).$$

Now apply the monotone convergence theorem to $g_n \uparrow \liminf_n f_n$. □

The inequality can be strict, and the reason is instructive.

Example 38.4.9 (The escaping bump)

On $([0, 1], \mathcal{B}, \mu)$ let $f_n = n \mathbb{1}_{(0, 1/n)}$. Then $f_n \rightarrow 0$ pointwise, so $\mu(\liminf f_n) = 0$, whereas $\mu(f_n) = 1$ for every n . The mass does not disappear; it escapes to infinity in the vertical direction. On $(\mathbb{R}, \mathcal{B}, \mu)$ the example $f_n = \mathbb{1}_{(n, n+1)}$ does the same thing horizontally.

To rule out escaping mass we need a hypothesis that pins the functions down, and the cheapest one is domination.

Theorem 38.4.10 (Dominated convergence theorem)

Let f_n, f be measurable with $f_n \rightarrow f$ almost everywhere, and suppose there is an integrable g with $|f_n| \leq g$ almost everywhere for every n . Then $f_n, f \in L^1(\mu)$ and

$$\mu(f_n) \rightarrow \mu(f), \quad \text{and indeed } \mu(|f_n - f|) \rightarrow 0.$$

Proof. Since $|f_n| \leq g$ we get $\mu(|f_n|) \leq \mu(g) < \infty$; letting $n \rightarrow \infty$ pointwise gives $|f| \leq g$ a.e., so f is integrable too. Now $|f_n - f| \leq 2g$, so $2g - |f_n - f| \geq 0$, and $2g - |f_n - f| \rightarrow 2g$ a.e. By Fatou,

$$\mu(2g) = \mu\left(\liminf_n (2g - |f_n - f|)\right) \leq \liminf_n \mu(2g - |f_n - f|) = \mu(2g) - \limsup_n \mu(|f_n - f|).$$

As $\mu(2g) < \infty$ we may cancel, giving $\limsup_n \mu(|f_n - f|) \leq 0$. Hence $\mu(|f_n - f|) \rightarrow 0$, and $|\mu(f_n) - \mu(f)| \leq \mu(|f_n - f|) \rightarrow 0$. $\square$

Example 38.4.11 (Bounded convergence)

If $\mu(E) < \infty$, $f_n \rightarrow f$ pointwise, and $\sup_n \|f_n\|_\infty \leq C < \infty$, then the constant function C is integrable and dominates, so $\mu(f_n) \rightarrow \mu(f)$. Note that no uniformity of the convergence is required – contrast with the Riemann theory, where the standard theorem needs uniform convergence.

Example 38.4.12

Compute $\lim_{n \rightarrow \infty} \int_0^\infty (1 + \frac{x}{n})^{-n} \sin(x/n) \, dx$. The integrand tends to 0 pointwise, and for $n \geq 2$ we have $(1 + x/n)^{-n} |\sin(x/n)| \leq (1 + x/2)^{-2}$, which is integrable on $(0, \infty)$. By dominated convergence the limit is 0.

§38.4.4 Comparison with the Riemann integral

It is reassuring to know that we have not thrown anything away.

Theorem 38.4.13

Let $f : [a, b] \rightarrow \mathbb{R}$ be Riemann integrable. Then f is Lebesgue measurable with respect to the completed Borel σ -algebra, is Lebesgue integrable, and the two integrals agree.

We will not give the full proof, but the mechanism is easy to describe. If f is Riemann integrable, choose partitions P_n refining each other with mesh tending to 0, and let ℓ_n, u_n be the associated lower and upper step functions, so $\ell_n \leq f \leq u_n$ with $\ell_n \uparrow \ell$ and $u_n \downarrow u$ for some measurable $\ell \leq f \leq u$. The Lebesgue integrals of ℓ_n and u_n are exactly the lower and upper Riemann sums, and by monotone (or dominated) convergence they converge to $\mu(\ell)$ and $\mu(u)$. Riemann integrability says these limits agree, so $\mu(u - \ell) = 0$, whence $\ell = f = u$ almost everywhere, and $\mu(f)$ is the common value.

Remark. The same argument gives Lebesgue's criterion: a bounded function on $[a, b]$ is Riemann integrable if and only if its set of discontinuities is Lebesgue null. And for a *continuous* f the fundamental theorem of calculus survives unchanged, since its proof uses nothing about the integral beyond $\int_x^{x+h} dt = h$ and linearity, both of which hold for the Lebesgue integral. So

$$\underbrace{\int_a^x f(t) \, dt}_{\text{Riemann}} = \underbrace{\int_{[a,x]} f \, d\mu}_{\text{Lebesgue}}$$

for continuous f , and all the usual techniques – substitution, integration by parts – extend to bounded measurable functions by the monotone class theorem.

The converse of Theorem 38.4.13 fails badly: $\mathbb{1}_{\mathbb{Q}}$ is Lebesgue integrable but not Riemann integrable. Better still, the Lebesgue theory handles unbounded domains and unbounded functions in a single framework, with no need for the improper-integral gymnastics of Analysis I.

§38.4.5 Integrals depending on a parameter

A standard and constantly useful application of dominated convergence.

Theorem 38.4.14 (Continuity and differentiation under the integral)

Let $U \subseteq \mathbb{R}$ be open, let $(E, \mathcal{E}, \mu)$ be a measure space, and let $f : U \times E \rightarrow \mathbb{R}$ be such that $x \mapsto f(t, x)$ is measurable for each t . Set $F(t) = \int_E f(t, x) \, d\mu(x)$.

- (i) Suppose $t \mapsto f(t, x)$ is continuous for each x , and $|f(t, x)| \leq g(x)$ for all $t \in U$ with g integrable. Then F is continuous on U .
- (ii) Suppose $t \mapsto f(t, x)$ is differentiable for each x , and $|\frac{\partial f}{\partial t}(t, x)| \leq g(x)$ for all $t \in U$ with g integrable. Then F is differentiable on U with

$$F'(t) = \int_E \frac{\partial f}{\partial t}(t, x) \, d\mu(x).$$

Proof. (i) Let $t_n \rightarrow t$ in U . Then $f(t_n, \cdot) \rightarrow f(t, \cdot)$ pointwise, dominated by g , so $F(t_n) \rightarrow F(t)$ by dominated convergence. Since sequential continuity suffices on $\mathbb{R}$, we are done.

(ii) Fix $t \in U$ and let $h_n \rightarrow 0$ with $h_n \neq 0$. Put

$$g_n(x) = \frac{f(t + h_n, x) - f(t, x)}{h_n} - \frac{\partial f}{\partial t}(t, x).$$

By the mean value theorem there is $\tilde{t}$ between t and $t + h_n$ with the difference quotient equal to $\frac{\partial f}{\partial t}(\tilde{t}, x)$, so $|g_n(x)| \leq 2g(x)$, an integrable bound. By differentiability $g_n(x) \rightarrow 0$ for each x , so by dominated convergence $\mu(g_n) \rightarrow 0$. But by linearity

$$\mu(g_n) = \frac{F(t + h_n) - F(t)}{h_n} - \int_E \frac{\partial f}{\partial t}(t, x) \, d\mu(x),$$

which gives the claim. □

§38.4.6 New measures from old

Two constructions come up constantly.

Proposition 38.4.15 (Image measures and the change of variables formula)

Let $f : (E, \mathcal{E}, \mu) \rightarrow (G, \mathcal{G})$ be measurable and $\nu = \mu \circ f^{-1}$. If $g : G \rightarrow \mathbb{R}$ is measurable

and either non-negative or ν -integrable, then

$$\nu(g) = \int_G g \, d\nu = \int_E g \circ f \, d\mu = \mu(g \circ f).$$

Proof. For $g = \mathbb{1}_A$ with $A \in \mathcal{G}$, both sides equal $\mu(f^{-1}(A)) = \nu(A)$. By linearity the identity holds for simple g ; by monotone convergence along the standard approximation it holds for non-negative measurable g ; and by splitting $g = g^+ - g^-$ it holds in the integrable case. $\square$

Specialising to a random variable X on $(\Omega, \mathcal{F}, \mathbb{P})$ with law μ_X gives the formula that we used without proof in IA:

$$\mathbb{E}[g(X)] = \int_{\Omega} g(X(\omega)) \, d\mathbb{P}(\omega) = \int_E g(x) \, d\mu_X(x).$$

In particular, the expectation of $g(X)$ depends only on the law of X , which is why in practice one only ever writes down distributions.

Proposition 38.4.16 (Measures with densities)

Let $f : (E, \mathcal{E}, \mu) \rightarrow [0, \infty]$ be measurable and define

$$\nu(A) = \mu(f \mathbb{1}_A), \quad A \in \mathcal{E}.$$

Then ν is a measure on $(E, \mathcal{E})$, and for measurable $g \geq 0$,

$$\nu(g) = \mu(fg).$$

We call f the **density** of ν with respect to μ and write $d\nu = f \, d\mu$.

Proof. $\nu(\emptyset) = 0$ is clear, and countable additivity follows from Theorem 38.4.6(iv) applied to $\sum_n f \mathbb{1}_{A_n} = f \mathbb{1}_{\bigsqcup A_n}$. The identity $\nu(g) = \mu(fg)$ holds for g an indicator by definition, hence for simple g by linearity, hence in general by monotone convergence. $\square$

If ν is a probability measure we call f a **probability density function**, and this recovers the continuous random variables of IA Probability: the statement ‘ X has density f ’ means precisely that μ_X has density f with respect to Lebesgue measure, and then $\mathbb{E}[g(X)] = \int_{\mathbb{R}} g(x) f(x) \, dx$.

§38.5 Product Measures and Fubini’s Theorem

§38.5.1 Product σ -algebras and sections

If we want to integrate functions of two variables – and we do, since that is how sums of independent random variables work – we need a measure on a product space.

Definition 38.5.1 (Product σ -algebra)

Let $(E_1, \mathcal{E}_1)$ and $(E_2, \mathcal{E}_2)$ be measurable spaces. On $E = E_1 \times E_2$ let

$$\mathcal{A} = \{A_1 \times A_2 : A_1 \in \mathcal{E}_1, A_2 \in \mathcal{E}_2\}$$

be the collection of **measurable rectangles**, a π -system since $(A_1 \times A_2) \cap (B_1 \times B_2) = (A_1 \cap B_1) \times (A_2 \cap B_2)$. The **product σ -algebra** is $\mathcal{E}_1 \otimes \mathcal{E}_2 = \sigma(\mathcal{A})$.

If E_1, E_2 are topological spaces with countable bases then $\mathcal{B}(E_1 \times E_2) = \mathcal{B}(E_1) \otimes \mathcal{B}(E_2)$; in particular $\mathcal{B}(\mathbb{R}^2) = \mathcal{B} \otimes \mathcal{B}$, and inductively $\mathcal{B}(\mathbb{R}^d) = \mathcal{B}^{\otimes d}$.

Lemma 38.5.2 (Sections are measurable)

Let $f : (E_1 \times E_2, \mathcal{E}_1 \otimes \mathcal{E}_2) \rightarrow \mathbb{R}$ be measurable. Then for each fixed $x_1 \in E_1$ the map $x_2 \mapsto f(x_1, x_2)$ is $\mathcal{E}_2$ -measurable.

Proof. Let $\mathcal{V}$ be the set of bounded measurable f for which the conclusion holds. This is a vector space; it contains $\mathbb{1}_E$; and for a rectangle $A = A_1 \times A_2$ we have $\mathbb{1}_A(x_1, x_2) = \mathbb{1}_{A_1}(x_1)\mathbb{1}_{A_2}(x_2)$, which as a function of x_2 is either $\mathbb{1}_{A_2}$ or 0, so $\mathbb{1}_A \in \mathcal{V}$. If $0 \leq f_n \uparrow f$ with $f_n \in \mathcal{V}$ and f bounded, then $x_2 \mapsto f(x_1, x_2)$ is a pointwise limit of measurable functions, hence measurable, so $f \in \mathcal{V}$. By the monotone class theorem (Theorem 38.3.7), $\mathcal{V}$ contains all bounded measurable functions. For general measurable f , apply this to the truncations $(-n) \vee f \wedge n$ and take limits. $\square$

Lemma 38.5.3 (Partial integrals are measurable)

Let $(E_i, \mathcal{E}_i, \mu_i)$ be finite measure spaces and let f on $E_1 \times E_2$ be measurable and either bounded or non-negative. Then

$$x_1 \mapsto \int_{E_2} f(x_1, x_2) \, d\mu_2(x_2)$$

is $\mathcal{E}_1$ -measurable, and is bounded (resp. non-negative) accordingly.

Proof. Again let $\mathcal{V}$ be the collection of bounded measurable f for which the conclusion holds. It is a vector space by linearity of the integral. For a rectangle, $\int_{E_2} \mathbb{1}_{A_1}(x_1)\mathbb{1}_{A_2}(x_2) \, d\mu_2 = \mathbb{1}_{A_1}(x_1)\mu_2(A_2)$, which is measurable and bounded by $\mu_2(E_2) < \infty$; likewise $\mathbb{1}_E \in \mathcal{V}$. If $0 \leq f_n \uparrow f$ with $f_n \in \mathcal{V}$ and f bounded, then by monotone convergence

$$\int_{E_2} f(x_1, x_2) \, d\mu_2(x_2) = \lim_n \int_{E_2} f_n(x_1, x_2) \, d\mu_2(x_2)$$

is an increasing limit of measurable functions, hence measurable, and bounded by $\mu_2(E_2)\|f\|_\infty$. So $\mathcal{V}$ contains all bounded measurable functions. The non-negative case follows by applying this to $f \wedge n$ and using monotone convergence again. $\square$

§38.5.2 The product measure

Theorem 38.5.4 (Existence and uniqueness of the product measure)

Let $(E_1, \mathcal{E}_1, \mu_1)$ and $(E_2, \mathcal{E}_2, \mu_2)$ be finite measure spaces. There is a unique measure

$\mu = \mu_1 \otimes \mu_2$ on $(E_1 \times E_2, \mathcal{E}_1 \otimes \mathcal{E}_2)$ with

$$\mu(A_1 \times A_2) = \mu_1(A_1)\mu_2(A_2) \quad \text{for all } A_i \in \mathcal{E}_i.$$

Proof. Uniqueness is Theorem 38.2.16: the rectangles form a π -system generating $\mathcal{E}_1 \otimes \mathcal{E}_2$ and containing E , and the total mass $\mu_1(E_1)\mu_2(E_2)$ is finite.

For existence, define

$$\mu(A) = \int_{E_1} \left(\int_{E_2} \mathbb{1}_A(x_1, x_2) \, d\mu_2(x_2) \right) d\mu_1(x_1),$$

which makes sense by Lemmas 38.5.2 and 38.5.3. On a rectangle,

$$\mu(A_1 \times A_2) = \int_{E_1} \mathbb{1}_{A_1}(x_1) \mu_2(A_2) \, d\mu_1(x_1) = \mu_1(A_1)\mu_2(A_2).$$

Clearly $\mu(\emptyset) = 0$. For countable additivity, let (A_n) be disjoint in $\mathcal{E}_1 \otimes \mathcal{E}_2$. Then $\mathbb{1}_{\bigsqcup_n A_n} = \sum_n \mathbb{1}_{A_n}$, and applying the monotone convergence theorem twice (once in each integral) together with linearity gives

$$\mu\left(\bigsqcup_n A_n\right) = \lim_N \sum_{n=1}^N \int_{E_1} \int_{E_2} \mathbb{1}_{A_n} \, d\mu_2 \, d\mu_1 = \sum_{n=1}^{\infty} \mu(A_n). \quad \square$$

§38.5.3 Fubini's theorem

Theorem 38.5.5 (Fubini–Tonelli)

Let $(E, \mathcal{E}, \mu) = (E_1 \times E_2, \mathcal{E}_1 \otimes \mathcal{E}_2, \mu_1 \otimes \mu_2)$ with μ_1, μ_2 finite.

(i) (Tonelli) If $f : E \rightarrow [0, \infty]$ is measurable then

$$\begin{aligned} \int_E f \, d\mu &= \int_{E_1} \left(\int_{E_2} f(x_1, x_2) \, d\mu_2(x_2) \right) d\mu_1(x_1) \\ &= \int_{E_2} \left(\int_{E_1} f(x_1, x_2) \, d\mu_1(x_1) \right) d\mu_2(x_2). \end{aligned}$$

(ii) (Fubini) If $f \in L^1(\mu)$, let

$$A_1 = \left\{ x_1 \in E_1 : \int_{E_2} |f(x_1, x_2)| \, d\mu_2(x_2) < \infty \right\}$$

and set $f_1(x_1) = \int_{E_2} f(x_1, x_2) \, d\mu_2(x_2)$ for $x_1 \in A_1$ and $f_1 = 0$ elsewhere. Then $\mu_1(A_1^c) = 0$, $f_1 \in L^1(\mu_1)$, and $\mu(f) = \mu_1(f_1)$. Symmetrically in the other coordinate.

Proof. (i) By the construction of μ in Theorem 38.5.4, the first identity holds for $f = \mathbb{1}_A$ with A a measurable rectangle, and the second holds by the symmetric construction; the two constructions agree by uniqueness, so both identities hold for indicators of rectangles, and hence – since the two sides are measures agreeing on a generating π -system – for $f = \mathbb{1}_A$ with $A \in \mathcal{E}$. By linearity they extend to simple f ,

and by monotone convergence along the standard approximation to all measurable $f \geq 0$.

(ii) Let $h(x_1) = \int_{E_2} |f(x_1, x_2)| \, d\mu_2(x_2)$. By part (i) applied to $|f|$,

$$\mu_1(h) = \mu(|f|) < \infty,$$

so h is integrable and hence finite μ_1 -almost everywhere; that is, $\mu_1(A_1^c) = 0$. Applying part (i) to f^+ and f^- separately, the functions $f_1^\pm(x_1) = \int_{E_2} f^\pm(x_1, x_2) \, d\mu_2(x_2)$ satisfy $\mu_1(f_1^\pm) = \mu(f^\pm) < \infty$, and $f_1 = f_1^+ - f_1^-$ on A_1 . Hence

$$\mu(f) = \mu(f^+) - \mu(f^-) = \mu_1(f_1^+) - \mu_1(f_1^-) = \mu_1(f_1). \quad \square$$

Remark. The integrability hypothesis in (ii) matters. On $(0, 1)^2$ with Lebesgue measure, let

$$f(x, y) = \frac{x^2 - y^2}{(x^2 + y^2)^2}.$$

One computes $\int_0^1 (\int_0^1 f \, dy) \, dx = \pi/4$ and $\int_0^1 (\int_0^1 f \, dx) \, dy = -\pi/4$. The two iterated integrals disagree, and indeed $\int \int |f| = \infty$, so Fubini does not apply. In practice one always runs Tonelli on $|f|$ first to check integrability, and only then applies Fubini to f .

Remark (σ -finite measures and higher dimensions). Everything above extends to σ -finite μ_i by exhausting E_i with sets of finite measure and taking limits. Moreover $(\mathcal{E}_1 \otimes \mathcal{E}_2) \otimes \mathcal{E}_3 = \mathcal{E}_1 \otimes (\mathcal{E}_2 \otimes \mathcal{E}_3)$, by a π -system argument, so the construction iterates: there is a unique measure $\mu_1 \otimes \cdots \otimes \mu_n$ on $\prod_i E_i$ with

$$(\mu_1 \otimes \cdots \otimes \mu_n)(A_1 \times \cdots \times A_n) = \prod_i \mu_i(A_i).$$

In particular, taking each μ_i to be Lebesgue measure on $\mathbb{R}$, we obtain **Lebesgue measure on $\mathbb{R}^d$** : the unique Borel measure with

$$\mu^d\left(\prod_{i=1}^d (a_i, b_i]\right) = \prod_{i=1}^d (b_i - a_i).$$

It is translation invariant, and Fubini says that integration over $\mathbb{R}^d$ may be performed one coordinate at a time in any order, for non-negative or integrable f .

§38.5.4 Product probability spaces and independence

Fubini gives the clean measure-theoretic statement of independence.

Proposition 38.5.6

Let $X = (X_1, \dots, X_n) : (\Omega, \mathcal{F}, \mathbb{P}) \rightarrow (\prod_i E_i, \bigotimes_i \mathcal{E}_i)$ be measurable. The following are equivalent:

- (i) $X_1, \dots, X_n$ are independent;
- (ii) $\mu_X = \bigotimes_{i=1}^n \mu_{X_i}$;
- (iii) for all bounded measurable $f_i : E_i \rightarrow \mathbb{R}$, $\mathbb{E}[\prod_i f_i(X_i)] = \prod_i \mathbb{E}[f_i(X_i)]$.

Proof. (i) $\Rightarrow$ (ii). On the π -system of rectangles,

$$\mu_X\left(\prod_i A_i\right) = \mathbb{P}(X_1 \in A_1, \dots, X_n \in A_n) = \prod_i \mathbb{P}(X_i \in A_i) = \left(\bigotimes_i \mu_{X_i}\right)\left(\prod_i A_i\right),$$

so the two probability measures agree by uniqueness of extension.

(ii) $\Rightarrow$ (iii). By the change of variables formula and Fubini (the integrand is bounded, hence integrable for a probability measure),

$$\mathbb{E}\left[\prod_i f_i(X_i)\right] = \int \prod_i f_i(x_i) d\left(\bigotimes_i \mu_{X_i}\right)(x) = \prod_i \int_{E_i} f_i d\mu_{X_i} = \prod_i \mathbb{E}[f_i(X_i)].$$

(iii) $\Rightarrow$ (i). Take $f_i = \mathbb{1}_{A_i}$. □

Example 38.5.7 (Densities of sums)

Let X, Y be independent real random variables with densities f, g . By Fubini, for $A \in \mathcal{B}$,

$$\mathbb{P}(X + Y \in A) = \int_{\mathbb{R}^2} \mathbb{1}_A(x + y) f(x) g(y) dx dy = \int_{\mathbb{R}} \mathbb{1}_A(v) \left(\int_{\mathbb{R}} f(v - y) g(y) dy \right) dv,$$

substituting $v = x + y$ and using translation invariance. So $X + Y$ has density the convolution $f * g$. This recovers, and now justifies, the formula from IA Probability.

§38.6 Norms and Inequalities

§38.6.1 L^p spaces

Having built the integral we can build function spaces out of it, and this is where measure theory starts to look like analysis again. Recall from IB Analysis and Topology that a **norm** on a real vector space V is a map $\|\cdot\| : V \rightarrow [0, \infty)$ with $\|\lambda v\| = |\lambda| \|v\|$, $\|u + v\| \leq \|u\| + \|v\|$, and $\|v\| = 0$ only for $v = 0$.

Definition 38.6.1 (L^p spaces)

Let $(E, \mathcal{E}, \mu)$ be a measure space and $1 \leq p \leq \infty$. For measurable $f : E \rightarrow \mathbb{R}$ put

$$\|f\|_p = \begin{cases} \left(\int_E |f|^p d\mu \right)^{1/p}, & 1 \leq p < \infty, \\ \text{ess sup } |f| = \inf\{\lambda \geq 0 : |f| \leq \lambda \text{ a.e.}\}, & p = \infty, \end{cases}$$

and let $L^p = L^p(E, \mathcal{E}, \mu)$ be the set of measurable f with $\|f\|_p < \infty$.

There is one wrinkle. If $\|f\|_p = 0$ then $|f|^p = 0$ almost everywhere, so $f = 0$ almost everywhere – but f need not be identically zero. So $\|\cdot\|_p$ is only a seminorm on L^p . The standard fix is to quotient out:

Definition 38.6.2

Write $f \sim g$ if $f = g$ μ -almost everywhere. This is an equivalence relation, and we write $\mathcal{L}^p = L^p / \sim$ for the space of equivalence classes. Then $\|\cdot\|_p$ is a genuine norm on $\mathcal{L}^p$.

In practice everyone abuses notation and talks about ‘the function $f \in \mathcal{L}^p$ ’, meaning a representative of its class; no confusion arises, because every operation we perform is insensitive to modification on a null set. We will do the same.

Homogeneity of $\|\cdot\|_p$ is clear, and the triangle inequality is easy for $p = 1$ (integrate $|f + g| \leq |f| + |g|$) and for $p = \infty$. For $1 < p < \infty$ it is Minkowski’s inequality, which we prove below via Hölder. Before that, two inequalities that need no such machinery.

§38.6.2 Markov, Chebyshev and Jensen

Proposition 38.6.3 (Markov’s inequality)

Let $f : E \rightarrow [0, \infty]$ be measurable. Then for every $\lambda > 0$,

$$\mu(\{f \geq \lambda\}) \leq \frac{\mu(f)}{\lambda}.$$

Proof. Integrate the pointwise inequality $\lambda \mathbb{1}_{\{f \geq \lambda\}} \leq f$. □

That is the whole proof, and yet it is the workhorse of the subject: it converts information about an average into information about a tail.

Corollary 38.6.4 (Chebyshev’s inequality)

If X is a random variable with $\mathbb{E}[X^2] < \infty$ then for $\lambda > 0$,

$$\mathbb{P}(|X - \mathbb{E}[X]| \geq \lambda) \leq \frac{\text{Var}(X)}{\lambda^2}.$$

More generally, $\mathbb{P}(|X| \geq \lambda) \leq \lambda^{-p} \mathbb{E}[|X|^p]$ for any $p > 0$.

Proof. Apply Markov to $|X - \mathbb{E}[X]|^2$, respectively $|X|^p$, with threshold λ^2 respectively λ^p . □

Next, convexity. Recall that $c : I \rightarrow \mathbb{R}$ on an interval I is **convex** if

$$c(tx + (1 - t)y) \leq tc(x) + (1 - t)c(y) \quad (x, y \in I, t \in [0, 1]),$$

equivalently if the slopes $\frac{c(t) - c(x)}{t - x}$ are non-decreasing in each argument. A convex function is continuous on I° , hence Borel measurable.

Lemma 38.6.5 (Supporting line)

Let c be convex on I and let $m \in I^\circ$. Then there are $a, b \in \mathbb{R}$ with $c(x) \geq ax + b$ for all $x \in I$ and $c(m) = am + b$.

Proof. Let

$$a = \sup \left\{ \frac{c(m) - c(x)}{m - x} : x \in I, x < m \right\},$$

which is finite by the slope characterisation of convexity (the slopes to the left of m are bounded above by any slope to the right). Set $b = c(m) - am$. For $y > m$ we have $a \leq \frac{c(y) - c(m)}{y - m}$, so $c(y) \geq ay + b$; for $y < m$, by definition of the supremum $\frac{c(m) - c(y)}{m - y} \leq a$, which rearranges to $c(y) \geq ay + b$ again. $\square$

Theorem 38.6.6 (Jensen's inequality)

Let X be a random variable taking values in an interval I with $\mathbb{E}|X| < \infty$, and let $c : I \rightarrow \mathbb{R}$ be convex. Then $\mathbb{E}[c(X)]$ is well defined in $(-\infty, \infty]$ and

$$c(\mathbb{E}[X]) \leq \mathbb{E}[c(X)].$$

Proof. Let $m = \mathbb{E}[X] \in I$. If $m \notin I^\circ$ then m is an endpoint of I and $X = m$ almost surely (a non-degenerate random variable on I has mean in the interior), so both sides are $c(m)$.

Otherwise take a, b as in Lemma 38.6.5, so $c(x) \geq ax + b$ on I . Then $c^-(X) \leq |a||X| + |b|$, so $\mathbb{E}[c^-(X)] < \infty$ and $\mathbb{E}[c(X)] = \mathbb{E}[c^+(X)] - \mathbb{E}[c^-(X)]$ is well defined in $(-\infty, \infty]$. Integrating $c(X) \geq aX + b$,

$$\mathbb{E}[c(X)] \geq a\mathbb{E}[X] + b = am + b = c(m) = c(\mathbb{E}[X]). \quad \square$$

Corollary 38.6.7 (Monotonicity of L^p norms on probability spaces)

Let $1 \leq p \leq q \leq \infty$. Then $\|X\|_p \leq \|X\|_q$ for any random variable X on a probability space, and hence $\mathcal{L}^q(\mathbb{P}) \subseteq \mathcal{L}^p(\mathbb{P})$.

Proof. The case $q = \infty$ is clear. For $q < \infty$, the map $c(x) = |x|^{q/p}$ is convex since $q/p \geq 1$. Applying Jensen to the random variable $|X|^p$ (assume first that X is bounded, so all expectations are finite),

$$(\mathbb{E}|X|^p)^{q/p} = c(\mathbb{E}|X|^p) \leq \mathbb{E}[c(|X|^p)] = \mathbb{E}|X|^q,$$

so $\|X\|_p \leq \|X\|_q$. For general $X \in \mathcal{L}^q$, apply this to $|X| \wedge n$ and let $n \rightarrow \infty$ using monotone convergence. $\square$

This is a genuinely probabilistic phenomenon: it uses $\mathbb{P}(\Omega) = 1$ crucially, and fails for infinite measure spaces, as we will see.

§38.6.3 Hölder and Minkowski

Definition 38.6.8

We call $p, q \in [1, \infty]$ **conjugate exponents** if $\frac{1}{p} + \frac{1}{q} = 1$, with the convention $\frac{1}{\infty} = 0$.

Theorem 38.6.9 (Hölder's inequality)

Let p, q be conjugate and let f, g be measurable on $(E, \mathcal{E}, \mu)$. Then

$$\mu(|fg|) \leq \|f\|_p \|g\|_q.$$

Proof. If $p = 1, q = \infty$: $|fg| \leq |f| \|g\|_\infty$ almost everywhere, and integrate. Symmetrically for $p = \infty$. So assume $1 < p < \infty$.

We may assume $\|f\|_p, \|g\|_q < \infty$, else the right side is infinite. We may also assume $\|f\|_p > 0$ (else $f = 0$ a.e. and both sides vanish), and by homogeneity we may rescale so that $\|f\|_p = 1$.

The point is that $d\mathbb{P} = |f|^p d\mu$ is then a probability measure. Writing

$$\mu(|fg|) = \int_E \frac{|g|}{|f|^{p-1}} \mathbb{1}_{\{|f|>0\}} |f|^p d\mu = \int_E \frac{|g|}{|f|^{p-1}} \mathbb{1}_{\{|f|>0\}} d\mathbb{P},$$

we may apply Corollary 38.6.7 with exponents $1 \leq q$ on the probability space $(E, \mathcal{E}, \mathbb{P})$:

$$\int \frac{|g|}{|f|^{p-1}} \mathbb{1}_{\{|f|>0\}} d\mathbb{P} \leq \left(\int \frac{|g|^q}{|f|^{q(p-1)}} \mathbb{1}_{\{|f|>0\}} d\mathbb{P} \right)^{1/q} = \left(\int_E |g|^q \mathbb{1}_{\{|f|>0\}} d\mu \right)^{1/q} \leq \|g\|_q,$$

where we used $q(p-1) = p$, so that $|f|^{-q(p-1)} |f|^p = 1$ on $\{|f| > 0\}$. This is the claim, since $\|f\|_p = 1$. $\square$

Remark. For $p = q = 2$ this is the Cauchy–Schwarz inequality $\mu(|fg|) \leq \|f\|_2 \|g\|_2$, which the reader has met in several guises already.

Theorem 38.6.10 (Minkowski's inequality)

For $1 \leq p \leq \infty$ and measurable f, g ,

$$\|f + g\|_p \leq \|f\|_p + \|g\|_p.$$

Proof. The cases $p = 1, \infty$ are immediate. Let $1 < p < \infty$ and assume $f, g \in L^p$. First, $|f + g|^p \leq 2^p(|f|^p + |g|^p)$ pointwise, so $f + g \in L^p$; and we may assume $\|f + g\|_p > 0$. Let q be conjugate to p , so $q(p-1) = p$. Then by the triangle inequality and Hölder,

$$\|f + g\|_p^p = \int_E |f + g|^{p-1} |f + g| d\mu$$

$$\begin{aligned}
&\leq \int_E |f + g|^{p-1} |f| \, d\mu + \int_E |f + g|^{p-1} |g| \, d\mu \\
&\leq \left(\int_E |f + g|^{q(p-1)} \, d\mu \right)^{1/q} (\|f\|_p + \|g\|_p) \\
&= \|f + g\|_p^{p/q} (\|f\|_p + \|g\|_p).
\end{aligned}$$

Dividing by $\|f + g\|_p^{p/q}$ and using $p - p/q = 1$ gives the result. $\square$

So $(\mathcal{L}^p, \|\cdot\|_p)$ is a normed vector space for every $1 \leq p \leq \infty$.

Example 38.6.11 (Containments and their failure)

On a probability space we have $\mathcal{L}^\infty \subseteq \mathcal{L}^q \subseteq \mathcal{L}^p \subseteq \mathcal{L}^1$ for $1 \leq p \leq q \leq \infty$, by Corollary 38.6.7. The same holds on any finite measure space, after rescaling. On $(\mathbb{R}, \mathcal{B}, \mu)$ with μ Lebesgue measure, however, *no* containment holds in either direction:

$$f(x) = x^{-1/2} \mathbb{1}_{(0,1)}(x) \in \mathcal{L}^1 \setminus \mathcal{L}^2, \quad g(x) = x^{-1} \mathbb{1}_{(1,\infty)}(x) \in \mathcal{L}^2 \setminus \mathcal{L}^1.$$

The first function is too singular at the origin for $\mathcal{L}^2$; the second has too fat a tail for $\mathcal{L}^1$. On a finite measure space the second failure mode is unavailable, which is exactly why the containments hold there.

$\mu(E) < \infty$

$\mu = \text{Lebesgue on } \mathbb{R}$

§38.6.4 Completeness

The great advantage of $\mathcal{L}^p$ over the space of Riemann integrable functions is that it is complete. Recall that a **Banach space** is a complete normed vector space.

Theorem 38.6.12 (Riesz–Fischer)

For $1 \leq p \leq \infty$, the space $\mathcal{L}^p(\mu)$ is a Banach space.

Proof. The case $p = \infty$ is straightforward (a Cauchy sequence in ess sup is uniformly Cauchy off a null set), so let $1 \leq p < \infty$ and let (f_n) be Cauchy in $\mathcal{L}^p$.

Extract a subsequence (f_{N_k}) with $\|f_{N_{k+1}} - f_{N_k}\|_p \leq 2^{-k}$, so that

$$S = \sum_{k=1}^{\infty} \|f_{N_{k+1}} - f_{N_k}\|_p \leq 1 < \infty.$$

By Minkowski, for every K ,

$$\left\| \sum_{k=1}^K |f_{N_{k+1}} - f_{N_k}| \right\|_p \leq S,$$

and letting $K \rightarrow \infty$ with the monotone convergence theorem (applied to the p -th powers, which increase),

$$\left\| \sum_{k=1}^{\infty} |f_{N_{k+1}} - f_{N_k}| \right\|_p \leq S < \infty.$$

In particular $\sum_k |f_{N_{k+1}} - f_{N_k}|$ is finite almost everywhere. On the set A where it is finite – which has full measure – the telescoping series

$$f_{N_1} + \sum_{k=1}^{\infty} (f_{N_{k+1}} - f_{N_k})$$

converges absolutely, so $f_{N_k}(x)$ converges for $x \in A$ by completeness of $\mathbb{R}$. Define $f = \lim_k f_{N_k}$ on A and $f = 0$ off A ; then f is measurable and $f_{N_k} \rightarrow f$ almost everywhere.

Finally, fix $\varepsilon > 0$ and take N with $\|f_n - f_m\|_p \leq \varepsilon$ for $n, m \geq N$. For $n \geq N$, Fatou's lemma gives

$$\|f_n - f\|_p^p = \mu\left(\lim_k |f_n - f_{N_k}|^p\right) \leq \liminf_k \mu(|f_n - f_{N_k}|^p) \leq \varepsilon^p.$$

So $f_n - f \in \mathcal{L}^p$, hence $f \in \mathcal{L}^p$, and $\|f_n - f\|_p \rightarrow 0$. □

Remark. The proof shows a little more: a sequence converging in $\mathcal{L}^p$ has a subsequence converging almost everywhere. We will use this repeatedly.

Remark (Dense subspaces). Each of

$$C([a, b]), \quad \{\text{simple functions}\}, \quad \{\text{linear combinations of indicators of intervals}\}$$

is dense in $\mathcal{L}^1([a, b])$ for Lebesgue measure. So $\mathcal{L}^1$ is precisely the completion of the continuous functions in the $\|\cdot\|_1$ norm – which is a far more satisfying description of ‘the integrable functions’ than anything the Riemann theory offers, and is the reason completeness matters.

§38.6.5 $\mathcal{L}^2$ as a Hilbert space

When $p = 2$ there is extra structure.

Definition 38.6.13 (Hilbert space)

An **inner product** on a real vector space V is a symmetric bilinear form $\langle \cdot, \cdot \rangle$ with $\langle v, v \rangle \geq 0$ and $\langle v, v \rangle = 0$ only for $v = 0$. It induces a norm $\|v\| = \sqrt{\langle v, v \rangle}$. A **Hilbert space** is an inner product space complete for this norm.

Corollary 38.6.14

$\mathcal{L}^2(\mu)$ is a Hilbert space with $\langle f, g \rangle = \int_E fg \, d\mu$.

Proof. The integral defining $\langle f, g \rangle$ converges by Cauchy–Schwarz, and the form is clearly symmetric and bilinear with $\langle f, f \rangle = \|f\|_2^2$. Completeness is Theorem 38.6.12. $\square$

Two identities follow by expanding, and are worth recording.

Lemma 38.6.15

For $f, g \in \mathcal{L}^2$:

$$\begin{aligned} \|f + g\|_2^2 &= \|f\|_2^2 + 2\langle f, g \rangle + \|g\|_2^2 \quad (\text{Pythagoras}), \\ \|f + g\|_2^2 + \|f - g\|_2^2 &= 2(\|f\|_2^2 + \|g\|_2^2) \quad (\text{parallelogram law}). \end{aligned}$$

We say f and g are **orthogonal**, written $f \perp g$, if $\langle f, g \rangle = 0$; by Pythagoras this happens iff $\|f + g\|_2^2 = \|f\|_2^2 + \|g\|_2^2$.

Example 38.6.16 (The probabilistic dictionary)

On a probability space, for $X, Y \in \mathcal{L}^2(\mathbb{P})$ with means m_X, m_Y ,

$$\text{Var}(X) = \|X - m_X\|_2^2, \quad \text{Cov}(X, Y) = \langle X - m_X, Y - m_Y \rangle.$$

So variance is squared distance from the mean, and uncorrelatedness is orthogonality of the centred variables. The Cauchy–Schwarz inequality becomes $|\text{Cov}(X, Y)| \leq \sqrt{\text{Var } X \text{Var } Y}$, and Pythagoras becomes the additivity of variance for uncorrelated variables.

Definition 38.6.17

For $V \subseteq \mathcal{L}^2(\mu)$ let $V^\perp = \{f \in \mathcal{L}^2 : \langle f, g \rangle = 0 \text{ for all } g \in V\}$. We call a subspace $V \subseteq \mathcal{L}^2$ **closed** if whenever $f_n \in V$ with $f_n \rightarrow f$ in $\mathcal{L}^2$, there is $v \in V$ with $v = f$ almost everywhere.

Theorem 38.6.18 (Orthogonal projection)

Let V be a closed subspace of $\mathcal{L}^2(\mu)$. Then every $f \in \mathcal{L}^2$ has a decomposition

$$f = v + u, \quad v \in V, \, u \in V^\perp,$$

unique up to null sets, and v is the unique closest point of V to f :

$$\|f - v\|_2 \leq \|f - g\|_2 \quad \text{for all } g \in V,$$

with equality only if $g = v$ a.e. We write $v = P_V f$.

Proof. Let $d = d(f, V) = \inf_{g \in V} \|f - g\|_2$ and choose $g_n \in V$ with $\|f - g_n\|_2 \rightarrow d$. We first show (g_n) is Cauchy. By the parallelogram law applied to $f - g_n$ and $f - g_m$,

$$\|g_n - g_m\|_2^2 = 2\|f - g_n\|_2^2 + 2\|f - g_m\|_2^2 - 4\left\|f - \frac{g_n + g_m}{2}\right\|_2^2.$$

Since $\frac{g_n + g_m}{2} \in V$, the last term is at least $4d^2$, so

$$\|g_n - g_m\|_2^2 \leq 2\|f - g_n\|_2^2 + 2\|f - g_m\|_2^2 - 4d^2 \rightarrow 0$$

as $n, m \rightarrow \infty$. By completeness $g_n \rightarrow g$ in $\mathcal{L}^2$ for some g , and since V is closed there is $v \in V$ with $v = g$ a.e. Then $\|f - v\|_2 = \lim_n \|f - g_n\|_2 = d$, so the infimum is attained at v .

Now set $u = f - v$ and let $h \in V$, $t \in \mathbb{R}$. Since $v + th \in V$,

$$d^2 \leq \|f - (v + th)\|_2^2 = d^2 - 2t\langle u, h \rangle + t^2\|h\|_2^2,$$

a quadratic in t minimised at $t = 0$; differentiating at $t = 0$ gives $\langle u, h \rangle = 0$. As $h \in V$ was arbitrary, $u \in V^\perp$.

For uniqueness, if also $f = w + z$ with $w \in V$, $z \in V^\perp$, then $(v - w) + (u - z) = 0$ with $v - w \in V$ and $u - z \in V^\perp$, so by Pythagoras $0 = \|v - w\|_2^2 + \|u - z\|_2^2$, giving $v = w$ and $u = z$ almost everywhere. $\square$

§38.6.6 Conditional expectation

We can now give the definition of conditional expectation that makes it a genuine mathematical object rather than a heuristic. The idea is: $\mathcal{G} \subseteq \mathcal{F}$ is a sub- σ -algebra representing partial information, and $\mathbb{E}[X | \mathcal{G}]$ should be the best prediction of X using only that information. In $\mathcal{L}^2$, ‘best prediction’ means ‘nearest point’, and that is orthogonal projection.

Let us start with the discrete case, which is the one from IA. Suppose $(G_n)_{n \in \mathbb{N}}$ are disjoint events with $\bigcup_n G_n = \Omega$ and $\mathbb{P}(G_n) > 0$, and put $\mathcal{G} = \sigma(G_n : n \in \mathbb{N})$.

Definition 38.6.19 (Conditional expectation, discrete case)

For $X \in \mathcal{L}^1(\mathbb{P})$ define

$$\mathbb{E}[X | \mathcal{G}] = \sum_{n=1}^{\infty} \mathbb{E}[X | G_n] \mathbb{1}_{G_n}, \quad \mathbb{E}[X | G_n] = \frac{\mathbb{E}[X \mathbb{1}_{G_n}]}{\mathbb{P}(G_n)}.$$

So $\mathbb{E}[X | \mathcal{G}]$ is the random variable which, on the event G_n , takes the value of the average of X over G_n . It is $\mathcal{G}$ -measurable by construction: it is constant on each atom of $\mathcal{G}$.

Proposition 38.6.20

Let $X \in \mathcal{L}^2(\mathbb{P})$ and let $\mathcal{G}$ be as above. Then $Y = \mathbb{E}[X | \mathcal{G}]$ is the orthogonal projection of X onto the closed subspace

$$\mathcal{L}^2(\mathcal{G}, \mathbb{P}) = \{W \in \mathcal{L}^2(\mathbb{P}) : W \text{ is } \mathcal{G}\text{-measurable}\}.$$

Proof. Any $\mathcal{G}$ -measurable W is constant on each G_n , so $W = \sum_n a_n \mathbb{1}_{G_n}$ for some $a_n \in \mathbb{R}$. Then

$$\mathbb{E}[(X-W)^2] = \mathbb{E}\left[\sum_n (X-a_n)^2 \mathbb{1}_{G_n}\right] = \sum_n \mathbb{P}(G_n) \left(\mathbb{E}[X^2 | G_n] - 2a_n \mathbb{E}[X | G_n] + a_n^2 \right).$$

Each summand is a quadratic in a_n minimised at $a_n = \mathbb{E}[X | G_n]$, independently of the others. Hence $\mathbb{E}[(X-W)^2]$ is minimised over $\mathcal{L}^2(\mathcal{G}, \mathbb{P})$ precisely at $W = Y$, and by Theorem 38.6.18 the minimiser is the orthogonal projection. $\square$

The picture is the whole content of the definition: $\mathbb{E}[X | \mathcal{G}]$ is the foot of the perpendicular from X to the subspace of $\mathcal{G}$ -measurable functions. Everything one expects of conditional expectation can be read off from it.

Definition 38.6.21 (Conditional expectation, general case)

Let $\mathcal{G} \subseteq \mathcal{F}$ be a sub- σ -algebra. For $X \in \mathcal{L}^2(\mathbb{P})$ define $\mathbb{E}[X | \mathcal{G}] = P_{\mathcal{L}^2(\mathcal{G}, \mathbb{P})} X$, the orthogonal projection onto the (closed) subspace of $\mathcal{G}$ -measurable square-integrable random variables.

That $\mathcal{L}^2(\mathcal{G}, \mathbb{P})$ is closed is exactly the remark after Theorem 38.6.12: a sequence converging in $\mathcal{L}^2$ has an a.e. convergent subsequence, and an a.e. limit of $\mathcal{G}$ -measurable functions is $\mathcal{G}$ -measurable.

Proposition 38.6.22 (Characterisation and basic properties)

Let $X \in \mathcal{L}^2(\mathbb{P})$ and $Y = \mathbb{E}[X | \mathcal{G}]$. Then Y is the a.s.-unique $\mathcal{G}$ -measurable element of $\mathcal{L}^2$ with

$$\mathbb{E}[Y \mathbb{1}_A] = \mathbb{E}[X \mathbb{1}_A] \quad \text{for all } A \in \mathcal{G}. \quad (*)$$

Consequently $\mathbb{E}[Y] = \mathbb{E}[X]$, the map $X \mapsto \mathbb{E}[X | \mathcal{G}]$ is linear and monotone, and $\|\mathbb{E}[X | \mathcal{G}]\|_1 \leq \|X\|_1$.

Proof. Orthogonality says $\langle X - Y, W \rangle = 0$ for all $\mathcal{G}$ -measurable $W \in \mathcal{L}^2$; taking $W = \mathbb{1}_A$ for $A \in \mathcal{G}$ (which is bounded, hence in $\mathcal{L}^2(\mathbb{P})$) gives $(*)$. Conversely if Y' is $\mathcal{G}$ -measurable and satisfies $(*)$ then $\langle X - Y', \mathbb{1}_A \rangle = 0$ for $A \in \mathcal{G}$, hence by linearity and monotone class $\langle X - Y', W \rangle = 0$ for all bounded $\mathcal{G}$ -measurable W , and by approximation for all $W \in \mathcal{L}^2(\mathcal{G}, \mathbb{P})$; so $Y' = P_{\mathcal{L}^2(\mathcal{G})} X = Y$ a.s.

Taking $A = \Omega$ in $(*)$ gives $\mathbb{E}Y = \mathbb{E}X$. Linearity is linearity of projection. For monotonicity, if $X \geq 0$, take $A = \{Y < 0\} \in \mathcal{G}$: then $\mathbb{E}[Y \mathbb{1}_A] = \mathbb{E}[X \mathbb{1}_A] \geq 0$, and $Y \mathbb{1}_A \leq 0$, so $Y \mathbb{1}_A = 0$ a.s. and $\mathbb{P}(A) = 0$. Finally, applying monotonicity to

$\pm X \leq |X|$ gives $|Y| \leq \mathbb{E}[|X| \mid \mathcal{G}]$ a.s., so $\mathbb{E}|Y| \leq \mathbb{E}[\mathbb{E}[|X| \mid \mathcal{G}]] = \mathbb{E}|X|$. $\square$

The $\mathcal{L}^1$ contraction property in the last line is what lets us extend the definition beyond $\mathcal{L}^2$.

Theorem 38.6.23 (Extension to $\mathcal{L}^1$)

The map $X \mapsto \mathbb{E}[X \mid \mathcal{G}]$ extends uniquely from $\mathcal{L}^2(\mathbb{P})$ to a linear contraction $\mathcal{L}^1(\mathbb{P}) \rightarrow \mathcal{L}^1(\mathbb{P})$, and the extension is still characterised by (*).

Proof. $\mathcal{L}^2(\mathbb{P})$ is dense in $\mathcal{L}^1(\mathbb{P})$: given $X \in \mathcal{L}^1$, the truncations $X_n = (-n) \vee X \wedge n$ are bounded, hence in $\mathcal{L}^2$, and $\|X_n - X\|_1 \rightarrow 0$ by dominated convergence. By Proposition 38.6.22 the map is a contraction for $\|\cdot\|_1$ on the dense subspace $\mathcal{L}^2$, and $\mathcal{L}^1$ is complete, so it extends uniquely by continuity. The identity (*) passes to the limit since $|\mathbb{E}[(X_n - X)\mathbb{1}_A]| \leq \|X_n - X\|_1$. $\square$

Remark. One can also prove existence directly in $\mathcal{L}^1$ via the Radon–Nikodym theorem, and that is the route usually taken in a course on martingales. The $\mathcal{L}^2$ route taken here is more elementary and, I think, more illuminating: it makes it clear that conditional expectation is *geometry*, not a formula.

Example 38.6.24 (Two extremes)

If $\mathcal{G} = \{\emptyset, \Omega\}$ then the only $\mathcal{G}$ -measurable functions are constants, and projecting onto the constants gives $\mathbb{E}[X \mid \mathcal{G}] = \mathbb{E}[X]$. If $\mathcal{G} = \mathcal{F}$ then X itself is $\mathcal{G}$ -measurable and $\mathbb{E}[X \mid \mathcal{F}] = X$. In general $\mathbb{E}[X \mid \mathcal{G}]$ interpolates between knowing nothing and knowing everything.

§38.7 Modes of Convergence

§38.7.1 The four modes

We have met several notions of convergence for random variables, and it is time to organise them.

Definition 38.7.1

Let X_n, X be random variables on $(\Omega, \mathcal{F}, \mathbb{P})$.

- (i) $X_n \rightarrow X$ **almost surely** if $\mathbb{P}(X_n \rightarrow X) = 1$.
- (ii) $X_n \rightarrow X$ **in probability**, written $X_n \xrightarrow{\mathbb{P}} X$, if $\mathbb{P}(|X_n - X| > \varepsilon) \rightarrow 0$ for every $\varepsilon > 0$.
- (iii) $X_n \rightarrow X$ **in $\mathcal{L}^p$** if $X_n, X \in \mathcal{L}^p$ and $\|X_n - X\|_p \rightarrow 0$.
- (iv) $X_n \rightarrow X$ **in distribution**, written $X_n \xrightarrow{d} X$, if $F_{X_n}(x) \rightarrow F_X(x)$ at every x at which F_X is continuous.

The last of these is different in kind from the others: it involves only the laws μ_{X_n}, μ_X , and the random variables need not even be defined on the same probability space. The reason for the continuity proviso is that otherwise the definition would be useless: if

$X_n = 1/n$ deterministically then $F_{X_n}(0) = 0$ for all n but $F_0(0) = 1$, and we certainly want $X_n \rightarrow 0$ in distribution.

Theorem 38.7.2 (The implications)

The following implications hold, and no others in general:

$$\begin{aligned} \text{in } \mathcal{L}^q &\implies \text{in } \mathcal{L}^p \ (p \leq q), & \text{in } \mathcal{L}^p &\implies \text{in probability,} \\ & & \text{a.s.} &\implies \text{in probability} \implies \text{in distribution.} \end{aligned}$$

Moreover if $X_n \xrightarrow{\mathbb{P}} X$ then $X_{n_k} \rightarrow X$ almost surely along a subsequence.

Proof. The first implication is Corollary 38.6.7. For the second, Markov's inequality gives

$$\mathbb{P}(|X_n - X| > \varepsilon) \leq \frac{\mathbb{E}|X_n - X|^p}{\varepsilon^p} = \frac{\|X_n - X\|_p^p}{\varepsilon^p} \rightarrow 0.$$

The implication 'a.s. $\implies$ in probability' and the subsequence statement are Theorem 38.3.14, applied to $|X_n - X|$ on the finite measure space $(\Omega, \mathcal{F}, \mathbb{P})$.

Finally suppose $X_n \xrightarrow{\mathbb{P}} X$ and let x be a continuity point of F_X . For $\varepsilon > 0$,

$$\{X_n \leq x\} \subseteq \{X \leq x + \varepsilon\} \cup \{|X_n - X| > \varepsilon\},$$

so $F_{X_n}(x) \leq F_X(x + \varepsilon) + \mathbb{P}(|X_n - X| > \varepsilon)$, and hence $\limsup_n F_{X_n}(x) \leq F_X(x + \varepsilon)$. Symmetrically $\{X \leq x - \varepsilon\} \subseteq \{X_n \leq x\} \cup \{|X_n - X| > \varepsilon\}$ gives $\liminf_n F_{X_n}(x) \geq F_X(x - \varepsilon)$. Letting $\varepsilon \downarrow 0$ and using continuity of F_X at x gives $F_{X_n}(x) \rightarrow F_X(x)$. $\square$

Example 38.7.3 (Counterexamples to the converses)

Work on $((0, 1), \mathcal{B}, \mu)$ unless stated otherwise.

- (i) *In probability but not in $\mathcal{L}^1$.* Let $X_n = n\mathbb{1}_{(0, 1/n)}$. Then $\mathbb{P}(|X_n| > \varepsilon) = 1/n \rightarrow 0$, but $\mathbb{E}[X_n] = 1$ for all n , so $X_n \not\xrightarrow{\mathbb{P}} 0$ in $\mathcal{L}^1$. This is the escaping bump of Example 38.4.9 again.
- (ii) *In probability but not almost surely.* Take the 'typewriter sequence': for $n = 2^k + j$ with $0 \leq j < 2^k$, let $X_n = \mathbb{1}_{(j2^{-k}, (j+1)2^{-k})}$. Then $\mathbb{P}(X_n \neq 0) = 2^{-k} \rightarrow 0$, so $X_n \xrightarrow{\mathbb{P}} 0$; but for every ω the sequence $X_n(\omega)$ takes the value 1 infinitely often, so $X_n \not\xrightarrow{\text{a.s.}} 0$ anywhere.
- (iii) *In $\mathcal{L}^1$ but not in $\mathcal{L}^2$.* Let $X_n = n^{1/2}\mathbb{1}_{(0, 1/n)}$. Then $\|X_n\|_1 = n^{-1/2} \rightarrow 0$ but

$$\|X_n\|_2^2 = 1.$$

- (iv) *In distribution but not in probability.* Let $X \sim N(0, 1)$ and $X_n = -X$ for all n . Since $-X \sim N(0, 1)$, we have $X_n \xrightarrow{d} X$; but $\mathbb{P}(|X_n - X| > \varepsilon) = \mathbb{P}(|2X| > \varepsilon)$ does not tend to zero.
- (v) *Almost surely but not in $\mathcal{L}^1$.* The bump $X_n = n^2 \mathbb{1}_{(0, 1/n)}$ converges to 0 pointwise on $(0, 1)$ but $\mathbb{E}X_n = n \rightarrow \infty$.

The one useful partial converse is that convergence in distribution to a *constant* implies convergence in probability: if $X_n \xrightarrow{d} c$ then $\mathbb{P}(|X_n - c| > \varepsilon) \leq 1 - F_{X_n}(c + \varepsilon/2) + F_{X_n}(c - \varepsilon) \rightarrow 0$.

§38.7.2 Uniform integrability

The examples above suggest the obstruction to upgrading convergence in probability to convergence in $\mathcal{L}^1$ is exactly the escaping-mass phenomenon. Uniform integrability is the hypothesis that rules it out.

We start with a lemma showing that a single integrable random variable never has escaping mass.

Lemma 38.7.4

Let $X \in \mathcal{L}^1(\mathbb{P})$. Then

$$I_X(\delta) = \sup \{ \mathbb{E}[|X| \mathbb{1}_A] : A \in \mathcal{F}, \mathbb{P}(A) \leq \delta \} \rightarrow 0 \quad \text{as } \delta \downarrow 0.$$

Proof. I_X is non-decreasing in δ , so suppose for contradiction that $I_X(\delta) \geq \varepsilon$ for all $\delta > 0$, for some $\varepsilon > 0$. Then we may pick $A_n \in \mathcal{F}$ with $\mathbb{P}(A_n) \leq 2^{-n}$ and $\mathbb{E}[|X| \mathbb{1}_{A_n}] \geq \varepsilon$. Since $\sum_n \mathbb{P}(A_n) < \infty$, the first Borel–Cantelli lemma gives $\mathbb{P}(A) = 0$ where $A = \limsup_n A_n$. Now $\mathbb{1}_{\bigcup_{m \geq n} A_m} \downarrow \mathbb{1}_A$, and $|X| \mathbb{1}_{\bigcup_{m \geq n} A_m} \leq |X| \in \mathcal{L}^1$, so by dominated convergence

$$\varepsilon \leq \mathbb{E}[|X| \mathbb{1}_{A_n}] \leq \mathbb{E}[|X| \mathbb{1}_{\bigcup_{m \geq n} A_m}] \rightarrow \mathbb{E}[|X| \mathbb{1}_A] = 0,$$

a contradiction. □

Definition 38.7.5 (Uniform integrability)

A family $\mathcal{X} \subseteq \mathcal{L}^1(\mathbb{P})$ is **uniformly integrable** (UI) if it is bounded in $\mathcal{L}^1$, i.e. $\sup_{X \in \mathcal{X}} \mathbb{E}|X| < \infty$, and

$$I_{\mathcal{X}}(\delta) = \sup \{ \mathbb{E}[|X| \mathbb{1}_A] : X \in \mathcal{X}, \mathbb{P}(A) \leq \delta \} \rightarrow 0 \quad \text{as } \delta \downarrow 0.$$

By Lemma 38.7.4, any finite family is UI. The following reformulation is usually the easiest to check.

Lemma 38.7.6 (Equivalent form of UI)

A family $\mathcal{X} \subseteq \mathcal{L}^1(\mathbb{P})$ is uniformly integrable if and only if

$$\sup_{X \in \mathcal{X}} \mathbb{E}[|X| \mathbb{1}_{\{|X| > K\}}] \longrightarrow 0 \quad \text{as } K \rightarrow \infty.$$

Proof. ($\Rightarrow$) By Markov's inequality, $\mathbb{P}(|X| > K) \leq \mathbb{E}|X|/K \leq I_{\mathcal{X}}(1)/K$ uniformly in $X \in \mathcal{X}$. So given $\delta > 0$ we may take K large enough that $\mathbb{P}(|X| > K) \leq \delta$ for all $X \in \mathcal{X}$, and then $\mathbb{E}[|X| \mathbb{1}_{\{|X| > K\}}] \leq I_{\mathcal{X}}(\delta)$, which tends to 0.

($\Leftarrow$) Fix $\varepsilon > 0$ and choose K with $\sup_X \mathbb{E}[|X| \mathbb{1}_{\{|X| > K\}}] < \varepsilon/2$. Then

$$\mathbb{E}|X| = \mathbb{E}[|X| \mathbb{1}_{\{|X| \leq K\}}] + \mathbb{E}[|X| \mathbb{1}_{\{|X| > K\}}] \leq K + \frac{\varepsilon}{2},$$

so $\mathcal{X}$ is $\mathcal{L}^1$ -bounded. And for A with $\mathbb{P}(A) \leq \delta$,

$$\mathbb{E}[|X| \mathbb{1}_A] \leq \mathbb{E}[|X| \mathbb{1}_A \mathbb{1}_{\{|X| \leq K\}}] + \mathbb{E}[|X| \mathbb{1}_{\{|X| > K\}}] \leq K\delta + \frac{\varepsilon}{2} < \varepsilon$$

for $\delta < \varepsilon/(2K)$. □

Example 38.7.7 (When UI holds and when it fails) (i) If $\mathcal{X}$ is bounded in $\mathcal{L}^p$ for some $p > 1$ then it is UI: by Hölder with conjugate q ,

$$\mathbb{E}[|X| \mathbb{1}_A] \leq \|X\|_p \mathbb{P}(A)^{1/q} \leq \left(\sup_X \|X\|_p \right) \delta^{1/q} \rightarrow 0.$$

(ii) If $|X| \leq Y$ for all $X \in \mathcal{X}$ with $Y \in \mathcal{L}^1$, then $\mathcal{X}$ is UI, by Lemma 38.7.4 applied to Y . So domination is a special case of uniform integrability.

(iii) The family $\{n \mathbb{1}_{(0, 1/n)} : n \in \mathbb{N}\}$ on $(0, 1)$ is bounded in $\mathcal{L}^1$ (each has norm 1) but not UI: taking $A = (0, 1/n)$ gives $\mathbb{P}(A) \rightarrow 0$ while $\mathbb{E}[X_n \mathbb{1}_A] = 1$.

§38.7.3 The Vitali convergence theorem

We can now state the theorem which makes uniform integrability the right concept: it characterises $\mathcal{L}^1$ convergence exactly. First a bounded case.

Theorem 38.7.8 (Bounded convergence in probability)

Let $X_n \xrightarrow{\mathbb{P}} X$ with $|X_n| \leq C < \infty$ almost surely for all n . Then $X_n \rightarrow X$ in $\mathcal{L}^1$.

Proof. Along a subsequence $X_{n_k} \rightarrow X$ a.s., so $|X| \leq C$ a.s. Given $\varepsilon > 0$, split according to whether $|X_n - X|$ exceeds $\varepsilon/2$:

$$\mathbb{E}|X_n - X| = \mathbb{E}[|X_n - X| \mathbb{1}_{\{|X_n - X| > \varepsilon/2\}}] + \mathbb{E}[|X_n - X| \mathbb{1}_{\{|X_n - X| \leq \varepsilon/2\}}],$$

$$\text{so} \quad \mathbb{E}|X_n - X| \leq 2C \mathbb{P}(|X_n - X| > \varepsilon/2) + \frac{\varepsilon}{2},$$

which is $< \varepsilon$ for n large. □

Theorem 38.7.9 (Vitali convergence theorem)

Let X_n, X be random variables. The following are equivalent:

- (i) $X_n, X \in \mathcal{L}^1(\mathbb{P})$ and $X_n \rightarrow X$ in $\mathcal{L}^1$;
- (ii) $\{X_n : n \in \mathbb{N}\}$ is uniformly integrable and $X_n \xrightarrow{\mathbb{P}} X$.

Proof. (i) $\Rightarrow$ (ii). Markov's inequality gives $\mathbb{P}(|X_n - X| > \varepsilon) \leq \mathbb{E}|X_n - X|/\varepsilon \rightarrow 0$, so $X_n \xrightarrow{\mathbb{P}} X$. For uniform integrability, fix $\varepsilon > 0$ and take N with $\mathbb{E}|X_n - X| < \varepsilon/2$ for $n \geq N$. The finite family $\{X, X_1, \dots, X_N\}$ is UI by Lemma 38.7.4, so there is $\delta > 0$ with $\mathbb{E}[|Y|\mathbb{1}_A] < \varepsilon/2$ for Y in that family and $\mathbb{P}(A) \leq \delta$. For $n > N$ and such A ,

$$\mathbb{E}[|X_n|\mathbb{1}_A] \leq \mathbb{E}[|X_n - X|\mathbb{1}_A] + \mathbb{E}[|X|\mathbb{1}_A] < \frac{\varepsilon}{2} + \frac{\varepsilon}{2} = \varepsilon.$$

So the whole family is UI.

(ii) $\Rightarrow$ (i). Along a subsequence $X_{n_k} \rightarrow X$ a.s., so by Fatou

$$\mathbb{E}|X| = \mathbb{E}\left[\liminf_k |X_{n_k}|\right] \leq \liminf_k \mathbb{E}|X_{n_k}| \leq \sup_n \mathbb{E}|X_n| < \infty,$$

so $X \in \mathcal{L}^1$. Now let $g_K(x) = (-K) \vee x \wedge K$ be the truncation at level K ; it is 1-Lipschitz, so

$$\mathbb{P}(|g_K(X_n) - g_K(X)| > \varepsilon) \leq \mathbb{P}(|X_n - X| > \varepsilon) \rightarrow 0,$$

and $|g_K(\cdot)| \leq K$, so by Theorem 38.7.8 $g_K(X_n) \rightarrow g_K(X)$ in $\mathcal{L}^1$. Therefore

$$\begin{aligned} \mathbb{E}|X_n - X| &\leq \mathbb{E}|X_n - g_K(X_n)| + \mathbb{E}|g_K(X_n) - g_K(X)| + \mathbb{E}|g_K(X) - X| \\ &\leq \mathbb{E}[|X_n|\mathbb{1}_{\{|X_n|>K\}}] + \mathbb{E}|g_K(X_n) - g_K(X)| + \mathbb{E}[|X|\mathbb{1}_{\{|X|>K\}}]. \end{aligned}$$

Given $\varepsilon > 0$, choose K so that the first and third terms are each below $\varepsilon/3$ – possible by Lemma 38.7.6 for the first, and by Lemma 38.7.4 for the third – and then n large so the middle term is below $\varepsilon/3$. $\square$

Remark. Vitali's theorem contains the dominated convergence theorem on a probability space as a special case: domination by an integrable Y gives uniform integrability, and a.s. convergence gives convergence in probability. It is strictly stronger, since UI families need not be dominated.

§38.8 Laws of Large Numbers

The empirical content of probability theory is that averages of many independent measurements stabilise. We now prove this, in two forms of increasing strength.

§38.8.1 The weak law

Theorem 38.8.1 (Weak law of large numbers)

Let (X_n) be i.i.d. random variables with $\mathbb{E}[X_1] = \nu$ and $\text{Var}(X_1) = \sigma^2 < \infty$. Then

$$\frac{1}{n} \sum_{i=1}^n X_i \xrightarrow{\mathbb{P}} \nu \quad \text{as } n \rightarrow \infty.$$

Proof. Replacing X_i by $X_i - \nu$ we may assume $\nu = 0$. Let $S_n = \sum_{i \leq n} X_i$. By independence the variances add, so $\text{Var}(S_n) = n\sigma^2$, and Chebyshev's inequality gives

$$\mathbb{P}\left(\left|\frac{S_n}{n}\right| > \varepsilon\right) \leq \frac{\text{Var}(S_n)}{n^2\varepsilon^2} = \frac{\sigma^2}{n\varepsilon^2} \rightarrow 0. \quad \square$$

Notice that the proof also gives convergence in $\mathcal{L}^2$, since $\mathbb{E}[(S_n/n)^2] = \sigma^2/n \rightarrow 0$. The theorem is 'weak' in two respects: it assumes a second moment, and it concludes only convergence in probability. Both can be improved.

§38.8.2 A strong law under fourth moments

Convergence in probability allows the averages to make large excursions infinitely often, provided they do so with vanishing probability – the typewriter sequence of Example 38.7.3 does exactly that. The strong law rules this out. Here is a proof requiring a fourth moment, which is short and instructive; we will remove the hypothesis in §10.

Theorem 38.8.2 (Strong law under a fourth moment)

Let (X_n) be independent with $\mathbb{E}[X_n] = \nu$ and $\mathbb{E}[X_n^4] \leq M < \infty$ for all n . Then

$$\frac{1}{n} \sum_{i=1}^n X_i \rightarrow \nu \quad \text{almost surely.}$$

Proof. Replacing X_n by $Y_n = X_n - \nu$, which satisfies $\mathbb{E}[Y_n^4] \leq 2^4(\mathbb{E}[X_n^4] + \nu^4) < \infty$ by convexity of $t \mapsto t^4$, we may assume $\nu = 0$ and $\mathbb{E}[X_n^4] \leq M$.

Expand $\mathbb{E}[S_n^4]$ where $S_n = \sum_{i \leq n} X_i$. A term $\mathbb{E}[X_i X_j X_k X_\ell]$ with some index appearing exactly once vanishes by independence and $\mathbb{E}[X_i] = 0$; so the only surviving terms are those of the form $\mathbb{E}[X_i^4]$ and $\mathbb{E}[X_i^2 X_j^2]$ with $i \neq j$. There are n of the former and $\binom{n}{2} \binom{4}{2} = 3n(n-1)$ of the latter (choosing which two of the four factors carry index i), and by Cauchy–Schwarz $\mathbb{E}[X_i^2 X_j^2] \leq \sqrt{\mathbb{E}[X_i^4]} \sqrt{\mathbb{E}[X_j^4]} \leq M$. Hence

$$\mathbb{E}[S_n^4] \leq nM + 3n(n-1)M \leq 3n^2M.$$

Therefore, by Theorem 38.4.6(iv),

$$\mathbb{E}\left[\sum_{n=1}^{\infty} \left(\frac{S_n}{n}\right)^4\right] = \sum_{n=1}^{\infty} \frac{\mathbb{E}[S_n^4]}{n^4} \leq \sum_{n=1}^{\infty} \frac{3M}{n^2} < \infty.$$

A non-negative random variable with finite expectation is finite almost surely, so $\sum_n (S_n/n)^4 < \infty$ a.s., whence $(S_n/n)^4 \rightarrow 0$ and $S_n/n \rightarrow 0$ almost surely. $\square$

§38.8.3 The strong law in general

The theorem we are really after is the following, and it is the sharpest possible: no moment beyond the first is required, and the first cannot be dispensed with.

Theorem 38.8.3 (Strong law of large numbers)

Let (X_n) be i.i.d. with $\mathbb{E}|X_1| < \infty$ and $\mathbb{E}[X_1] = \nu$. Then

$$\frac{1}{n} \sum_{i=1}^n X_i \longrightarrow \nu \quad \text{almost surely, and in } \mathcal{L}^1.$$

We will prove this in §10 as a consequence of Birkhoff's ergodic theorem; the ergodic-theoretic route is the one taken in lectures and it is genuinely the cleanest. For now, observe that Kolmogorov's zero-one law already tells us something: the event $\{\frac{1}{n} \sum_{i \leq n} X_i \rightarrow c\}$ is a tail event, so it has probability 0 or 1, and $\limsup_n \frac{1}{n} \sum_{i \leq n} X_i$ is an almost surely constant element of $[-\infty, \infty]$. The strong law identifies that constant as $\mathbb{E}[X_1]$.

Remark. The integrability hypothesis cannot be weakened. If $\mathbb{E}|X_1| = \infty$ then by the second Borel–Cantelli lemma applied to $A_n = \{|X_n| > n\}$ – whose probabilities sum to ∞ precisely when $\mathbb{E}|X_1| = \infty$ – we get $|X_n| > n$ infinitely often almost surely, and hence S_n/n cannot converge (since $\frac{X_n}{n} = \frac{S_n}{n} - \frac{n-1}{n} \frac{S_{n-1}}{n-1}$ would have to tend to zero). For a Cauchy sample, for instance, S_n/n has the same Cauchy distribution for every n and does not converge at all.

Remark (How fast?). The strong law says $S_n/n \rightarrow \nu$; the central limit theorem of §9 will say that the error is of order $n^{-1/2}$ in distribution. Sharper still, the *law of the iterated logarithm* states that if $\mathbb{E}X_1 = 0$ and $\text{Var } X_1 = 1$ then

$$\limsup_n \frac{S_n}{\sqrt{2n \log \log n}} = 1, \quad \liminf_n \frac{S_n}{\sqrt{2n \log \log n}} = -1 \quad \text{a.s.}$$

In particular $S_n/\sqrt{n}$ does *not* converge almost surely – it oscillates forever between $\pm\sqrt{2 \log \log n}$ – so the central limit theorem really is a statement about distributions and nothing more.

§38.9 Fourier Transforms and Characteristic Functions

§38.9.1 The Fourier transform in L^1

We now allow complex-valued functions. For $f = u + iv$ with u, v real and integrable, define $\int f = \int u + i \int v$; this is complex-linear, and the fundamental estimate still holds:

Lemma 38.9.1

For $f \in L^1(\mathbb{R}^d; \mathbb{C})$ we have $|\int f| \leq \int |f|$.

Proof. Choose $\alpha \in \mathbb{C}$ with $|\alpha| = 1$ and $\alpha \int f = |\int f|$. Then $|\int f| = \int \alpha f$ is real, so it equals $\int \text{Re}(\alpha f) \leq \int |\alpha f| = \int |f|$. $\square$

Write $L^p(\mathbb{R}^d)$ for the complex L^p spaces with respect to Lebesgue measure, and $\langle u, x \rangle = \sum_i u_i x_i$.

Definition 38.9.2 (Fourier transform)

For $f \in L^1(\mathbb{R}^d)$ the **Fourier transform** is

$$\hat{f}(u) = \int_{\mathbb{R}^d} f(x) e^{i\langle u, x \rangle} dx, \quad u \in \mathbb{R}^d.$$

For a finite Borel measure μ on $\mathbb{R}^d$, set $\hat{\mu}(u) = \int_{\mathbb{R}^d} e^{i\langle u, x \rangle} d\mu(x)$.

Remark. Immediately $|\hat{f}(u)| \leq \|f\|_1$ and $|\hat{\mu}(u)| \leq \mu(\mathbb{R}^d)$. Moreover if $u_n \rightarrow u$ then $e^{i\langle u_n, x \rangle} \rightarrow e^{i\langle u, x \rangle}$ pointwise, dominated by $|f|$ (respectively by 1, integrable for a finite measure), so by dominated convergence $\hat{f}$ and $\hat{\mu}$ are *continuous and bounded*. If μ has density f then $\hat{\mu} = \hat{f}$.

Different authors put the 2π and the sign in different places; the convention above is the one used in this course, and it is chosen so that the characteristic function below comes out with no constants at all.

Definition 38.9.3 (Characteristic function)

Let X be an $\mathbb{R}^d$ -valued random variable with law μ_X . Its **characteristic function** is

$$\varphi_X(u) = \mathbb{E}[e^{i\langle u, X \rangle}] = \hat{\mu}_X(u).$$

So φ_X is continuous, $\varphi_X(0) = 1$, $|\varphi_X(u)| \leq 1$, and $\varphi_X(-u) = \overline{\varphi_X(u)}$. Our goals are: (a) φ_X determines μ_X ; (b) pointwise convergence of φ_{X_n} implies convergence in distribution of X_n ; and (c) hence the central limit theorem. All three go through Gaussians.

§38.9.2 Convolution**Definition 38.9.4 (Convolution)**

Let $f \in L^1(\mathbb{R}^d)$ and let ν be a probability measure on $\mathbb{R}^d$. Define

$$(f * \nu)(x) = \begin{cases} \int_{\mathbb{R}^d} f(x-y) d\nu(y), & \text{if } y \mapsto f(x-y) \in L^1(\nu), \\ 0, & \text{otherwise.} \end{cases}$$

If ν has density g we write $f * g$. For probability measures μ, ν the convolution $\mu * \nu$ is the law of $X + Y$ with $X \sim \mu$, $Y \sim \nu$ independent, so

$$(\mu * \nu)(A) = \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} \mathbb{1}_A(x+y) d\nu(y) d\mu(x).$$

Proposition 38.9.5

For $1 \leq p < \infty$ and $f \in L^p(\mathbb{R}^d)$, the map $f \mapsto f * \nu$ is a contraction of $L^p(\mathbb{R}^d)$: $\|f * \nu\|_p \leq \|f\|_p$. In particular $y \mapsto f(x-y)$ lies in $L^p(\nu)$ for almost every x .

Proof. Since ν is a probability measure, Jensen's inequality applied to the convex

function $t \mapsto |t|^p$ gives

$$\left| \int f(x-y) \, d\nu(y) \right|^p \leq \int |f(x-y)|^p \, d\nu(y).$$

Integrating in x and applying Tonelli together with translation invariance of Lebesgue measure,

$$\int_{\mathbb{R}^d} \int_{\mathbb{R}^d} |f(x-y)|^p \, d\nu(y) \, dx = \int_{\mathbb{R}^d} \left(\int_{\mathbb{R}^d} |f(x-y)|^p \, dx \right) d\nu(y) = \|f\|_p^p. \quad \square$$

Proposition 38.9.6

$\widehat{f * \nu} = \hat{f} \hat{\nu}$ and $\widehat{\mu * \nu} = \hat{\mu} \hat{\nu}$. If μ has density f then $\mu * \nu$ has density $f * \nu$.

Proof. The second identity is a one-liner: with $X \sim \mu$, $Y \sim \nu$ independent,

$$\widehat{\mu * \nu}(u) = \mathbb{E}[e^{i\langle u, X+Y \rangle}] = \mathbb{E}[e^{i\langle u, X \rangle}] \mathbb{E}[e^{i\langle u, Y \rangle}] = \hat{\mu}(u) \hat{\nu}(u),$$

using Proposition 38.5.6(iii). The first follows by Fubini:

$$\widehat{f * \nu}(u) = \iint f(x-y) e^{i\langle u, x \rangle} \, d\nu(y) \, dx = \int e^{i\langle u, y \rangle} \left(\int f(z) e^{i\langle u, z \rangle} \, dz \right) d\nu(y),$$

which is $\hat{f}(u) \hat{\nu}(u)$, on substituting $z = x - y$. For the density claim, with A Borel,

$$(\mu * \nu)(A) = \iint \mathbb{1}_A(x+y) f(x) \, dx \, d\nu(y) = \int \mathbb{1}_A(v) \left(\int f(v-y) \, d\nu(y) \right) dv. \quad \square$$

In probabilistic language: the characteristic function of a sum of independent random variables is the product of their characteristic functions. That single fact is what makes characteristic functions the tool of choice for limit theorems about sums.

§38.9.3 Gaussians

Definition 38.9.7

For $t > 0$ let g_t denote the density of the $N(0, tI_d)$ distribution on $\mathbb{R}^d$:

$$g_t(x) = (2\pi t)^{-d/2} e^{-|x|^2/(2t)}.$$

Proposition 38.9.8

$\hat{g}_t(u) = e^{-|u|^2 t/2}$, and consequently $\hat{g}_t = (2\pi)^{d/2} t^{d/2} g_{1/t}$. The Fourier inversion formula

$$g_t(x) = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} e^{-i\langle u, x \rangle} \hat{g}_t(u) \, du$$

holds for every $t > 0$.

Proof. Take $d = 1$ and $t = 1$ first, and let $\varphi(u) = \hat{g}_1(u) = \mathbb{E}[e^{iuZ}]$ where $Z \sim N(0, 1)$. Differentiating under the integral sign – which is legitimate by Theorem 38.4.14,

since $|\partial_u(e^{iux}g_1(x))| \leq |x|g_1(x)$ is integrable – and then integrating by parts,

$$\varphi'(u) = i \int_{\mathbb{R}} x e^{iux} g_1(x) \, dx = \frac{i}{\sqrt{2\pi}} \int_{\mathbb{R}} e^{iux} (x e^{-x^2/2}) \, dx,$$

$$\varphi'(u) = \frac{i}{\sqrt{2\pi}} \left[-e^{iux} e^{-x^2/2} \right]_{-\infty}^{\infty} + \frac{i^2 u}{\sqrt{2\pi}} \int_{\mathbb{R}} e^{iux} e^{-x^2/2} \, dx,$$

so $\varphi'(u) = -u\varphi(u)$. Hence $\frac{d}{du}(e^{u^2/2}\varphi(u)) = 0$, and since $\varphi(0) = 1$ we get $\varphi(u) = e^{-u^2/2}$.

In general, if $Z = (Z_1, \dots, Z_d)$ has i.i.d. $N(0, 1)$ entries then $\sqrt{t}Z$ has density g_t , and by independence

$$\hat{g}_t(u) = \mathbb{E}[e^{i\langle u, \sqrt{t}Z \rangle}] = \prod_{j=1}^d \mathbb{E}[e^{iu_j \sqrt{t}Z_j}] = \prod_{j=1}^d e^{-u_j^2 t/2} = e^{-|u|^2 t/2}.$$

Comparing with the definition of $g_{1/t}$ gives $\hat{g}_t = (2\pi)^{d/2} t^{d/2} g_{1/t}$. Applying the transform twice,

$$\hat{\hat{g}}_t = (2\pi)^{d/2} t^{d/2} \hat{g}_{1/t} = (2\pi)^{d/2} t^{d/2} (2\pi)^{d/2} t^{-d/2} g_t = (2\pi)^d g_t,$$

and since g_t is even, $\hat{\hat{g}}_t(x) = \int e^{-i\langle u, x \rangle} \hat{g}_t(u) \, du$, which is the inversion formula. $\square$

$$X \sim N(0, 1) \\ \varphi(u) = e^{-u^2/2}$$

$$X \sim U[-1, 1] \\ \varphi(u) = \frac{\sin u}{u}$$

Definition 38.9.9 (Gaussian convolution)

A **Gaussian convolution** is a function of the form $f * g_t$ with $f \in L^1(\mathbb{R}^d)$ and $t > 0$.

Gaussian convolutions are the technical device that makes everything work: they are smooth, their Fourier transforms decay rapidly, and they approximate arbitrary L^p functions.

Lemma 38.9.10

Fourier inversion holds for every Gaussian convolution:

$$(f * g_t)(x) = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} e^{-i\langle u, x \rangle} \widehat{f * g_t}(u) \, du = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} e^{-i\langle u, x \rangle} \hat{f}(u) e^{-|u|^2 t/2} \, du.$$

Proof. Note first that $\widehat{f * g_t}(u) = \hat{f}(u) e^{-|u|^2 t/2}$ is integrable, since $|\hat{f}| \leq \|f\|_1$. Now use inversion for g_t and Fubini (justified since $(x, u) \mapsto f(x - y) \hat{g}_t(u)$ is absolutely

integrable):

$$\begin{aligned}(2\pi)^d(f * g_t)(x) &= \int_{\mathbb{R}^d} f(x-y) \left(\int_{\mathbb{R}^d} e^{-i\langle u, y \rangle} \hat{g}_t(u) \, du \right) dy \\ &= \int_{\mathbb{R}^d} e^{-i\langle u, x \rangle} \left(\int_{\mathbb{R}^d} f(x-y) e^{i\langle u, x-y \rangle} dy \right) \hat{g}_t(u) \, du \\ &= \int_{\mathbb{R}^d} e^{-i\langle u, x \rangle} \hat{f}(u) \hat{g}_t(u) \, du,\end{aligned}$$

substituting $z = x - y$ in the inner integral. $\square$

Lemma 38.9.11 (Gaussian convolutions approximate)

Let $1 \leq p < \infty$ and $f \in L^p(\mathbb{R}^d)$. Then $\|f * g_t - f\|_p \rightarrow 0$ as $t \downarrow 0$.

Proof. The space $C_c(\mathbb{R}^d)$ of continuous compactly supported functions is dense in $L^p(\mathbb{R}^d)$. Given $\varepsilon > 0$ pick $h \in C_c$ with $\|f - h\|_p < \varepsilon/3$; by Proposition 38.9.5,

$$\|f * g_t - h * g_t\|_p = \|(f - h) * g_t\|_p \leq \|f - h\|_p < \varepsilon/3,$$

so it suffices to prove the result for $h \in C_c(\mathbb{R}^d)$.

Let $e(y) = \int_{\mathbb{R}^d} |h(x-y) - h(x)|^p \, dx$. Since h is bounded with compact support, dominated convergence shows e is continuous with $e(0) = 0$, and $e(y) \leq 2^{p+1} \|h\|_p^p$ for all y . By Jensen as in Proposition 38.9.5,

$$\begin{aligned}\|h * g_t - h\|_p^p &\leq \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} |h(x-y) - h(x)|^p \, dx g_t(y) \, dy \\ &= \int_{\mathbb{R}^d} e(y) g_t(y) \, dy = \int_{\mathbb{R}^d} e(\sqrt{t}z) g_1(z) \, dz,\end{aligned}$$

substituting $y = \sqrt{t}z$. As $t \downarrow 0$ the integrand tends to $e(0) = 0$ pointwise and is dominated by $2^{p+1} \|h\|_p^p g_1(z)$, so the integral tends to 0. $\square$

§38.9.4 Fourier inversion and Plancherel

Theorem 38.9.12 (Fourier inversion)

Let $f \in L^1(\mathbb{R}^d)$ with $\hat{f} \in L^1(\mathbb{R}^d)$. Then for almost every x ,

$$f(x) = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} e^{-i\langle u, x \rangle} \hat{f}(u) \, du.$$

Proof. By Lemma 38.9.10, for every $t > 0$,

$$(f * g_t)(x) = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} e^{-i\langle u, x \rangle} \hat{f}(u) e^{-|u|^2 t/2} \, du.$$

As $t \downarrow 0$ the right-hand side converges, for every x , to $\frac{1}{(2\pi)^d} \int e^{-i\langle u, x \rangle} \hat{f}(u) \, du$ by dominated convergence with dominating function $|\hat{f}| \in L^1$. On the left, Lemma 38.9.11 gives $f * g_t \rightarrow f$ in L^1 , hence in measure by Markov's inequality, hence

almost everywhere along a subsequence $t_k \downarrow 0$. Uniqueness of limits gives the result almost everywhere. $\square$

Corollary 38.9.13

The Fourier transform is injective on $L^1(\mathbb{R}^d)$: if $\hat{f} = \hat{g}$ then $f = g$ almost everywhere.

Proof. Apply the theorem to $f - g$, whose transform is $0 \in L^1$. $\square$

Theorem 38.9.14 (Plancherel identity)

For $f \in L^1(\mathbb{R}^d) \cap L^2(\mathbb{R}^d)$ we have $\|\hat{f}\|_2 = (2\pi)^{d/2} \|f\|_2$.

Proof. Suppose first that $\hat{f} \in L^1$ as well. Then f and $\hat{f}$ are both bounded (being inverse transforms of L^1 functions) and integrable, so Fubini applies to $(x, u) \mapsto f(x)\hat{f}(u)$, and using inversion,

$$\begin{aligned} (2\pi)^d \|f\|_2^2 &= (2\pi)^d \int f(x) \overline{f(x)} \, dx = \int \left(\int e^{-i\langle u, x \rangle} \hat{f}(u) \, du \right) \overline{f(x)} \, dx \\ &= \int \hat{f}(u) \overline{\left(\int e^{i\langle u, x \rangle} f(x) \, dx \right)} \, du = \int |\hat{f}(u)|^2 \, du = \|\hat{f}\|_2^2. \end{aligned}$$

For general $f \in L^1 \cap L^2$, apply the above to $f_t = f * g_t$, whose transform $\hat{f} e^{-|u|^2 t/2}$ is integrable. By Lemma 38.9.11, $\|f_t\|_2 \rightarrow \|f\|_2$; and $|\hat{f}(u)|^2 e^{-|u|^2 t}$ increases to $|\hat{f}(u)|^2$ as $t \downarrow 0$, so $\|\hat{f}_t\|_2^2 \uparrow \|\hat{f}\|_2^2$ by monotone convergence. Passing to the limit in $(2\pi)^d \|f_t\|_2^2 = \|\hat{f}_t\|_2^2$ gives the result. $\square$

Corollary 38.9.15 (The Fourier transform on L^2)

The map $F_0(f) = (2\pi)^{-d/2} \hat{f}$, defined on the dense subspace $L^1 \cap L^2$ of $L^2(\mathbb{R}^d)$, extends uniquely to a linear isometry $F : L^2(\mathbb{R}^d) \rightarrow L^2(\mathbb{R}^d)$, the **Fourier–Plancherel transform**. It is in fact a surjective isometry, with $\langle Ff, Fg \rangle = \langle f, g \rangle$.

Proof. $L^1 \cap L^2$ contains all $f \mathbb{1}_{B(0,n)}$ for $f \in L^2$, hence is dense; F_0 is an isometry there by Theorem 38.9.14; and L^2 is complete, so the extension exists and is unique. Preservation of the inner product follows by polarisation. $\square$

Example 38.9.16

Not every measure has an L^1 transform. For the Dirac mass δ_0 on $\mathbb{R}$ we get $\hat{\delta}_0(u) = \int e^{iux} \, d\delta_0(x) = 1$, which is not integrable, and indeed δ_0 has no density. This is exactly the case the inversion theorem excludes.

§38.9.5 Characteristic functions determine laws

Theorem 38.9.17 (Uniqueness)

Let X be an $\mathbb{R}^d$ -valued random variable. Then φ_X determines μ_X . If moreover $\varphi_X \in L^1(\mathbb{R}^d)$, then μ_X has a density given almost everywhere by

$$f_X(x) = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} e^{-i\langle u, x \rangle} \varphi_X(u) \, du.$$

Proof. Let Z be a standard Gaussian vector in $\mathbb{R}^d$ independent of X , so $\sqrt{t}Z$ has density g_t and $X + \sqrt{t}Z$ has law $\mu_X * g_t$, which has density $f_t = \mu_X * g_t$. Since $\mu_X * g_t = (\mu_X * g_{t/2}) * g_{t/2}$ and $\mu_X * g_{t/2} \in L^1$, this is a Gaussian convolution, so Lemma 38.9.10 gives

$$f_t(x) = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} e^{-i\langle u, x \rangle} \varphi_X(u) e^{-|u|^2 t/2} \, du,$$

which depends on μ_X only through φ_X .

Now let $g : \mathbb{R}^d \rightarrow \mathbb{R}$ be bounded and continuous. Then $g(X + \sqrt{t}Z) \rightarrow g(X)$ almost surely as $t \downarrow 0$, and $|g(X + \sqrt{t}Z)| \leq \|g\|_\infty$, so by bounded convergence

$$\int_{\mathbb{R}^d} g(x) f_t(x) \, dx = \mathbb{E}[g(X + \sqrt{t}Z)] \rightarrow \mathbb{E}[g(X)] = \int_{\mathbb{R}^d} g \, d\mu_X.$$

The left-hand side is determined by φ_X , hence so is $\int g \, d\mu_X$ for every bounded continuous g ; and two Borel probability measures agreeing against all such g are equal. So φ_X determines μ_X .

If $\varphi_X \in L^1$, dominated convergence shows $f_t(x) \rightarrow f_X(x)$ for every x , with f_X as displayed, and $f_X \geq 0$ as a limit of the non-negative f_t . For g bounded continuous with compact support, $|g(x)f_t(x)| \leq \|g\|_\infty (2\pi)^{-d} \|\varphi_X\|_1 \mathbb{1}_{\text{supp } g}$, an integrable bound, so

$$\int g f_X = \lim_{t \downarrow 0} \int g f_t = \int g \, d\mu_X,$$

whence μ_X has density f_X . □

§38.9.6 Weak convergence and Lévy's continuity theorem

Definition 38.9.18 (Weak convergence)

Borel probability measures μ_n on $\mathbb{R}^d$ **converge weakly** to μ , written $\mu_n \xrightarrow{w} \mu$, if $\mu_n(g) \rightarrow \mu(g)$ for every bounded continuous $g : \mathbb{R}^d \rightarrow \mathbb{R}$. For random vectors we say $X_n \rightarrow X$ weakly if $\mu_{X_n} \xrightarrow{w} \mu_X$.

Remark. For $d = 1$ weak convergence coincides with convergence in distribution as defined in §7. (One direction: apply the definition to continuous approximations of $\mathbb{1}_{(-\infty, x]}$ from above and below. The other uses the Skorokhod representation or a direct argument with the distribution functions.) It also suffices to test against $g \in C_c^\infty(\mathbb{R}^d)$, the smooth compactly supported functions, by a routine approximation.

Theorem 38.9.19 (Lévy's continuity theorem)

Let X_n, X be $\mathbb{R}^d$ -valued random vectors with $\varphi_{X_n}(u) \rightarrow \varphi_X(u)$ for every $u \in \mathbb{R}^d$. Then $X_n \rightarrow X$ weakly.

Proof. By the remark it suffices to show $\mathbb{E}[g(X_n)] \rightarrow \mathbb{E}[g(X)]$ for $g \in C_c^\infty(\mathbb{R}^d)$. Such a g is bounded, integrable, and Lipschitz with some constant $\|g\|_{\text{Lip}}$.

Let Z be a standard Gaussian vector independent of everything, and let $\varepsilon > 0$. Choose $t > 0$ small enough that $2\|g\|_{\text{Lip}}\sqrt{t}\mathbb{E}|Z| < 2\varepsilon/3$. Then

$$\begin{aligned} |\mathbb{E}[g(X_n)] - \mathbb{E}[g(X)]| &\leq \mathbb{E}|g(X_n) - g(X_n + \sqrt{t}Z)| + \mathbb{E}|g(X) - g(X + \sqrt{t}Z)| \\ &\quad + |\mathbb{E}[g(X_n + \sqrt{t}Z)] - \mathbb{E}[g(X + \sqrt{t}Z)]| \\ &\leq \frac{2\varepsilon}{3} + |\mathbb{E}[g(X_n + \sqrt{t}Z)] - \mathbb{E}[g(X + \sqrt{t}Z)]|, \end{aligned}$$

using the Lipschitz bound on the first two terms. For the remaining term, write $f_{t,n} = \mu_{X_n} * g_t$ for the density of $X_n + \sqrt{t}Z$; by Lemma 38.9.10,

$$\mathbb{E}[g(X_n + \sqrt{t}Z)] = \int_{\mathbb{R}^d} g(x) f_{t,n}(x) \, dx = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} g(x) e^{-i\langle u, x \rangle} \varphi_{X_n}(u) e^{-\frac{|u|^2 t}{2}} \, du \, dx.$$

The integrand converges pointwise as $n \rightarrow \infty$ (since $\varphi_{X_n} \rightarrow \varphi_X$ pointwise) and is dominated by $|g(x)|e^{-|u|^2 t/2}$, which is integrable on $\mathbb{R}^d \times \mathbb{R}^d$ because $|\varphi_{X_n}| \leq 1$. So by dominated convergence the whole expression converges to $\mathbb{E}[g(X + \sqrt{t}Z)]$, and the last term is below $\varepsilon/3$ for n large. $\square$

The converse is trivial: if $X_n \rightarrow X$ weakly, then testing against $x \mapsto \cos\langle u, x \rangle$ and $x \mapsto \sin\langle u, x \rangle$ gives $\varphi_{X_n}(u) \rightarrow \varphi_X(u)$. So convergence in distribution is *equivalent* to pointwise convergence of characteristic functions, and this is what makes the following possible.

§38.9.7 The central limit theorem

Theorem 38.9.20 (Central limit theorem)

Let (X_n) be i.i.d. real random variables with $\mathbb{E}[X_1] = 0$ and $\text{Var}(X_1) = 1$, and let $S_n = \sum_{i=1}^n X_i$. Then

$$\frac{S_n}{\sqrt{n}} \longrightarrow Z \sim N(0, 1) \quad \text{weakly, i.e. } \mathbb{P}\left(\frac{S_n}{\sqrt{n}} \leq x\right) \rightarrow \mathbb{P}(Z \leq x) \text{ for all } x \in \mathbb{R}.$$

Proof. Let $\varphi = \varphi_{X_1}$. Since $\mathbb{E}[X_1^2] < \infty$, Theorem 38.4.14 lets us differentiate twice under the expectation:

$$\varphi'(u) = i\mathbb{E}[X_1 e^{iuX_1}], \quad \varphi''(u) = -\mathbb{E}[X_1^2 e^{iuX_1}],$$

the dominating functions being $|X_1|$ and X_1^2 . So $\varphi(0) = 1$, $\varphi'(0) = i\mathbb{E}[X_1] = 0$ and $\varphi''(0) = -\mathbb{E}[X_1^2] = -1$. Taylor's theorem with Peano remainder gives

$$\varphi(v) = 1 - \frac{v^2}{2} + o(v^2) \quad \text{as } v \rightarrow 0.$$

Now by independence,

$$\varphi_{S_n/\sqrt{n}}(u) = \mathbb{E}\left[e^{i\frac{u}{\sqrt{n}}(X_1 + \dots + X_n)}\right] = \prod_{j=1}^n \mathbb{E}\left[e^{i\frac{u}{\sqrt{n}}X_j}\right] = \left[\varphi\left(\frac{u}{\sqrt{n}}\right)\right]^n = \left[1 - \frac{u^2}{2n} + o\left(\frac{1}{n}\right)\right]^n.$$

Fix u . For n large the bracket is within a neighbourhood of 1 where the principal branch of $\log$ satisfies $\log(1+z) = z + O(|z|^2)$, so

$$\log \varphi_{S_n/\sqrt{n}}(u) = n \log \left(1 - \frac{u^2}{2n} + o(n^{-1}) \right) = n \left(-\frac{u^2}{2n} + o(n^{-1}) \right) \longrightarrow -\frac{u^2}{2}.$$

Hence $\varphi_{S_n/\sqrt{n}}(u) \rightarrow e^{-u^2/2} = \varphi_Z(u)$ for every u , and Lévy's continuity theorem gives $S_n/\sqrt{n} \rightarrow Z$ weakly. Since the distribution function of Z is continuous everywhere, the convergence holds at every x . $\square$

Remark. For general i.i.d. X_i with mean ν and variance $\sigma^2 \in (0, \infty)$, apply the theorem to $(X_i - \nu)/\sigma$ to get

$$\frac{S_n - n\nu}{\sigma\sqrt{n}} \longrightarrow N(0, 1) \quad \text{weakly.}$$

This is the version met in IA Probability, where it was proved for special cases using moment generating functions; the argument here is the general one, and the reason it works is that characteristic functions always exist whereas moment generating functions need not.

§38.9.8 Gaussian random vectors

Definition 38.9.21

A random vector X in $\mathbb{R}^d$ is a **Gaussian vector** if $\langle X, v \rangle$ is a (possibly degenerate) real Gaussian random variable for every $v \in \mathbb{R}^d$.

Proposition 38.9.22

Let X be a Gaussian vector in $\mathbb{R}^d$ with mean $m = \mathbb{E}[X]$ and covariance matrix $V = (\text{Cov}(X_i, X_j))_{ij}$. Then:

- (i) $AX + b$ is a Gaussian vector in $\mathbb{R}^m$ for any $m \times d$ matrix A and $b \in \mathbb{R}^m$;
- (ii) $\varphi_X(u) = \exp(i\langle m, u \rangle - \frac{1}{2}\langle u, Vu \rangle)$, so m and V determine the law of X ;
- (iii) if V is invertible then X has density

$$f_X(x) = (2\pi)^{-d/2} (\det V)^{-1/2} \exp \left(-\frac{1}{2} \langle x - m, V^{-1}(x - m) \rangle \right);$$

- (iv) sub-vectors $X_{(1)}, X_{(2)}$ of X are independent if and only if $\text{Cov}(X_{(1)}, X_{(2)}) = 0$.

Proof sketch. (i) $\langle AX + b, v \rangle = \langle X, A^T v \rangle + \langle b, v \rangle$ is Gaussian.

(ii) $\langle u, X \rangle$ is real Gaussian with mean $\langle m, u \rangle$ and variance $\langle u, Vu \rangle$, and a real $N(\alpha, \sigma^2)$ variable Y has $\mathbb{E}[e^{iY}] = e^{i\alpha - \sigma^2/2}$ by Proposition 38.9.8 and translation. Taking $\varphi_X(u) = \mathbb{E}[e^{i\langle u, X \rangle}]$ gives the formula, and Theorem 38.9.17 gives uniqueness.

(iii) Write $V = \Sigma \Sigma^T$ and check that $m + \Sigma Z$, for Z standard Gaussian, has the stated characteristic function; then change variables in the density of Z .

(iv) If $\text{Cov}(X_{(1)}, X_{(2)}) = 0$ then V is block diagonal and φ_X factorises as $\varphi_{X_{(1)}} \varphi_{X_{(2)}}$, so by uniqueness $\mu_X = \mu_{X_{(1)}} \otimes \mu_{X_{(2)}}$ and Proposition 38.5.6 applies. The converse

is immediate. $\square$

Part (iv) deserves emphasis: for *jointly* Gaussian variables, uncorrelated is the same as independent. This is false in general – if $X \sim N(0, 1)$ and $\epsilon = \pm 1$ with equal probability independently of X , then X and ϵX are each standard Gaussian and uncorrelated, but obviously not independent; the pair $(X, \epsilon X)$ is not a Gaussian vector.

Proposition 38.9.23 (Slutsky-type results)

Let $X_n \rightarrow X$ weakly in $\mathbb{R}^d$. Then

- (i) $h(X_n) \rightarrow h(X)$ weakly for any continuous $h : \mathbb{R}^d \rightarrow \mathbb{R}^k$;
- (ii) if $|X_n - Y_n| \rightarrow 0$ in probability then $Y_n \rightarrow X$ weakly;
- (iii) if $Y_n \rightarrow c$ in probability for a constant c , then $(X_n, Y_n) \rightarrow (X, c)$ weakly.

In particular $X_n + Y_n \rightarrow X + c$ weakly, and for $d = 1$ also $X_n Y_n \rightarrow cX$ weakly.

Proof. (i) If g is bounded continuous then so is $g \circ h$.

(ii) It suffices to test against bounded Lipschitz g . Splitting on whether $|X_n - Y_n|$ exceeds $\eta = \varepsilon/(3\|g\|_{\text{Lip}})$,

$$\mathbb{E}|g(X_n) - g(Y_n)| \leq \|g\|_{\text{Lip}}\eta + 2\|g\|_{\infty}\mathbb{P}(|X_n - Y_n| > \eta) < \frac{2\varepsilon}{3}$$

for n large, and $|\mathbb{E}[g(X_n)] - \mathbb{E}[g(X)]| < \varepsilon/3$ for n large.

(iii) $(X_n, c) \rightarrow (X, c)$ weakly, since $g(\cdot, c)$ is bounded continuous; and $|(X_n, Y_n) - (X_n, c)| = |Y_n - c| \rightarrow 0$ in probability, so (ii) applies. $\square$

These are the results one uses in statistics to justify replacing an unknown variance by a consistent estimator inside a central limit theorem.

§38.10 Ergodic Theory

§38.10.1 Measure-preserving transformations

Ergodic theory studies the long-run behaviour of a system evolving under repeated application of a single map. We will develop just enough of it to prove the strong law of large numbers in full generality, which turns out to be a special case.

Throughout, $(E, \mathcal{E}, \mu)$ is a σ -finite measure space.

Definition 38.10.1 (Measure-preserving)

A measurable map $\Theta : E \rightarrow E$ is **measure-preserving** if $\mu(\Theta^{-1}(A)) = \mu(A)$ for all $A \in \mathcal{E}$.

If Θ is measure-preserving then $\mu \circ \Theta^{-1} = \mu$, so by the change of variables formula (Proposition 38.4.15), for any $f \in L^1(\mu)$ we have $f \circ \Theta \in L^1(\mu)$ with

$$\int_E f \circ \Theta \, d\mu = \int_E f \, d\mu.$$

Definition 38.10.2 (Invariance and ergodicity)

A set $A \in \mathcal{E}$ is **invariant** if $\Theta^{-1}(A) = A$, and a measurable $f : E \rightarrow \mathbb{R}$ is invariant if $f \circ \Theta = f$. We write $\mathcal{E}_\Theta$ for the collection of invariant sets.

We say Θ is **ergodic** if every invariant A satisfies $\mu(A) = 0$ or $\mu(A^c) = 0$.

One checks at once that $\mathcal{E}_\Theta$ is a σ -algebra, and that f is invariant if and only if it is $\mathcal{E}_\Theta$ -measurable. Consequently, if Θ is ergodic then every invariant f is almost everywhere constant: the sets $\{f \leq y\}$ are invariant, so $y \mapsto \mu(\{f \leq y\})$ takes only the values 0 and $\mu(E)$, and f equals $\inf\{y : \mu(f > y) = 0\}$ a.e.

Ergodicity says that the system cannot be split into two non-trivial pieces which do not communicate. It is the dynamical analogue of irreducibility for a Markov chain.

Example 38.10.3 (Circle rotation)

Take $(E, \mathcal{E}, \mu) = ((0, 1], \mathcal{B}, \text{Lebesgue})$ and, for $a \in (0, 1)$,

$$\Theta_a(x) = x + a \bmod 1.$$

This preserves μ by the translation invariance established in §2.5. It is ergodic if and only if a is irrational. If $a = p/q$ is rational then $\Theta_a^q = \text{id}$, so the union of q well-separated small intervals spaced $1/q$ apart is invariant and non-trivial. If a is irrational, the orbit $\{x, x \oplus a, x \oplus 2a, \dots\}$ of any point is dense in the circle, and this can be turned into a proof of ergodicity (one convenient route uses Fourier coefficients: if f is invariant and in L^2 then its Fourier coefficients satisfy $\hat{f}(k)e^{2\pi ika} = \hat{f}(k)$, forcing $\hat{f}(k) = 0$ for $k \neq 0$).

Our object of study is the sequence of **ergodic averages**. For measurable f set

$$S_0(f) = 0, \quad S_n(f) = f + f \circ \Theta + \dots + f \circ \Theta^{n-1}.$$

The question is what $S_n(f)/n$ does as $n \rightarrow \infty$: does the time average of f along an orbit converge, and if so, to what?

§38.10.2 The maximal ergodic lemma

Everything follows from the following deceptively simple inequality.

Lemma 38.10.4 (Maximal ergodic lemma)

Let Θ be measure-preserving on $(E, \mathcal{E}, \mu)$ and let $f \in L^1(\mu)$. Put $S^* = \sup_{n \geq 0} S_n(f)$.

Then

$$\int_{\{S^* > 0\}} f \, d\mu \geq 0.$$

Proof. Put $S_n^* = \max_{0 \leq k \leq n} S_k$, so $S_n^* \geq 0$ (as $S_0 = 0$) and $S_n^* \uparrow S^*$. For $0 \leq k \leq n$,

$$S_{k+1} = f + S_k \circ \Theta \leq f + S_n^* \circ \Theta.$$

Let $A_n = \{S_n^* > 0\}$, so $A_n \uparrow \{S^* > 0\}$. On A_n the maximum defining S_n^* is attained at some $k \geq 1$, so

$$S_n^* = \max_{1 \leq k \leq n} S_k \leq \max_{0 \leq k \leq n-1} (f + S_n^* \circ \Theta) = f + S_n^* \circ \Theta \quad \text{on } A_n.$$

Integrating over A_n ,

$$\int_{A_n} S_n^* \, d\mu \leq \int_{A_n} S_n^* \circ \Theta \, d\mu + \int_{A_n} f \, d\mu.$$

On A_n^c we have $S_n^* = 0 \leq S_n^* \circ \Theta$, so adding $\int_{A_n^c} S_n^* \, d\mu \leq \int_{A_n^c} S_n^* \circ \Theta \, d\mu$ gives

$$\int_E S_n^* \, d\mu \leq \int_E S_n^* \circ \Theta \, d\mu + \int_{A_n} f \, d\mu = \int_E S_n^* \, d\mu + \int_{A_n} f \, d\mu,$$

using that Θ preserves μ . As S_n^* is integrable (being bounded by $\sum_{k \leq n} |f| \circ \Theta^k$), we may cancel and obtain $\int_{A_n} f \, d\mu \geq 0$. Finally $f \mathbb{1}_{A_n} \rightarrow f \mathbb{1}_{\{S^* > 0\}}$ pointwise with $|f \mathbb{1}_{A_n}| \leq |f| \in L^1$, so dominated convergence gives the claim. $\square$

§38.10.3 Birkhoff's ergodic theorem

Theorem 38.10.5 (Birkhoff)

Let Θ be measure-preserving on the σ -finite space $(E, \mathcal{E}, \mu)$ and let $f \in L^1(\mu)$. Then there is an invariant $\bar{f} \in L^1(\mu)$ with $\mu(|\bar{f}|) \leq \mu(|f|)$ and

$$\frac{S_n(f)}{n} \longrightarrow \bar{f} \quad \text{almost everywhere.}$$

If Θ is ergodic and μ is a probability measure, then $\bar{f} = \mu(f)$ almost everywhere.

Proof (non-examinable). Observe that

$$\limsup_n \frac{S_n(f)}{n} = \limsup_n \frac{S_n(f) \circ \Theta}{n},$$

since $S_{n+1}(f) = f + S_n(f) \circ \Theta$ and $f/n \rightarrow 0$; similarly for $\liminf$. So both $\limsup_n S_n/n$ and $\liminf_n S_n/n$ are invariant functions, hence $\mathcal{E}_\Theta$ -measurable. For $a < b$ put

$$D = D_{a,b} = \left\{ \liminf_n \frac{S_n(f)}{n} < a < b < \limsup_n \frac{S_n(f)}{n} \right\},$$

a measurable invariant set. We show $\mu(D) = 0$.

Assume without loss of generality $b > 0$ (otherwise replace f by $-f$ and swap the roles of a and b). Let $B \subseteq D$ be measurable with $\mu(B) < \infty$, and put $g = f - b\mathbb{1}_B \in L^1(\mu)$. Then

$$S_n(g) = S_n(f) - bS_n(\mathbb{1}_B) \geq S_n(f) - bn,$$

which is positive for some n at every point of D , by the definition of $\limsup$. Restrict the measure space to D : since D is invariant, Θ is still measure-preserving for $\mu|_D$, because

$$\mu|_D(\Theta^{-1}A) = \mu(\Theta^{-1}A \cap D) = \mu(\Theta^{-1}(A \cap D)) = \mu(A \cap D) = \mu|_D(A).$$

On this restricted space $\{S^*(g) > 0\} = D$, so the maximal ergodic lemma gives

$$0 \leq \int_D g \, d\mu = \int_D f \, d\mu - b\mu(B),$$

that is, $b\mu(B) \leq \int_D f \, d\mu$. By σ -finiteness we may choose $B_n \uparrow D$ with $\mu(B_n) < \infty$ and let $n \rightarrow \infty$, obtaining $b\mu(D) \leq \int_D f \, d\mu$. Running the same argument with $-f$ and $-a$ in place of f and b gives $-a\mu(D) \leq -\int_D f \, d\mu$, so

$$b\mu(D) \leq \int_D f \, d\mu \leq a\mu(D).$$

Since $a < b$ this forces $\mu(D) = 0$ or $\mu(D) = \infty$; but $\int_D f \, d\mu$ is finite, so $\mu(D) = 0$.

Now let

$$\Delta = \left\{ \liminf_n \frac{S_n(f)}{n} < \limsup_n \frac{S_n(f)}{n} \right\} = \bigcup_{a < b, a, b \in \mathbb{Q}} D_{a,b},$$

a countable union of null sets, so $\mu(\Delta) = 0$. Off Δ the limit $\lim_n S_n(f)/n$ exists in $[-\infty, \infty]$; define $\bar{f}$ to be that limit on Δ^c and 0 on Δ . Then $\bar{f}$ is invariant and $S_n(f)/n \rightarrow \bar{f}$ almost everywhere.

Finally, since Θ is measure-preserving, $\mu(|f \circ \Theta^k|) = \mu(|f|)$, so $\mu(|S_n(f)|) \leq n\mu(|f|)$, and by Fatou

$$\mu(|\bar{f}|) = \mu\left(\liminf_n \left| \frac{S_n(f)}{n} \right| \right) \leq \liminf_n \mu\left(\left| \frac{S_n(f)}{n} \right| \right) \leq \mu(|f|) < \infty.$$

In particular $\bar{f}$ is finite almost everywhere. If Θ is ergodic then $\bar{f}$ is a.e. constant; if additionally $\mu(E) = 1$, the von Neumann theorem below identifies the constant as $\mu(f)$. $\square$

§38.10.4 Von Neumann's L^p ergodic theorem

Theorem 38.10.6 (von Neumann)

Let $(E, \mathcal{E}, \mu)$ be a *finite* measure space, Θ measure-preserving, and $1 \leq p < \infty$. Then for $f \in L^p(\mu)$,

$$\frac{S_n(f)}{n} \longrightarrow \bar{f} \quad \text{in } L^p(\mu),$$

where $\bar{f}$ is the almost-everywhere limit from Birkhoff's theorem.

Proof. Since Θ preserves μ , $\|f \circ \Theta^i\|_p = \|f\|_p$, so by Minkowski

$$\left\| \frac{S_n(f)}{n} \right\|_p \leq \frac{1}{n} \sum_{i=0}^{n-1} \|f \circ \Theta^i\|_p = \|f\|_p. \quad (\#)$$

So $f \mapsto S_n(f)/n$ is a contraction of L^p , uniformly in n ; this is the key.

Fix $\varepsilon > 0$. For $K > 0$ let $f_K = (-K) \vee f \wedge K$. Then

$$\|f - f_K\|_p^p = \int_E |f - f_K|^p \mathbb{1}_{\{|f| > K\}} d\mu \rightarrow 0$$

as $K \rightarrow \infty$ by dominated convergence (the integrand is at most $2^p |f|^p \in L^1$ and tends to 0 pointwise). Choose K with $\|f - f_K\|_p < \varepsilon/3$.

Since μ is finite we have $f_K \in L^1(\mu)$, so Birkhoff gives $S_n(f_K)/n \rightarrow \bar{f}_K$ almost everywhere, and $|S_n(f_K)/n| \leq K$, so that $|\bar{f}_K| \leq K$. By bounded convergence (Theorem 38.4.10, with dominating constant $2K$, integrable as $\mu(E) < \infty$),

$$\left\| \frac{S_n(f_K)}{n} - \bar{f}_K \right\|_p^p \leq (2K)^{p-1} \left\| \frac{S_n(f_K)}{n} - \bar{f}_K \right\|_1 \rightarrow 0,$$

so this term is below $(\varepsilon/3)^p$ for n large.

Also $f \in L^p(\mu) \subseteq L^1(\mu)$ since μ is finite, so Birkhoff applies to f too and $S_n(f)/n \rightarrow \bar{f}$ a.e. By Fatou and the contraction property (#),

$$\begin{aligned} \|\bar{f} - \bar{f}_K\|_p^p &= \int_E \liminf_n \left| \frac{S_n(f - f_K)}{n} \right|^p d\mu \leq \liminf_n \left\| \frac{S_n(f - f_K)}{n} \right\|_p^p \\ &\leq \|f - f_K\|_p^p < (\varepsilon/3)^p. \end{aligned}$$

In particular $\bar{f} \in L^p$. Combining the three estimates via the triangle inequality,

$$\left\| \frac{S_n(f)}{n} - \bar{f} \right\|_p \leq \left\| \frac{S_n(f - f_K)}{n} \right\|_p + \left\| \frac{S_n(f_K)}{n} - \bar{f}_K \right\|_p + \|\bar{f}_K - \bar{f}\|_p < \varepsilon$$

for n large. □

Corollary 38.10.7

If μ is a probability measure and Θ is ergodic then, for $f \in L^1(\mu)$, $\bar{f} = \mu(f)$ almost everywhere.

Proof. Ergodicity makes the invariant function $\bar{f}$ a.e. constant, say $\bar{f} = c$. By von Neumann with $p = 1$, $\mu(S_n(f)/n) \rightarrow \mu(\bar{f}) = c$; but $\mu(S_n(f)/n) = \frac{1}{n} \sum_{k < n} \mu(f \circ \Theta^k) = \mu(f)$ for every n . So $c = \mu(f)$. □

§38.10.5 Bernoulli shifts

To apply the ergodic theorems to i.i.d. sequences we need the right dynamical system. Let $E = \mathbb{R}^{\mathbb{N}}$, the space of real sequences $x = (x_n)$, and let

$$\mathcal{C} = \left\{ \prod_{n=1}^{\infty} A_n : A_n \in \mathcal{B}, A_n = \mathbb{R} \text{ for all large } n \right\}$$

be the collection of **cylinder sets**, a π -system. Put $\mathcal{E} = \sigma(\mathcal{C})$, the **cylindrical σ -algebra**; it coincides with $\sigma(\{f_n : n \in \mathbb{N}\})$ where $f_n(x) = x_n$ are the coordinate maps, and with $\mathcal{B}(\mathbb{R}^{\mathbb{N}})$ for the product topology.

Let m be a probability measure on $\mathbb{R}$, and let (X_n) be i.i.d. with law m – these exist by Theorem 38.3.12. Define $X : \Omega \rightarrow E$ by $X(\omega) = (X_1(\omega), X_2(\omega), \dots)$. This is $\mathcal{F}$ - $\mathcal{E}$ measurable, since for a cylinder set A ,

$$X^{-1}(A) = \bigcap_{n=1}^N X_n^{-1}(A_n) \in \mathcal{F}.$$

Let $\mu = \mathbb{P} \circ X^{-1}$. On cylinder sets,

$$\mu\left(\prod_{n=1}^{\infty} A_n\right) = \lim_{N \rightarrow \infty} \mathbb{P}(X_1 \in A_1, \dots, X_N \in A_N) = \prod_{n=1}^{\infty} m(A_n)$$

(the product being eventually 1). By uniqueness of extension, μ is the unique probability measure on $(E, \mathcal{E})$ with this property; we write $\mu = m^{\otimes \mathbb{N}}$ and call $(E, \mathcal{E}, \mu)$ the **canonical model** for an i.i.d. sequence of law m .

Definition 38.10.8

The **shift map** $\Theta : E \rightarrow E$ is $\Theta(x_1, x_2, x_3, \dots) = (x_2, x_3, x_4, \dots)$.

Theorem 38.10.9

The shift map Θ is measure-preserving and ergodic on $(E, \mathcal{E}, \mu)$.

Proof. For a cylinder set $A = \prod_n A_n$ with $A_n = \mathbb{R}$ for $n > N$,

$$\mu(\Theta^{-1}A) = \mathbb{P}(X_2 \in A_1, \dots, X_{N+1} \in A_N) = \prod_{n=1}^N m(A_n) = \mu(A),$$

using that the X_i are i.i.d. As the cylinder sets form a π -system generating $\mathcal{E}$ and both μ and $\mu \circ \Theta^{-1}$ are probability measures, uniqueness of extension gives $\mu \circ \Theta^{-1} = \mu$.

For ergodicity, recall the tail σ -algebra $\mathcal{T} = \bigcap_n \mathcal{T}_n$ with $\mathcal{T}_n = \sigma(f_k : k > n)$. For a cylinder set A ,

$$\Theta^{-n}(A) = \{x : (x_{n+1}, x_{n+2}, \dots) \in A\} \in \mathcal{T}_n,$$

and since $\{A : \Theta^{-n}(A) \in \mathcal{T}_n\}$ is a σ -algebra containing $\mathcal{C}$, this holds for all $A \in \mathcal{E}$. So if A is invariant then $A = \Theta^{-n}(A) \in \mathcal{T}_n$ for every n , whence $A \in \mathcal{T}$. By Kol-

Kolmogorov's zero-one law (Theorem 38.3.16), applied to the independent coordinate variables under μ , we get $\mu(A) \in \{0, 1\}$. $\square$

§38.10.6 The strong law of large numbers

We can now finish the job.

Theorem 38.10.10

Let m be a probability measure on $\mathbb{R}$ with $\int_{\mathbb{R}} |x| \, dm(x) < \infty$ and $\int_{\mathbb{R}} x \, dm(x) = \nu$. Then, on the canonical model $(E, \mathcal{E}, \mu) = (\mathbb{R}^{\mathbb{N}}, \sigma(\mathcal{C}), m^{\otimes \mathbb{N}})$,

$$\mu\left(\left\{x \in \mathbb{R}^{\mathbb{N}} : \frac{x_1 + \cdots + x_n}{n} \rightarrow \nu\right\}\right) = 1.$$

Proof. Take $f(x) = x_1$, the first coordinate map. Then by the change of variables formula,

$$\int_E |f| \, d\mu = \int_{\mathbb{R}} |x| \, dm(x) < \infty,$$

so $f \in L^1(\mu)$, and $\mu(f) = \nu$. Moreover

$$S_n(f)(x) = f(x) + f(\Theta x) + \cdots + f(\Theta^{n-1}x) = x_1 + x_2 + \cdots + x_n.$$

By Theorem 38.10.9 the shift is measure-preserving and ergodic, so Birkhoff's theorem gives $S_n(f)/n \rightarrow \bar{f}$ almost everywhere, and Corollary 38.10.7 identifies $\bar{f} = \mu(f) = \nu$. $\square$

Proof of Theorem 38.8.3. Let (X_n) be i.i.d. on $(\Omega, \mathcal{F}, \mathbb{P})$ with $\mathbb{E}|X_1| < \infty$ and common law m , and let $X : \Omega \rightarrow \mathbb{R}^{\mathbb{N}}$ be the associated map, so $\mathbb{P} \circ X^{-1} = m$. Then

$$\mathbb{P}\left(\frac{1}{n} \sum_{i=1}^n X_i \rightarrow \mathbb{E}[X_1]\right) = \mu\left(\left\{x : \frac{x_1 + \cdots + x_n}{n} \rightarrow \nu\right\}\right) = 1$$

by Theorem 38.10.10, since the event on the left is the X -preimage of the event on the right. Convergence in $\mathcal{L}^1$ follows from von Neumann's theorem with $p = 1$ applied to the same f . $\square$

Remark. It is worth appreciating what has happened. The strong law is a statement about i.i.d. sequences, and its proof consisted of: (a) realising the sequence as a point of a single measure space $\mathbb{R}^{\mathbb{N}}$; (b) noticing that 'shift the sequence along by one' is a measure-preserving ergodic transformation of that space; and (c) applying a completely general theorem about time averages. The independence enters only through Kolmogorov's zero-one law in step (b). Birkhoff's theorem is much more general than the strong law – it applies to stationary sequences that are far from independent – and this is why ergodic theory has become a subject in its own right.

Example 38.10.11 (Normal numbers)

Take m uniform on $\{0, 1, \dots, 9\}$, so that (X_n) are the digits of a uniformly random real in $[0, 1)$. Applying the strong law to $\mathbb{1}_{\{X_n=k\}}$ gives that, almost surely, the

digit k has asymptotic frequency $1/10$ in the decimal expansion, for each k . Since a countable intersection of almost sure events is almost sure, Lebesgue-almost every real number is **normal** to base 10. Exhibiting one explicitly is another matter entirely.

§38.11 Closing Remarks

It is worth stepping back to see the shape of what we have built.

We began with the problem of assigning a size to subsets of a space, and found that we could not do it for all of them – Carathéodory’s theorem told us how far we could get, Dynkin’s lemma told us that the answer was unique, and Vitali told us that we could not do better. From there, the class of measurable functions and the Lebesgue integral came almost for free, and the payoff was immediate: the monotone convergence theorem, Fatou’s lemma and the dominated convergence theorem give us exactly the licence to exchange limits and integrals that the Riemann theory withheld. Fubini’s theorem let us integrate in product spaces, which is to say, handle several random variables at once.

The second half was the harvest. The L^p spaces gave us a complete normed setting for analysis, with L^2 a Hilbert space in which conditional expectation is nothing more exotic than orthogonal projection. Uniform integrability isolated exactly the hypothesis under which convergence in probability upgrades to convergence in L^1 . Characteristic functions turned convolution into multiplication and thereby turned the central limit theorem into a Taylor expansion. And ergodic theory turned the strong law of large numbers into a statement about a shift map on sequence space.

Two threads run through all of it. The first is the π -system argument: almost every uniqueness statement we proved – uniqueness of Lebesgue measure, of product measures, of the law determined by a distribution function or a characteristic function, of conditional expectation – came from Dynkin’s lemma or its functional cousin the monotone class theorem. The second is approximation from below: simple functions approximate non-negative measurable functions, and every theorem about the integral was proved first for indicators, then simple functions, then by monotone convergence in general. If you remember nothing else from this course, remember those two techniques; between them they prove most of it.

39 Quantum Information and Computation

A computer is a physical object, and a computation is something that a physical object does. That sounds like a platitude, but it has teeth: whatever we can and cannot compute is decided not by mathematics alone but by the laws of physics that the computer happens to obey. For most of the twentieth century the physics we implicitly assumed was classical, and the resulting theory of computation – Turing machines, Boolean circuits, the class P – is the one that everybody learns first. Nature, however, is not classical. If we allow our computer to store information in genuinely quantum degrees of freedom, and to process it by genuinely quantum evolutions, we get a strictly richer toolkit: superposition, entanglement, interference, and measurement.

In this course we will see what that toolkit buys us. We will meet tasks that are flatly *impossible* classically but routine quantumly (teleporting a state using only classical communication, distributing a provably secure cryptographic key), tasks that quantum mechanics *forbids* (cloning an unknown state, signalling faster than light), and – the headline act – algorithms that solve computational problems dramatically faster than any classical algorithm we know, culminating in Shor’s polynomial-time factoring algorithm and Grover’s quadratic speedup for unstructured search. Along the way the mathematics stays remarkably elementary: almost everything is linear algebra on finite-dimensional complex vector spaces, done in a notation that makes the bookkeeping painless.

This article constitutes my notes for the ‘Quantum Information and Computation’ course, held in Lent 2023 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§39.1 Quantum States

We begin with the raw material. Everything in this course takes place in a finite-dimensional complex inner product space, and almost everything reduces to manipulating vectors and operators on such a space. The reader will have met all of this before in IB Quantum Mechanics and in IA Vectors and Matrices; the only genuinely new ingredient is a notation, and a habit of thinking of the vectors as *information*.

§39.1.1 Dirac Notation

Let $\mathcal{V}$ be a finite-dimensional complex vector space equipped with a Hermitian inner product¹. Following Dirac, we write a vector of $\mathcal{V}$ as $|v\rangle$, and call it a **ket**. The inner product of $|v\rangle$ and $|w\rangle$ is written $\langle v|w\rangle$, and we adopt the physicists’ convention that it is *antilinear in the first argument and linear in the second*, so that

$$\langle v|\lambda w_1 + \mu w_2\rangle = \lambda \langle v|w_1\rangle + \mu \langle v|w_2\rangle, \quad \langle \lambda v_1 + \mu v_2|w\rangle = \lambda^* \langle v_1|w\rangle + \mu^* \langle v_2|w\rangle,$$

¹Strictly, the state space of a quantum system is a *Hilbert space*: a complex inner product space that is complete with respect to the induced norm. In finite dimensions completeness is automatic, and we will never need infinite-dimensional spaces in this course.

with $\langle v|w\rangle = \langle w|v\rangle^*$ and $\langle v|v\rangle \geq 0$, with equality if and only if $|v\rangle = 0$. The induced norm is $\| |v\rangle \| = \sqrt{\langle v|v\rangle}$.

Once a vector $|v\rangle$ is fixed, the map $|w\rangle \mapsto \langle v|w\rangle$ is a linear functional on $\mathcal{V}$, that is, an element of the dual space $\mathcal{V}^*$. We write it $\langle v|$ and call it a **bra**. Concretely, if we have chosen an orthonormal basis and written $|v\rangle$ as a column vector of components, then $\langle v|$ is the conjugate-transposed row vector,

$$|v\rangle = \begin{pmatrix} a_1 \\ \vdots \\ a_n \end{pmatrix}, \quad \langle v| = (a_1^* \quad \cdots \quad a_n^*),$$

and $\langle v|w\rangle$ is literally the matrix product $\langle v|w\rangle$. This is the whole point of the notation: the ‘bracket’ $\langle v|w\rangle$ splits into a bra and a ket, and every expression we write can be read as a product of compatible matrices.

The other product we can form is the **outer product** $|v\rangle\langle w|$, which is the linear map

$$|v\rangle\langle w| : |x\rangle \longmapsto |v\rangle \langle w|x\rangle.$$

As a matrix this is a column times a row, so it is an $n \times n$ matrix of rank at most one. Outer products are the reason Dirac notation is so pleasant to compute with: operators, states and inner products all live in the same formalism, and juxtaposition always means composition.

Definition 39.1.1 (Complete Orthonormal Basis)

An orthonormal basis $\{|e_1\rangle, \dots, |e_n\rangle\}$ of $\mathcal{V}$ is **complete** if

$$\sum_{i=1}^n |e_i\rangle\langle e_i| = I.$$

In finite dimensions any orthonormal basis is complete – the identity above is just the statement that $|v\rangle = \sum_i |e_i\rangle \langle e_i|v\rangle$, which is the usual expansion of a vector in an orthonormal basis. The completeness relation is nonetheless worth naming, because inserting a resolution of the identity in the middle of an expression is by far the most common computational move we will make.

If $|\psi\rangle = \sum_i c_i |e_i\rangle$ then $c_i = \langle e_i|\psi\rangle$, and

$$\langle \psi|\psi\rangle = \sum_i |c_i|^2.$$

We call $|\psi\rangle$ **normalised** if this is 1, in which case the numbers $|c_i|^2$ form a probability distribution on the basis labels. This is not a coincidence, as we will see when we come to measurement; the c_i are called **probability amplitudes**.

§39.1.2 Qubits

The elementary unit of classical information is the **bit**, an element of $\{0, 1\}$. Its quantum counterpart is a two-dimensional state space.

Definition 39.1.2 (Qubit)

A **qubit** is a quantum system whose state space is $\mathcal{V} = \mathbb{C}^2$, equipped with a distinguished orthonormal basis

$$|0\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad |1\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix},$$

called the **computational basis** (or standard basis, or Z -basis).

Physically a qubit could be the spin of a spin- $\frac{1}{2}$ particle, with $|0\rangle$ and $|1\rangle$ the spin-up and spin-down states along a chosen axis; or the polarisation of a photon, with $|0\rangle, |1\rangle$ horizontal and vertical. For our purposes the physical realisation is irrelevant: all that matters is that we have a two-dimensional space and can prepare, evolve and measure states in it.

The crucial difference from a classical bit is that a general state of a qubit is a *superposition*

$$|\psi\rangle = a|0\rangle + b|1\rangle, \quad |a|^2 + |b|^2 = 1.$$

A second basis will be with us constantly.

Definition 39.1.3 (Conjugate Basis)

The **conjugate basis** (or Hadamard basis, or X -basis) of a qubit is $\{|+\rangle, |-\rangle\}$, where

$$|+\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle), \quad |-\rangle = \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle).$$

One checks immediately that this is orthonormal, and that $|0\rangle = \frac{1}{\sqrt{2}}(|+\rangle + |-\rangle)$ and $|1\rangle = \frac{1}{\sqrt{2}}(|+\rangle - |-\rangle)$, so the relationship is symmetric. The pair of bases has the property that a basis vector of one is an equal superposition of the basis vectors of the other; such a pair is called **mutually unbiased**, and this is exactly the property that will make the BB84 protocol of §39.8.2 secure.

There is one further subtlety about states which we should get out of the way immediately. The state of a system is not really a vector, but a *ray*: the vectors $|\psi\rangle$ and $e^{i\theta}|\psi\rangle$ represent the same physical state, and no measurement whatsoever can tell them apart. We call $e^{i\theta}$ a **global phase**, and we are free to discard it whenever convenient. What we may *not* discard is a *relative* phase: the states

$$\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) \quad \text{and} \quad \frac{1}{\sqrt{2}}(|0\rangle + e^{i\theta}|1\rangle)$$

are genuinely different states for $\theta \neq 0$, and are readily distinguished by measuring in the conjugate basis. Keeping this distinction straight is one of the small skills the course teaches.

§39.1.3 The Bloch Sphere

Because a qubit state is a normalised vector in $\mathbb{C}^2$ up to global phase, it is described by exactly two real parameters, and there is a very useful picture of the resulting two-parameter family.

Write $|\psi\rangle = a|0\rangle + b|1\rangle$ with $|a|^2 + |b|^2 = 1$. Using the freedom of global phase we may take a real and non-negative, so $a = \cos(\theta/2)$ for a unique $\theta \in [0, \pi]$, and then $|b| = \sin(\theta/2)$, so $b = e^{i\varphi} \sin(\theta/2)$ for some $\varphi \in [0, 2\pi)$. Thus every qubit state can be written

$$|\psi\rangle = \cos \frac{\theta}{2} |0\rangle + e^{i\varphi} \sin \frac{\theta}{2} |1\rangle,$$

and the pair (θ, φ) is unique except at the poles $\theta = 0, \pi$, where φ is irrelevant. But (θ, φ) are precisely spherical polar coordinates on the unit sphere $S^2 \subseteq \mathbb{R}^3$. So the pure states of a qubit are in bijection with the points of a sphere, called the **Bloch sphere**.

The poles are $|0\rangle$ (north, $\theta = 0$) and $|1\rangle$ (south, $\theta = \pi$); the state $|+\rangle$ where the x -axis meets the equator, with $|-\rangle$ antipodal to it round the back; and $\frac{1}{\sqrt{2}}(|0\rangle \pm i|1\rangle)$ sit at the two ends of the y -axis. The picture is a good source of intuition, but it comes with a warning attached: *orthogonal states are antipodal, not perpendicular*. The angle between two states on the Bloch sphere is twice the angle between them in $\mathbb{C}^2$.

Remark. The Bloch sphere is genuinely special to two dimensions. For a d -dimensional system the set of pure states is complex projective space $\mathbb{CP}^{d-1}$, which for $d = 2$ happens to be a 2-sphere but for $d \geq 3$ has no such friendly picture. This is one reason why almost all of our concrete examples will be built from qubits.

§39.1.4 Composite Systems and Tensor Products

A single qubit is not much of a computer. To do anything interesting we need to combine systems, and the mathematical operation that does this is the tensor product.

Definition 39.1.4 (Tensor Product)

Let $\mathcal{V}$ and $\mathcal{W}$ be inner product spaces with orthonormal bases $\{|e_1\rangle, \dots, |e_m\rangle\}$ and $\{|f_1\rangle, \dots, |f_n\rangle\}$. Their **tensor product** $\mathcal{V} \otimes \mathcal{W}$ is the mn -dimensional space with orthonormal basis $\{|e_i\rangle \otimes |f_j\rangle\}_{i,j}$, and the map $(|v\rangle, |w\rangle) \mapsto |v\rangle \otimes |w\rangle$ is extended bilinearly.

Concretely, if $|v\rangle$ has components $(a_1, \dots, a_m)$ and $|w\rangle$ has components $(b_1, \dots, b_n)$, then $|v\rangle \otimes |w\rangle$ has the mn components $a_i b_j$, listed in lexicographic order:

$$|v\rangle \otimes |w\rangle = (a_1 b_1, a_1 b_2, \dots, a_1 b_n, a_2 b_1, \dots, a_m b_n)^\top.$$

The inner product on $\mathcal{V} \otimes \mathcal{W}$ is determined by

$$(\langle v_1| \otimes \langle w_1|)(|v_2\rangle \otimes |w_2\rangle) = \langle v_1|v_2\rangle \langle w_1|w_2\rangle,$$

extended sesquilinearly. In components, if $|A\rangle$ and $|B\rangle$ have coefficient matrices (a_{ij}) and (b_{ij}) with respect to the product basis $|e_i\rangle |f_j\rangle$, then

$$\langle A|B\rangle = \sum_{ij} a_{ij}^* b_{ij},$$

as one would hope.

We will almost always drop the $\otimes$, writing $|v\rangle |w\rangle$, or even $|vw\rangle$, for $|v\rangle \otimes |w\rangle$. This is safe provided we remember that *the order matters*: $|v\rangle |w\rangle$ and $|w\rangle |v\rangle$ live in $\mathcal{V} \otimes \mathcal{W}$ and $\mathcal{W} \otimes \mathcal{V}$ respectively, and even when $\mathcal{V} = \mathcal{W}$ they are different vectors. We also write $\mathcal{V}^{\otimes n}$ for the n -fold tensor power. If $\mathcal{V} = \mathbb{C}^2$ then $\mathcal{V}^{\otimes n}$ has dimension 2^n , with orthonormal basis

$$|i_1 i_2 \cdots i_n\rangle, \quad i_j \in \{0, 1\},$$

indexed by the 2^n bit strings of length n . Note the exponential: n qubits carry 2^n complex amplitudes.

We can now state the first two postulates of quantum mechanics in the form we will use them.

Axiom 39.1.5 (States)

To an isolated quantum system S we associate a finite-dimensional inner product space $\mathcal{V}$. The states of S are the rays of $\mathcal{V}$, represented by normalised vectors $|\psi\rangle$ determined up to a global phase.

Axiom 39.1.6 (Composite Systems)

If S_1 and S_2 are quantum systems with state spaces $\mathcal{V}_1$ and $\mathcal{V}_2$, then the composite system $S_1 S_2$ has state space $\mathcal{V}_1 \otimes \mathcal{V}_2$.

The second postulate is where quantum mechanics diverges most sharply from classical intuition. Classically, the state of a pair of systems is a pair of states; the state space of the composite is the *Cartesian product*, of dimension $m + n$. Quantum mechanically it is the tensor product, of dimension mn , and most of the vectors in it are not of the form $|v\rangle |w\rangle$ at all.

Definition 39.1.7 (Product and Entangled States)

A state $|\Psi\rangle \in \mathcal{V} \otimes \mathcal{W}$ is a **product state** if $|\Psi\rangle = |\psi\rangle \otimes |\varphi\rangle$ for some $|\psi\rangle \in \mathcal{V}$, $|\varphi\rangle \in \mathcal{W}$. Otherwise it is **entangled**.

Example 39.1.8

Let $\mathcal{V} = \mathcal{W} = \mathbb{C}^2$ and consider

$$|\phi^+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle).$$

Suppose it were a product state, say $|\phi^+\rangle = (a|0\rangle + b|1\rangle) \otimes (c|0\rangle + d|1\rangle)$. Expanding,

$$|\phi^+\rangle = ac|00\rangle + ad|01\rangle + bc|10\rangle + bd|11\rangle,$$

so we would need $ad = bc = 0$ and $ac = bd = 1/\sqrt{2}$. The latter forces all four of a, b, c, d to be nonzero, contradicting the former. Hence $|\phi^+\rangle$ is entangled.

Counting parameters shows that entanglement is the norm rather than the exception: the product states of two qubits form a set of real dimension $2 + 2 = 4$ inside the 6-real-dimensional set of all two-qubit states. Almost every state of a composite system is entangled, and the whole of §39.4 is devoted to what one can do with that fact.

§39.1.5 Operators

The Dirac notation extends painlessly to linear maps. If A is a linear operator on $\mathcal{V}$ we write $A|\psi\rangle$ for its action, and $\langle\psi|A|\varphi\rangle$ – also written $\langle\psi|A|\varphi\rangle$ – for the inner product of $|\psi\rangle$ with $A|\varphi\rangle$. There is a unique operator $A^\dagger$, the **adjoint**, satisfying

$$\langle v|Aw\rangle = \langle A^\dagger v|w\rangle \quad \text{for all } |v\rangle, |w\rangle,$$

whose matrix is the conjugate transpose of that of A ; one has $(AB)^\dagger = B^\dagger A^\dagger$, and with the convention $|\psi\rangle^\dagger = \langle\psi|$ the rule ‘dagger reverses everything’ holds universally. An operator with $A = A^\dagger$ is **self-adjoint** or **Hermitian**.

In a fixed basis, the outer products $|e_i\rangle\langle e_j|$ are the matrix units, so any operator can be expanded as

$$A = \sum_{i,j} A_{ij} |e_i\rangle\langle e_j|, \quad A_{ij} = \langle e_i|A|e_j\rangle.$$

For a qubit this reads

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} = a|0\rangle\langle 0| + b|0\rangle\langle 1| + c|1\rangle\langle 0| + d|1\rangle\langle 1|.$$

Another identity worth recording is $\text{Tr}(|v\rangle\langle w|) = \langle w|v\rangle$, and more generally

$$\text{Tr}(A|\psi\rangle\langle\psi|) = \langle\psi|A|\psi\rangle.$$

We will use this repeatedly to convert expectation values into traces, where they are easier to manipulate.

Four operators on $\mathbb{C}^2$ will appear on nearly every page.

Definition 39.1.9 (Pauli Matrices)

The **Pauli matrices** are

$$\sigma_0 = I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

They are Hermitian, unitary and traceless, they square to the identity, and together with I they form a basis of the space of 2×2 complex matrices. Their action on the computational basis is

$$\sigma_x|0\rangle = |1\rangle, \quad \sigma_y|0\rangle = i|1\rangle, \quad \sigma_z|0\rangle = |0\rangle,$$

$$\sigma_x |1\rangle = |0\rangle, \quad \sigma_y |1\rangle = -i|0\rangle, \quad \sigma_z |1\rangle = -|1\rangle,$$

so σ_x is a bit flip, σ_z is a phase flip, and $\sigma_y = i\sigma_x\sigma_z$ is both at once. They satisfy the cyclic relations

$$\sigma_x\sigma_y = i\sigma_z, \quad \sigma_y\sigma_z = i\sigma_x, \quad \sigma_z\sigma_x = i\sigma_y,$$

and any two distinct Pauli matrices anticommute. Geometrically, $\sigma_x, \sigma_y, \sigma_z$ generate rotations about the three axes of the Bloch sphere.

§39.1.6 Projectors

Projection operators will carry all the weight in our discussion of measurement, so we set up the vocabulary now.

Definition 39.1.10 (Projector)

An operator Π on $\mathcal{V}$ is a **(orthogonal) projector** if $\Pi^2 = \Pi$ and $\Pi^\dagger = \Pi$.

If $|v\rangle$ is normalised then $\Pi_v = |v\rangle\langle v|$ is a projector, since

$$\Pi_v\Pi_v = |v\rangle\langle v||v\rangle\langle v| = |v\rangle\langle v|v\rangle\langle v| = |v\rangle\langle v| = \Pi_v,$$

and $\Pi_v|x\rangle = |v\rangle\langle v|x\rangle$ is the component of $|x\rangle$ along $|v\rangle$; in particular Π_v kills everything orthogonal to $|v\rangle$. More generally, if $\mathcal{E} \subseteq \mathcal{V}$ is a subspace with orthonormal basis $|e_1\rangle, \dots, |e_d\rangle$, then

$$\Pi_{\mathcal{E}} = \sum_{k=1}^d |e_k\rangle\langle e_k|$$

is the orthogonal projector onto $\mathcal{E}$, as one checks by extending to an orthonormal basis of $\mathcal{V}$. Its rank is $\dim \mathcal{E}$, and $\text{Tr } \Pi_{\mathcal{E}} = \dim \mathcal{E}$.

If $\mathcal{V} = \mathcal{E}_1 \oplus \dots \oplus \mathcal{E}_d$ is an orthogonal direct sum decomposition, the corresponding projectors satisfy

$$\Pi_i\Pi_j = \delta_{ij}\Pi_i, \quad \sum_{i=1}^d \Pi_i = I.$$

Such a family is exactly the data of a projective measurement, as we will see.

§39.1.7 Tensor Products of Operators

Given linear maps A on $\mathcal{V}$ and B on $\mathcal{W}$, we define $A \otimes B$ on $\mathcal{V} \otimes \mathcal{W}$ by its action on product vectors,

$$(A \otimes B)(|v\rangle \otimes |w\rangle) = (A|v\rangle) \otimes (B|w\rangle),$$

extended linearly. In components this is the familiar Kronecker product: for 2×2 matrices,

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \quad B = \begin{pmatrix} p & q \\ r & s \end{pmatrix} \implies A \otimes B = \begin{pmatrix} aB & bB \\ cB & dB \end{pmatrix} = \begin{pmatrix} ap & aq & bp & bq \\ ar & as & br & bs \\ cp & cq & dp & dq \\ cr & cs & dr & ds \end{pmatrix}.$$

The operators of the form $A \otimes I$ are those acting on the first system only, and $I \otimes B$ those acting on the second; these are the **local** operations, and the constraint that Alice and Bob can only perform local operations on their halves of a shared state is the central restriction in everything we do with entanglement.

Example 39.1.11

Local operations act very differently on an entangled state than one might guess. With $|\phi^+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$ and A as above,

$$\begin{aligned}(A \otimes I) |\phi^+\rangle &= \frac{1}{\sqrt{2}} [(A|0\rangle)|0\rangle + (A|1\rangle)|1\rangle] = \frac{1}{\sqrt{2}} [a|00\rangle + b|01\rangle + c|10\rangle + d|11\rangle], \\ (I \otimes A) |\phi^+\rangle &= \frac{1}{\sqrt{2}} [|0\rangle(A|0\rangle) + |1\rangle(A|1\rangle)] = \frac{1}{\sqrt{2}} [a|00\rangle + c|01\rangle + b|10\rangle + d|11\rangle].\end{aligned}$$

The two differ only by transposing A . In particular, for a symmetric A we have $(A \otimes I) |\phi^+\rangle = (I \otimes A) |\phi^+\rangle$: acting on one half of a maximally entangled pair is the same as acting on the other. This innocuous-looking fact is the engine of superdense coding.

Finally, we record a construction that lets us ‘look at one half’ of a composite state.

Definition 39.1.12 (Partial Inner Product)

Let $|v\rangle \in \mathcal{V}$. The **partial inner product** with $|v\rangle$ is the linear map $\mathcal{V} \otimes \mathcal{W} \rightarrow \mathcal{W}$ determined on the basis by

$$|e_i\rangle |f_j\rangle \mapsto \langle v|e_i\rangle |f_j\rangle.$$

We write it $\langle v|$ again, so that $\langle v|(|\alpha\rangle|\beta\rangle) = \langle v|\alpha\rangle|\beta\rangle$.

When $\mathcal{V}$ and $\mathcal{W}$ are isomorphic one must of course say which factor is meant, and we will do so by labelling the systems, writing $\langle v|_A$ and so on. The notation is heavily overloaded but never actually ambiguous in practice.

§39.2 Measurement

We now come to the part of the formalism with no classical analogue at all: what happens when we look at a quantum system. We state the remaining two postulates, extract the Born rule, and then answer the question that motivates the whole of quantum information theory – *when can two states be told apart?*

§39.2.1 Unitary Evolution

Axiom 39.2.1 (Evolution)

The evolution of a closed quantum system over a finite time interval is given by a unitary operator on its state space: if the system is in state $|\psi(t_1)\rangle$ at time t_1 , then at t_2 it is in state $|\psi(t_2)\rangle = U(t_1, t_2) |\psi(t_1)\rangle$ for some unitary $U(t_1, t_2)$ depending only on t_1 and t_2 .

Recall from IA Vectors and Matrices that for a linear operator U on a finite-dimensional inner product space the following are equivalent: $U^\dagger U = U U^\dagger = I$; U preserves inner products, $\langle Uv|Uw\rangle = \langle v|w\rangle$; U maps some (equivalently, every) orthonormal basis to an orthonormal basis; the columns of the matrix of U form an orthonormal set.

The postulate is a consequence of the Schrödinger equation of IB Quantum Mechanics,

$$i\hbar \frac{\partial}{\partial t} |\psi(t)\rangle = H |\psi(t)\rangle,$$

with H the Hermitian Hamiltonian; for time-independent H we get

$$U(t_1, t_2) = \exp\left(-\frac{i}{\hbar} H(t_2 - t_1)\right),$$

which is unitary precisely because H is Hermitian. In this course we will forget about Hamiltonians entirely and simply take ‘the allowed operations are the unitaries’ as a black-box rule.

Two consequences deserve emphasis. First, unitary evolution is *deterministic* and *reversible*: the state at any time determines the state at any other. All the probability in quantum mechanics enters through measurement. Second, since unitaries preserve inner products, *the overlap $\langle\psi|\varphi\rangle$ between two states can never be changed by evolution*. Two states that start out non-orthogonal stay non-orthogonal forever, no matter what we do to them. Almost every impossibility theorem in this course is an application of that one sentence.

§39.2.2 Observables and the Born Rule

Definition 39.2.2 (Observable)

An **observable** of a quantum system with state space $\mathcal{V}$ is a self-adjoint operator A on $\mathcal{V}$.

By the spectral theorem, a self-adjoint A has real eigenvalues $a_1, \dots, a_k$ (which we take to be distinct) and $\mathcal{V}$ decomposes as an orthogonal direct sum of the corresponding eigenspaces. Writing P_j for the projector onto the a_j -eigenspace, we obtain the **spectral decomposition**

$$A = \sum_j a_j P_j, \quad P_i P_j = \delta_{ij} P_i, \quad \sum_j P_j = I.$$

If a_j is a non-degenerate eigenvalue with unit eigenvector $|\varphi_j\rangle$ then $P_j = |\varphi_j\rangle\langle\varphi_j|$ has rank one; if a_j has multiplicity m then $P_j = \sum_{i=1}^m |\varphi_j^i\rangle\langle\varphi_j^i|$ for an orthonormal basis of the eigenspace.

Axiom 39.2.3 (Measurement; the Born Rule)

If the observable $A = \sum_j a_j P_j$ is measured on a system in normalised state $|\psi\rangle$, the outcome is one of the eigenvalues a_j , obtained with probability

$$p(a_j) = \langle\psi|P_j|\psi\rangle = \|P_j|\psi\rangle\|^2,$$

and the post-measurement state of the system is

$$\frac{P_j|\psi\rangle}{\sqrt{p(a_j)}}.$$

Since $\sum_j P_j = I$ and $\langle\psi|\psi\rangle = 1$, the probabilities do sum to one. A measurement of this form is called a **projective** or **von Neumann** measurement. Note that the state after

the measurement is (the normalisation of) the projection of $|\psi\rangle$ onto the eigenspace we found – the notorious ‘collapse of the wavefunction’. Measuring twice in a row gives the same answer both times, since P_j applied to a vector already in its range does nothing.

In practice the eigenvalues themselves rarely matter; what matters is *which* projector fired. So we will usually specify a measurement simply by giving the family of projectors, and speak of ‘the measurement $\{P_j\}$ ’ with outcomes labelled by j .

Definition 39.2.4 (Complete and Incomplete Measurements)

A projective measurement $\{P_j\}$ is **complete** if every P_j has rank 1, and **incomplete** otherwise.

A complete measurement is the same thing as a choice of orthonormal basis $\{|e_j\rangle\}$, with $P_j = |e_j\rangle\langle e_j|$. Then, writing $|\psi\rangle = \sum_j a_j |e_j\rangle$,

$$p(j) = |\langle e_j|\psi\rangle|^2 = |a_j|^2,$$

and the post-measurement state is

$$\frac{P_j |\psi\rangle}{\sqrt{p(j)}} = \frac{|e_j\rangle \langle e_j|\psi\rangle}{\sqrt{p(j)}} = |e_j\rangle$$

up to a global phase. So the amplitudes really are amplitudes for outcomes, exactly as promised in §39.1.1, and the state collapses onto a basis vector. We say we have **measured in the basis $\{|e_j\rangle\}$** .

An incomplete measurement corresponds instead to an orthogonal decomposition $\mathcal{V} = \mathcal{E}_1 \oplus \cdots \oplus \mathcal{E}_d$ into subspaces of arbitrary dimension: the outcome tells us which subspace, and the state collapses into that subspace but is not otherwise disturbed. It is a coarse-graining of a complete measurement, in the sense that if we refine each $\mathcal{E}_i$ into an orthonormal basis and perform the complete measurement instead, then summing the probabilities of the outcomes lying in $\mathcal{E}_i$ recovers $p(i)$.

Example 39.2.5 (Parity Measurement)

Take two qubits and decompose $\mathbb{C}^2 \otimes \mathbb{C}^2 = \mathcal{E}_0 \oplus \mathcal{E}_1$, where

$$\mathcal{E}_0 = \text{span}\{|00\rangle, |11\rangle\}, \quad \mathcal{E}_1 = \text{span}\{|01\rangle, |10\rangle\}$$

are the even- and odd-parity subspaces, ‘parity’ meaning $b_1 \oplus b_2$. The corresponding measurement $\{\Pi_0, \Pi_1\}$ with $\Pi_0 = |00\rangle\langle 00| + |11\rangle\langle 11|$, $\Pi_1 = |01\rangle\langle 01| + |10\rangle\langle 10|$ tells us the parity of the two bits and nothing else. Applied to the state $|\phi^+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$ it returns 0 with certainty and leaves the state untouched – even though a complete measurement in the computational basis would destroy the entanglement completely. Measuring less can be worth more.

We will constantly want to measure a *subsystem* of a composite system, and there is a useful special case of the Born rule for this.

Proposition 39.2.6 (Extended Born Rule)

Let $S_1 S_2$ be a composite system with state spaces $\mathcal{V}, \mathcal{W}$ having complete orthonormal

bases $\{|e_i\rangle\}_{i=1}^m$, $\{|f_j\rangle\}_{j=1}^n$, and let

$$|\psi\rangle = \sum_{i,j} a_{ij} |e_i\rangle |f_j\rangle.$$

Suppose we measure S_1 in the basis $\{|e_i\rangle\}$, that is, we perform the projective measurement with projectors $P_k \otimes I$, $P_k = |e_k\rangle\langle e_k|$. Then the outcome is k with probability

$$p(k) = \langle\psi|P_k \otimes I|\psi\rangle = \sum_{j=1}^n |a_{kj}|^2,$$

and the post-measurement state is

$$|\psi_{\text{after}}\rangle = \frac{(P_k \otimes I)|\psi\rangle}{\sqrt{p(k)}} = |e_k\rangle \otimes \frac{\sum_j a_{kj} |f_j\rangle}{\sqrt{\sum_j |a_{kj}|^2}}.$$

Proof. The projectors $P_k \otimes I$ project onto the mutually orthogonal subspaces $\mathcal{E}_k = |e_k\rangle \otimes \mathcal{W}$, whose direct sum is $\mathcal{V} \otimes \mathcal{W}$, so this is a legitimate (in general incomplete) projective measurement. Expanding,

$$\langle\psi|P_k \otimes I|\psi\rangle = \sum_{i,j} \sum_{i',j'} a_{ij}^* a_{i'j'} \langle e_i|e_k\rangle \langle e_k|e_{i'}\rangle \langle f_j|f_{j'}\rangle = \sum_j |a_{kj}|^2,$$

using orthonormality. Applying $P_k \otimes I$ to $|\psi\rangle$ retains only the terms with $i = k$, giving $|e_k\rangle \otimes \sum_j a_{kj} |f_j\rangle$, and dividing by $\sqrt{p(k)}$ normalises it. $\square$

Notice what the second half of this says: the state of S_2 after we measure S_1 depends on the outcome k . Measuring here changes the description of the state over there, instantaneously and no matter how far away it is. Whether this permits *signalling* is a question we will settle – in the negative – in §39.3.4.

Example 39.2.7 (Measuring One Qubit of Three)

Let

$$|\psi\rangle = \frac{i}{2} |000\rangle + \frac{1+i}{2\sqrt{2}} |001\rangle - \frac{1}{2} |101\rangle + \frac{3}{10} |110\rangle - \frac{2i}{5} |111\rangle,$$

which one checks is normalised: $\frac{1}{4} + \frac{1}{4} + \frac{1}{4} + \frac{9}{100} + \frac{4}{25} = 1$. Measure the first qubit in the computational basis. By the extended Born rule we sum $|a|^2$ over the basis states beginning with 1:

$$p(1) = \frac{1}{4} + \frac{9}{100} + \frac{4}{25} = \frac{1}{2},$$

so the outcome is 1 with probability $\frac{1}{2}$, and in that case the state becomes

$$|1\rangle \otimes \frac{-\frac{1}{2} |01\rangle + \frac{3}{10} |10\rangle - \frac{2i}{5} |11\rangle}{\sqrt{1/2}} = |1\rangle \otimes \left(-\frac{1}{\sqrt{2}} |01\rangle + \frac{3}{5\sqrt{2}} |10\rangle - \frac{4i}{5\sqrt{2}} |11\rangle \right).$$

Remark. Measuring in an arbitrary basis is no more powerful than measuring in the computational basis, provided we may first apply a unitary. If $\mathcal{B} = \{|e_i\rangle\}$ and $\mathcal{C} = \{|e'_i\rangle\}$ are two orthonormal bases, let U be the unitary with $U|e_i\rangle = |e'_i\rangle$. Measuring $|\psi\rangle$ in $\mathcal{C}$

gives outcome i with probability

$$|\langle e'_i | \psi \rangle|^2 = |\langle e_i | U^\dagger | \psi \rangle|^2,$$

which is exactly the probability of outcome i when $U^\dagger | \psi \rangle$ is measured in $\mathcal{B}$. So ‘apply $U^\dagger$, then measure in the standard basis’ simulates any complete measurement, and we may as well assume that all measurements in a circuit are standard measurements.

§39.2.3 Distinguishing Quantum States

Here is the question that separates quantum information from classical information theory. Someone hands us a system, promising that its state is either $|\alpha_0\rangle$ or $|\alpha_1\rangle$, both known to us. Can we determine which?

Classically the answer is trivially yes: distinct classical states are distinct, and looking tells you which. Quantum mechanically the answer is a sharp and surprising one.

Definition 39.2.8 (Reliably Distinguishable)

Two states $|\psi\rangle, |\varphi\rangle$ are **reliably distinguishable** if there is a measurement with two distinguished outcomes 0, 1 such that measuring $|\psi\rangle$ gives outcome 0 with probability 1, and measuring $|\varphi\rangle$ gives outcome 1 with probability 1.

Theorem 39.2.9

Two states $|\psi\rangle$ and $|\varphi\rangle$ are reliably distinguishable if and only if $\langle \psi | \varphi \rangle = 0$.

Proof. Suppose first that $\langle \psi | \varphi \rangle = 0$. Extend $|\psi\rangle$ to a complete orthonormal basis $\{|\psi\rangle, |f_1\rangle, \dots, |f_{m-1}\rangle\}$ of $\mathcal{V}$ and consider the incomplete measurement $\{\Pi_0, \Pi_1\}$ with $\Pi_0 = |\psi\rangle\langle\psi|$ and $\Pi_1 = I - \Pi_0$. Then measuring $|\psi\rangle$ gives outcome 0 with probability $\langle \psi | \Pi_0 | \psi \rangle = 1$, while measuring $|\varphi\rangle$ gives outcome 0 with probability $|\langle \psi | \varphi \rangle|^2 = 0$, hence outcome 1 with certainty.

Conversely, suppose such a measurement $\{\Pi_0, \Pi_1, \dots\}$ exists. Then $\langle \psi | \Pi_0 | \psi \rangle = 1$ forces $\Pi_0 | \psi \rangle = | \psi \rangle$, since $\|\Pi_0 | \psi \rangle\|^2 = 1 = \| | \psi \rangle \|^2$ and Π_0 is a contraction which fixes a unit vector only if that vector lies in its range. Similarly $\langle \varphi | \Pi_1 | \varphi \rangle = 1$ gives $\Pi_1 | \varphi \rangle = | \varphi \rangle$. But the ranges of Π_0 and Π_1 are orthogonal subspaces, so

$$\langle \psi | \varphi \rangle = \langle \Pi_0 \psi | \Pi_1 \varphi \rangle = \langle \psi | \Pi_0 \Pi_1 | \varphi \rangle = 0. \quad \square$$

So non-orthogonal states cannot be told apart with certainty, ever, by any measurement. Note also the trivial but important corollary that $|\psi\rangle$ and $e^{i\theta} |\psi\rangle$ are indistinguishable, which is what justified our identification of states with rays.

What if we allow ourselves to be wrong sometimes? Suppose the two candidate states are equally likely a priori and we must guess. We could ignore the system entirely and flip a coin, succeeding with probability $\frac{1}{2}$. Can we do better, and how much better?

Before answering, note that there is no point being clever about the *form* of the measurement. If we adjoin an ancilla in a fixed state $|A\rangle$, apply a unitary U to the enlarged system and then measure with $\{\Pi_i\}$, the outcome probabilities are

$$p(i) = \langle \alpha_j A | U^\dagger \Pi_i U | \alpha_j A \rangle,$$

and $\{U^\dagger \Pi_i U\}$ is again a family of orthogonal projectors summing to the identity. So the whole procedure is just *some* projective measurement performed directly on $|\alpha_j\rangle|A\rangle$; and since the ancilla contributes the same factor $\langle A|A\rangle = 1$ in both cases, we may as well restrict attention to two-outcome projective measurements $\{\Pi_0, \Pi_1\}$ on the original system, with $\Pi_0 + \Pi_1 = I$. We guess $|\alpha_0\rangle$ on outcome 0 and $|\alpha_1\rangle$ on outcome 1.

Theorem 39.2.10 (Holevo–Helstrom, Pure States)

Let $|\alpha_0\rangle, |\alpha_1\rangle$ be given with equal prior probabilities $\frac{1}{2}$, and write $|\langle\alpha_0|\alpha_1\rangle| = \cos\theta$ with $\theta \in [0, \pi/2]$. Then the average success probability of any measurement strategy satisfies

$$p_S \leq \frac{1}{2} + \frac{\sin\theta}{2},$$

and there is a measurement attaining this bound.

Proof. With the two-outcome measurement $\{\Pi_0, \Pi_1 = I - \Pi_0\}$ the average success probability is

$$\begin{aligned} p_S &= \frac{1}{2} \langle\alpha_0|\Pi_0|\alpha_0\rangle + \frac{1}{2} \langle\alpha_1|\Pi_1|\alpha_1\rangle \\ &= \frac{1}{2} \langle\alpha_0|\Pi_0|\alpha_0\rangle + \frac{1}{2} (1 - \langle\alpha_1|\Pi_0|\alpha_1\rangle) \\ &= \frac{1}{2} + \frac{1}{2} \text{Tr}[\Pi_0\Delta], \quad \Delta := |\alpha_0\rangle\langle\alpha_0| - |\alpha_1\rangle\langle\alpha_1|, \end{aligned}$$

where we used $\langle\psi|A|\psi\rangle = \text{Tr}(A|\psi\rangle\langle\psi|)$. So we must maximise $\text{Tr}(\Pi_0\Delta)$ over projectors Π_0 .

Now Δ is self-adjoint, so it has real eigenvalues and an orthonormal eigenbasis. It annihilates every vector orthogonal to both $|\alpha_0\rangle$ and $|\alpha_1\rangle$, so it acts nontrivially only on $\text{span}\{|\alpha_0\rangle, |\alpha_1\rangle\}$, and has at most two nonzero eigenvalues. Also $\text{Tr}\Delta = 1 - 1 = 0$, so those eigenvalues are δ and $-\delta$ for some $\delta \geq 0$; write $|p\rangle, |m\rangle$ for corresponding orthonormal eigenvectors, so

$$\Delta = \delta |p\rangle\langle p| - \delta |m\rangle\langle m|.$$

To find δ , pick a normalised $|\alpha_0^\perp\rangle \in \text{span}\{|\alpha_0\rangle, |\alpha_1\rangle\}$ orthogonal to $|\alpha_0\rangle$, so that $\{|\alpha_0\rangle, |\alpha_0^\perp\rangle\}$ is an orthonormal basis of that plane, and write $|\alpha_1\rangle = c_0 |\alpha_0\rangle + c_1 |\alpha_0^\perp\rangle$ with $|c_0|^2 + |c_1|^2 = 1$. In this basis

$$\Delta = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} - \begin{pmatrix} |c_0|^2 & c_0 c_1^* \\ c_0^* c_1 & |c_1|^2 \end{pmatrix} = \begin{pmatrix} |c_1|^2 & -c_0 c_1^* \\ -c_0^* c_1 & -|c_1|^2 \end{pmatrix},$$

whose determinant is $-|c_1|^4 - |c_0|^2 |c_1|^2 = -|c_1|^2$. Since the eigenvalues are $\pm\delta$, their product is $-\delta^2$, so $\delta = |c_1|$. But $|c_0| = |\langle\alpha_0|\alpha_1\rangle| = \cos\theta$, so $\delta = \sin\theta$.

Therefore

$$p_S = \frac{1}{2} + \frac{\sin\theta}{2} [\langle p|\Pi_0|p\rangle - \langle m|\Pi_0|m\rangle].$$

For any projector and any unit vector, $0 \leq \langle\varphi|\Pi_0|\varphi\rangle \leq 1$, so the bracket is at most 1, giving $p_S \leq \frac{1}{2} + \frac{\sin\theta}{2}$. Equality holds when $\langle p|\Pi_0|p\rangle = 1$ and $\langle m|\Pi_0|m\rangle = 0$, which is achieved by the choice $\Pi_0 = |p\rangle\langle p|$, $\Pi_1 = I - |p\rangle\langle p|$. $\square$

The geometry is worth drawing. In the plane spanned by the two states, $|\alpha_0\rangle$ and $|\alpha_1\rangle$ subtend an angle $\frac{\pi}{2} - \theta$; the optimal measurement basis $\{|p\rangle, |m\rangle\}$ is the pair of orthogonal directions that ‘straddles’ them symmetrically.

Two sanity checks. If the states are orthogonal, $\theta = \pi/2$ and the bound reads $p_S \leq 1$, attained: this is the theorem above. If the states are equal, $\theta = 0$ and $p_S \leq \frac{1}{2}$: we can do no better than guessing, as we must. And in between we interpolate smoothly. There is no sharp line between ‘distinguishable’ and ‘indistinguishable’; there is a continuum, governed entirely by the overlap $|\langle\alpha_0|\alpha_1\rangle|$.

§39.3 No Cloning and No Signalling

Having established what quantum states can do, we now establish two things that they cannot do. Both are one-line consequences of linearity, and both turn out to be indispensable: the first is what makes quantum cryptography possible, and the second is what stops quantum mechanics from contradicting relativity.

§39.3.1 Going to the Church of the Higher Hilbert Space

Before proving impossibility results we should be careful about what we are allowed to try. The most general thing we can do to a system S in state $|\psi\rangle$ is:

- (i) (*ancilla*) adjoin an auxiliary system A in a fixed state $|A\rangle$, so that the joint state of SA is $|\psi\rangle|A\rangle \in \mathcal{V}_S \otimes \mathcal{V}_A$;
- (ii) (*unitary*) apply a unitary U to the whole of SA ;
- (iii) (*measure*) perform a measurement on SA , keep the post-measurement state of S , and discard A .

This is often called *going to the church of the higher Hilbert space*: any messy, noisy, irreversible-looking process on S can be modelled as a clean unitary evolution on a larger closed system, followed by throwing part of it away. The point of the ancilla is not merely bookkeeping – it provides somewhere for S to become entangled *with*, which is exactly how information leaks out of a system in practice.

We will therefore prove our impossibility theorems in this general setting, and they will apply to any physical process whatsoever.

§39.3.2 The No-Cloning Theorem

Classical information can be copied freely: read the bit, write it down again. Can quantum information be copied? A copier would be a device that takes the state $|\psi\rangle$ we

want to duplicate, a blank system B initially in some fixed state $|0\rangle$, and a machine M in some fixed ‘ready’ state $|M_0\rangle$, and produces two copies of $|\psi\rangle$:

$$|\psi\rangle_A |0\rangle_B |M_0\rangle_M \mapsto |\psi\rangle_A |\psi\rangle_B |M_\psi\rangle_M.$$

Note that the machine is allowed to end up in a state $|M_\psi\rangle$ that depends on what was copied – we are not demanding that it be reset.

Theorem 39.3.1 (No-Cloning Theorem)

Let $\mathcal{S}$ be any set of states of a system A containing at least one pair of distinct non-orthogonal states. Then there is no unitary^a U which clones every state in $\mathcal{S}$.

^aAnd hence no process at all: by the discussion of §39.3.1, a general process is a unitary on a larger system followed by a measurement, and we may let M absorb both the ancilla and, by the principle of deferred measurement, any measurement performed.

Proof. Let $|\xi\rangle, |\eta\rangle \in \mathcal{S}$ be distinct and non-orthogonal, so that $0 < |\langle\xi|\eta\rangle| < 1$. Suppose such a U existed. Then

$$U |\xi\rangle_A |0\rangle_B |M_0\rangle_M = |\xi\rangle_A |\xi\rangle_B |M_\xi\rangle_M, \quad U |\eta\rangle_A |0\rangle_B |M_0\rangle_M = |\eta\rangle_A |\eta\rangle_B |M_\eta\rangle_M.$$

Unitaries preserve inner products, so taking the inner product of the two left-hand sides and of the two right-hand sides must give the same answer. The inner product on a tensor product factorises, so

$$\langle\xi|\eta\rangle \langle 0|0\rangle \langle M_0|M_0\rangle = \langle\xi|\eta\rangle \langle\xi|\eta\rangle \langle M_\xi|M_\eta\rangle,$$

that is, $\langle\xi|\eta\rangle = \langle\xi|\eta\rangle^2 \langle M_\xi|M_\eta\rangle$. Taking absolute values and dividing by $|\langle\xi|\eta\rangle| \neq 0$ gives

$$1 = |\langle\xi|\eta\rangle| |\langle M_\xi|M_\eta\rangle|.$$

But $|\langle\xi|\eta\rangle| < 1$ and $|\langle M_\xi|M_\eta\rangle| \leq 1$ by Cauchy–Schwarz, so the right-hand side is strictly less than 1. This is a contradiction. $\square$

The theorem is sharp in both directions. A set of *mutually orthogonal* states *can* be cloned: extend them to an orthonormal basis $\{|e_i\rangle\}$ and let U be any unitary with $U|e_i\rangle|0\rangle = |e_i\rangle|e_i\rangle$, which exists because the images are orthonormal. This is exactly the statement that *classical* information – information encoded in orthogonal states – can be copied. It is the superposition states in between that resist duplication.

Remark. It is worth noticing which feature of quantum mechanics is doing the work. It is linearity, nothing else. If $U|\psi\rangle|0\rangle = |\psi\rangle|\psi\rangle$ for all $|\psi\rangle$, then the left-hand side is linear in $|\psi\rangle$ and the right-hand side is quadratic, and the two cannot agree.

Why should we care? Suppose we could clone. Then we could take an unknown state, make a million copies, and measure them all in different bases, thereby learning the state to arbitrary precision from a single copy. But the amplitudes of an unknown

state are continuous parameters, so a single qubit would carry an unbounded amount of extractable classical information. That would be strange enough. In fact, it is worse.

§39.3.3 Cloning Would Permit Superluminal Signalling

Suppose Alice and Bob each hold one qubit of the entangled state

$$|\phi^+\rangle_{AB} = \frac{1}{\sqrt{2}} (|00\rangle + |11\rangle),$$

and are separated by a light-year. Alice wants to send Bob one bit *now*. Here is her protocol. To send ‘yes’, she measures her qubit in the basis $\{|0\rangle, |1\rangle\}$; to send ‘no’, she measures it in the basis $\{|+\rangle, |-\rangle\}$.

Consider what happens to Bob’s qubit. Writing $|\phi^+\rangle$ in the conjugate basis,

$$|\phi^+\rangle = \frac{1}{\sqrt{2}} (|00\rangle + |11\rangle) = \frac{1}{\sqrt{2}} (|++\rangle + |--\rangle),$$

as one checks by expanding. So by the extended Born rule, if Alice measures in the standard basis then with probability $\frac{1}{2}$ each Bob’s qubit is left in the state $|0\rangle$ or $|1\rangle$; if she measures in the conjugate basis then with probability $\frac{1}{2}$ each it is left in $|+\rangle$ or $|-\rangle$.

Bob therefore holds a qubit prepared in one of two *ensembles*: an equal mixture of $\{|0\rangle, |1\rangle\}$, or an equal mixture of $\{|+\rangle, |-\rangle\}$. If he could tell these ensembles apart, he would learn Alice’s bit instantly. But he cannot: for any measurement $\{\Pi_i\}$ on his qubit,

$$p_{\text{yes}}(i) = \frac{1}{2} \langle 0|\Pi_i|0\rangle + \frac{1}{2} \langle 1|\Pi_i|1\rangle = \frac{1}{2} \text{Tr}[\Pi_i (|0\rangle\langle 0| + |1\rangle\langle 1|)] = \frac{1}{2} \text{Tr} \Pi_i,$$

$$p_{\text{no}}(i) = \frac{1}{2} \langle +|\Pi_i|+\rangle + \frac{1}{2} \langle -|\Pi_i|-\rangle = \frac{1}{2} \text{Tr}[\Pi_i (|+\rangle\langle +| + |-\rangle\langle -|)] = \frac{1}{2} \text{Tr} \Pi_i,$$

since both $|0\rangle\langle 0| + |1\rangle\langle 1|$ and $|+\rangle\langle +| + |-\rangle\langle -|$ equal the identity. The two probability distributions are *identical*, whatever measurement Bob makes. No signal.

But now suppose Bob could clone. He makes N copies of his qubit and measures each in the standard basis. If Alice sent ‘yes’, his qubit was $|0\rangle$ or $|1\rangle$, so all N outcomes agree. If she sent ‘no’, his qubit was $|\pm\rangle$, and each of the N measurements gives 0 or 1 independently and uniformly, so the probability that they all agree is $2 \cdot 2^{-N} = 2^{-N+1}$. Bob declares ‘yes’ if the outcomes agree and ‘no’ otherwise, and is wrong with probability at most 2^{-N+1} , which he can make as small as he likes.

So cloning would give instantaneous communication across arbitrary distances, in flat contradiction with special relativity. The no-cloning theorem is not a technical curiosity; it is what keeps quantum mechanics consistent with the rest of physics.

§39.3.4 The No-Signalling Principle

The argument above shows that Bob cannot detect Alice’s *choice of basis*. In fact something much stronger is true: Bob cannot detect *whether Alice measured at all*.

Theorem 39.3.2 (No-Signalling Principle)

Let $|\phi_{AB}\rangle \in \mathcal{V}_A \otimes \mathcal{V}_B$ be an arbitrary (possibly entangled) state shared by Alice and Bob, and let Bob perform a complete measurement in a basis $\{|b\rangle\}$ of $\mathcal{V}_B$. The probability distribution of Bob’s outcome is the same whether or not Alice first performs a measurement on her system, and is independent of which measurement

she performs.

Proof. Fix a complete orthonormal basis $\{|a\rangle\}$ of $\mathcal{V}_A$, write $P_a = |a\rangle\langle a|$ and $P_b = |b\rangle\langle b|$, and expand

$$|\phi_{AB}\rangle = \sum_{a,b} c_{ab} |a\rangle |b\rangle.$$

If Alice does nothing, the extended Born rule gives Bob outcome b with probability

$$p(b) = \langle \phi_{AB} | I_A \otimes P_b | \phi_{AB} \rangle = \sum_a |c_{ab}|^2.$$

Suppose instead Alice first measures in the basis $\{|a\rangle\}$. She gets outcome a with probability $p(a) = \sum_b |c_{ab}|^2$, and the joint state becomes

$$|\phi''_{AB}\rangle = \frac{(P_a \otimes I_B) |\phi_{AB}\rangle}{\sqrt{p(a)}}.$$

Bob's conditional probability of outcome b is then

$$\begin{aligned} p(b | a) &= \langle \phi''_{AB} | I_A \otimes P_b | \phi''_{AB} \rangle \\ &= \frac{1}{p(a)} \langle \phi_{AB} | (P_a \otimes I)(I \otimes P_b)(P_a \otimes I) | \phi_{AB} \rangle \\ &= \frac{1}{p(a)} \langle \phi_{AB} | P_a \otimes P_b | \phi_{AB} \rangle, \end{aligned}$$

using $P_a^2 = P_a$ and the fact that operators on different factors commute. Hence the joint distribution is $p(a, b) = p(a)p(b | a) = \langle \phi_{AB} | P_a \otimes P_b | \phi_{AB} \rangle = |c_{ab}|^2$, and Bob's marginal is

$$\sum_a p(a, b) = \sum_a |c_{ab}|^2 = p(b),$$

exactly as before. Since Alice measuring in any other basis is the same as applying a unitary to her half and then measuring in $\{|a\rangle\}$, and unitaries of the form $U \otimes I$ leave Bob's marginal alone by the same computation, the result is independent of her choice. $\square$

So the ‘collapse’ induced at a distance is real as a change in our *description* of Bob's system, but it carries no information whatsoever. It is only when Alice tells Bob, over an ordinary classical channel, what she did and what she got, that the correlations become visible. Every protocol in this course respects this: teleportation, superdense coding and key distribution all require classical communication, and all are therefore limited by the speed of light.

§39.4 Entanglement

Entanglement is the resource that makes quantum information interesting. In this section we meet the canonical entangled states, and then confront the fact – established by Bell, and by now verified experimentally beyond any reasonable doubt – that the correlations they exhibit cannot be reproduced by *any* classical mechanism.

§39.4.1 The Bell Basis

Definition 39.4.1 (Bell States)

The **Bell states** of a pair of qubits are

$$|\phi^\pm\rangle = \frac{1}{\sqrt{2}}(|00\rangle \pm |11\rangle), \quad |\psi^\pm\rangle = \frac{1}{\sqrt{2}}(|01\rangle \pm |10\rangle).$$

They form an orthonormal basis of $\mathbb{C}^2 \otimes \mathbb{C}^2$, the **Bell basis**.

Orthonormality is immediate from the orthonormality of the computational basis. Each Bell state is entangled, by the same argument we gave for $|\phi^+\rangle$. They are also **maximally** entangled, in a sense we can make precise here informally: measuring either qubit alone in *any* basis gives a uniformly random outcome, so an observer with access to one qubit has no information at all, while the pair together is in a perfectly definite state. All of the information is in the correlations.

These states are also known as **EPR pairs**, after the 1935 paper of Einstein, Podolsky and Rosen, who considered a state of this kind and argued that quantum mechanics must be incomplete. Their reasoning, in modern dress: measuring Alice's qubit of $|\phi^+\rangle$ in the standard basis determines Bob's outcome with certainty, and by no-signalling this cannot be a physical influence; so Bob's outcome must have been predetermined by some *element of reality* which the quantum state fails to record. Call such a hidden parameter λ . EPR concluded that the wavefunction is an incomplete description of reality. It was thirty years before Bell showed that this conclusion is not merely unnecessary but *false*.

Before we get there, a computational fact which we will use constantly.

Proposition 39.4.2

Write $X = \sigma_x$, $Z = \sigma_z$ and $Y = i\sigma_y = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$. Then all four Bell states are obtained from $|\phi^+\rangle$ by a local operation on the first qubit:

$$\begin{aligned} |\phi^+\rangle &= (I \otimes I) |\phi^+\rangle, & |\phi^-\rangle &= (Z \otimes I) |\phi^+\rangle, \\ |\psi^+\rangle &= (X \otimes I) |\phi^+\rangle, & |\psi^-\rangle &= (Y \otimes I) |\phi^+\rangle. \end{aligned}$$

The same holds with the operators acting on the second qubit instead, except that $|\psi^-\rangle = -(I \otimes Y) |\phi^+\rangle$.

Proof. Direct computation. For instance

$$(X \otimes I) |\phi^+\rangle = \frac{1}{\sqrt{2}}((X|0\rangle)|0\rangle + (X|1\rangle)|1\rangle) = \frac{1}{\sqrt{2}}(|10\rangle + |01\rangle) = |\psi^+\rangle,$$

and

$$(Y \otimes I) |\phi^+\rangle = \frac{1}{\sqrt{2}}((Y|0\rangle)|0\rangle + (Y|1\rangle)|1\rangle) = \frac{1}{\sqrt{2}}(-|10\rangle + |01\rangle) = |\psi^-\rangle,$$

since $Y|0\rangle = -|1\rangle$ and $Y|1\rangle = |0\rangle$. The remaining cases are similar, and the statements for the second qubit follow from the example of §39.1.7, since I, X, Z are symmetric matrices and Y is antisymmetric. $\square$

The moral is striking: Alice, acting only on her own qubit, can steer the joint state to any of four mutually orthogonal – and hence perfectly distinguishable – states. She has

two bits of leverage over a system she only half owns. We will cash this in as superdense coding in §39.6.

§39.4.2 Bell Inequalities and the CHSH Game

Let us take the EPR argument seriously and ask what a *local hidden variable* theory would predict. The setup: Alice and Bob are far apart, sharing some system. Alice chooses one of two binary-outcome measurements, labelled by $s \in \{0, 1\}$, and obtains an outcome $a \in \{-1, +1\}$; Bob chooses $t \in \{0, 1\}$ and gets $b \in \{-1, +1\}$. The experiment is repeated many times and they compare notes, computing the four correlations $\mathbb{E}[ab \mid s, t]$.

A **local hidden variable** (LHV) model asserts that there is a random variable λ , distributed according to some law $p(\lambda)$, and functions

$$A_0(\lambda), A_1(\lambda), B_0(\lambda), B_1(\lambda) \in \{-1, +1\}$$

such that Alice's outcome for setting s is $A_s(\lambda)$ and Bob's for setting t is $B_t(\lambda)$. *Locality* is the assumption that A_s does not depend on t and vice versa – Alice's outcome cannot depend on a choice made outside her light cone. *Realism* is the assumption that all four values exist simultaneously, even though only two of them are measured in any given run.

Theorem 39.4.3 (CHSH Inequality)

In any local hidden variable model, the quantity

$$S = \mathbb{E}[A_0 B_0] + \mathbb{E}[A_0 B_1] + \mathbb{E}[A_1 B_0] - \mathbb{E}[A_1 B_1]$$

satisfies $|S| \leq 2$.

Proof. Fix λ and consider

$$\begin{aligned} & A_0(\lambda)B_0(\lambda) + A_0(\lambda)B_1(\lambda) + A_1(\lambda)B_0(\lambda) - A_1(\lambda)B_1(\lambda) \\ &= A_0(\lambda) [B_0(\lambda) + B_1(\lambda)] + A_1(\lambda) [B_0(\lambda) - B_1(\lambda)]. \end{aligned}$$

Since $B_0(\lambda), B_1(\lambda) \in \{-1, +1\}$, one of $B_0 + B_1$ and $B_0 - B_1$ is 0 and the other is ± 2 . Hence the whole expression is $\pm 2A_s(\lambda)$ for one of $s = 0, 1$, and so lies in $\{-2, +2\}$. Averaging over λ with respect to $p(\lambda)$ and using linearity of expectation gives $|S| \leq 2$. $\square$

The inequality is a genuine constraint on the observable correlations, derived from nothing but locality and realism. And quantum mechanics violates it.

Theorem 39.4.4 (Quantum Violation of CHSH)

Let Alice and Bob share the state $|\psi^-\rangle = \frac{1}{\sqrt{2}}(|01\rangle - |10\rangle)$, and let each measure the spin observable along a direction in a fixed plane: Alice measures $A(\alpha) = \cos \alpha \sigma_z + \sin \alpha \sigma_x$ and Bob measures $B(\beta) = \cos \beta \sigma_z + \sin \beta \sigma_x$. Then

$$\mathbb{E}[A(\alpha)B(\beta)] = -\cos(\alpha - \beta),$$

and with the choices $\alpha_0 = 0$, $\alpha_1 = \frac{\pi}{2}$, $\beta_0 = \frac{\pi}{4}$, $\beta_1 = -\frac{\pi}{4}$ we obtain

$$S = -2\sqrt{2}, \quad |S| = 2\sqrt{2} > 2.$$

Proof. Each $A(\alpha)$ is Hermitian with $A(\alpha)^2 = I$ (using $\sigma_z^2 = \sigma_x^2 = I$ and $\sigma_z\sigma_x + \sigma_x\sigma_z = 0$), so its eigenvalues are ± 1 and it is a legitimate ± 1 -valued observable. The correlation is the expectation of the observable $A(\alpha) \otimes B(\beta)$ in the state $|\psi^-\rangle$.

We use the fact that $|\psi^-\rangle$ is *rotationally invariant*: for any 2×2 unitary U with $\det U = 1$ we have $(U \otimes U) |\psi^-\rangle = |\psi^-\rangle$, because $|\psi^-\rangle$ spans the antisymmetric part of $\mathbb{C}^2 \otimes \mathbb{C}^2$ and $U \otimes U$ acts on it by $\det U$. Rather than invoke this, though, let us simply compute. Write $|\psi^-\rangle = \frac{1}{\sqrt{2}}(|01\rangle - |10\rangle)$ and note the useful identities

$$\sigma_z \otimes \sigma_z |\psi^-\rangle = -|\psi^-\rangle, \quad \sigma_x \otimes \sigma_x |\psi^-\rangle = -|\psi^-\rangle,$$

the first because $\sigma_z \otimes \sigma_z |01\rangle = -|01\rangle$ and likewise for $|10\rangle$; the second because $\sigma_x \otimes \sigma_x$ swaps $|01\rangle \leftrightarrow |10\rangle$, which negates the antisymmetric combination. We also need the cross terms:

$$(\sigma_z \otimes \sigma_x) |\psi^-\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle) = |\phi^+\rangle,$$

since $\sigma_z \otimes \sigma_x |01\rangle = |00\rangle$ and $\sigma_z \otimes \sigma_x |10\rangle = -|11\rangle$. As $\langle \psi^- | \phi^+ \rangle = 0$, we get $\langle \psi^- | \sigma_z \otimes \sigma_x | \psi^- \rangle = 0$, and symmetrically $\langle \psi^- | \sigma_x \otimes \sigma_z | \psi^- \rangle = 0$. Therefore

$$\begin{aligned} \mathbb{E}[A(\alpha)B(\beta)] &= \langle \psi^- | (\cos \alpha \sigma_z + \sin \alpha \sigma_x) \otimes (\cos \beta \sigma_z + \sin \beta \sigma_x) | \psi^- \rangle \\ &= \cos \alpha \cos \beta (-1) + \sin \alpha \sin \beta (-1) + 0 + 0 \\ &= -\cos(\alpha - \beta). \end{aligned}$$

Now we simply evaluate the four correlations. Writing $C_{st} = \mathbb{E}[A(\alpha_s)B(\beta_t)] = -\cos(\alpha_s - \beta_t)$,

$$\begin{aligned} C_{00} &= -\cos(0 - \frac{\pi}{4}) = -\frac{1}{\sqrt{2}}, & C_{01} &= -\cos(0 + \frac{\pi}{4}) = -\frac{1}{\sqrt{2}}, \\ C_{10} &= -\cos(\frac{\pi}{2} - \frac{\pi}{4}) = -\frac{1}{\sqrt{2}}, & C_{11} &= -\cos(\frac{\pi}{2} + \frac{\pi}{4}) = +\frac{1}{\sqrt{2}}, \end{aligned}$$

so that

$$S = C_{00} + C_{01} + C_{10} - C_{11} = -\frac{1}{\sqrt{2}} - \frac{1}{\sqrt{2}} - \frac{1}{\sqrt{2}} - \frac{1}{\sqrt{2}} = -\frac{4}{\sqrt{2}} = -2\sqrt{2},$$

and $|S| = 2\sqrt{2} \approx 2.828 > 2$, as claimed. $\square$

Three of the four pairs of directions are separated by $\pi/4$, while α_1 and β_1 are separated by $3\pi/4$; that last pair is the one carrying the minus sign in S , so all four terms contribute $-1/\sqrt{2}$ and we collect $4/\sqrt{2} = 2\sqrt{2}$.

This is a genuinely astonishing state of affairs, and it deserves to be stated plainly. The CHSH inequality is a theorem about *any* theory in which measurement outcomes are determined by local properties carried by the particles. Quantum mechanics predicts, and experiment confirms, that the inequality is violated. Therefore no such theory can be correct. Entanglement is not a matter of pre-arranged correlations, like a pair of gloves posted in separate boxes; it is something with no classical counterpart at all.

Remark. The value $2\sqrt{2}$ is not accidental: **Tsirelson's bound** says that $|S| \leq 2\sqrt{2}$ for *any* quantum states and observables, so quantum mechanics saturates but does not exceed it. There is nothing in the no-signalling principle alone that forbids $S = 4$ – hypothetical ‘PR boxes’ achieving this are perfectly consistent with relativity – so quantum mechanics sits strictly between the classical and the merely-relativistic worlds. Why it sits exactly where it does remains a good question.

§39.4.3 The Schmidt Decomposition

Deciding by hand whether a given bipartite state is entangled, as we did for $|\phi^+\rangle$ in §39.1.7, is not a calculation one wants to repeat often. Happily there is a normal form for bipartite pure states which settles the question at a glance, and tells us rather more besides.

Theorem 39.4.5 (Schmidt Decomposition)

Let $|\Psi\rangle \in \mathcal{V}_A \otimes \mathcal{V}_B$ be normalised, where $\dim \mathcal{V}_A = m$ and $\dim \mathcal{V}_B = n$. Then there are orthonormal sets $\{|a_1\rangle, \dots, |a_k\rangle\} \subseteq \mathcal{V}_A$ and $\{|b_1\rangle, \dots, |b_k\rangle\} \subseteq \mathcal{V}_B$, with $k \leq \min(m, n)$, and reals $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_k > 0$ satisfying $\sum_i \lambda_i^2 = 1$, such that

$$|\Psi\rangle = \sum_{i=1}^k \lambda_i |a_i\rangle \otimes |b_i\rangle.$$

The integer k and the numbers λ_i are determined by $|\Psi\rangle$ alone.

Proof. Fix orthonormal bases $\{|e_i\rangle\}$ of $\mathcal{V}_A$ and $\{|f_j\rangle\}$ of $\mathcal{V}_B$ and write

$$|\Psi\rangle = \sum_{i=1}^m \sum_{j=1}^n C_{ij} |e_i\rangle |f_j\rangle,$$

so that the state is nothing but an $m \times n$ complex matrix C with $\sum_{ij} |C_{ij}|^2 = 1$. By the singular value decomposition of IB Linear Algebra we may write $C = UDV$, where U is an $m \times m$ unitary, V is an $n \times n$ unitary, and D is $m \times n$ with non-negative reals $\lambda_1 \geq \dots \geq \lambda_{\min(m,n)}$ on its leading diagonal and zeros elsewhere. Substituting $C_{ij} = \sum_{\ell} U_{i\ell} \lambda_{\ell} V_{\ell j}$ and exchanging the order of summation,

$$|\Psi\rangle = \sum_{\ell} \lambda_{\ell} \left(\sum_i U_{i\ell} |e_i\rangle \right) \otimes \left(\sum_j V_{\ell j} |f_j\rangle \right) = \sum_{\ell} \lambda_{\ell} |a_{\ell}\rangle \otimes |b_{\ell}\rangle,$$

where the bracketed vectors are named $|a_\ell\rangle$ and $|b_\ell\rangle$. The columns of U are orthonormal and the rows of V are orthonormal, so

$$\langle a_\ell | a_{\ell'} \rangle = \sum_i U_{i\ell}^* U_{i\ell'} = \delta_{\ell\ell'}, \quad \langle b_\ell | b_{\ell'} \rangle = \sum_j V_{\ell j} V_{\ell' j}^* = \delta_{\ell\ell'},$$

as required. Deleting the terms with $\lambda_\ell = 0$ and keeping the rest in decreasing order leaves exactly k terms, and $1 = \langle \Psi | \Psi \rangle = \sum_\ell \lambda_\ell^2$.

For uniqueness, observe that the λ_ℓ^2 are precisely the nonzero eigenvalues of $CC^\dagger$, listed with multiplicity. Changing the two bases replaces C by PCQ for unitaries P, Q , which replaces $CC^\dagger$ by $P(CC^\dagger)P^\dagger$ and so leaves the eigenvalues alone. Hence k and the λ_ℓ depend only on $|\Psi\rangle$. $\square$

Definition 39.4.6 (Schmidt Rank and Coefficients)

In the notation of the theorem, k is the **Schmidt rank** of $|\Psi\rangle$ and $\lambda_1, \dots, \lambda_k$ are its **Schmidt coefficients**.

The point of all this is the following one-line criterion.

Corollary 39.4.7

A bipartite pure state is a product state if and only if its Schmidt rank is 1; equivalently, it is entangled if and only if $k \geq 2$.

Proof. If $k = 1$ then $|\Psi\rangle = |a_1\rangle |b_1\rangle$ is a product. Conversely, a product state $|\psi\rangle |\varphi\rangle$ is already in Schmidt form with $k = 1$, and k is unique. $\square$

Example 39.4.8

For $|\phi^+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$ we have $C = \frac{1}{\sqrt{2}}I$, whose singular values are $\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}$. So the Schmidt rank is 2 and the state is entangled – which is the argument of §39.1.7 with the cleverness removed. Similarly $|\psi^-\rangle$ has $C = \frac{1}{\sqrt{2}}\begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$, again with both singular values $\frac{1}{\sqrt{2}}$.

The Schmidt coefficients say more than merely ‘entangled or not’: they measure *how* entangled a state is. Notice that they are unchanged by local unitaries, since $(U_A \otimes U_B) |\Psi\rangle = \sum_i \lambda_i (U_A |a_i\rangle) \otimes (U_B |b_i\rangle)$ is again in Schmidt form with the same coefficients. So anything Alice and Bob can compute from the λ_i is a genuine property of their shared resource, invariant under whatever they choose to do locally. A two-qubit state with $\lambda_1 = \lambda_2 = 1/\sqrt{2}$ is called **maximally entangled**, and the four Bell states are exactly the maximally entangled states of two qubits, up to local unitaries. We will meet the λ_i^2 again in §39.15.2 as the eigenvalues of the reduced density matrix, which is where their interpretation as a probability distribution comes from.

Remark. There is no Schmidt decomposition for three or more parties. The three-qubit states

$$|\text{GHZ}\rangle = \frac{1}{\sqrt{2}}(|000\rangle + |111\rangle), \quad |W\rangle = \frac{1}{\sqrt{3}}(|001\rangle + |010\rangle + |100\rangle)$$

are both entangled, and neither can be converted into the other by local operations

even with a small probability of success: multipartite entanglement comes in genuinely different kinds, and classifying them is an active research problem.

§39.4.4 Entanglement as a Resource

The modern point of view treats entanglement as a commodity. Alice and Bob are imagined to be restricted to **LOCC**: local operations (unitaries, measurements, ancillas on their own systems) and classical communication. Under this restriction, entanglement cannot be created – a product state stays a product state – so shared entangled pairs, or **ebits**, are a resource which is consumed by protocols.

The two basic conversion rates are established by the protocols of the next section, and they are worth stating in advance:

1 ebit + 1 qubit of communication $\geq$ 2 bits of communication (superdense coding),

1 ebit + 2 bits of communication $\geq$ 1 qubit of communication (teleportation).

Both are optimal. Neither is possible classically, and neither is possible without the shared entanglement.

§39.5 Quantum Gates and Circuits

A quantum computation, in the model we shall use, is a sequence of unitary operators applied to a fixed number of qubits, followed by a measurement. The unitaries are drawn from a fixed repertoire of **gates**, each acting on a small number of qubits, and we picture the whole thing as a **circuit**: time runs left to right, each qubit is a horizontal wire, and a gate is a box straddling the wires it acts on.

§39.5.1 Single-Qubit Gates

The most important gate in the subject is the following.

Definition 39.5.1 (Hadamard Gate)

The **Hadamard gate** is

$$H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}.$$

It is Hermitian, unitary, and satisfies $H^2 = I$. Its action is

$$H|0\rangle = |+\rangle, \quad H|1\rangle = |-\rangle, \quad H|+\rangle = |0\rangle, \quad H|-\rangle = |1\rangle,$$

so H is exactly the change of basis between the computational and conjugate bases. Compactly,

$$H|x\rangle = \frac{1}{\sqrt{2}} (|0\rangle + (-1)^x |1\rangle) = \frac{1}{\sqrt{2}} \sum_{y \in \{0,1\}} (-1)^{xy} |y\rangle, \quad x \in \{0,1\}.$$

The reason H matters so much is that it manufactures superpositions. Applying it to each of n qubits initialised to $|0\rangle$ gives

$$H^{\otimes n} |0\rangle^{\otimes n} = |+\rangle^{\otimes n} = \frac{1}{\sqrt{2^n}} \sum_{x \in \{0,1\}^n} |x\rangle,$$

the **equal superposition** over all 2^n bit strings, at a cost of n gates. An exponentially large superposition for a linear price is the starting point of every quantum algorithm we will meet. More generally, one checks by induction that

$$H^{\otimes n} |x\rangle = \frac{1}{\sqrt{2^n}} \sum_{y \in \{0,1\}^n} (-1)^{x \cdot y} |y\rangle,$$

where $x \cdot y = x_1 y_1 + \cdots + x_n y_n \bmod 2$.

The Pauli operators give three more gates, written $X = \sigma_x$, $Y = i\sigma_y$ and $Z = \sigma_z$ in this context (the factor of i in Y is a global phase convention which makes the entries real). Thus

$$X |k\rangle = |k \oplus 1\rangle, \quad Z |k\rangle = (-1)^k |k\rangle,$$

where $\oplus$ is addition modulo 2: X is the quantum NOT gate, and Z inserts a relative sign. Finally we will need a continuous family.

Definition 39.5.2 (Phase Gate)

For $\theta \in \mathbb{R}$ the **phase gate** is

$$P_\theta = \begin{pmatrix} 1 & 0 \\ 0 & e^{i\theta} \end{pmatrix}.$$

Note $Z = P_\pi$, and two other special cases have names: $S = P_{\pi/2}$ and $T = P_{\pi/4}$. In circuits, a single-qubit gate is drawn as a labelled box on a wire:

§39.5.2 Two-Qubit Gates

To do anything beyond acting on qubits separately we need gates which couple them.

Definition 39.5.3 (Controlled- X)

The **controlled-not** or **CNOT** gate CX on two qubits is defined by

$$CX |i\rangle |j\rangle = |i\rangle |i \oplus j\rangle, \quad i, j \in \{0, 1\},$$

so that in the computational basis

$$CX = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix} = \begin{pmatrix} I & 0 \\ 0 & X \end{pmatrix}.$$

The first qubit is the **control** and the second the **target**: if the control is $|0\rangle$ nothing happens, and if it is $|1\rangle$ then X is applied to the target. By linearity, $CX |0\rangle |\psi\rangle = |0\rangle |\psi\rangle$ and $CX |1\rangle |\psi\rangle = |1\rangle X |\psi\rangle$ for any $|\psi\rangle$. The gate is drawn with a filled dot on the control wire and a $\oplus$ on the target:

Replacing X by Z gives the **controlled- Z** gate,

$$\text{CZ} = \begin{pmatrix} I & 0 \\ 0 & Z \end{pmatrix}, \quad \text{CZ} |i\rangle |j\rangle = (-1)^{ij} |i\rangle |j\rangle.$$

The second expression makes it obvious that CZ is *symmetric* in its two qubits, so it does not matter which we call the control. That is not at all obvious from the circuit picture, and it is a good illustration of how much easier algebra can be than diagrams.

The two controlled gates are conjugate to one another via Hadamards on the target, since $HXH = Z$:

$$\text{CZ} = (I \otimes H) \text{CX} (I \otimes H).$$

A more surprising identity is that conjugating CX by Hadamards on *both* wires reverses the roles of control and target.

Proposition 39.5.4

$(H \otimes H) \text{CX} (H \otimes H)$ is the CNOT gate with control and target interchanged. Diagrammatically,

Proof. Since $H^2 = I$ we may split the conjugation into two steps:

$$(H \otimes H) \text{CX} (H \otimes H) = (H \otimes I) \left[(I \otimes H) \text{CX} (I \otimes H) \right] (H \otimes I) = (H \otimes I) \text{CZ} (H \otimes I),$$

using the identity $\text{CZ} = (I \otimes H) \text{CX} (I \otimes H)$ noted above. But CZ is symmetric in its two qubits, so it is equally the controlled- Z gate with the *second* qubit as control; conjugating by H on the first wire therefore turns it into the controlled- X gate with the second qubit as control, which is what we wanted. $\square$

Finally, the **swap** gate $|i\rangle |j\rangle \mapsto |j\rangle |i\rangle$ is drawn with two crosses joined by a wire, and factors as three CNOTs:

§39.5.3 Reversible Computation and the Toffoli Gate

There is an immediate obstacle to running classical computations on a quantum computer: quantum gates are unitary and hence invertible, whereas classical gates typically are not. The AND gate throws away information – from the output 0 one cannot recover the input – and no unitary can do that.

The fix is standard, and it is the same trick we saw with the ancilla. Any function $f : \{0, 1\}^m \rightarrow \{0, 1\}^n$ can be made reversible by remembering its input: define

$$\tilde{f} : \{0, 1\}^{m+n} \rightarrow \{0, 1\}^{m+n}, \quad \tilde{f}(b, c) = (b, c \oplus f(b)).$$

Then $\tilde{f}$ is a bijection – indeed an involution, since

$$\tilde{f}(\tilde{f}(b, c)) = \tilde{f}(b, c \oplus f(b)) = (b, c \oplus f(b) \oplus f(b)) = (b, c),$$

and f is recovered as $f(b) =$ the second component of $\tilde{f}(b, 0)$. So computing f and computing $\tilde{f}$ are equivalent tasks, up to a constant factor in resources.

The gate that makes this work in practice is the following three-qubit gate.

Definition 39.5.5 (Toffoli Gate)

The **Toffoli gate**, or controlled-controlled-NOT, is the map

$$T : |i\rangle |j\rangle |k\rangle \mapsto |i\rangle |j\rangle |k \oplus ij\rangle.$$

Setting $k = 0$ gives $|i\rangle |j\rangle |0\rangle \mapsto |i\rangle |j\rangle |i \wedge j\rangle$, so Toffoli computes AND; setting $j = k = 1$ gives $|i\rangle |1\rangle |1\rangle \mapsto |i\rangle |1\rangle |\neg i\rangle$, so it computes NOT. Since $\{\text{AND}, \text{NOT}\}$ is universal for Boolean logic, the Toffoli gate alone (with the freedom to initialise ancillas and ignore garbage outputs) is universal for classical computation. In particular:

Proposition 39.5.6

Any classical circuit computing f with G gates can be converted into a reversible circuit computing $\tilde{f}$ with $O(G)$ Toffoli gates and $O(G)$ ancillary bits, and hence into a quantum circuit of the same size.

We will not prove this carefully – the only real content is the bookkeeping needed to uncompute the intermediate ‘garbage’ bits so that the ancillas are returned to $|0\rangle$ – but the consequence is important: *a quantum computer can do anything a classical computer can do, with at most polynomial overhead.* Quantum computation is not a different kind of computability; it is a claim about efficiency.

§39.5.4 Universal Gate Sets

Which sets of gates suffice to build everything?

Definition 39.5.7 (Universal Gate Set)

A set $\mathcal{G}$ of gates is **universal** if every unitary on every number of qubits can be written as a finite product of gates from $\mathcal{G}$ (acting on specified qubits).

Theorem 39.5.8

The set consisting of CX together with all single-qubit unitaries is universal.

We shall not give a complete proof, but the shape of the argument is worth knowing, since it is entirely constructive and each of its three steps is elementary.

Proof sketch. Step 1: two-level unitaries suffice. Call a unitary on $\mathbb{C}^{2^n}$ **two-level** if it acts as the identity on all but two of the computational basis vectors, so that it is essentially a 2×2 unitary embedded in a large space. Given any unitary U , one clears the entries of its first column below the diagonal one at a time by multiplying by suitable two-level unitaries – exactly the Givens-rotation procedure used to compute a QR factorisation – then repeats on the second column, and so on. After at most $\frac{1}{2}2^n(2^n - 1)$ such steps we have reduced U to the identity, so U is a product of that many two-level unitaries.

Step 2: a two-level unitary is a multiply-controlled single-qubit gate. Suppose the two-level unitary V acts nontrivially on the span of $|x\rangle$ and $|y\rangle$, where $x, y \in \mathbb{B}_n$. Choose a path $x = z_0, z_1, \dots, z_\ell = y$ in which consecutive strings differ in one bit (a Gray code path), and apply CNOTs to relabel, so that we may assume x and y differ in a single bit, say the last. Then V is a single-qubit gate on the last qubit, controlled on the other $n - 1$ qubits taking the prescribed values – and a control on the value 0 is a control on 1 conjugated by X .

Step 3: multiple controls reduce to single controls. A gate controlled on $n - 1$ qubits can be built from Toffoli gates, which compute the AND of the controls into an ancilla, a singly-controlled gate, and the same Toffolis again to uncompute the ancilla. The proposition below then reduces a singly-controlled single-qubit gate to CNOTs and single-qubit gates, and the Toffoli gate itself is a fixed circuit of CNOTs and single-qubit gates. $\square$

The last step used the following pretty construction, which is worth seeing in full.

Proposition 39.5.9

Let U be a single-qubit unitary. Then there are single-qubit unitaries A, B, C with $ABC = I$ and a phase δ such that $U = e^{i\delta}AXBXC$. Consequently the controlled- U gate factors as

Proof. Writing $R_y(\theta) = \exp(-i\theta\sigma_y/2)$ and $R_z(\theta) = \exp(-i\theta\sigma_z/2)$ for the Bloch-sphere rotations about the y - and z -axes, every single-qubit unitary has an Euler-angle decomposition

$$U = e^{i\delta} R_z(\alpha) R_y(\beta) R_z(\gamma)$$

for some real $\delta, \alpha, \beta, \gamma$ – this is the statement that $SU(2)$ surjects onto $SO(3)$, together with the Euler decomposition of a rotation of $\mathbb{R}^3$. Now put

$$A = R_z(\alpha) R_y\left(\frac{\beta}{2}\right), \quad B = R_y\left(-\frac{\beta}{2}\right) R_z\left(-\frac{\alpha+\gamma}{2}\right), \quad C = R_z\left(\frac{\gamma-\alpha}{2}\right).$$

Then $ABC = R_z(\alpha) R_z\left(-\frac{\alpha+\gamma}{2}\right) R_y\left(\frac{\beta}{2}\right) R_y\left(-\frac{\beta}{2}\right) R_z\left(\frac{\gamma-\alpha}{2}\right) = R_z(\alpha) R_z(-\alpha) = I$. On the other hand $X\sigma_y X = -\sigma_y$ and $X\sigma_z X = -\sigma_z$, so $XR_y(\theta)X = R_y(-\theta)$ and $XR_z(\theta)X = R_z(-\theta)$, whence $AXBX = R_y\left(\frac{\beta}{2}\right) R_z\left(\frac{\alpha+\gamma}{2}\right)$ and

$$AXBXC = R_z(\alpha) R_y\left(\frac{\beta}{2}\right) R_y\left(\frac{\beta}{2}\right) R_z\left(\frac{\alpha+\gamma}{2}\right) R_z\left(\frac{\gamma-\alpha}{2}\right) = R_z(\alpha) R_y(\beta) R_z(\gamma) = e^{-i\delta} U.$$

For the circuit: if the control is $|0\rangle$ the two CNOTs do nothing and the target sees $ABC = I$, while the phase gate P_δ acts trivially on $|0\rangle$. If the control is $|1\rangle$ the target sees $AXBXC = e^{-i\delta}U$ and the phase gate contributes the compensating factor $e^{i\delta}$. So the circuit implements $|0\rangle\langle 0| \otimes I + |1\rangle\langle 1| \otimes U$, which is controlled- U . $\square$

The theorem is very useful but slightly unsatisfying, because it involves a continuum of gates. A physical device will only be able to implement finitely many, so we ask for less.

Definition 39.5.10 (Approximate Universality)

A finite set $\mathcal{G}$ of gates is **approximately universal** if for every n , every unitary U on n qubits and every $\varepsilon > 0$, there is a circuit $\tilde{U}$ built from gates of $\mathcal{G}$ with

$$\|U - \tilde{U}\|_{\text{op}} < \varepsilon,$$

where $\|A\|_{\text{op}} = \sup_{\|\psi\rangle=1} \|A|\psi\rangle\|$ is the operator norm.

Approximation in operator norm is exactly what we want, since if $\|U - \tilde{U}\|_{\text{op}} < \varepsilon$ then all measurement probabilities differ by $O(\varepsilon)$, and errors accumulate at worst additively along a circuit.

Theorem 39.5.11

The set $\mathcal{G} = \{H, CX, T\}$, where $T = P_{\pi/4}$, is approximately universal.

Remark. One might worry that approximating to accuracy ε could require a number of gates growing like $1/\varepsilon$, which would destroy any speedup. The **Solovay–Kitaev theorem** says otherwise: for any approximately universal set closed under inverses, accuracy ε on a single qubit is achievable with $O(\log^c(1/\varepsilon))$ gates, for a small constant c . So the overhead is polylogarithmic, and we may cheerfully talk about ‘applying a unitary U ’ without worrying about which gate set is used to build it.

§39.5.5 Circuits and Measurement

A quantum circuit on n qubits consists of: an input state $|b_1\rangle \cdots |b_k\rangle |0\rangle \cdots |0\rangle$, with the input bit string in the first few qubits and the rest as workspace; a sequence of gates from a fixed universal set; and a measurement of some designated qubits in the computational basis at the end. The output is the string of measurement outcomes.

Two conventions make life easier. First, we draw a measurement as a meter symbol, and a wire carrying a classical bit as a doubled line. Second, we use the **principle of deferred measurement**: any circuit in which measurements occur partway through, with later gates conditioned on the outcomes, can be replaced by an equivalent circuit in which all measurements occur at the very end, replacing each classically-controlled gate by a quantum-controlled one. So we lose nothing by assuming all measurements come last; but for exposition it is often clearer to draw them where they physically happen, as we will for teleportation.

Finally, note that we do not need to add randomness to the model by hand, as one

does for classical probabilistic computation. A Hadamard on $|0\rangle$ followed by a standard measurement gives a perfect fair coin. Randomness comes free.

§39.6 Superdense Coding

We can now start spending our entanglement. The first protocol is due to Bennett and Wiesner: Alice sends Bob *two* classical bits by physically transmitting a single qubit, provided they share an ebit in advance.

Recall from §39.4.1 that Alice can convert $|\phi^+\rangle$ into any of the four Bell states by acting on her qubit alone. Since the Bell states are orthonormal, they are reliably distinguishable by a measurement in the Bell basis. That is the entire protocol.

Proposition 39.6.1 (Superdense Coding)

Suppose Alice and Bob share the state $|\phi^+\rangle_{AB}$, with Alice holding qubit A and Bob holding B . Then Alice can transmit any two-bit message to Bob by sending him the single qubit A .

Proof. Alice applies to her qubit the local operation determined by her message:

message	Alice's operation on A	resulting state of AB
00	I	$ \phi^+\rangle$
01	X	$ \psi^+\rangle$
10	Z	$ \phi^-\rangle$
11	Y	$ \psi^-\rangle$

She then sends qubit A to Bob, who now holds both qubits and performs a complete projective measurement in the Bell basis, with projectors $|\phi^+\rangle\langle\phi^+|$, $|\phi^-\rangle\langle\phi^-|$, $|\psi^+\rangle\langle\psi^+|$, $|\psi^-\rangle\langle\psi^-|$. Since the four possible states are exactly these four orthonormal vectors, the outcome identifies Alice's message with probability 1. $\square$

Bob's Bell measurement is performed in practice by rotating the Bell basis to the computational basis and then measuring in the standard way. The circuit that does this is a CNOT followed by a Hadamard, run on the two qubits:

Here $U \in \{I, X, Z, Y\}$ encodes Alice's message, and one checks that the CNOT-then-Hadamard circuit maps

$$|\phi^+\rangle \mapsto |00\rangle, \quad |\psi^+\rangle \mapsto |01\rangle, \quad |\phi^-\rangle \mapsto |10\rangle, \quad |\psi^-\rangle \mapsto |11\rangle,$$

so the pair of measurement outcomes (m_1, m_2) is exactly Alice's message. For instance

$$|\phi^-\rangle = \frac{1}{\sqrt{2}}(|00\rangle - |11\rangle) \xrightarrow{\text{CX}} \frac{1}{\sqrt{2}}(|00\rangle - |10\rangle) = |-\rangle|0\rangle \xrightarrow{H \otimes I} |1\rangle|0\rangle,$$

as claimed.

Two remarks. First, the protocol is optimal: *Holevo's theorem* says that a single qubit can never convey more than one bit of classical information on its own, and the shared entanglement is what allows us to double this. Second, the qubit Alice transmits is, by itself, completely uninformative – it is maximally entangled with Bob's, and by the argument of §39.3.3 any measurement on it alone yields uniformly random results. An eavesdropper who intercepts the qubit in transit learns exactly nothing about the message.

§39.7 Quantum Teleportation

Superdense coding sends classical information down a quantum channel. Teleportation does the reverse, and is more startling: Alice transfers an *unknown* qubit state to Bob using only two classical bits and a shared ebit. No quantum system travels between them.

Theorem 39.7.1 (Quantum Teleportation)

Suppose Alice holds a qubit C in an arbitrary unknown state $|\psi\rangle_C$, and that Alice and Bob share the Bell state $|\phi^+\rangle_{AB}$. Then by performing a measurement on CA and sending Bob the two-bit outcome over a classical channel, Alice can arrange for Bob's qubit B to end in the state $|\psi\rangle$.

Proof. Write $|\psi\rangle_C = a|0\rangle + b|1\rangle$. The initial state of the three qubits CAB is

$$|\Psi_0\rangle = |\psi\rangle_C \otimes |\phi^+\rangle_{AB} = \frac{1}{\sqrt{2}} [a|000\rangle + a|011\rangle + b|100\rangle + b|111\rangle].$$

Alice applies CX with C as control and A as target. This flips the second bit exactly when the first is 1:

$$|\Psi_1\rangle = \frac{1}{\sqrt{2}} [a|000\rangle + a|011\rangle + b|110\rangle + b|101\rangle].$$

She then applies H to C , replacing $|0\rangle_C \mapsto |+\rangle_C$ and $|1\rangle_C \mapsto |-\rangle_C$:

$$|\Psi_2\rangle = \frac{1}{\sqrt{2}} [a|+\rangle|00\rangle + a|+\rangle|11\rangle + b|-\rangle|10\rangle + b|-\rangle|01\rangle].$$

Expanding $|\pm\rangle = \frac{1}{\sqrt{2}}(|0\rangle \pm |1\rangle)$ and collecting terms according to the state of CA ,

$$\begin{aligned} |\Psi_2\rangle &= \frac{1}{2} \left[|00\rangle (a|0\rangle + b|1\rangle) + |01\rangle (a|1\rangle + b|0\rangle) \right. \\ &\quad \left. + |10\rangle (a|0\rangle - b|1\rangle) + |11\rangle (a|1\rangle - b|0\rangle) \right] \\ &= \frac{1}{2} \left[|00\rangle |\psi\rangle + |01\rangle X|\psi\rangle + |10\rangle Z|\psi\rangle + |11\rangle XZ|\psi\rangle \right], \end{aligned}$$

where in the last line we used $X|\psi\rangle = a|1\rangle + b|0\rangle$, $Z|\psi\rangle = a|0\rangle - b|1\rangle$ and $XZ|\psi\rangle = a|1\rangle - b|0\rangle$.

Alice now measures C and A in the computational basis. By the extended Born rule each of the four outcomes ij occurs with probability $\frac{1}{4}$ – *independently of a and b* ,

which is essential, since otherwise the outcome distribution would leak information about $|\psi\rangle$ and hence permit signalling. Given outcome ij , Bob's qubit is left in the state $X^j Z^i |\psi\rangle$.

Alice sends the two bits i, j to Bob classically. Since $X^2 = Z^2 = I$, Bob applies X^j and then Z^i to his qubit, recovering

$$Z^i X^j X^j Z^i |\psi\rangle = |\psi\rangle. \quad \square$$

Several things are worth pausing over.

No cloning is violated. At the end, Bob has $|\psi\rangle$ and Alice does not: her qubit C was measured and collapsed to $|i\rangle$, destroying the original. Teleportation moves a state; it does not copy it.

No signalling is violated. Bob's qubit, before he hears from Alice, is in a uniformly random one of $|\psi\rangle, X|\psi\rangle, Z|\psi\rangle, XZ|\psi\rangle$, and by the computation of §39.3.3 this is indistinguishable from a maximally mixed qubit. He learns nothing until the classical bits arrive, so the protocol runs at the speed of the classical channel.

Alice does not learn $|\psi\rangle$. She acquires two random bits, which by construction carry no information about a and b . This is consistent with the fact that an unknown qubit state cannot be determined from a single copy.

The first half of the protocol is a Bell measurement. Applying CX then H and measuring in the computational basis is precisely a measurement of CA in the Bell basis, as we saw in §39.6 – the same circuit, run in the same direction. So the protocol reads: Alice performs a Bell measurement on the unknown qubit and her half of the entangled pair; the result is two random bits which tell Bob which of four unitaries to undo.

Remark. Teleportation consumes exactly one ebit and two classical bits per qubit sent, and both costs are optimal. One classical bit would not suffice: if it did, then combined with superdense coding one could send two classical bits using one ebit and one classical bit, and iterating would give unlimited communication for free.

§39.8 Quantum Cryptography

Our third application of quantum information is the one that has actually been deployed commercially. The task is **key distribution**: Alice and Bob, who have never met, wish to establish a shared secret bit string, in the presence of an eavesdropper Eve who can listen to everything. Classically this is impossible without computational assumptions. Quantum mechanically it can be done, and the security rests on physics rather than on the presumed hardness of factoring.

§39.8.1 The One-Time Pad

First, why we want a key at all. Suppose Alice and Bob already share a uniformly random secret string $K \in \{0, 1\}^n$, and Alice wishes to send a message $M \in \{0, 1\}^n$ over a public channel.

Definition 39.8.1 (One-Time Pad)

The **one-time pad** protocol is: Alice transmits the ciphertext $C = M \oplus K$; Bob computes $C \oplus K = M \oplus K \oplus K = M$.

Proposition 39.8.2

The one-time pad is perfectly secure: for any message M , the ciphertext C is uniformly distributed on $\{0, 1\}^n$, and hence independent of M .

Proof. For fixed M , the map $K \mapsto M \oplus K$ is a bijection of $\{0, 1\}^n$, so if K is uniform then so is C . Thus $\Pr(C = c \mid M = m) = 2^{-n}$ for every c and m , and Eve's posterior distribution on M equals her prior. $\square$

This is unbreakable, not merely hard to break, and there is no cleverness in it whatsoever. Its drawback is in the name: the pad must be used only *once*. If Alice sends $C_1 = M_1 \oplus K$ and $C_2 = M_2 \oplus K$ with the same key, then Eve computes

$$C_1 \oplus C_2 = M_1 \oplus M_2,$$

which typically reveals a great deal about both messages. So Alice and Bob need a fresh key, as long as the message, for every transmission – and they need to establish it privately. That is the problem we now solve.

§39.8.2 The BB84 Protocol

We assume Alice and Bob have two channels: an *authenticated classical channel*, which Eve may listen to but not tamper with or spoof, and a *quantum channel* down which Alice can send qubits, and over which Eve may do absolutely anything.

The idea, due to Bennett and Brassard in 1984, exploits two facts we have already proved. Non-orthogonal states cannot be reliably distinguished (§39.2.3), and unknown states cannot be cloned (§39.3.2). So if Alice encodes her bits in randomly chosen states from two mutually unbiased bases, Eve cannot read them without guessing the basis – and guessing wrong disturbs the state, leaving evidence.

Recall the two bases

$$\mathcal{B}_0 = \{|0\rangle, |1\rangle\}, \quad \mathcal{B}_1 = \{|+\rangle, |-\rangle\},$$

which are mutually unbiased: $|\langle a|b\rangle|^2 = \frac{1}{2}$ for every $|a\rangle \in \mathcal{B}_0$, $|b\rangle \in \mathcal{B}_1$. On the Bloch circle in the x - z plane the four states are spaced at right angles:

(The dashed directions are the *Breidbart basis*, which will be Eve's best guess; more on that below. Remember that the Bloch picture doubles angles, so states $\pi/2$ apart on the circle are orthogonal in $\mathbb{C}^2$, and the Breidbart vectors, at $\pi/4$, have overlap $\cos(\pi/8)$ with their neighbours.)

Definition 39.8.3 (BB84)

The **BB84 protocol** runs as follows.

- (i) Alice generates two uniformly random strings $x, y \in \{0, 1\}^m$. The string x holds the raw key bits; the string y records which basis is used for each.
- (ii) Alice prepares the m -qubit state $|\psi_{xy}\rangle = |\psi_{x_1 y_1}\rangle \otimes \cdots \otimes |\psi_{x_m y_m}\rangle$, where

$$|\psi_{00}\rangle = |0\rangle, \quad |\psi_{10}\rangle = |1\rangle, \quad |\psi_{01}\rangle = |+\rangle, \quad |\psi_{11}\rangle = |-\rangle,$$

that is, the bit x_i is encoded in the basis $\mathcal{B}_{y_i}$. She sends the qubits to Bob.

- (iii) Bob generates a uniformly random string $y' \in \{0, 1\}^m$ and measures the i th qubit he receives in the basis $\mathcal{B}_{y'_i}$, recording the outcomes as $x' \in \{0, 1\}^m$.
- (iv) (*Sifting.*) Alice and Bob announce y and y' on the classical channel and discard every position i with $y_i \neq y'_i$. The retained bits form the **sifted key** $\tilde{x}, \tilde{x}'$.
- (v) (*Parameter estimation.*) They publicly compare a random sample of the sifted bits to estimate the **bit error rate**, then discard the sampled positions.
- (vi) (*Reconciliation and privacy amplification.*) They correct residual errors and compress the remaining string to remove any partial information Eve may hold.

Proposition 39.8.4

In the absence of noise or eavesdropping, $x'_i = x_i$ at every retained position, and the expected length of the sifted key is $m/2$.

Proof. If $y'_i = y_i$ then Bob measures in the same basis in which Alice prepared, so $|\psi_{x_i y_i}\rangle$ is a basis vector of $\mathcal{B}_{y'_i}$ and the Born rule gives outcome x_i with probability 1. Since y and y' are independent and uniform, $\Pr(y_i = y'_i) = \frac{1}{2}$ for each i independently, so the expected number of retained positions is $m/2$. $\square$

If Bob happens to choose the wrong basis, the mutual unbiasedness makes his outcome a fair coin, uncorrelated with x_i – which is exactly why those positions are thrown away.

Example 39.8.5

Take $m = 8$, and suppose

$$x = 01110100, \quad y = 11010001,$$

so that Alice sends $|+\rangle, |-\rangle, |1\rangle, |-\rangle, |0\rangle, |1\rangle, |0\rangle, |+\rangle$. Suppose Bob receives these undisturbed and picks $y' = 01110110$.

i	1	2	3	4	5	6	7	8
x_i	0	1	1	1	0	1	0	0
y_i	1	1	0	1	0	0	0	1
sent	$ +\rangle$	$ -\rangle$	$ 1\rangle$	$ -\rangle$	$ 0\rangle$	$ 1\rangle$	$ 0\rangle$	$ +\rangle$
y'_i	0	1	1	1	0	1	1	0
keep?	$\times$	$\checkmark$	$\times$	$\checkmark$	$\checkmark$	$\times$	$\times$	$\times$

At $i = 1$ Bob measures $|+\rangle$ in $\mathcal{B}_0$ and gets a uniformly random bit, so this position is (rightly) discarded. At $i = 2$ he measures $|-\rangle$ in $\mathcal{B}_1$ and obtains $x'_2 = 1$ with certainty. Sifting keeps positions 2, 4, 5, giving the key $\tilde{x} = 110$.

§39.8.3 Eavesdropping

Now suppose Eve is on the line. Her problem is that she does not know y , so she does not know which basis to measure in, and she cannot make a copy of the qubit to keep for later by the no-cloning theorem. Consider the simplest attack.

Definition 39.8.6 (Intercept-and-Resend)

In the **intercept-and-resend** attack, Eve intercepts each qubit, measures it in some fixed basis, and forwards the post-measurement state to Bob.

Which basis should she use? She is trying to distinguish four equally likely states, but really she wants to guess the *bit* x_i , so she wants a measurement that does well at separating $\{|0\rangle, |+\rangle\}$ (bit 0) from $\{|1\rangle, |-\rangle\}$ (bit 1). The natural candidate is the basis that bisects them.

Definition 39.8.7 (Braidbart Basis)

The **Braidbart basis** is $\{|\alpha_0\rangle, |\alpha_1\rangle\}$, where

$$|\alpha_0\rangle = \cos \frac{\pi}{8} |0\rangle + \sin \frac{\pi}{8} |1\rangle, \quad |\alpha_1\rangle = -\sin \frac{\pi}{8} |0\rangle + \cos \frac{\pi}{8} |1\rangle.$$

These are the dashed vectors in the picture above: on the Bloch circle they sit at $\pi/4$,

halfway between the $|0\rangle$ and $|+\rangle$ directions, and at $5\pi/4$. A short computation gives

$$|\langle\alpha_0|0\rangle|^2 = |\langle\alpha_0|+\rangle|^2 = \cos^2 \frac{\pi}{8} \approx 0.854, \quad |\langle\alpha_1|1\rangle|^2 = |\langle\alpha_1|-\rangle|^2 = \cos^2 \frac{\pi}{8},$$

so whichever of the four states Alice sent, Eve infers the correct bit with probability $\cos^2(\pi/8) \approx 85\%$. (This is precisely the Holevo–Helstrom optimum of §39.2.3 applied to the two equiprobable mixtures.)

That sounds good for Eve, but it is not free.

Proposition 39.8.8

If Eve performs the intercept-and-resend attack in the Breidbart basis, then at every sifted position Bob’s bit disagrees with Alice’s with probability $\frac{1}{4}$.

Proof. Suppose $y_i = y'_i = 0$ and $x_i = 0$, so Alice sends $|0\rangle$ and Bob measures in $\mathcal{B}_0$; the other cases are identical by symmetry. Eve’s measurement returns 0 with probability $|\langle\alpha_0|0\rangle|^2$ and then forwards $|\alpha_0\rangle$; otherwise it returns 1 and she forwards $|\alpha_1\rangle$. Bob then measures in $\mathcal{B}_0$ and gets the wrong answer 1 with probability $|\langle 1|\alpha_j\rangle|^2$. Hence

$$\begin{aligned} \Pr(x'_i \neq x_i) &= |\langle\alpha_0|0\rangle|^2 |\langle 1|\alpha_0\rangle|^2 + |\langle\alpha_1|0\rangle|^2 |\langle 1|\alpha_1\rangle|^2 \\ &= \cos^2 \frac{\pi}{8} \sin^2 \frac{\pi}{8} + \sin^2 \frac{\pi}{8} \cos^2 \frac{\pi}{8} \\ &= 2 \cos^2 \frac{\pi}{8} \sin^2 \frac{\pi}{8} = \frac{1}{2} \sin^2 \frac{\pi}{4} = \frac{1}{4}. \square \end{aligned}$$

This is the crux of BB84. Eve’s interference is not merely detectable in principle; it produces a bit error rate of 25% on the sifted key, which Alice and Bob will see immediately in step (v) when they compare a random sample. If the observed error rate is above the threshold they expect from channel noise, they abort and try again. If it is below, they may conclude that Eve has only partial information, and proceed to squeeze her out.

Remark. A full security proof must handle arbitrary attacks, not just intercept-and-resend: Eve is entitled to entangle each qubit with an ancilla of her own, forward the qubit, and defer her measurement until after she has heard the basis announcements. Proving security against such *coherent* attacks is genuinely hard and well beyond this course. The conclusion, though, is the one the simple analysis suggests: there is a threshold error rate (around 11% for BB84) below which a secret key can be extracted, and above which no key is possible.

§39.8.4 Reconciliation and Privacy Amplification

Even with no eavesdropper, real channels are noisy, so $\tilde{x}$ and $\tilde{x}'$ will differ in a few positions. Alice and Bob repair this classically.

Example 39.8.9 (Information Reconciliation with a Hamming Code)

Suppose the estimated bit error rate is around $\frac{1}{7}$ and Alice and Bob hold blocks

$a, b \in \{0, 1\}^7$ differing in at most one position. Let

$$\tilde{H} = \begin{pmatrix} 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 \end{pmatrix}$$

be the parity check matrix of the $[7, 4]$ Hamming code, whose columns are the binary representations of $1, \dots, 7$. Alice computes her syndrome $s^A = \tilde{H}a^\top$ and announces it publicly. Bob computes $s^B = \tilde{H}b^\top$ and forms $s = s^B - s^A = \tilde{H}(b - a)^\top$. Since $b - a$ has weight at most one, and the columns of $\tilde{H}$ are distinct and nonzero, s identifies the error position uniquely (or is zero if there is none), and Bob corrects his string to a .

The cost is that Alice has broadcast three bits of information about a . Together with whatever Eve learned from the quantum channel, this leaves her with partial knowledge of the reconciled string. The final step removes it.

Definition 39.8.10 (Privacy Amplification)

Privacy amplification is the compression of a partially-secret string into a shorter, fully-secret one, by applying a publicly agreed function whose output is nearly uniform given Eve's partial information.

Example 39.8.11

Suppose Alice and Bob share $a^* = (a_1, a_2, a_3) \in \{0, 1\}^3$, uniformly distributed, and Eve knows the value of at most one of the three bits. Let

$$c = (a_1 \oplus a_3, a_2 \oplus a_3) \in \{0, 1\}^2.$$

Conditioning on any single bit a_j leaves the other two uniform and independent, and one checks by enumerating the eight possibilities that c is then uniform on $\{0, 1\}^2$. So Eve's knowledge of one bit of a^* tells her nothing at all about c : we have traded three partially-secret bits for two perfectly secret ones.

In practice one uses a randomly chosen function from a two-universal family of hash functions, and a theorem (the **leftover hash lemma**) guarantees that if Eve's information about the n -bit string is at most t bits, then hashing down to roughly $n - t$ bits produces an essentially uniform key. The output of BB84 is then fed to a one-time pad, and Alice and Bob may talk in perfect confidence.

§39.9 Computational Complexity

We turn now from communication to computation. Before we can say that a quantum algorithm is 'faster', we need to be precise about what we are counting, so this section sets up the classical framework and its quantum analogue.

§39.9.1 Computational Tasks and the Circuit Model

Write $\mathbb{B}_n = \{0, 1\}^n$ for the set of bit strings of length n , and $\mathbb{B}^* = \bigcup_{n \geq 1} \mathbb{B}_n$. A **computational task** takes an input string and produces an output string. The special case in which the output has length 1 is a **decision problem**, and is conveniently encoded by a **language** $L \subseteq \mathbb{B}^*$: the task is to decide, given w , whether $w \in L$. For example, the set of primes written in binary is a language, and the associated decision problem is primality testing. Not every task is a decision problem – **FACTOR**(x), which returns a nontrivial factor of x , is not – but the theory is cleanest for decision problems and we will phrase most things that way.

Our model of computation will be the **circuit model**. For each input size n we specify a circuit C_n : the input $x \in \mathbb{B}_n$ is padded with a supply of extra bits set to 0 (the workspace), a prescribed sequence of Boolean gates is applied to prescribed bits, and the answer is read off from designated output bits. The gates are drawn from a fixed finite universal set, say $\{\text{AND}, \text{OR}, \text{NOT}\}$.

Definition 39.9.1 (Time Complexity)

The **size** of the circuit C_n is its number of gates, written $T(n)$; this is the **running time** of the algorithm. If $T(n) = O(n^k)$ for some fixed k , we write $T(n) = O(\text{poly}(n))$ and call the algorithm **poly-time**.

We may also allow the workspace to be seeded with k uniformly random bits, in which case the output is a random variable and we demand that it be correct with probability bounded away from $\frac{1}{2}$.

Definition 39.9.2 (Classical Complexity Classes)

P is the class of languages whose membership problem has a deterministic poly-time algorithm. **BPP** (**bounded-error probabilistic poly-time**) is the class of languages having a randomised poly-time algorithm which answers correctly with probability at least $\frac{2}{3}$ on every input.

The constant $\frac{2}{3}$ is arbitrary: any constant strictly greater than $\frac{1}{2}$ gives the same class, since running the algorithm $O(\log(1/\varepsilon))$ times and taking a majority vote drives the error below ε by a Chernoff bound. Clearly $\text{P} \subseteq \text{BPP}$, and it is widely believed (though not known) that they are equal. **BPP**, not **P**, is the right notion of ‘efficiently solvable in practice’ classically, and it is **BPP** that the quantum class must be compared with.

Definition 39.9.3 (NP)

A **verifier** for a language L is an algorithm V taking two inputs w (the instance) and c (the **certificate**) such that

- (i) if $w \in L$ then $V(w, c)$ accepts for some c ;
- (ii) if $w \notin L$ then $V(w, c)$ rejects for every c .

V is poly-time if it runs in time $O(\text{poly}(|w|))$ (which in particular bounds the length of any useful certificate). The class **NP** consists of the languages admitting a poly-time verifier.

Equivalently, **NP** is what a non-deterministic machine can do in polynomial time: at

each binary choice the machine forks and explores both branches, accepting if any branch accepts. Problems in NP are easy to *check* but may be hard to *solve*.

The archetype is Boolean satisfiability.

Definition 39.9.4 (SAT)

Given a Boolean formula f in variables $x_1, \dots, x_n$, decide whether there is an assignment with $f(x_1, \dots, x_n) = 1$.

Certificates are satisfying assignments, so $\text{SAT} \in \text{NP}$; and by the Cook–Levin theorem every problem in NP reduces to it in polynomial time, so SAT is **NP-complete**. Brute force takes $O(2^n)$ time, and no substantially better general algorithm is known.

§39.9.2 Quantum Circuits and BQP

The quantum circuit model is the direct analogue. For each n we specify a circuit C_n acting on $\text{poly}(n)$ qubits: the input is $|x_1\rangle \cdots |x_n\rangle |0\rangle \cdots |0\rangle$, we apply a sequence of gates drawn from a fixed approximately universal set, and we measure designated qubits in the computational basis at the end. Two remarks, both made earlier: no separate source of randomness is needed, since measurement supplies it; and by deferred measurement we may assume all measurements happen at the end.

Definition 39.9.5 (BQP)

BQP (**bounded-error quantum poly-time**) is the class of languages L for which there is a family of quantum circuits (C_n) , of size $O(\text{poly}(n))$ and generated by a poly-time classical algorithm, whose output is a correct decision of ‘ $x \in L$?’ with probability at least $\frac{2}{3}$ for every input x .

The uniformity condition – that a classical machine can print the description of C_n in time $\text{poly}(n)$ – is needed to prevent us from smuggling uncomputable information into the choice of circuit; the same caveat applies to the classical circuit classes.

What is known about BQP?

Proposition 39.9.6

$\text{P} \subseteq \text{BPP} \subseteq \text{BQP} \subseteq \text{PSPACE}$.

The first inclusion is trivial. The second holds because a quantum computer can simulate a classical one: by §39.5.3 any classical circuit becomes a reversible circuit of Toffoli gates with polynomial overhead, and Hadamards supply the random bits. The third holds because the amplitude of a given final basis state can be written as a sum over computational paths, and a classical machine can evaluate that sum one term at a time, reusing space; this is the quantum analogue of the fact that $\text{NP} \subseteq \text{PSPACE}$.

What is *not* known is anything separating these classes. In particular, nobody has proved $\text{BPP} \neq \text{BQP}$, so we have no proof that quantum computers are more powerful than classical ones; a proof would imply $\text{P} \neq \text{PSPACE}$, which is a famous open problem. What we have instead is strong evidence: problems such as factoring lie in BQP and are not believed to lie in BPP.

Remark. The relationship between BQP and NP is subtle and often misstated. It is *not* believed that $\text{NP} \subseteq \text{BQP}$: quantum computers are not thought to solve NP-complete problems efficiently. Grover’s algorithm gives a quadratic speedup for exhaustive search, taking 2^n to $2^{n/2}$, which is a real improvement but not a polynomial-time algorithm. Nor is $\text{BQP} \subseteq \text{NP}$ believed. Factoring, the flagship quantum success, is in $\text{NP} \cap \text{coNP}$ and is generally thought not to be NP-complete, so Shor’s algorithm is not evidence that $\text{NP} \subseteq \text{BQP}$.

§39.9.3 Query Complexity

Almost all the quantum algorithms we can currently prove things about are stated in a slightly different framework, where the input is not a string but a *function*, presented as a black box.

Definition 39.9.7 (Black-Box Promise Problem)

A **black-box** or **oracle** problem is a computational task whose input is a function $f : \mathbb{B}_m \rightarrow \mathbb{B}_n$, accessible only by evaluating it at points of our choosing. A **promise** is an a priori restriction on which f may occur.

Definition 39.9.8 (Query Complexity)

The **query complexity** of an algorithm for a black-box problem is the number of evaluations of f it performs. Its **total complexity** is the size of the whole circuit, counting each oracle call as one gate.

The virtue of this framework is that we can *prove* separations in it: because the algorithm is only allowed to learn about f through queries, adversary arguments give unconditional lower bounds on the classical query complexity, and these can be beaten provably by quantum algorithms. The vice is that a query separation does not automatically give a separation for explicitly-presented inputs. Still, the two most important quantum algorithms in existence – Shor’s and Grover’s – both come from this circle of ideas.

§39.10 Quantum Oracles and Phase Kickback

§39.10.1 Quantum Oracles

A classical oracle for f is a box that eats x and produces $f(x)$. This will not do quantum mechanically, since it is not reversible. We use instead the reversible form of §39.5.3.

Definition 39.10.1 (Quantum Oracle)

Let $f : \mathbb{B}_m \rightarrow \mathbb{B}_n$. The corresponding **quantum oracle** is the operator U_f on $m+n$ qubits defined on the computational basis by

$$U_f |x\rangle |y\rangle = |x\rangle |y \oplus f(x)\rangle.$$

The first register is the **input register** and the second the **output register**.

Proposition 39.10.2

U_f is unitary.

Proof. U_f acts on the computational basis as the map $\tilde{f}(x, y) = (x, y \oplus f(x))$ of $\mathbb{B}_{m+n}$ to itself, which we showed in §39.5.3 to be an involution and hence a permutation. A linear map permuting an orthonormal basis has a permutation matrix, which has orthonormal columns, so it is unitary. $\square$

Setting $y = 0$ recovers f , so U_f is at least as useful as a classical oracle. But it is strictly more useful, because we may feed it a superposition. If

$$|\varphi_m\rangle = H^{\otimes m} |0\rangle^{\otimes m} = \frac{1}{\sqrt{2^m}} \sum_{x \in \mathbb{B}_m} |x\rangle$$

is the equal superposition, then

$$U_f |\varphi_m\rangle |0\rangle = \frac{1}{\sqrt{2^m}} \sum_{x \in \mathbb{B}_m} |x\rangle |f(x)\rangle.$$

In a *single* query we have produced a state which somehow contains all 2^m values of f at once. This is often called **quantum parallelism**, and it is important to see immediately why it is not by itself useful: if we measure this state we get a single random pair $(x, f(x))$, exactly as if we had queried the classical oracle at a random point. The values are all there, but reading them out destroys all but one.

The art of quantum algorithm design lies in arranging for the unwanted branches to *interfere destructively*, so that the measurement reveals a global property of f rather than one of its values. The first tool for this is the following.

§39.10.2 Phase Kickback**Proposition 39.10.3 (Phase Kickback)**

Let $f : \mathbb{B}_m \rightarrow \mathbb{B}_1$ and set $|-\rangle = \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$. Then for every $x \in \mathbb{B}_m$,

$$U_f |x\rangle |-\rangle = (-1)^{f(x)} |x\rangle |-\rangle.$$

Proof. We compute directly:

$$\begin{aligned} U_f |x\rangle |-\rangle &= \frac{1}{\sqrt{2}} (|x\rangle |f(x)\rangle - |x\rangle |1 \oplus f(x)\rangle) \\ &= \begin{cases} \frac{1}{\sqrt{2}} |x\rangle (|0\rangle - |1\rangle) = |x\rangle |-\rangle, & f(x) = 0, \\ \frac{1}{\sqrt{2}} |x\rangle (|1\rangle - |0\rangle) = -|x\rangle |-\rangle, & f(x) = 1, \end{cases} \end{aligned}$$

which is $(-1)^{f(x)} |x\rangle |-\rangle$ in both cases. $\square$

So if we prepare the output register in $|-\rangle$ rather than $|0\rangle$, the oracle does not change the state at all except to attach a sign – the value of f has been ‘kicked back’ from the output register into the phase of the input register. Applying this to the equal superposition,

$$U_f (|\varphi_m\rangle \otimes |-\rangle) = \left(\frac{1}{\sqrt{2^m}} \sum_{x \in \mathbb{B}_m} (-1)^{f(x)} |x\rangle \right) \otimes |-\rangle,$$

and the output register factors out and may be discarded. We are left with the m -qubit state

$$|f\rangle := \frac{1}{\sqrt{2^m}} \sum_{x \in \mathbb{B}_m} (-1)^{f(x)} |x\rangle,$$

in which the whole of f is encoded in a pattern of signs. Signs are what interference is made of, and every algorithm in the next section starts here. Note that $|-\rangle$ is prepared from $|0\rangle$ by HX , or equivalently from $|1\rangle$ by H .

§39.11 Quantum Algorithms I: Oracle Problems

§39.11.1 Deutsch's Algorithm

We begin with the smallest possible example, which nonetheless contains the whole idea. Let $f : \mathbb{B}_1 \rightarrow \mathbb{B}_1$ be one of the four functions from one bit to one bit. Two of them ($f(0) = f(1)$) are **constant**, and two ($f(0) \neq f(1)$) are **balanced**.

Problem (Deutsch). *Given an oracle for $f : \mathbb{B}_1 \rightarrow \mathbb{B}_1$, decide whether f is constant or balanced.*

Classically, we must evaluate both $f(0)$ and $f(1)$: knowing one value tells us nothing about the other, so one query is not enough and two queries suffice. Quantum mechanically one query suffices.

Proposition 39.11.1

The following circuit decides Deutsch's problem with certainty, using a single query to U_f . The outcome is 0 if f is constant and 1 if f is balanced.

Proof. After the initial gates the state is $|+\rangle|-\rangle$, that is, $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) \otimes |-\rangle$. By phase kickback the oracle produces

$$\frac{1}{\sqrt{2}} \left((-1)^{f(0)} |0\rangle + (-1)^{f(1)} |1\rangle \right) \otimes |-\rangle = \pm \frac{1}{\sqrt{2}} \left(|0\rangle + (-1)^{f(0) \oplus f(1)} |1\rangle \right) \otimes |-\rangle,$$

where we pulled out the global sign $(-1)^{f(0)}$. The first register is therefore $\pm|+\rangle$ if $f(0) \oplus f(1) = 0$ and $\pm|-\rangle$ if $f(0) \oplus f(1) = 1$. Applying H turns these into $\pm|0\rangle$ and $\pm|1\rangle$ respectively, and the measurement returns $f(0) \oplus f(1)$ with certainty. This is 0 exactly when f is constant. $\square$

The single query has told us a *relational* fact about f – the value of $f(0) \oplus f(1)$ – without telling us either individual value. That trade is the whole of quantum speedup in miniature.

§39.11.2 The Deutsch–Jozsa Algorithm

Now scale it up. Let $f : \mathbb{B}_n \rightarrow \mathbb{B}_1$, and promise that f is either **constant** or **balanced**, meaning that $f(x) = 0$ for exactly half of the 2^n inputs.

Problem (Deutsch–Jozsa). *Given an oracle for such an f , decide with certainty which case holds.*

Proposition 39.11.2

Classically, $2^{n-1} + 1$ queries are necessary and sufficient to decide with certainty.

Proof. Sufficient: if we query $2^{n-1} + 1$ distinct points and all the answers agree, f cannot be balanced, since a balanced function takes each value only 2^{n-1} times; and if two answers disagree, f is certainly not constant.

Necessary: suppose an algorithm claims to decide after at most 2^{n-1} queries. Run it against an adversary who answers 0 to every query. After 2^{n-1} queries the algorithm must commit to an answer, but the responses so far are consistent both with the constant function 0 and with a balanced function which is 0 on the queried points and 1 elsewhere. Whatever it answers, one of these two functions defeats it. $\square$

So the classical query complexity is exponential in n . Quantum mechanically it is one.

Theorem 39.11.3 (Deutsch–Jozsa)

The circuit above uses a single query to U_f and $3n + 2$ further operations, and its measurement outcome is $0 \cdots 0$ with probability 1 if f is constant, and with probability 0 if f is balanced.

Proof. The initial gates prepare $|\varphi_n\rangle \otimes |-\rangle$, and by phase kickback (§39.10.2) the oracle leaves the output register in $|-\rangle$ and the input register in

$$|f\rangle = \frac{1}{\sqrt{2^n}} \sum_{x \in \mathbb{B}_n} (-1)^{f(x)} |x\rangle.$$

We now apply $H^{\otimes n}$ and measure. The amplitude of the outcome $0 \cdots 0$ is

$$\langle 0 \cdots 0 | H^{\otimes n} |f\rangle = \langle \varphi_n | f \rangle = \frac{1}{2^n} \sum_{x \in \mathbb{B}_n} (-1)^{f(x)},$$

using $H^{\otimes n} |0 \cdots 0\rangle = |\varphi_n\rangle$ and $H^{\otimes n} = (H^{\otimes n})^\dagger$.

If f is constant, this sum is $\pm 2^n$, so the amplitude is ± 1 and the outcome is $0 \cdots 0$ with probability 1. (Indeed in that case $|f\rangle = \pm |\varphi_n\rangle$ directly.) If f is balanced, the sum has 2^{n-1} terms equal to $+1$ and 2^{n-1} equal to -1 , so it vanishes and the

outcome $0 \cdots 0$ has probability 0. Hence measuring all zeros certifies ‘constant’, and any other outcome certifies ‘balanced’.

The gate count is $n+1$ Hadamards and one X before the oracle, n Hadamards after, and n measurements, giving $3n+2$ operations besides the single query. $\square$

The interference is visible in the formula: for a balanced function the $+1$ and -1 contributions to the all-zeros amplitude cancel exactly.

Remark. The separation here is exponential but slightly fragile. If we relax ‘with certainty’ to ‘with probability $1 - \varepsilon$ ’, the classical problem becomes easy: query k points at random and answer ‘constant’ if all agree. This errs only when f is balanced but the k samples happened to agree, which has probability $2 \cdot 2^{-k}$, so $k = O(\log(1/\varepsilon))$ queries suffice, independently of n . Deutsch–Jozsa separates *exact* quantum computation from exact classical computation. For a separation which survives bounded error we need Simon’s problem.

§39.11.3 The Bernstein–Vazirani Algorithm

Deutsch–Jozsa extracts a single bit of global information. The next algorithm extracts n bits, and does so in one query rather than n ; it is the cleanest illustration of the fact that a quantum query can be asked ‘in the Fourier basis’.

Problem (Bernstein–Vazirani). Let $a \in \mathbb{B}_n$ be unknown and let $f : \mathbb{B}_n \rightarrow \mathbb{B}_1$ be the linear function

$$f(x) = a \cdot x = a_1 x_1 + \cdots + a_n x_n \bmod 2.$$

Given an oracle for f , determine a .

Proposition 39.11.4

Classically, n queries are necessary and sufficient.

Proof. Sufficient: query the n standard basis vectors, since $f(e_i) = a_i$. Necessary: each query returns one bit, so k queries have at most 2^k possible transcripts; if $k < n$ then two of the 2^n possible values of a produce the same transcript and cannot be told apart. (One can say this more sharply: the values $f(x)$ for x in a queried set S determine $a \cdot x$ only for $x \in \text{span}(S)$, so they pin a down only to a coset of $\text{span}(S)^\perp$, which is a single point exactly when S spans $\mathbb{B}_n$.) $\square$

The quantum algorithm is the Deutsch–Jozsa circuit, unchanged; only the analysis differs.

Theorem 39.11.5 (Bernstein–Vazirani)

The circuit above outputs a with certainty, using one query to U_f .

Proof. As before the state before the final Hadamards is

$$|f\rangle = \frac{1}{\sqrt{2^n}} \sum_{x \in \mathbb{B}_n} (-1)^{f(x)} |x\rangle = \frac{1}{\sqrt{2^n}} \sum_{x \in \mathbb{B}_n} (-1)^{a \cdot x} |x\rangle.$$

But that is exactly the formula $H^{\otimes n} |a\rangle = 2^{-n/2} \sum_x (-1)^{a \cdot x} |x\rangle$ recorded in §39.5. So $|f\rangle = H^{\otimes n} |a\rangle$, and since $H^{\otimes n}$ is its own inverse, applying it once more returns $|a\rangle$ exactly. The measurement reads off the n bits of a with probability 1. $\square$

The algorithm is worth a moment's thought, because the trick is not 'parallelism' in any useful sense. The oracle was applied to a superposition of all 2^n inputs, but what the circuit exploits is that the string a we are looking for is the *Fourier transform* of the sign pattern $(-1)^{a \cdot x}$; the final Hadamards simply undo a transform that the oracle performed for us. Every algorithm in this course has this shape: encode the unknown in a phase pattern, then transform to a basis in which that pattern is a single basis vector.

§39.11.4 Simon's Algorithm

Problem (Simon). Let $f : \mathbb{B}_n \rightarrow \mathbb{B}_n$, promised to be either injective, or two-to-one with a hidden period: there is $\xi \in \mathbb{B}_n$, $\xi \neq 0$, with

$$f(x) = f(y) \iff y = x \text{ or } y = x \oplus \xi.$$

Decide which case holds, and in the second case find ξ .

Proposition 39.11.6

Any classical randomised algorithm solving Simon's problem with bounded error requires $\Omega(2^{n/2})$ queries.

Proof sketch. Classically, the only way to learn anything is to find a collision $f(x) = f(y)$ with $x \neq y$, whereupon $\xi = x \oplus y$. If we query k distinct points, there are $\binom{k}{2}$ pairs, and for a uniformly random ξ the probability that some queried pair differs by ξ is at most $\binom{k}{2} / (2^n - 1)$. For this to be bounded below by a constant we need $k = \Omega(2^{n/2})$. This is the birthday bound, and it is tight. $\square$

The quantum algorithm needs $O(n)$ queries.

Theorem 39.11.7 (Simon)

Simon's problem can be solved with bounded error using $O(n)$ queries to U_f and $O(n^3)$ further classical steps.

Proof. Prepare the input register in the equal superposition and the output register in $|0\rangle$, and query the oracle:

$$U_f |\varphi_n\rangle |0\rangle = \frac{1}{\sqrt{2^n}} \sum_{x \in \mathbb{B}_n} |x\rangle |f(x)\rangle.$$

Measure the output register. In the two-to-one case the outcome is some value $z = f(x_0) = f(x_0 \oplus \xi)$, and by the extended Born rule the input register collapses to

$$|\text{coset}\rangle = \frac{1}{\sqrt{2}} (|x_0\rangle + |x_0 \oplus \xi\rangle).$$

Measuring this directly would give x_0 or $x_0 \oplus \xi$, each with probability $\frac{1}{2}$, and x_0 is uniformly random, so we would learn nothing. Instead apply $H^{\otimes n}$. Using $H^{\otimes n} |u\rangle = 2^{-n/2} \sum_y (-1)^{u \cdot y} |y\rangle$,

$$\begin{aligned} H^{\otimes n} |\text{coset}\rangle &= \frac{1}{\sqrt{2^{n+1}}} \sum_{y \in \mathbb{B}_n} [(-1)^{x_0 \cdot y} + (-1)^{(x_0 \oplus \xi) \cdot y}] |y\rangle \\ &= \frac{1}{\sqrt{2^{n+1}}} \sum_{y \in \mathbb{B}_n} (-1)^{x_0 \cdot y} [1 + (-1)^{\xi \cdot y}] |y\rangle, \end{aligned}$$

using bilinearity of the mod-2 dot product. The bracket is 2 if $\xi \cdot y = 0$ and 0 otherwise, so

$$H^{\otimes n} |\text{coset}\rangle = \frac{1}{\sqrt{2^{n-1}}} \sum_{y: \xi \cdot y = 0} (-1)^{x_0 \cdot y} |y\rangle.$$

Measuring the input register therefore returns a uniformly random y from the 2^{n-1} -element subspace $\xi^\perp = \{y : \xi \cdot y = 0\}$. Note that x_0 has vanished into the phases, exactly as we wanted.

Repeat the whole procedure. Each run yields a uniformly random $y^{(i)} \in \xi^\perp$, that is, a linear equation $\xi \cdot y^{(i)} = 0$ over $\mathbb{F}_2$ satisfied by the unknown ξ . Once we have

$n - 1$ linearly independent equations, the solution space is one-dimensional and its unique nonzero element is ξ ; we find it by Gaussian elimination in $O(n^3)$ steps. Finally we verify by checking $f(0) = f(\xi)$, which also distinguishes the two-to-one case from the injective case (in the injective case, the analysis above is replaced by the observation that the measured y are uniform on all of $\mathbb{B}_n$, and the equations will have only the trivial solution).

It remains to bound the number of repetitions. Each new sample is uniform on the $(n - 1)$ -dimensional space $\xi^\perp$, so if we already have k independent vectors, the probability that the next one lies in their span is $2^k/2^{n-1} \leq \frac{1}{2}$ for $k \leq n - 2$. Hence each run increases the rank with probability at least $\frac{1}{2}$, and by a standard argument $O(n)$ runs suffice to obtain $n - 1$ independent equations with probability at least $\frac{2}{3}$. $\square$

Simon's problem gives an exponential separation between quantum and classical query complexity that is robust to bounded error. Historically it is the crucial precedent: it is a *hidden subgroup problem* for the group $\mathbb{B}_n = (\mathbb{Z}/2\mathbb{Z})^n$, and Shor's algorithm is the same idea for the group $\mathbb{Z}_N$, where the Hadamard transform is replaced by the quantum Fourier transform.

§39.12 The Quantum Fourier Transform

The Hadamard transform $H^{\otimes n}$ is the Fourier transform of the group $(\mathbb{Z}/2\mathbb{Z})^n$, and it was what made Simon's algorithm work. To find periods in $\mathbb{Z}_N$ we need the Fourier transform of $\mathbb{Z}_N$, and remarkably it can be implemented in $O((\log N)^2)$ gates – exponentially faster than the classical fast Fourier transform, which takes $O(N \log N)$ operations on N numbers.

§39.12.1 Definition and Basic Properties

Let $\mathcal{V}_N$ be an N -dimensional state space with orthonormal basis

$$\mathcal{B}_N = \{|0\rangle, |1\rangle, \dots, |N-1\rangle\},$$

whose labels we read as elements of $\mathbb{Z}_N = \mathbb{Z}/N\mathbb{Z}$, and put $\omega = e^{2\pi i/N}$, a primitive N th root of unity.

Definition 39.12.1 (Quantum Fourier Transform)

The **quantum Fourier transform** modulo N is the linear map QFT_N on $\mathcal{V}_N$ given on the basis by

$$\text{QFT}_N |k\rangle = \frac{1}{\sqrt{N}} \sum_{\ell=0}^{N-1} \omega^{k\ell} |\ell\rangle.$$

Its matrix has entries $(\text{QFT}_N)_{jk} = \langle j | \text{QFT}_N | k \rangle = \omega^{jk}/\sqrt{N}$, that is,

$$\text{QFT}_N = \frac{1}{\sqrt{N}} \begin{pmatrix} 1 & 1 & 1 & \cdots \\ 1 & \omega & \omega^2 & \cdots \\ 1 & \omega^2 & \omega^4 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix},$$

the Vandermonde matrix of the N th roots of unity. For $N = 2$ we have $\omega = -1$ and $\text{QFT}_2 = H$, so the QFT genuinely generalises the Hadamard gate.

Proposition 39.12.2

QFT_N is unitary.

Proof. Everything follows from the geometric sum

$$\sum_{\ell=0}^{N-1} \omega^{j\ell} = \begin{cases} N, & j \equiv 0 \pmod{N}, \\ \frac{1 - \omega^{jN}}{1 - \omega^j} = 0, & \text{otherwise,} \end{cases}$$

valid since $\omega^{jN} = 1$ always, while $\omega^j \neq 1$ when $N \nmid j$. Hence

$$(\text{QFT}_N^\dagger \text{QFT}_N)_{jk} = \sum_{\ell} \overline{(\text{QFT}_N)_{\ell j}} (\text{QFT}_N)_{\ell k} = \frac{1}{N} \sum_{\ell=0}^{N-1} \omega^{\ell(k-j)} = \delta_{jk},$$

so $\text{QFT}_N^\dagger \text{QFT}_N = I$. □

The point of the Fourier transform, here as everywhere, is that it converts periodicity in the label into periodicity in the frequency. That is what we now exploit.

§39.12.2 Periodicity Determination

Problem (Periodicity Determination). *Let $f : \mathbb{Z}_N \rightarrow Y$ be a function, promised to be periodic with some period $r \mid N$ – so $f(x+r) = f(x)$ for all x – and injective within each period. Given an oracle for f , determine r .*

Classically the best possible is $O(\sqrt{N})$ queries, again by a birthday-paradox argument: we must find a collision. We shall get down to $O(\log \log N)$ queries.

Let us first see what goes wrong with the obvious approach. Prepare the equal superposition $|\psi_N\rangle = N^{-1/2} \sum_{x=0}^{N-1} |x\rangle$, set the output register to $|0\rangle$, and query the oracle to obtain

$$|F\rangle = \frac{1}{\sqrt{N}} \sum_{x=0}^{N-1} |x\rangle |f(x)\rangle.$$

Write $A = N/r$, the number of complete periods. Now measure the output register. The possible outcomes are the r values $f(x_0)$ for $x_0 \in \{0, \dots, r-1\}$; the basis states contributing to outcome $f(x_0)$ are those with $x = x_0 + jr$ for $j = 0, \dots, A-1$, so by the extended Born rule each outcome has probability $A/N = 1/r$, and the input register collapses to

$$|\text{per}\rangle = \frac{1}{\sqrt{A}} \sum_{j=0}^{A-1} |x_0 + jr\rangle.$$

This state *is* the period, laid out in front of us. But if we now measure it, we obtain a single uniformly random $x_0 + j_0 r$, and since x_0 itself is uniformly random and unknown, this tells us nothing whatever about r . The information is in the *spacing* of the terms, not in any one of them, and the computational basis is blind to spacing.

The Fourier transform sees nothing but spacing.

Theorem 39.12.3

With $|\text{per}\rangle$ as above and $\omega = e^{2\pi i/N}$,

$$\text{QFT}_N |\text{per}\rangle = \frac{1}{\sqrt{r}} \sum_{k=0}^{r-1} \omega^{x_0 k N/r} |kN/r\rangle.$$

Measuring this state returns $c = k_0 N/r$ for a uniformly random $k_0 \in \{0, \dots, r-1\}$.

Proof. Applying the definition and exchanging the order of summation,

$$\begin{aligned} \text{QFT}_N |\text{per}\rangle &= \frac{1}{\sqrt{A}} \sum_{j=0}^{A-1} \frac{1}{\sqrt{N}} \sum_{y=0}^{N-1} \omega^{(x_0+jr)y} |y\rangle \\ &= \frac{1}{\sqrt{NA}} \sum_{y=0}^{N-1} \omega^{x_0 y} \underbrace{\left[\sum_{j=0}^{A-1} (\omega^{ry})^j \right]}_{=: S_y} |y\rangle. \end{aligned}$$

Now S_y is a geometric series with ratio $\omega^{ry} = e^{2\pi i r y/N} = e^{2\pi i y/A}$. This equals 1 exactly when $A \mid y$, in which case $S_y = A$; otherwise

$$S_y = \frac{1 - \omega^{ryA}}{1 - \omega^{ry}} = \frac{1 - e^{2\pi i y}}{1 - \omega^{ry}} = 0.$$

So only the r multiples $y = kA = kN/r$, $k = 0, \dots, r-1$, survive, each with coefficient $A/\sqrt{NA} = \sqrt{A/N} = 1/\sqrt{r}$ times a phase. This gives the stated formula, and since each of the r terms has modulus $1/\sqrt{r}$, the measurement outcomes are uniform. $\square$

Notice what has happened. The unknown offset x_0 , which ruined the naive approach, has been converted into a phase $\omega^{x_0 k N/r}$ and therefore has no effect on measurement probabilities at all. Meanwhile the periodicity r in the label has been inverted into a periodicity N/r in the outcome.

It remains to extract r from a sample. We know $c = k_0 N/r$, hence

$$\frac{c}{N} = \frac{k_0}{r},$$

and the left-hand side is known. If $\gcd(k_0, r) = 1$, then cancelling c/N to lowest terms produces exactly k_0/r , and we read off r as the denominator. If not, we obtain a denominator $\tilde{r}$ which is a proper divisor of r ; we can detect this by testing whether $f(0) = f(\tilde{r})$, and if not, try again.

So the question is how often a random k_0 is coprime to r .

Theorem 39.12.4 (Coprimalty Theorem)

Let φ denote Euler's totient function. There are constants $c > 0$ and r_0 such that for all $r \geq r_0$,

$$\varphi(r) \geq c \frac{r}{\log \log r}.$$

Equivalently $\varphi(r) = \Omega(r/\log \log r)$.

This is a standard result of analytic number theory; it follows from Mertens' theorem on $\prod_{p \leq x} (1 - 1/p)$, proved in the Part II Number Theory course (see the section on the distribution of primes in my notes for that course, `../number-theory/`). Since k_0 is uniform on $\{0, \dots, r-1\}$, the probability that it is coprime to r is $\varphi(r)/r = \Omega(1/\log \log r)$.

Lemma 39.12.5

Suppose a trial succeeds with probability p and is repeated M times independently. Then the probability of at least one success exceeds $1 - \varepsilon$ provided $M \geq \frac{1}{p} \log \frac{1}{\varepsilon}$.

Proof. The probability of no success is $(1 - p)^M \leq e^{-pM}$, which is at most ε when $pM \geq \log(1/\varepsilon)$. $\square$

Corollary 39.12.6

For any fixed $\varepsilon \in (0, 1)$, the period r can be determined with probability at least $1 - \varepsilon$ using $O(\log \log N)$ queries to f and $O(\text{poly}(\log N))$ further steps.

Proof. Each round of the algorithm uses three queries (one to build $|F\rangle$, and two to test whether $f(0) = f(\tilde{r})$), and succeeds with probability $p = \Omega(1/\log \log r)$. By the lemma, $M = O(\log \log r) = O(\log \log N)$ rounds give success probability $1 - \varepsilon$. The remaining work per round is the QFT_N , which by §39.12.3 costs $O((\log N)^2)$ gates when N is a power of two, together with $O(\text{poly}(\log N))$ arithmetic to cancel the fraction c/N . $\square$

§39.12.3 Efficient Implementation of the QFT

Everything above is useless unless QFT_N can actually be built. We show it can, when $N = 2^n$, using $O(n^2)$ gates. (When N is not a power of two one approximates it by one, at the cost of a more delicate analysis; we will meet this in Shor's algorithm.)

Write $x \in \{0, \dots, 2^n - 1\}$ in binary as $x = \sum_{i=0}^{n-1} 2^i x_i$, so that x_{n-1} is the most significant bit, and use the notation

$$0.x_a x_b \cdots x_z = \frac{x_a}{2} + \frac{x_b}{4} + \cdots$$

for binary fractions. The key is the following factorisation.

Proposition 39.12.7

For $N = 2^n$,

$$\begin{aligned} \text{QFT}_N |x\rangle &= \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i(0.x_0)} |1\rangle) \otimes \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i(0.x_1 x_0)} |1\rangle) \\ &\quad \otimes \cdots \otimes \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i(0.x_{n-1} \cdots x_0)} |1\rangle). \end{aligned}$$

In particular $\text{QFT}_N |x\rangle$ is always a *product* state.

Proof. Writing $y = \sum_{j=0}^{n-1} 2^j y_j$ as well,

$$\text{QFT}_N |x\rangle = \frac{1}{\sqrt{2^n}} \sum_{y_0, \dots, y_{n-1} \in \{0,1\}} \exp \left[\frac{2\pi i xy}{2^n} \right] |y_{n-1}\rangle \cdots |y_0\rangle,$$

and

$$\frac{xy}{2^n} = \sum_{j=0}^{n-1} y_j \frac{x}{2^{n-j}}.$$

Only the fractional part of the exponent matters, since $e^{2\pi i m} = 1$ for integers m , and the fractional part of $x/2^{n-j}$ is exactly $0.x_{n-j-1}x_{n-j-2} \cdots x_0$. So the exponent splits as a sum of terms each involving a single y_j , and the sum over all y factorises into a product of n independent sums over $y_j \in \{0,1\}$, the factor associated with y_j being

$$\frac{1}{\sqrt{2}} \sum_{y_j \in \{0,1\}} e^{2\pi i y_j (0.x_{n-j-1} \cdots x_0)} |y_j\rangle = \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i (0.x_{n-j-1} \cdots x_0)} |1\rangle).$$

Writing the factors in the order $j = n-1, n-2, \dots, 0$, in which the output kets $|y_{n-1}\rangle \cdots |y_0\rangle$ appear, the first is $\frac{1}{\sqrt{2}}(|0\rangle + e^{2\pi i (0.x_0)} |1\rangle)$ and the last is $\frac{1}{\sqrt{2}}(|0\rangle + e^{2\pi i (0.x_{n-1} \cdots x_0)} |1\rangle)$, as claimed. $\square$

We can now read the circuit straight off. Note that

$$H |x_i\rangle = \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i (0.x_i)} |1\rangle),$$

since the phase is $+1$ if $x_i = 0$ and $e^{i\pi} = -1$ if $x_i = 1$. So a Hadamard creates the leading digit of each fraction, and we need only append the remaining digits, one at a time, with controlled phase gates.

Definition 39.12.8 (Controlled Phase Gate)

For $d \geq 1$ let

$$R_d = \begin{pmatrix} 1 & 0 \\ 0 & e^{i\pi/2^d} \end{pmatrix}, \quad \text{where } e^{i\pi/2^d} = e^{2\pi i (0.0 \cdots 01)}$$

with d zeros after the point followed by a 1, and write CR_d for the corresponding two-qubit controlled gate.

Thus $R_1 = \text{diag}(1, i) = S$, and CR_d applied with control $|x_i\rangle$ multiplies the $|1\rangle$ component of the target by $e^{2\pi i (0.0 \cdots 0x_i)}$, appending x_i in the $(d+1)$ st binary place. Here is the circuit for $n = 3$, that is, QFT_8 .

Tracking the top wire, for example:

$$\begin{aligned} |x_2\rangle &\xrightarrow{H} \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i(0.x_2)} |1\rangle) \\ &\xrightarrow{CR_1} \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i(0.x_2)} e^{2\pi i(0.0x_1)} |1\rangle) \\ &\xrightarrow{CR_2} \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i(0.x_2)} e^{2\pi i(0.0x_1)} e^{2\pi i(0.00x_0)} |1\rangle) = \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i(0.x_2x_1x_0)} |1\rangle), \end{aligned}$$

which is the factor that the proposition demands. Comparing with the proposition, the outputs appear in the reverse of the natural order, so we finish with $\lfloor n/2 \rfloor$ swap gates.

Proposition 39.12.9

QFT_{2^n} can be implemented exactly using n Hadamard gates, $\frac{1}{2}n(n-1)$ controlled phase gates and $O(n)$ swaps, hence with $O(n^2) = O((\log N)^2)$ gates in total.

Compare the classical fast Fourier transform, which needs $\Theta(N \log N) = \Theta(2^n n)$ operations to transform a vector of 2^n numbers. The quantum circuit is exponentially smaller. Of course we cannot *read out* the transformed amplitudes – a measurement gives us just one sample – so this is not a general-purpose speedup for signal processing. It is only useful when a single sample from the Fourier spectrum is what we want, which, happily, is exactly the situation in period finding.

§39.12.4 Phase Estimation

Period finding is a special case of a more general and very useful primitive.

Problem (Phase Estimation). *Let U be a unitary with an eigenvector $|u\rangle$ and eigenvalue $e^{2\pi i\phi}$, where $\phi \in [0, 1)$. Given the ability to prepare $|u\rangle$ and to apply controlled- U^{2^j} for $j = 0, 1, \dots$, estimate ϕ .*

Proposition 39.12.10

Suppose $\phi = 0.\phi_1\phi_2\cdots\phi_t$ exactly, in t binary digits. Then the circuit above outputs $\phi_1\cdots\phi_t$ with certainty.

Proof. Since $U^{2^j} |u\rangle = e^{2\pi i 2^j \phi} |u\rangle$, applying controlled- U^{2^j} with control qubit in state $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$ leaves $|u\rangle$ alone and kicks the eigenvalue back into the control:

$$\frac{1}{\sqrt{2}} (|0\rangle + |1\rangle) |u\rangle \mapsto \frac{1}{\sqrt{2}} (|0\rangle + e^{2\pi i 2^j \phi} |1\rangle) |u\rangle,$$

which is phase kickback again, now with a continuous phase. Doing this on all t

control qubits, with the i th control (counting from the top) applying $U^{2^{t-i}}$, leaves the control register in the product state

$$\bigotimes_{i=1}^t \frac{1}{\sqrt{2}} \left(|0\rangle + e^{2\pi i 2^{t-i} \phi} |1\rangle \right).$$

Writing $\phi = \sum_{k=1}^t \phi_k 2^{-k}$, the number $2^{t-i} \phi$ has fractional part $0.\phi_{t-i+1} \cdots \phi_t$, so the i th factor is $\frac{1}{\sqrt{2}} \left(|0\rangle + e^{2\pi i (0.\phi_{t-i+1} \cdots \phi_t)} |1\rangle \right)$. Comparing with the previous proposition – taking $x_0 = \phi_t, x_1 = \phi_{t-1}, \dots, x_{t-1} = \phi_1$, that is, $x = 2^t \phi$ – the control register holds precisely $\text{QFT}_{2^t} |2^t \phi\rangle$. Applying $\text{QFT}_{2^t}^\dagger$ therefore returns the basis state $|2^t \phi\rangle = |\phi_1 \phi_2 \cdots \phi_t\rangle$ exactly, and the measurement reads off the digits. $\square$

When ϕ is not an exact t -bit fraction the same circuit returns the best t -bit approximation with probability at least $4/\pi^2 \approx 0.405$, and one can boost this to $1 - \varepsilon$ by using $t + O(\log(1/\varepsilon))$ qubits. We will not need the general estimate in the form stated, but the underlying calculation – bounding a geometric sum whose ratio is close to but not equal to 1 – reappears in the analysis of Shor’s algorithm below, where the truncation of an infinite domain to $\mathbb{Z}_{2^m}$ causes exactly this kind of near-resonance.

Remark. Period finding is phase estimation in disguise. Given $f(x) = a^x \bmod N$ with period r , consider the unitary $U : |y\rangle \mapsto |ay \bmod N\rangle$. Its eigenvectors are the states $|u_k\rangle = r^{-1/2} \sum_{s=0}^{r-1} e^{-2\pi i k s / r} |a^s \bmod N\rangle$ with eigenvalues $e^{2\pi i k / r}$, so estimating a phase of U gives k/r for a random k , which is precisely the output of §39.12.2. This is the modern way to present Shor’s algorithm; we shall follow the original route instead, since the truncation issue is then visible rather than hidden.

§39.13 Shor’s Factoring Algorithm

We come to the most celebrated result in the subject. Given an n -bit integer N , we want a nontrivial factor. The best known classical algorithm, the number field sieve, runs in time $\exp\left(O(n^{1/3}(\log n)^{2/3})\right)$, which is subexponential but far from polynomial; the presumed hardness of this problem is what secures RSA. Shor’s algorithm factors in time $O(n^3)$.

The algorithm has two halves. The first is pure number theory and entirely classical: it reduces factoring to finding the period of a certain function. The second is the quantum period-finding routine of §39.12.2, adapted to cope with the fact that the period does not divide the size of the domain.

§39.13.1 Factoring as a Periodicity Problem

Fix N , and choose $1 < a < N$ at random. If $\gcd(a, N) > 1$ we have already found a factor by Euclid’s algorithm, so assume $\gcd(a, N) = 1$.

Theorem 39.13.1 (Euler)

If $\gcd(a, N) = 1$ then $a^{\varphi(N)} \equiv 1 \pmod{N}$. In particular there is a least $r \geq 1$ with $a^r \equiv 1 \pmod{N}$, called the **order** of a modulo N .

This is proved in IA Numbers and Sets: the units modulo N form a group of order $\varphi(N)$,

and the order of an element divides the order of the group. Consider now the **modular exponentiation function**

$$f : \mathbb{Z} \rightarrow \mathbb{Z}_N, \quad f(k) = a^k \bmod N.$$

Since $f(k_1 + k_2) = f(k_1)f(k_2)$ and $f(r) = 1$, the function f is periodic with period exactly r , and it is injective within each period (if $a^{k_1} \equiv a^{k_2}$ with $0 \leq k_1 < k_2 < r$ then $a^{k_2-k_1} \equiv 1$, contradicting minimality of r). So we have a periodicity problem. Why does its solution factor N ?

Proposition 39.13.2

Suppose r is even and $a^{r/2} \not\equiv -1 \pmod{N}$. Then $\gcd(a^{r/2} - 1, N)$ and $\gcd(a^{r/2} + 1, N)$ are nontrivial factors of N .

Proof. Since r is even we may write

$$a^r - 1 = (a^{r/2} - 1)(a^{r/2} + 1) \equiv 0 \pmod{N},$$

so N divides the product. Now $N \nmid (a^{r/2} - 1)$, since r is the *least* exponent with $a^r \equiv 1$ and $r/2 < r$; and $N \nmid (a^{r/2} + 1)$ by hypothesis. So neither factor is divisible by N , yet their product is: the prime factorisation of N must therefore be split between them, and $\gcd(a^{r/2} \pm 1, N)$ are proper nontrivial divisors, computable by Euclid's algorithm in $O(n^3)$ time. $\square$

Example 39.13.3

Let $N = 15$ and $a = 7$. The powers of 7 modulo 15 are 1, 7, 4, 13, 1, $\dots$, so $r = 4$, which is even, and $a^{r/2} = 49 \equiv 4 \not\equiv -1$. Then

$$\gcd(a^{r/2} - 1, N) = \gcd(48, 15) = 3, \quad \gcd(a^{r/2} + 1, N) = \gcd(50, 15) = 5,$$

and indeed $15 = 3 \times 5$.

Of course the hypotheses might fail. The following says that they usually do not.

Theorem 39.13.4

Let N be odd and not a prime power. If a is chosen uniformly at random from the units modulo N , then with probability at least $\frac{1}{2}$ the order r of a is even and $a^{r/2} \not\equiv -1 \pmod{N}$.

The proof uses the Chinese remainder theorem and the structure of $(\mathbb{Z}/p^k\mathbb{Z})^\times$ as a cyclic group; we take it on trust. Combined with the previous proposition, a random a gives us a factor with probability at least $\frac{1}{2}$, so $O(\log(1/\varepsilon))$ attempts succeed with probability $1 - \varepsilon$.

The excluded cases are easy to handle separately. If N is even, output 2. If $N = c^\ell$ for some $\ell > 1$, we can find c classically in polynomial time: for each $\ell \leq \log_2 N$ compute $\lfloor N^{1/\ell} \rfloor$ to sufficient precision and test.

Method (Shor's Algorithm)

To find a nontrivial factor of N :

- (i) If N is even, output 2 and stop.
- (ii) If $N = c^\ell$ with $\ell > 1$, output c and stop.
- (iii) Choose $1 < a < N$ uniformly at random and compute $b = \gcd(a, N)$. If $b > 1$, output b and stop.
- (iv) Use the quantum period-finding subroutine to find the order r of a modulo N . If it fails, return to (iii).
- (v) If r is even and $t = \gcd(a^{r/2} + 1, N)$ satisfies $1 < t < N$, output t and stop. Otherwise return to (iii).

Only step (iv) is quantum. Everything else is classical arithmetic that we already know how to do quickly.

§39.13.2 Period Finding on a Truncated Domain

There is a difficulty that we glossed over in §39.12.2. There, the period r divided the size N of the domain, which made the geometric sum collapse exactly. Here f is defined on all of $\mathbb{Z}$, and we must truncate to a finite domain $\mathbb{Z}_M$; but we do not know r , so we cannot choose M to be a multiple of it. The sum will no longer vanish exactly, and we must show that it is nonetheless sharply peaked.

Take $M = 2^m$, where m is minimal with $2^m > N^2$ (the reason for this choice will emerge), and let $D = \{0, 1, \dots, 2^m - 1\}$. Write $2^m = Br + b$ with $0 \leq b < r$, so $B = \lfloor 2^m/r \rfloor$.

Running the circuit, the state after the oracle is

$$\begin{aligned}
 |\Psi\rangle &= \frac{1}{\sqrt{2^m}} \sum_{x \in D} |x\rangle |f(x)\rangle = \frac{1}{\sqrt{2^m}} \sum_{x_0=0}^{b-1} \sum_{j=0}^B |x_0 + jr\rangle |f(x_0)\rangle \\
 &\quad + \frac{1}{\sqrt{2^m}} \sum_{x_0=b}^{r-1} \sum_{j=0}^{B-1} |x_0 + jr\rangle |f(x_0)\rangle,
 \end{aligned}$$

the split reflecting the fact that the residues $x_0 < b$ occur $B + 1$ times in D and the rest occur B times. Measuring the output register gives some $y = f(x_0)$, leaving the input register in

$$|\text{per}\rangle = \frac{1}{\sqrt{A}} \sum_{j=0}^{A-1} |x_0 + jr\rangle, \quad A = \begin{cases} B + 1, & x_0 < b, \\ B, & x_0 \geq b. \end{cases}$$

Applying QFT_{2^m} , with $\omega = e^{2\pi i/2^m}$,

$$\text{QFT}_{2^m} |\text{per}\rangle = \frac{1}{\sqrt{A2^m}} \sum_{c=0}^{2^m-1} \omega^{x_0 c} \left[\sum_{j=0}^{A-1} (\omega^{cr})^j \right] |c\rangle = \sum_{c=0}^{2^m-1} g(c) |c\rangle,$$

say. This is the same expression as before, but now ω^{cr} is in general not a root of unity of order dividing A , so the inner sum does not vanish. It is, however, still a geometric series, and it is large exactly when ω^{cr} is close to 1, that is, when $cr/2^m$ is close to an integer k , that is, when

$$c \approx \frac{k 2^m}{r}.$$

Theorem 39.13.5

For each $k \in \{0, 1, \dots, r-1\}$ let c_k be the unique integer with $|c_k - k2^m/r| < \frac{1}{2}$. Then

$$\Pr(c = c_k) = |g(c_k)|^2 > \frac{\gamma}{r}$$

for an absolute constant γ , which may be taken to be $4/\pi^2$.

Proof sketch. First, c_k is well defined. If $k2^m/r$ were exactly a half-integer $\ell + \frac{1}{2}$, then $k2^{m+1} = r(2\ell + 1)$; writing $r = 2^s u$ with u odd and comparing the power of 2 on each side gives $m+1 \leq s$, so $2^{m+1} \mid r$, contradicting $r < N < 2^m$. Summing the geometric series,

$$\sum_{j=0}^{A-1} (\omega^{cr})^j = \frac{1 - e^{2\pi i A c r / 2^m}}{1 - e^{2\pi i c r / 2^m}},$$

and writing $cr/2^m = k + \delta$ with $|\delta| < r/2^{m+1}$, the numerator and denominator are $|1 - e^{2\pi i A \delta}| = 2|\sin(\pi A \delta)|$ and $2|\sin(\pi \delta)|$. Since $A \approx 2^m/r$ we have $|A\delta| \lesssim \frac{1}{2}$, so we are on the part of the sine curve where $|\sin(\pi A \delta)| \geq 2|A\delta|$, while $|\sin(\pi \delta)| \leq \pi|\delta|$. Hence the ratio is at least $2A/\pi$, and

$$|g(c_k)|^2 \geq \frac{1}{A2^m} \cdot \frac{4A^2}{\pi^2} = \frac{4}{\pi^2} \cdot \frac{A}{2^m} \approx \frac{4}{\pi^2} \cdot \frac{1}{r},$$

as claimed. □

So with constant probability our measured c satisfies $|c - k2^m/r| < \frac{1}{2}$ for some k , and by the coprimality theorem, with probability $\Omega(1/\log \log r)$ this k is coprime to r . Repeating $O(\log \log N)$ times, we may assume both.

§39.13.3 Recovering r by Continued Fractions

Dividing by 2^m , our measurement gives a known rational $c/2^m$ with

$$\left| \frac{c}{2^m} - \frac{k}{r} \right| < \frac{1}{2^{m+1}} < \frac{1}{2N^2},$$

using $2^m > N^2$. Since $r < N$ this is the classic setting of Diophantine approximation, and two facts from the Part II Number Theory course finish the job.

Lemma 39.13.6

There is at most one fraction k/r in lowest terms with $r < N$ and $|c/2^m - k/r| < 1/(2N^2)$.

Proof. Suppose k'/r' and k''/r'' both satisfy this, with $r', r'' < N$, and are distinct. Then

$$\left| \frac{k'}{r'} - \frac{k''}{r''} \right| = \frac{|k'r'' - k''r'|}{r'r''} \geq \frac{1}{r'r''} > \frac{1}{N^2},$$

since the numerator is a nonzero integer. But by the triangle inequality the two fractions are within $2 \cdot \frac{1}{2N^2} = \frac{1}{N^2}$ of each other, a contradiction. $\square$

This is precisely why we chose m minimal with $2^m > N^2$: any smaller and the approximation would not determine k/r ; any larger and we waste qubits. It remains to *find* the fraction, and here we appeal to continued fractions.

Recall from Part II Number Theory² that every rational $x \in (0, 1)$ has a finite continued fraction expansion

$$x = \frac{1}{a_1 + \frac{1}{a_2 + \frac{1}{\ddots + \frac{1}{a_\ell}}}} = [a_1, a_2, \dots, a_\ell]$$

with a_i positive integers, obtained by the Euclidean algorithm; the truncations $p_k/q_k = [a_1, \dots, a_k]$ are the **convergents**, and satisfy the recurrences

$$p_k = a_k p_{k-1} + p_{k-2}, \quad q_k = a_k q_{k-1} + q_{k-2},$$

with $p_0 = 0, q_0 = 1, p_1 = 1, q_1 = a_1$, together with $q_k p_{k-1} - p_k q_{k-1} = (-1)^k$ and hence $\gcd(p_k, q_k) = 1$.

Theorem 39.13.7

If c and 2^m are $O(m)$ -bit integers, the continued fraction expansion of $c/2^m$ has length $\ell = O(m)$ and it, together with all its convergents, can be computed in $O(m^3)$ time.

Proof sketch. Each $a_k \geq 1$, so the recurrences give $p_k \geq p_{k-2} + p_{k-1} \geq 2p_{k-2}$ and likewise for q_k ; hence $p_k, q_k \geq 2^{\lfloor k/2 \rfloor}$. Since $q_\ell = 2^m$ (after cancellation, at most 2^m), we need $\ell = O(m)$ steps. Each step is a division of $O(m)$ -bit integers, costing $O(m^2)$, so the total is $O(m^3)$. $\square$

Theorem 39.13.8 (Legendre)

²The continued fraction machinery quoted here – the recurrences for the convergents, the identity $q_k p_{k-1} - p_k q_{k-1} = (-1)^k$, and Legendre's theorem below – is developed in full in the 'Continued Fractions' section of my Number Theory notes, [../number-theory/](#); there Legendre's theorem is proved for irrational x , and the rational case needed here is proved in exactly the same way.

Let $x \in \mathbb{Q}$ with $0 < x < 1$, and let p/q be a rational in lowest terms with

$$\left| x - \frac{p}{q} \right| < \frac{1}{2q^2}.$$

Then p/q is a convergent of the continued fraction expansion of x .

Now apply this with $x = c/2^m$ and $p/q = k/r$: since $r < N$ we have

$$\left| \frac{c}{2^m} - \frac{k}{r} \right| < \frac{1}{2N^2} < \frac{1}{2r^2},$$

so k/r is one of the convergents of $c/2^m$. We compute them all – there are only $O(m)$ – and test each candidate denominator q by checking whether $a^q \equiv 1 \pmod{N}$. The lemma above guarantees that at most one candidate can pass the approximation test, and since $\gcd(k, r) = 1$ the fraction k/r appears in lowest terms, so its denominator is exactly r .

Example 39.13.9

Take $N = 39$ and $a = 7$, which are coprime. Since $39^2 = 1521$ and $2^{10} = 1024 < 1521 < 2048 = 2^{11}$, we set $m = 11$ and $M = 2^{11} = 2048$.

Suppose the measurement returns $c = 853$. We expand

$$\frac{853}{2048} = [2, 2, 2, 42, 4],$$

obtained by the Euclidean algorithm: $2048 = 2 \cdot 853 + 342$, $853 = 2 \cdot 342 + 169$, $342 = 2 \cdot 169 + 4$, $169 = 42 \cdot 4 + 1$, $4 = 4 \cdot 1$. The convergents are

$$\frac{1}{2}, \quad \frac{2}{5}, \quad \frac{5}{12}, \quad \frac{212}{509}, \quad \frac{853}{2048}.$$

We need a denominator $r < 39$, which rules out the last two; and of the remaining three,

$$\left| \frac{853}{2048} - \frac{1}{2} \right| = 0.0835, \quad \left| \frac{853}{2048} - \frac{2}{5} \right| = 0.0165, \quad \left| \frac{853}{2048} - \frac{5}{12} \right| = 0.000163,$$

while $1/(2N^2) = 1/3042 = 0.000329$. Only $5/12$ passes. So we take $r = 12$, and indeed one checks $7^{12} \equiv 1 \pmod{39}$ while no smaller power is 1.

Now $r = 12$ is even, and computing the powers of 7 modulo 39 gives $7^6 \equiv 25$, which is not $-1 \equiv 38$. Since $\gcd(x, N)$ depends only on x modulo N , we compute

$$\gcd(7^6 + 1, 39) = \gcd(26, 39) = 13, \quad \gcd(7^6 - 1, 39) = \gcd(24, 39) = 3,$$

and indeed $39 = 13 \times 3$.

Remark. Without continued fractions, one could search all fractions k/r with $r < N$ directly, but there are $\Theta(N^2)$ of them, and $N^2 = \Theta(\exp(2n))$: the classical post-processing would then dominate and destroy the speedup entirely. The continued fraction algorithm is what makes the last step polynomial, and it is a nice illustration that a quantum algorithm is usually a quantum subroutine wrapped in a great deal of classical cleverness.

§39.13.4 Complexity

Let us total up the cost of one run, with $n = \lceil \log_2 N \rceil$ and $m = O(n)$.

- Preparing the equal superposition: $m = O(n)$ Hadamard gates.
- The oracle U_f for modular exponentiation: computing $a^x \bmod N$ by repeated squaring needs $O(m)$ modular multiplications of n -bit numbers, each $O(n^2)$, so $O(n^3)$ gates in the reversible implementation.
- Measuring the output register: $O(n)$ single-qubit measurements.
- QFT_{2^m} : $O(m^2) = O(n^2)$ gates.
- Measuring the input register: $O(n)$ measurements.
- Continued fractions to recover r : $O(n^3)$ classical steps.
- Euclid's algorithm for the final gcd: $O(n^3)$.

So a single run costs $O(n^3)$, dominated by the modular exponentiation. We need $O(\log \log N) = O(\log n)$ runs to get a good value of c , and $O(\log(1/\varepsilon))$ choices of a to get a useful order r . The total is $O(n^3 \log n)$, and with a little more care $O(n^3)$; in any case, polynomial.

Remark. It is worth being clear about what Shor's algorithm does and does not show. It does not show that factoring is easy in any absolute sense, and it does not show $\text{NP} \subseteq \text{BQP}$ – factoring is not believed to be NP -complete. What it does show is that a problem believed to be outside BPP lies in BQP , which is the strongest evidence we have that quantum computers are more powerful than classical ones. It also, incidentally, breaks RSA.

§39.14 Grover's Search Algorithm

Shor's algorithm exploits a great deal of structure – periodicity – and gets an exponential speedup. What can we do when there is no structure at all?

Problem (Unstructured Search). *We are given a database of N items, exactly one of which is 'good', and the ability to test any single item for goodness. Locate the good item.*

Proposition 39.14.1

Classically, $\Omega(N)$ queries are needed to succeed with any fixed constant probability.

Proof. Testing an item and finding it bad tells us nothing about the location of the good item beyond excluding that one. After M queries we have excluded M possibilities and the good item is uniform on the remaining $N - M$, so the probability of having found it is M/N . For this to be at least $1 - \varepsilon$ we need $M \geq (1 - \varepsilon)N$. $\square$

Grover's algorithm does it in $O(\sqrt{N})$ queries. That is only a quadratic speedup, but it applies to *everything*: unstructured search is the abstract form of brute-force, and in particular of SAT.

§39.14.1 Setup: Reflections

Take $N = 2^n$, so items are labelled by n -bit strings, and let $x_0 \in \mathbb{B}_n$ be the good one. The database is the Boolean function $f : \mathbb{B}_n \rightarrow \mathbb{B}_1$ with $f(x_0) = 1$ and $f(x) = 0$ otherwise, and we are given the oracle U_f .

Definition 39.14.2 (Reflection Operator)

For a normalised $|\alpha\rangle \in \mathcal{V}$, write

$$\Pi_{|\alpha\rangle} = |\alpha\rangle\langle\alpha|, \quad I_{|\alpha\rangle} = I - 2|\alpha\rangle\langle\alpha|.$$

Then $I_{|\alpha\rangle}|\alpha\rangle = -|\alpha\rangle$ and $I_{|\alpha\rangle}|\psi\rangle = |\psi\rangle$ for every $|\psi\rangle \perp |\alpha\rangle$, so $I_{|\alpha\rangle}$ is the reflection of $\mathcal{V}$ in the hyperplane $|\alpha\rangle^\perp$. It is unitary and self-inverse. Note also the conjugation rule

$$UI_{|\alpha\rangle}U^\dagger = U(I - 2|\alpha\rangle\langle\alpha|)U^\dagger = I - 2|U\alpha\rangle\langle U\alpha| = I_{U|\alpha\rangle},$$

valid for any unitary U ; we will use it to build one reflection out of another.

Write $I_{x_0} := I_{|x_0\rangle}$, so that

$$I_{x_0}|x\rangle = \begin{cases} -|x\rangle, & x = x_0, \\ +|x\rangle, & x \neq x_0, \end{cases}$$

and write I_0 for the case $x_0 = 0 \cdots 0$. The oracle gives us I_{x_0} for free.

Proposition 39.14.3

$U_f(|\psi\rangle \otimes |-\rangle) = (I_{x_0}|\psi\rangle) \otimes |-\rangle$ for every $|\psi\rangle$.

Proof. By phase kickback (§39.10.2), $U_f|x\rangle|-\rangle = (-1)^{f(x)}|x\rangle|-\rangle$, which is $-|x\rangle|-\rangle$ if $x = x_0$ and $+|x\rangle|-\rangle$ otherwise. This is exactly the action of $I_{x_0} \otimes I$ on basis states, and both sides are linear. $\square$

So from now on we may forget the output register and simply say that one query implements the reflection I_{x_0} .

§39.14.2 The Grover Iterate

We start, as always, from the equal superposition

$$|\psi_0\rangle = H^{\otimes n}|0\rangle^{\otimes n} = \frac{1}{\sqrt{N}} \sum_{x \in \mathbb{B}_n} |x\rangle,$$

which has overlap $\langle x_0|\psi_0\rangle = 1/\sqrt{N}$ with the target – small, but not zero. The idea is to amplify it.

Definition 39.14.4 (Grover Iterate)

Write $H_n = H^{\otimes n}$. The **Grover iterate** is

$$Q = -H_n I_0 H_n I_{x_0}.$$

By the conjugation rule, $H_n I_0 H_n = H_n I_{|0\dots 0\rangle} H_n^\dagger = I_{H_n|0\dots 0\rangle} = I_{|\psi_0\rangle}$, so

$$Q = -I_{|\psi_0\rangle} I_{|x_0\rangle} :$$

a reflection in $|x_0\rangle^\perp$, followed by a reflection in $|\psi_0\rangle^\perp$, followed by an overall sign. Each iterate costs one query (for I_{x_0}) plus $O(n)$ gates (for $H_n I_0 H_n$; the reflection I_0 about the all-zeros state is a multiply-controlled phase, built from $O(n)$ Toffoli gates and ancillas).

Everything now happens in a two-dimensional real plane.

Theorem 39.14.5

Let $\mathcal{P} = \text{span}_{\mathbb{R}}\{|x_0\rangle, |\psi_0\rangle\}$. Then

- (i) $\mathcal{P}$ is invariant under Q , and on $\mathcal{P}$ the operator Q acts as a rotation through 2α , where $\sin \alpha = \langle x_0 | \psi_0 \rangle = 1/\sqrt{N}$;
- (ii) on $\mathcal{P}^\perp$, Q acts as $-I$.

Proof. All the vectors and operators here have real entries in the computational basis, so we may work in real Euclidean space.

For (ii), if $|\xi\rangle$ is orthogonal to both $|x_0\rangle$ and $|\psi_0\rangle$ then both reflections fix it, so $Q|\xi\rangle = -|\xi\rangle$.

For (i), note first that $I_{|x_0\rangle}|v\rangle = |v\rangle - 2\langle x_0|v\rangle|x_0\rangle$ and $I_{|\psi_0\rangle}|v\rangle = |v\rangle - 2\langle \psi_0|v\rangle|\psi_0\rangle$, so each maps $\mathcal{P}$ into $\mathcal{P}$; hence so does Q . Restricted to the plane $\mathcal{P}$, $I_{|x_0\rangle}$ is the reflection in the line $L_1 = \mathcal{P} \cap |x_0\rangle^\perp$ and $I_{|\psi_0\rangle}$ the reflection in $L_2 = \mathcal{P} \cap |\psi_0\rangle^\perp$.

Now recall the elementary fact that the composition of reflections in two lines of the plane meeting at angle θ is a rotation through 2θ . Let β be the angle between $|x_0\rangle$ and $|\psi_0\rangle$, so $\cos \beta = \langle x_0 | \psi_0 \rangle = 1/\sqrt{N}$; then the angle between their perpendiculars L_1 and L_2 is also β , and $I_{|\psi_0\rangle} I_{|x_0\rangle}$ is a rotation through 2β .

Finally we deal with the sign. In a plane, $-R$ where R is the reflection in a line L is the reflection in $L^\perp$; so $-I_{|\psi_0\rangle} = I_{|\psi_0^\perp\rangle}$ on $\mathcal{P}$, where $|\psi_0^\perp\rangle$ is the unit vector in $\mathcal{P}$ perpendicular to $|\psi_0\rangle$. Therefore

$$Q|_{\mathcal{P}} = I_{|\psi_0^\perp\rangle} I_{|x_0\rangle},$$

which is a rotation through twice the angle between the corresponding mirror lines. That angle is now $\frac{\pi}{2} - \beta = \alpha$, where $\sin \alpha = \cos \beta = 1/\sqrt{N}$. Hence Q rotates through 2α . $\square$

The picture, drawn in the plane $\mathcal{P}$ with the orthonormal basis $\{|x_0^\perp\rangle, |x_0\rangle\}$, where $|x_0^\perp\rangle$ is the normalised superposition of all the *bad* items:

The state starts at angle α above the ‘all bad’ axis, and each application of Q swings it a further 2α towards $|x_0\rangle$. When it arrives, a measurement in the computational basis returns x_0 .

Corollary 39.14.6

Let m be the integer nearest to $\frac{\pi/2 - \alpha}{2\alpha}$, so that

$$m \approx \frac{\pi}{4} \sqrt{N}.$$

Then after m iterations a standard measurement returns x_0 with probability $1 - O(1/N)$.

Proof. After m iterations the state makes an angle $(2m + 1)\alpha$ with $|x_0^\perp\rangle$, so the probability of measuring x_0 is $\sin^2((2m + 1)\alpha)$. This is maximised by choosing m so that $(2m + 1)\alpha$ is as close as possible to $\pi/2$. For large N , $\alpha = \arcsin(1/\sqrt{N}) \approx 1/\sqrt{N}$ is small, so

$$m \approx \frac{\pi/2}{2\alpha} \approx \frac{\pi}{4} \sqrt{N},$$

and rounding to the nearest integer costs us at most α in angle, hence at most $O(\alpha^2) = O(1/N)$ in probability. $\square$

Notice that m does not depend on x_0 – only on N . That is essential: we would hardly be able to run the algorithm if the number of steps depended on the answer.

Example 39.14.7

Let $N = 4$, so $n = 2$. Here $\sin \alpha = \frac{1}{2}$, so $\alpha = \pi/6$ and each iterate rotates by $2\alpha = \pi/3$. The initial state $|\psi_0\rangle = |++\rangle$ makes an angle $\alpha = \pi/6$ with $|x_0^\perp\rangle$, so after a single iterate it makes an angle $\pi/6 + \pi/3 = \pi/2$: it is *exactly* $|x_0\rangle$. One query, and the measurement gives x_0 with certainty – whereas classically we would need up to three. Let us verify directly for $x_0 = 11$. We have $|\psi_0\rangle = \frac{1}{2}(|00\rangle + |01\rangle + |10\rangle + |11\rangle)$, so

$$I_{x_0} |\psi_0\rangle = \frac{1}{2} (|00\rangle + |01\rangle + |10\rangle - |11\rangle).$$

Now $I_{|\psi_0\rangle} |v\rangle = |v\rangle - 2\langle\psi_0|v\rangle |\psi_0\rangle$, and $\langle\psi_0|I_{x_0}\psi_0\rangle = \frac{1}{4}(1 + 1 + 1 - 1) = \frac{1}{2}$, so

$$-I_{|\psi_0\rangle} I_{x_0} |\psi_0\rangle = |\psi_0\rangle - I_{x_0} |\psi_0\rangle = \frac{1}{2} (0 + 0 + 0 + 2|11\rangle) = |11\rangle,$$

as promised.

§39.14.3 Multiple Targets and Unknown r

Now suppose there are $r \geq 1$ good items $x_1, \dots, x_r$, with r known. Define

$$I_G = I - 2 \sum_{i=1}^r |x_i\rangle\langle x_i|,$$

which flips the sign of every good basis state, and is again implemented by one oracle query. Put $Q_G = -I_{|\psi_0\rangle} I_G$, and let

$$|\psi_G\rangle = \frac{1}{\sqrt{r}} \sum_{i=1}^r |x_i\rangle, \quad |\psi_B\rangle = \frac{1}{\sqrt{N-r}} \sum_{x \text{ bad}} |x\rangle$$

be the equal superpositions of good and bad items, which are orthonormal. Then

$$|\psi_0\rangle = \sqrt{\frac{r}{N}} |\psi_G\rangle + \sqrt{\frac{N-r}{N}} |\psi_B\rangle$$

lies in the plane $\mathcal{P}_G = \text{span}\{|\psi_G\rangle, |\psi_B\rangle\}$.

Proposition 39.14.8

On the plane $\mathcal{P}_G$, the operator Q_G acts as a rotation through 2α , where $\sin \alpha = \langle \psi_0 | \psi_G \rangle = \sqrt{r/N}$.

Proof. The only new point is that I_G is not of the form $I_{|v\rangle}$ for a single vector. But restricted to $\mathcal{P}_G$ it is: writing a general element as $a|\psi_G\rangle + b|\psi_B\rangle$, we have

$$I_G (a|\psi_G\rangle + b|\psi_B\rangle) = -a|\psi_G\rangle + b|\psi_B\rangle,$$

since I_G negates each good basis vector and fixes each bad one, so on $\mathcal{P}_G$ it agrees with $I_{|\psi_G\rangle}$. The proof of the previous theorem now goes through verbatim with $|\psi_G\rangle$ in place of $|x_0\rangle$. $\square$

So the number of iterations is now $m \approx \frac{\pi}{4} \sqrt{N/r}$: the more solutions there are, the faster we find one, exactly as one would hope.

The interesting case is when r is *unknown*, which is the realistic one – for SAT we have no idea how many satisfying assignments there are. Here we must be careful: running too many iterations is as bad as running too few, since the state rotates *past* $|\psi_G\rangle$ and back down again. The fix is randomisation.

Method 39.14.9 (Grover with Unknown r)

Choose K uniformly at random in $(0, \frac{\pi}{4} \sqrt{N})$, apply Q_G that many times to $|\psi_0\rangle$, measure, and test the outcome with one further query. Repeat until a good item is found.

Proposition 39.14.10

Assuming $r \ll N$, each round of this procedure finds a good item with probability bounded below by an absolute constant, using $O(\sqrt{N})$ queries.

Proof sketch. Each iterate rotates by $2\alpha \approx 2\sqrt{r/N}$, so applying K of them rotates by a total angle $2K\alpha$, which as K ranges over $(0, \frac{\pi}{4}\sqrt{N})$ ranges over $(0, \frac{\pi}{2}\sqrt{r})$ – many full turns. The final angle is therefore close to uniform on the circle. If the final state makes an angle within $\pm\pi/4$ of $|\psi_G\rangle$, the probability of measuring a good item is at least $\cos^2(\pi/4) = \frac{1}{2}$. Half of all angles have this property, so the overall success probability per round is about $\frac{1}{4}$. Hence $O(1)$ rounds suffice in expectation, each using $O(\sqrt{N})$ queries. $\square$

§39.14.4 Optimality

Is $\sqrt{N}$ the best possible? Yes, and this is one of the few places in the subject where we have a matching lower bound.

Theorem 39.14.11 (BBBV)

Any quantum algorithm that solves unstructured search on N items with bounded error must make $\Omega(\sqrt{N})$ queries. Moreover $\frac{\pi}{4}(1 - \varepsilon)\sqrt{N}$ queries do not suffice for any $\varepsilon > 0$, so Grover’s algorithm is optimal even in its constant.

The proof is a ‘hybrid argument’: one shows that a single query can change the state of the computation by only $O(1/\sqrt{N})$ in norm on average over the possible locations of the target, so that after T queries the algorithm cannot distinguish the N possible oracles unless $T = \Omega(\sqrt{N})$.

The consequence is worth emphasising, because it cuts both ways. On one hand, Grover’s algorithm gives a genuine and completely general speedup: any problem for which we know nothing better than brute-force search over 2^n candidates – which includes every NP-complete problem – can be attacked in time $O(2^{n/2})$ instead of $O(2^n)$. Since SAT is NP-complete, this applies across the whole of NP.

On the other hand, the lower bound says that this is *all* that generic quantum search can do. To do better one must exploit structure, as Shor does. There is no reason to expect NP-complete problems to have the kind of structure that admits an exponential speedup, and most people do not expect quantum computers to solve them efficiently.

Remark. In practice the quadratic speedup is less dramatic than it sounds, since $\sqrt{2^n} = 2^{n/2}$ is still exponential: Grover turns a 128-bit search into a 64-bit search. Its main cryptographic consequence is that symmetric key lengths should be doubled, whereas Shor’s algorithm destroys RSA and elliptic-curve cryptography outright.

§39.15 Mixed States and Density Matrices

Throughout the course we have described states by vectors, and repeatedly run into situations where that is not quite the right language: a qubit which is ‘ $|0\rangle$ or $|1\rangle$ with probability $\frac{1}{2}$ each’, or ‘half of an entangled pair, considered on its own’. In both cases the system has no state vector of its own, yet it certainly has well-defined measurement statistics. The right object is a **density matrix**, and it lets us say cleanly several things we could previously only say by circumlocution.

The general theory of density operators – the ensemble ambiguity, the partial trace, von Neumann entropy, and the way decoherence turns a pure state into a mixture –

is developed at length in the Part II Principles of Quantum Mechanics course, and I have written it up in my notes for that course (see the section ‘Density Operators and Mixed States’ in `../principles-of-quantum-mechanics/`). I shall not repeat that development here. What follows is the minimum needed to make our earlier informal talk of ‘ensembles’ and ‘half of an entangled pair’ precise, together with the one genuinely quantum-information-theoretic use of the formalism: the reduced density matrix as a measure of entanglement.

§39.15.1 Density Matrices

Definition 39.15.1 (Density Matrix)

Suppose a system is prepared in the state $|\psi_i\rangle$ with probability p_i , where $\sum_i p_i = 1$. The **density matrix** of this **ensemble** is

$$\rho = \sum_i p_i |\psi_i\rangle\langle\psi_i|.$$

A state described by a rank-one $\rho = |\psi\rangle\langle\psi|$ is called **pure**; otherwise it is **mixed**.

Proposition 39.15.2

An operator ρ is the density matrix of some ensemble if and only if it is self-adjoint, positive semi-definite, and has $\text{Tr } \rho = 1$.

Proof. Each $|\psi_i\rangle\langle\psi_i|$ is self-adjoint and positive semi-definite with trace $\langle\psi_i|\psi_i\rangle = 1$, and these properties are preserved by convex combinations. Conversely, given such a ρ , the spectral theorem gives $\rho = \sum_i \lambda_i |e_i\rangle\langle e_i|$ with $\lambda_i \geq 0$ and $\sum \lambda_i = \text{Tr } \rho = 1$, exhibiting ρ as the density matrix of the ensemble $\{(\lambda_i, |e_i\rangle)\}$. $\square$

The Born rule extends immediately: the probability of outcome j in the measurement $\{P_j\}$ is

$$p(j) = \sum_i p_i \langle\psi_i|P_j|\psi_i\rangle = \text{Tr}(P_j\rho),$$

and unitary evolution acts by $\rho \mapsto U\rho U^\dagger$. Since *all* predictions depend on ρ alone, two ensembles with the same density matrix are physically indistinguishable, however different they look. This is exactly the phenomenon we met in §39.3.3.

Example 39.15.3

The ‘yes’ ensemble $\{(\frac{1}{2}, |0\rangle), (\frac{1}{2}, |1\rangle)\}$ and the ‘no’ ensemble $\{(\frac{1}{2}, |+\rangle), (\frac{1}{2}, |-\rangle)\}$ have density matrices

$$\frac{1}{2}|0\rangle\langle 0| + \frac{1}{2}|1\rangle\langle 1| = \frac{1}{2}I, \quad \frac{1}{2}|+\rangle\langle +| + \frac{1}{2}|-\rangle\langle -| = \frac{1}{2}I,$$

which are equal. This *is* the proof that Alice’s choice of measurement basis is undetectable by Bob, in one line. The state $\frac{1}{2}I$ is called the **maximally mixed** state of a qubit.

A useful invariant is the **purity** $\text{Tr}(\rho^2)$, which satisfies $\frac{1}{d} \leq \text{Tr}(\rho^2) \leq 1$ for a d -dimensional system, with equality on the right exactly for pure states and on the left

exactly for $\frac{1}{d}I$. For a qubit one can write

$$\rho = \frac{1}{2} (I + \mathbf{n} \cdot \vec{\sigma}), \quad \mathbf{n} \in \mathbb{R}^3, \quad |\mathbf{n}| \leq 1,$$

where $\vec{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$; the pure states are those with $|\mathbf{n}| = 1$. So the density matrices of a qubit fill out the solid *Bloch ball*, with the pure states of §39.1.3 forming its surface and the maximally mixed state at the centre.

surface ($|\mathbf{n}| = 1$): pure states
interior ($|\mathbf{n}| < 1$): mixed states

The picture makes the geometry of mixing transparent: an ensemble $\{(p_i, \rho_i)\}$ has Bloch vector $\sum_i p_i \mathbf{n}_i$, so mixing is literally taking convex combinations inside the ball, and every interior point can be written as a mixture in infinitely many ways – which is precisely the ambiguity of ensembles noted above.

§39.15.2 The Reduced Density Matrix

The other use of density matrices is to describe a subsystem.

Definition 39.15.4 (Partial Trace)

Let ρ_{AB} be a density matrix on $\mathcal{V}_A \otimes \mathcal{V}_B$. Its **partial trace** over B is the operator on $\mathcal{V}_A$ defined by

$$\rho_A = \text{Tr}_B \rho_{AB} = \sum_j (I_A \otimes \langle f_j |) \rho_{AB} (I_A \otimes |f_j\rangle),$$

where $\{|f_j\rangle\}$ is any orthonormal basis of $\mathcal{V}_B$; the result does not depend on the choice.

Proposition 39.15.5

ρ_A is the unique operator on $\mathcal{V}_A$ such that $\text{Tr}(M\rho_A) = \text{Tr}((M \otimes I)\rho_{AB})$ for every operator M on $\mathcal{V}_A$. Consequently ρ_A correctly predicts the statistics of every measurement performed on A alone.

Example 39.15.6

Take $|\phi^+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$, so

$$\rho_{AB} = \frac{1}{2} (|00\rangle\langle 00| + |00\rangle\langle 11| + |11\rangle\langle 00| + |11\rangle\langle 11|).$$

Tracing out B , the cross terms $|00\rangle\langle 11|$ contribute $\langle 1|0\rangle \langle 0|1\rangle = 0$ and similarly for the other, so

$$\rho_A = \frac{1}{2} (|0\rangle\langle 0| + |1\rangle\langle 1|) = \frac{1}{2}I.$$

Alice's half of a Bell pair is maximally mixed: she has *no* information at all. This is the precise sense in which $|\phi^+\rangle$ is maximally entangled, and it is also a one-line proof of the no-signalling principle for this state.

Notice what this says about the relationship between the whole and its parts: ρ_{AB} is pure (we know the joint state exactly) while ρ_A is maximally mixed (we know nothing about the part). Classically this is impossible – complete knowledge of a pair entails complete knowledge of each member. Entanglement is precisely the failure of that principle.

Proposition 39.15.7

A pure state $|\Psi\rangle_{AB}$ is a product state if and only if ρ_A is pure.

So the purity $\text{Tr}(\rho_A^2)$ is a quantitative measure of how entangled a pure bipartite state is, running from 1 (product) down to $1/\dim \mathcal{V}_A$ (maximally entangled).

§39.16 Quantum Error Correction

The last thing standing between us and a working quantum computer is that quantum systems are appallingly fragile. A qubit interacts with its environment, becomes entangled with it, and – by the discussion above – its reduced state becomes mixed: the information leaks away. This process is called **decoherence**, and without some way of fighting it no quantum computation of any length is possible.

Classically, we fight noise by redundancy: send 000 instead of 0, and take a majority vote. Quantumly this looks hopeless for three reasons.

- (i) We cannot copy an unknown state, by the no-cloning theorem.
- (ii) We cannot measure the encoded qubits to see whether an error has occurred, since measurement destroys superpositions.
- (iii) Errors are continuous, not discrete: instead of a bit flip we may get a rotation by a tiny angle ϵ , and there are uncountably many such.

Remarkably, all three objections can be met. We illustrate with the simplest example.

§39.16.1 The Three-Qubit Bit-Flip Code

Suppose the only errors that occur are bit flips X , acting independently on each qubit with probability $p < \frac{1}{2}$, and suppose at most one qubit is affected. Encode

$$|0\rangle \mapsto |0_L\rangle = |000\rangle, \quad |1\rangle \mapsto |1_L\rangle = |111\rangle,$$

so that a general qubit $a|0\rangle + b|1\rangle$ becomes $a|000\rangle + b|111\rangle$. This is *not* cloning: we have not produced three copies of $a|0\rangle + b|1\rangle$, which would be the quite different state $(a|0\rangle + b|1\rangle)^{\otimes 3}$. Encoding is done with two CNOTs:

The two ancillas measure the parities $s_1 = b_1 \oplus b_2$ and $s_2 = b_2 \oplus b_3$ of the three data qubits. This is the key move, and it answers objection (ii): we measure a *comparison* of the qubits, not the qubits themselves. Concretely, the measurement is the incomplete projective measurement with the four rank-two projectors

$$\begin{aligned}\Pi_{00} &= |000\rangle\langle 000| + |111\rangle\langle 111|, & \Pi_{10} &= |100\rangle\langle 100| + |011\rangle\langle 011|, \\ \Pi_{01} &= |001\rangle\langle 001| + |110\rangle\langle 110|, & \Pi_{11} &= |010\rangle\langle 010| + |101\rangle\langle 101|,\end{aligned}$$

projecting onto the four two-dimensional subspaces of $(\mathbb{C}^2)^{\otimes 3}$ on which the parity pattern is constant.

Proposition 39.16.1

If at most one bit flip has occurred, the syndrome (s_1, s_2) identifies which qubit was affected, and the encoded state is undisturbed by the measurement.

Proof. Write $\mathcal{C} = \text{span}\{|000\rangle, |111\rangle\}$ for the code space. The four error operators I, X_1, X_2, X_3 map $\mathcal{C}$ into the four subspaces

$$\mathcal{C}, \quad \text{span}\{|100\rangle, |011\rangle\}, \quad \text{span}\{|010\rangle, |101\rangle\}, \quad \text{span}\{|001\rangle, |110\rangle\},$$

which are mutually orthogonal and are exactly the ranges of $\Pi_{00}, \Pi_{10}, \Pi_{11}, \Pi_{01}$ respectively. So the syndrome measurement determines which of the four occurred; and since the corrupted state $X_j(a|000\rangle + b|111\rangle)$ lies *entirely* inside one of these subspaces, the corresponding projector acts on it as the identity. The state is therefore not disturbed at all, and in particular the superposition coefficients a, b – which we do not know and must not learn – are untouched. Applying X_j to the indicated qubit restores the encoded state. $\square$

That deals with objections (i) and (ii). Objection (iii), the continuum of possible errors, is dealt with by an argument of striking elegance.

Proposition 39.16.2 (Discretisation of Errors)

Suppose the noise acts on the first qubit by an arbitrary operator, which we may expand in the Pauli basis as $E = c_0I + c_1X + c_2Y + c_3Z$. If the code can correct each of I, X, Y, Z on that qubit, then measuring the syndrome projects the corrupted

state onto one of the correctable cases, which we then correct exactly.

Proof idea. Since $\{I, X, Y, Z\}$ spans the space of one-qubit operators, the corrupted state $E_1 |\psi_L\rangle$ is a superposition of the four states $|\psi_L\rangle, X_1 |\psi_L\rangle, Y_1 |\psi_L\rangle, Z_1 |\psi_L\rangle$. If these lie in mutually orthogonal syndrome subspaces, then the syndrome measurement collapses the superposition onto exactly one of them, with the corresponding probability, and we correct it. A continuous error has been *digitised* by the act of measurement. $\square$

The proposition is the reason the whole enterprise is possible. It says that we do not have to fight a continuum: we need only design a code which handles the three Pauli errors on each qubit, and the syndrome measurement will digitise everything else for us. Quantum error correction is therefore, in the end, a discrete combinatorial problem, much like its classical counterpart.

§39.16.2 The Phase-Flip Code

The three-qubit code corrects X errors only. A Z error on any of the three qubits sends $a|000\rangle + b|111\rangle$ to $a|000\rangle - b|111\rangle$, which lies in the code space, produces the syndrome 00, and is therefore invisible; and it is a genuine error, since it takes $|+_L\rangle$ to $|-_L\rangle$.

But a phase flip is a bit flip in disguise. Since $HZH = X$, conjugating everything by $H^{\otimes 3}$ turns Z errors into X errors, and the code

$$|0_L\rangle = |+++\rangle, \quad |1_L\rangle = |--\rangle$$

corrects an arbitrary single Z error, by running the previous analysis in the conjugate basis. Concretely, one encodes with the same two CNOTs followed by a Hadamard on each of the three qubits, and the syndrome measurement extracts the two parities of the $\pm$ labels, which amounts to measuring the observables X_1X_2 and X_2X_3 rather than Z_1Z_2 and Z_2Z_3 . This code, of course, is now blind to X errors: $X|+\rangle = |+\rangle$, so a bit flip on any qubit does nothing detectable, and indeed nothing at all.

Neither code alone is any use against general noise. The way out is to use both at once.

§39.16.3 Shor's Nine-Qubit Code

Definition 39.16.3 (Shor Code)

The **Shor nine-qubit code** encodes one qubit into nine by

$$\begin{aligned} |0_L\rangle &= \frac{1}{2\sqrt{2}} (|000\rangle + |111\rangle) \otimes (|000\rangle + |111\rangle) \otimes (|000\rangle + |111\rangle), \\ |1_L\rangle &= \frac{1}{2\sqrt{2}} (|000\rangle - |111\rangle) \otimes (|000\rangle - |111\rangle) \otimes (|000\rangle - |111\rangle). \end{aligned}$$

The structure is a **concatenation**: take the phase-flip code $|0\rangle \mapsto |+++\rangle, |1\rangle \mapsto |--\rangle$, and then encode each of its three qubits using the bit-flip code, replacing $|\pm\rangle$ by $\frac{1}{\sqrt{2}}(|000\rangle \pm |111\rangle)$. The encoding circuit is correspondingly two-layered: two CNOTs spread the data qubit across three blocks, a Hadamard on each block leader creates the $|\pm\rangle$ superpositions, and two further CNOTs inside each block expand $|0\rangle, |1\rangle$ to $|000\rangle, |111\rangle$.

Theorem 39.16.4

The Shor code corrects an arbitrary error on any single one of the nine qubits.

Proof. By the discretisation proposition it is enough to correct X , Y and Z on each qubit, and since $Y = iXZ$ up to a phase it is enough to handle X and Z separately.

An X error on some qubit lies inside one block. Measuring the parities Z_1Z_2 and Z_2Z_3 *within each block*, which is six syndrome bits in all, identifies both the affected block and the affected qubit inside it, exactly as in §39.16.1: each block carries a state of the form $\alpha|000\rangle + \beta|111\rangle$. Note that these measurements reveal nothing about α and β , and so nothing about the encoded qubit.

A Z error on any qubit of a block has the same effect on that block, namely to negate the relative sign of $|000\rangle$ and $|111\rangle$; so at the level of the outer code it is a single phase flip on one of the three ‘logical’ qubits $|\pm\rangle$. Measuring the outer syndrome – the two observables comparing the signs of blocks 1,2 and blocks 2,3, that is, $X_1 \cdots X_6$ and $X_4 \cdots X_9$ – identifies which block was affected, and applying Z to any one qubit of that block repairs it.

Since the two syndromes commute and address disjoint information, both can be measured, and an error which is simultaneously a bit flip and a phase flip on one qubit (that is, a Y) is corrected by correcting each part. Finally, an arbitrary single-qubit error is a linear combination of I, X, Y, Z on that qubit, and the syndrome measurement collapses it onto one of the four correctable cases. $\square$

Remark. Nine qubits is not optimal: the five-qubit code achieves the same thing, and one can show that five is the minimum. Modern codes are described in the [stabiliser](#) formalism, where a code space is specified as the joint $+1$ eigenspace of a commuting family of Pauli operators – for the Shor code, the six operators Z_1Z_2, Z_2Z_3 within blocks and the two operators $X_1 \cdots X_6, X_4 \cdots X_9$ across blocks. Syndrome extraction is then just measurement of the stabiliser generators, and the whole theory acquires a pleasantly algebraic flavour, closely parallel to the theory of linear codes in Part II Coding and Cryptography.

§39.16.4 Fault Tolerance

We have been assuming that encoding, syndrome extraction and correction are themselves error-free, which is absurd: the correction circuitry is built from the same faulty components as everything else, and a single faulty gate in a syndrome extraction can spread an error onto several data qubits at once. A **fault-tolerant** construction is one designed so that this does not happen – so that a single fault anywhere produces at most one error per encoded block, which the code can then remove. Given such a construction, one may concatenate: encode each qubit of a code in another copy of the code, and repeat. If a block fails only when two of its constituents fail, then an error rate p at one level becomes something like Cp^2 at the next, and iterating ℓ times gives $(Cp)^{2^\ell}/C$, which tends to zero rapidly provided $p < 1/C$. That threshold behaviour is the content of the following.

Theorem 39.16.5 (Threshold Theorem)

There is a constant $p_{\text{th}} > 0$ such that, if the physical error rate per gate is below p_{th} , then any quantum circuit of size T can be simulated with error at most ε by a fault-tolerant circuit of size $O(T \text{ poly} \log(T/\varepsilon))$.

This is the reason anyone believes large-scale quantum computing to be possible in principle. It says that error correction is not a losing battle – once the hardware is good enough, concatenating codes suppresses errors faster than the extra machinery introduces them, and the overhead is only polylogarithmic.

§39.17 Closing Remarks

Let us take stock of what quantum mechanics has bought us.

Impossibility. Non-orthogonal states cannot be reliably distinguished (§39.2.3); unknown states cannot be cloned (§39.3.2); measurement at a distance cannot signal (§39.3.4). These are not engineering limitations but theorems, and each follows from linearity and unitarity in a few lines.

New protocols. Entanglement lets us send two classical bits down one qubit (§39.6) and one qubit down two classical bits (§39.7), and lets us distribute cryptographic keys whose security rests on physics rather than on computational assumptions (§39.8). None of these is possible classically.

New algorithms. Superposition, phase kickback and interference give exact one-query solutions to Deutsch and Deutsch–Jozsa (§39.11), an exponential bounded-error separation in Simon’s problem (§39.11.4), polynomial-time factoring via period-finding and the quantum Fourier transform (§39.13), and a provably optimal quadratic speedup for unstructured search (§39.14).

And what quantum mechanics does not buy us. A quantum computer computes exactly the same functions as a classical one; the difference is only in efficiency, and even there we have no *proof* of a separation, only very strong evidence. Grover’s bound tells us that generic search cannot do better than quadratic, so NP-complete problems are almost certainly not going to fall. And every protocol we have seen respects relativistic causality: nothing here travels faster than a classical message.

Perhaps the deepest lesson is Landauer's: *information is physical*. The theory of computation is not a branch of pure mathematics floating free of the world, but a description of what physical systems can be made to do. Change the physics and you change the theory. It is a striking thought that the answer to 'what is efficiently computable?' should depend on the correct theory of nature – and a slightly unsettling one that we do not yet know the final answer to either question.

40 Representation Theory

Groups are, in the end, a way of talking about symmetry. But a group presented abstractly – as a set with a multiplication table, or as generators and relations – is a slippery thing to get hold of. Representation theory takes the view that the way to understand a group is to watch it *act*, and the most tractable things a group can act on are vector spaces. A representation is exactly that: a group acting by invertible linear maps. Once we are in the world of linear algebra we can bring the whole toolbox – eigenvalues, traces, direct sums, tensor products – to bear on questions that started out being about groups.

The astonishing thing, and the thing that makes this course so satisfying, is how much information survives when we throw away almost everything. To each representation we attach its **character**, a single complex-valued function on the group recording only the trace of each group element. This looks like a hopeless loss of information, and yet over $\mathbb{C}$ the character determines the representation completely. The characters of the irreducible representations satisfy beautiful orthogonality relations, they can be assembled into a finite square array called the character table, and that little table encodes a remarkable amount about the group. We will use it to prove Burnside's theorem, that every group of order $p^a q^b$ is soluble – a purely group-theoretic statement for which no purely group-theoretic proof was known for decades.

This article constitutes my notes for the 'Representation Theory' course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§40.1 Representations

§40.1.1 Some Preliminaries

Before we begin properly, it is worth being clear about what we are assuming, since this course sits right on top of *Linear Algebra* and *Groups, Rings and Modules*.

Throughout, ‘vector space’ means a *finite dimensional* vector space unless we say otherwise. Our base field will be written F or k , and although a fair amount of what we do works over any field, the theory only becomes really clean when F is algebraically closed of characteristic zero. So the reader should keep $F = \mathbb{C}$ firmly in mind: essentially every theorem with any content in this course is a theorem about complex representations.

Recall from linear algebra that if V is a vector space over F , then

$$\mathrm{GL}(V) = \{\alpha : V \rightarrow V \mid \alpha \text{ is linear and invertible}\}$$

is a group under composition, the **general linear group** of V . If $\dim V = n$ then a choice of basis $e_1, \dots, e_n$ identifies V with F^n and hence identifies $\mathrm{GL}(V)$ with the group $\mathrm{GL}_n(F)$ of invertible $n \times n$ matrices over F . Changing basis changes the identification by conjugation: if α has matrix A in one basis and A' in another, then $A' = P^{-1}AP$ for the change of basis matrix P . This is worth saying out loud now, because *everything* in this course is invariant under conjugation, and that is not a coincidence.

We will need one more piece of linear algebra constantly.

Proposition 40.1.1 (Diagonalisability)

Let $\alpha \in \mathrm{GL}(V)$ with V a finite dimensional $\mathbb{C}$ -vector space, and suppose $\alpha^m = \mathrm{id}$ for some $m \geq 1$. Then α is diagonalisable.

Proof. The polynomial $X^m - 1$ annihilates α , and over $\mathbb{C}$ it factors as $\prod_{j=0}^{m-1} (X - \omega^j)$ where $\omega = e^{2\pi i/m}$, which has no repeated roots. A linear map is diagonalisable if and only if its minimal polynomial splits into distinct linear factors, and the minimal polynomial divides $X^m - 1$, so we are done. $\square$

In particular, if g is an element of a finite group and α is the linear map by which g acts, then α is diagonalisable, with eigenvalues roots of unity. This single observation is responsible for a surprising amount of what follows.

There is also a version for several maps at once, whose proof the reader has essentially seen in *Linear Algebra* when simultaneously diagonalising commuting operators.

Proposition 40.1.2 (Simultaneous diagonalisation)

Let $\alpha, \beta \in \mathrm{GL}(V)$ be diagonalisable, with V a $\mathbb{C}$ -vector space. If $\alpha\beta = \beta\alpha$, then there is a basis of V in which α and β are both diagonal.

Proof. Write $V = \bigoplus_{\lambda} V_{\lambda}$ as a sum of eigenspaces of α . If $v \in V_{\lambda}$ then $\alpha(\beta v) = \beta(\alpha v) = \lambda\beta v$, so β preserves each V_{λ} . Now $\beta|_{V_{\lambda}}$ is diagonalisable (its minimal polynomial divides that of β , which has distinct linear factors), so pick an eigenbasis of β on each V_{λ} and put them together. $\square$

On the group theory side, recall that an **action** of a group G on a set X is a map $G \times X \rightarrow X$, written $(g, x) \mapsto g \cdot x$, satisfying $e \cdot x = x$ and $g \cdot (h \cdot x) = (gh) \cdot x$. Equivalently – and this is the point of view we want – an action of G on X is precisely a group homomorphism $G \rightarrow \text{Sym}(X)$, the group of all bijections $X \rightarrow X$.

Recall also that the **conjugacy class** of $g \in G$ is

$$\text{ccl}_G(g) = \{xgx^{-1} \mid x \in G\},$$

that these classes partition G , and that by the orbit–stabiliser theorem $|\text{ccl}_G(g)| = |G : C_G(g)|$ where $C_G(g) = \{x \in G \mid xg = gx\}$ is the centraliser. Conjugacy classes will play the role for us that ‘points’ play elsewhere, so here is a picture to fix ideas.

The moral of the course, stated far too early, is that the natural ‘coordinates’ on a group are indexed by its conjugacy classes, and the natural ‘functions’ in those coordinates are the irreducible characters. There will be exactly as many of the latter as the former.

§40.1.2 Definitions and First Examples

We now come to the central definition. Since an action of G on a set is a homomorphism into $\text{Sym}(X)$, and since a vector space is a set with extra structure, the right thing to do is to replace Sym by GL .

Definition 40.1.3 (Representation)

Let G be a group and V a vector space over F . A **representation** of G on V is a group homomorphism

$$\rho : G \rightarrow \text{GL}(V).$$

We call V the **representation space**, and we write the representation as the pair (ρ, V) , or often just as ρ or just as V when the rest is clear.

Unwinding the definition of homomorphism, giving a representation is the same as giving, for each $g \in G$, a linear map $\rho(g) : V \rightarrow V$ such that $\rho(e) = \text{id}_V$ and $\rho(gh) = \rho(g)\rho(h)$ for all $g, h \in G$. Note that invertibility comes for free from these two conditions, since $\rho(g)\rho(g^{-1}) = \rho(e) = \text{id}_V$; so we may as well only ask for linear maps.

Definition 40.1.4 (Degree)

The **degree** (or **dimension**) of a representation (ρ, V) is $\dim_F V$.

Definition 40.1.5 (Faithful representation)

A representation ρ is **faithful** if $\ker \rho = \{e\}$, i.e. if ρ is injective.

A faithful representation realises G concretely as a group of matrices, which is often exactly what one wants. Non-faithful representations are not a defect, though; they are how the theory sees the normal subgroups of G .

Everything is much clearer with examples, so let us collect a good supply now. Almost all of these will reappear repeatedly.

Example 40.1.6 (The trivial representation)

For any group G and any vector space V , the map $\rho(g) = \text{id}_V$ for all g is a representation. When $V = F$ is one dimensional this is called **the** trivial representation, and we write it $\mathbf{1}$ or $\mathbf{1}_G$. It is faithful only when G is trivial.

Example 40.1.7 (Representations of a cyclic group)

Let $G = C_m = \langle g \rangle$ be cyclic of order m , and let V be a $\mathbb{C}$ -vector space. A representation of G is determined by $\alpha = \rho(g) \in \text{GL}(V)$, and the only constraint is $\alpha^m = \text{id}$. So representations of C_m on V correspond exactly to elements of $\text{GL}(V)$ of order dividing m .

By our proposition above, such an α is diagonalisable, so there is a basis in which

$$\rho(g) = \begin{pmatrix} \omega^{a_1} & & \\ & \ddots & \\ & & \omega^{a_n} \end{pmatrix}, \quad \omega = e^{2\pi i/m}$$

for some $a_1, \dots, a_n$. So every representation of C_m breaks up into one-dimensional pieces $g \mapsto \omega^a$. We will see this is a special case of a general theorem.

Example 40.1.8 (Dihedral groups)

Let $D_{2n} = \langle r, s \mid r^n = s^2 = e, srs^{-1} = r^{-1} \rangle$ be the symmetry group of a regular n -gon. There is an obvious representation on $\mathbb{R}^2$ (and hence on $\mathbb{C}^2$): let r act by rotation through $2\pi/n$ and s by reflection in the x -axis, so

$$\rho(r) = \begin{pmatrix} \cos \frac{2\pi}{n} & -\sin \frac{2\pi}{n} \\ \sin \frac{2\pi}{n} & \cos \frac{2\pi}{n} \end{pmatrix}, \quad \rho(s) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

One checks the relations hold, and ρ is faithful. This is the representation you should picture whenever D_{2n} comes up.

The dashed lines are the n axes of reflection; r rotates by $2\pi/n$ and each reflection swaps the two half-planes cut out by its axis.

Example 40.1.9 (Symmetric groups on the standard space)

Let $G = S_n$ act on $V = F^n$ with basis $e_1, \dots, e_n$ by permuting coordinates:

$$\rho(\sigma)(e_i) = e_{\sigma(i)}.$$

Extending linearly gives a representation of degree n ; the matrix of $\rho(\sigma)$ is the permutation matrix of σ . It is faithful.

Example 40.1.10 (The sign representation)

Let $G = S_n$ and $V = F$, with $\rho(\sigma) = \text{sign}(\sigma)$. This is a one-dimensional representation, not faithful for $n \geq 3$ (its kernel is A_n).

Two more constructions deserve to be called out because they will be with us for the whole course.

Definition 40.1.11 (Permutation representation)

Let G act on a finite set X . Let FX be the F -vector space with basis $\{e_x \mid x \in X\}$, so $\dim FX = |X|$. Then

$$\rho(g) \left(\sum_{x \in X} \lambda_x e_x \right) = \sum_{x \in X} \lambda_x e_{g \cdot x}$$

defines a representation of G , the **permutation representation** associated to the action.

Definition 40.1.12 (Regular representation)

Taking $X = G$ with G acting on itself by left multiplication gives the **regular representation** of G , on the vector space FG of dimension $|G|$.

The regular representation is always faithful (if $g \neq e$ then $g \cdot e = g \neq e$, so $\rho(g) \neq \text{id}$), which already tells us something: *every* finite group has a faithful representation, so every finite group is isomorphic to a group of matrices. We will see later that FG is much more than a bookkeeping device – it contains every irreducible representation of G , each with multiplicity equal to its degree.

§40.1.3 Equivalence of Representations

The representation of S_3 on $\mathbb{C}^3$ by permutation matrices, and the ‘same’ representation written in a different basis, should not be counted as different. We need to say when two representations are the same.

Definition 40.1.13 (G -homomorphism)

Let (ρ, V) and (ρ', V') be representations of G over F . A linear map $\varphi : V \rightarrow V'$ is a **G -homomorphism** (or is **G -linear**, or **intertwines** ρ and ρ') if

$$\varphi \circ \rho(g) = \rho'(g) \circ \varphi \quad \text{for all } g \in G.$$

We write $\text{Hom}_G(V, V')$ for the set of all such maps.

The condition says exactly that the square

$$\begin{array}{ccc} V & \xrightarrow{\rho(g)} & V \\ \varphi \downarrow & & \downarrow \varphi \\ V' & \xrightarrow{\rho'(g)} & V' \end{array}$$

commutes for every g . Note that $\text{Hom}_G(V, V')$ is an F -subspace of $\text{Hom}_F(V, V')$, since the condition is linear in φ .

Definition 40.1.14 (Isomorphism of representations)

We say (ρ, V) and (ρ', V') are **isomorphic** (or **equivalent**), written $V \cong V'$, if there is a G -homomorphism $\varphi : V \rightarrow V'$ which is a linear isomorphism.

If φ is such an isomorphism then $\rho'(g) = \varphi \rho(g) \varphi^{-1}$, so at the level of matrices, isomorphism of representations of the same degree n means: there is a single $P \in \text{GL}_n(F)$ with $R'(g) = P R(g) P^{-1}$ for all g , where R, R' are the matrix representations. In other words, isomorphism is ‘simultaneous change of basis’. It is straightforward to check that this is an equivalence relation.

Remark. Note the ‘simultaneous’ – one matrix P must work for every g at once. Two representations can have $\rho(g)$ conjugate to $\rho'(g)$ for each individual g and still fail to be isomorphic.

Example 40.1.15

Any two one-dimensional representations $\rho, \rho' : G \rightarrow \text{GL}_1(F) = F^\times$ are isomorphic if and only if they are *equal*, since $\text{GL}_1(F)$ is abelian and conjugation does nothing.

§40.1.4 Representations as Modules

There is a second, slicker way of packaging all this, which the reader will recognise from *Groups, Rings and Modules*. It is worth setting up because it makes several later constructions obvious.

Definition 40.1.16 (Group algebra)

Let G be a finite group and F a field. The **group algebra** FG is the F -vector space with basis $\{g \mid g \in G\}$, that is

$$FG = \left\{ \sum_{g \in G} \lambda_g g \mid \lambda_g \in F \right\},$$

equipped with the multiplication extending the group multiplication bilinearly:

$$\left(\sum_g \lambda_g g \right) \left(\sum_h \mu_h h \right) = \sum_{g,h} \lambda_g \mu_h (gh).$$

This makes FG into a ring (indeed an F -algebra) of dimension $|G|$ over F , with identity the element $1 \cdot e$. It is commutative precisely when G is abelian.

Proposition 40.1.17

Let G be a finite group. There is a bijective correspondence between representations of G over F and FG -modules, under which a representation (ρ, V) corresponds to the module structure

$$\left(\sum_g \lambda_g g \right) \cdot v = \sum_g \lambda_g \rho(g)(v).$$

Under this correspondence, G -homomorphisms correspond to FG -module homomorphisms, and isomorphism of representations to isomorphism of modules.

Proof. Given (ρ, V) , the displayed formula is well defined and one checks the module axioms directly: F -bilinearity is built in, and associativity $(ab)v = a(bv)$ reduces by bilinearity to the case $a = g$, $b = h$ basis elements, where it is $\rho(gh) = \rho(g)\rho(h)$.

Conversely, given an FG -module V , restricting scalars along $F \hookrightarrow FG$ makes V an F -vector space, and $\rho(g) : v \mapsto g \cdot v$ is F -linear with $\rho(g)\rho(g^{-1}) = \text{id}$, so $\rho(g) \in \text{GL}(V)$; and $\rho(gh) = \rho(g)\rho(h)$ by associativity. These two constructions are mutually inverse.

Finally, a linear map $\varphi : V \rightarrow V'$ satisfies $\varphi(g \cdot v) = g \cdot \varphi(v)$ for all g if and only if it satisfies $\varphi(a \cdot v) = a \cdot \varphi(v)$ for all $a \in FG$, by linearity. $\square$

Remark. We insist that our FG -modules are finite dimensional over F , matching our convention on representations. The regular representation is precisely FG regarded as a module over itself.

From now on we will use the two languages interchangeably, saying ‘ V is a G -space’ or ‘ V is a $\mathbb{C}G$ -module’ or ‘ V is a representation of G ’ as convenient, and writing gv for $\rho(g)(v)$.

§40.1.5 Subrepresentations and Irreducibility**Definition 40.1.18** (Subrepresentation)

Let (ρ, V) be a representation of G . A subspace $W \leq V$ is **G -invariant** (or is a **subrepresentation**, or a **G -subspace**) if $\rho(g)(W) \subseteq W$ for all $g \in G$.

If W is G -invariant then in fact $\rho(g)(W) = W$ for each g , since $\rho(g^{-1})(W) \subseteq W$ gives the reverse inclusion. So ρ restricts to a representation $\rho|_W : G \rightarrow \mathrm{GL}(W)$. In module language, subrepresentations are exactly FG -submodules.

Every representation has the **trivial** subrepresentations 0 and V . The interesting question is whether there are any others.

Definition 40.1.19 (Irreducible)

A representation (ρ, V) is **irreducible** (or **simple**) if $V \neq 0$ and the only G -invariant subspaces of V are 0 and V .

Example 40.1.20

Every one-dimensional representation is irreducible, since it has no nonzero proper subspaces at all.

Example 40.1.21 (The standard representation of S_n)

Let $V = \mathbb{C}^n$ carry the permutation action of S_n . This is *not* irreducible for $n \geq 2$: the line

$$U = \langle e_1 + e_2 + \cdots + e_n \rangle$$

is fixed pointwise by every σ , so is a subrepresentation isomorphic to the trivial representation. Its complement

$$W = \left\{ \sum_i \lambda_i e_i \mid \sum_i \lambda_i = 0 \right\}$$

is also G -invariant, of dimension $n - 1$; it is called the **standard representation** of S_n . We have $V = U \oplus W$. We will prove later (using characters, in about two lines) that W is irreducible.

Example 40.1.22 (A reducible but indecomposable representation)

Irreducibility is genuinely sensitive to the ground field. Let $G = C_p = \langle g \rangle$ and let $F = \mathbb{F}_p$. Define a representation on F^2 by

$$\rho(g^k) = \begin{pmatrix} 1 & k \\ 0 & 1 \end{pmatrix}.$$

This is a homomorphism since the matrices multiply by adding the top-right entries, and $\rho(g^p) = I$ as $p \equiv 0$. The subspace $\langle e_1 \rangle$ is invariant, so ρ is reducible. But it has *no* invariant complement: any invariant line would give an eigenvector of $\rho(g)$ other than a multiple of e_1 , and $\rho(g)$ has 1 as its only eigenvalue with a one-dimensional eigenspace.

So over $\mathbb{F}_p$ things can go wrong. The next section shows that over $\mathbb{C}$ (or any field whose characteristic does not divide $|G|$) they never do.

Definition 40.1.23 (Direct sums)

If (ρ_1, V_1) and (ρ_2, V_2) are representations of G , their **direct sum** is the representation on $V_1 \oplus V_2$ given by $g \cdot (v_1, v_2) = (gv_1, gv_2)$. In matrix terms, choosing bases of V_1 and V_2 and concatenating,

$$\rho(g) = \begin{pmatrix} \rho_1(g) & 0 \\ 0 & \rho_2(g) \end{pmatrix}.$$

Definition 40.1.24 (Completely reducible)

A representation is **completely reducible** (or **semisimple**) if it is a direct sum of irreducible subrepresentations.

Here is the picture to have in mind. If $V = V_1 \oplus \cdots \oplus V_k$ with each V_i irreducible, then in a suitable basis every matrix $\rho(g)$ is block diagonal with blocks of sizes $\dim V_i$, *simultaneously for all g* :

$$\rho(g) = \begin{array}{|c|c|c|c|} \hline \rho_1 & & & \\ \hline & \rho_2 & & 0 \\ \hline & & \rho_3 & \\ \hline & 0 & & \rho_4 \\ \hline \end{array}$$

block sizes $\dim V_1, \dots, \dim V_k$

Complete reducibility says that we can always reduce to this shape, and so the problem of understanding all representations of G splits into two: find the irreducible ones, and find how a given representation decomposes. The first is the hard and interesting part.

Definition 40.1.25 (Decomposable)

A representation V is **decomposable** if $V = V_1 \oplus V_2$ for nonzero subrepresentations V_1, V_2 , and **indecomposable** otherwise.

Irreducible implies indecomposable, always. The example over $\mathbb{F}_p$ above is indecomposable but not irreducible; the content of Maschke's theorem is that over $\mathbb{C}$ the two notions coincide.

Example 40.1.26 (Quotients)

If $W \leq V$ is a subrepresentation then the quotient space V/W carries a representation, $g(v+W) = gv+W$, which is well defined precisely because W is invariant. This is the **quotient representation**. If $V = W \oplus U$ as representations then $V/W \cong U$.

§40.1.6 Representations of Abelian Groups

Let us do one complete classification straight away, since it is easy and instructive.

Proposition 40.1.27

Let G be a finite abelian group and let $\rho : G \rightarrow \mathrm{GL}(V)$ be a representation over $\mathbb{C}$. Then there is a basis of V in which every $\rho(g)$ is diagonal.

Proof. Each $\rho(g)$ has finite order, hence is diagonalisable. The maps $\{\rho(g)\}_{g \in G}$ pairwise commute since G is abelian. Now induct on $|G|$ using simultaneous diagonalisation: diagonalise $\rho(g_1)$, then $\rho(g_2)$ preserves each of its eigenspaces, and so on. $\square$

Corollary 40.1.28

Every irreducible complex representation of a finite abelian group is one-dimensional.

Proof. In the basis given by the proposition, every coordinate line is G -invariant. So if $\dim V > 1$ then V has a proper nonzero invariant subspace. $\square$

We will see in due course that the converse holds too: if every irreducible complex representation of G is one-dimensional then G is abelian. This is our first hint that the representation theory really does remember the group.

Example 40.1.29 (C_m , completely)

The irreducible complex representations of $C_m = \langle g \rangle$ are exactly the m degree-one representations

$$\rho_j : g^k \mapsto \omega^{jk}, \quad \omega = e^{2\pi i/m}, \quad j = 0, 1, \dots, m-1,$$

and these are pairwise non-isomorphic. Note there are m of them, and C_m has m conjugacy classes.

Example 40.1.30 ($C_2 \times C_2$)

The Klein four-group $V_4 = \{e, a, b, ab\}$ has four one-dimensional representations, determined by the four choices of $(\rho(a), \rho(b)) \in \{\pm 1\}^2$. Again: four irreducibles, four conjugacy classes.

§40.2 Complete Reducibility and Maschke's Theorem

The example over $\mathbb{F}_p$ in the last section was worrying: a representation which is reducible but which cannot be broken up. Maschke's theorem says this cannot happen in the situation we care about. It is the theorem that makes the whole course work.

Theorem 40.2.1 (Maschke's Theorem)

Let G be a finite group and let V be a representation of G over a field F with

$\text{char } F \nmid |G|$ (for instance $F = \mathbb{C}$). If $W \leq V$ is a subrepresentation, then there is a subrepresentation $U \leq V$ with

$$V = W \oplus U.$$

Before proving it, let us see why the hypothesis matters, and what the idea is. The obstruction is that W certainly has *some* vector space complement; the issue is whether we can choose one which is G -invariant. The trick, which we will use again and again, is **averaging over the group**: take any complement, take the projection onto W along it, and average that projection over G to make it G -linear. Averaging requires dividing by $|G|$, and that is exactly where the characteristic hypothesis is used.

Proof. Choose any vector space complement W' of W in V , and let $\pi : V \rightarrow W$ be the corresponding projection: so $\pi(v) = v$ for $v \in W$, and $\ker \pi = W'$. There is no reason for π to be G -linear. Define $\tilde{\pi} : V \rightarrow V$ by

$$\tilde{\pi}(v) = \frac{1}{|G|} \sum_{g \in G} g \pi(g^{-1}v).$$

This makes sense because $|G|$ is invertible in F . We claim $\tilde{\pi}$ is a G -linear projection onto W .

It is linear, being a sum of composites of linear maps.

Its image lies in W : each term $g\pi(g^{-1}v)$ lies in $gW = W$, as W is G -invariant.

It restricts to the identity on W : if $w \in W$ then $g^{-1}w \in W$, so $\pi(g^{-1}w) = g^{-1}w$, so $g\pi(g^{-1}w) = w$. Averaging $|G|$ copies of w gives w .

It is G -linear: for $h \in G$ and $v \in V$,

$$\tilde{\pi}(hv) = \frac{1}{|G|} \sum_{g \in G} g \pi(g^{-1}hv) = \frac{1}{|G|} \sum_{g' \in G} hg' \pi(g'^{-1}v) = h \tilde{\pi}(v),$$

where we substituted $g = hg'$, which is a bijection of G as g ranges over G .

Now set $U = \ker \tilde{\pi}$. This is a subrepresentation, since $\tilde{\pi}$ is G -linear: if $\tilde{\pi}(v) = 0$ then $\tilde{\pi}(gv) = g\tilde{\pi}(v) = 0$. Finally, because $\tilde{\pi}$ is a projection onto W we have $\tilde{\pi}^2 = \tilde{\pi}$ and $V = \text{img } \tilde{\pi} \oplus \ker \tilde{\pi} = W \oplus U$, using $v = \tilde{\pi}(v) + (v - \tilde{\pi}(v))$. $\square$

Over $\mathbb{C}$ there is a second proof which is arguably more memorable, and which will generalise to compact groups in the last section of these notes. It is due to Weyl and is usually called the **unitary trick**. Recall from *Linear Algebra* that a Hermitian inner product on a complex vector space V is a map $\langle \cdot, \cdot \rangle : V \times V \rightarrow \mathbb{C}$, linear in the second variable, with $\langle w, v \rangle = \overline{\langle v, w \rangle}$ and $\langle v, v \rangle > 0$ for $v \neq 0$.

Definition 40.2.2 (G -invariant inner product)

An inner product on a representation V of G is **G -invariant** if $\langle gv, gw \rangle = \langle v, w \rangle$ for all $g \in G$ and $v, w \in V$.

Lemma 40.2.3 (Weyl's unitary trick)

Let G be finite and V a complex representation of G . Then V carries a G -invariant

Hermitian inner product. Equivalently, there is a basis of V in which every $\rho(g)$ is a unitary matrix, i.e. $\rho(G) \leq U(V)$.

Proof. Take any Hermitian inner product $(\cdot, \cdot)$ on V – for instance, choose a basis and use the standard one – and average:

$$\langle v, w \rangle = \frac{1}{|G|} \sum_{g \in G} (gv, gw).$$

Sesquilinearity and Hermitian symmetry are inherited termwise. Positive definiteness holds because $\langle v, v \rangle = \frac{1}{|G|} \sum_g (gv, gv)$ is a sum of positive terms when $v \neq 0$. And for $h \in G$,

$$\langle hv, hw \rangle = \frac{1}{|G|} \sum_g (ghv, ghw) = \frac{1}{|G|} \sum_{g'} (g'v, g'w) = \langle v, w \rangle$$

by reindexing $g' = gh$. Choosing an orthonormal basis for $\langle \cdot, \cdot \rangle$ (Gram–Schmidt) makes each $\rho(g)$ unitary. $\square$

Second proof of Maschke’s theorem over $\mathbb{C}$. Equip V with a G -invariant inner product and let $U = W^\perp$. This is a complement to W as a vector space, and it is G -invariant: if $u \in W^\perp$, $w \in W$ and $g \in G$, then

$$\langle w, gu \rangle = \langle g^{-1}w, u \rangle = 0$$

since $g^{-1}w \in W$. So $gu \in W^\perp$. $\square$

The reader should notice that both proofs are the same idea wearing different clothes: average something over G to make it G -equivariant. Almost every construction in this course is an instance of this.

Corollary 40.2.4 (Complete reducibility)

Let G be finite and F a field of characteristic not dividing $|G|$. Then every representation of G over F is a direct sum of irreducible representations.

Proof. Induct on $\dim V$. If $V = 0$ this is the empty direct sum, and if V is irreducible we are done. Otherwise V has a subrepresentation $0 \neq W \leq V$, and by Maschke $V = W \oplus U$ with U a subrepresentation. Both W and U have strictly smaller dimension than V , so by induction each decomposes into irreducibles, and concatenating gives the result. $\square$

Corollary 40.2.5

For G finite and $\text{char } F \nmid |G|$, a representation is irreducible if and only if it is indecomposable.

Remark. Both hypotheses are needed. Finiteness of G matters: the representation of $(\mathbb{Z}, +)$ on $\mathbb{C}^2$ with $n \mapsto \begin{pmatrix} 1 & n \\ 0 & 1 \end{pmatrix}$ is reducible but indecomposable. And the characteristic hypothesis matters, as our C_p over $\mathbb{F}_p$ example shows. The study of the failing case is

modular representation theory and is much harder; we shall stay firmly over $\mathbb{C}$.

Remark (Standing convention). From this point on, unless we explicitly say otherwise, G is a *finite* group and all representations are *finite dimensional over $\mathbb{C}$* . We will relax the finiteness of G only in the final section, on topological groups.

§40.3 Schur's Lemma

Maschke tells us that every representation is built from irreducibles. Schur's lemma tells us how the irreducible pieces interact, and it is astonishingly simple.

Theorem 40.3.1 (Schur's Lemma)

Let V, W be irreducible complex representations of a group G .

- (i) Any G -homomorphism $\varphi : V \rightarrow W$ is either 0 or an isomorphism.
- (ii) Any G -endomorphism $\varphi : V \rightarrow V$ is a scalar multiple of the identity, $\varphi = \lambda \text{id}_V$.

Proof. (i) Let $\varphi \in \text{Hom}_G(V, W)$. Then $\ker \varphi$ is a subrepresentation of V : if $\varphi(v) = 0$ then $\varphi(gv) = g\varphi(v) = 0$. Similarly $\text{img } \varphi$ is a subrepresentation of W . Since V is irreducible, $\ker \varphi$ is 0 or V ; since W is irreducible, $\text{img } \varphi$ is 0 or W . If $\varphi \neq 0$ then $\ker \varphi \neq V$, so $\ker \varphi = 0$, and $\text{img } \varphi \neq 0$, so $\text{img } \varphi = W$. Hence φ is bijective, and its inverse is automatically G -linear.

(ii) Here we use that we are over $\mathbb{C}$: the map φ has an eigenvalue λ , since $\mathbb{C}$ is algebraically closed and $V \neq 0$ is finite dimensional. Then $\varphi - \lambda \text{id}_V$ is a G -homomorphism $V \rightarrow V$ (as id_V certainly is one) with nonzero kernel, so by (i) it is not an isomorphism, hence it is 0. $\square$

Remark. Part (i) works over any field, and indeed for modules over any ring: it says simple modules admit no interesting maps between them. Part (ii) genuinely needs $\mathbb{C}$ algebraically closed. Over $\mathbb{R}$, the rotation representation of C_n on $\mathbb{R}^2$ ($n \geq 3$) is irreducible and its endomorphism algebra is $\mathbb{C}$, not $\mathbb{R}$.

The following restatement is often the most useful form.

Corollary 40.3.2

For irreducible complex representations V, W of G ,

$$\dim_{\mathbb{C}} \text{Hom}_G(V, W) = \begin{cases} 1 & \text{if } V \cong W, \\ 0 & \text{otherwise.} \end{cases}$$

Proof. If $V \not\cong W$ then by (i) every G -homomorphism is zero. If $V \cong W$, fix an isomorphism $\theta : V \rightarrow W$. For any $\varphi \in \text{Hom}_G(V, W)$ the composite $\theta^{-1}\varphi \in \text{End}_G(V)$ is a scalar λ by (ii), so $\varphi = \lambda\theta$. Hence $\text{Hom}_G(V, W) = \mathbb{C}\theta$ is one dimensional. $\square$

Schur's lemma has immediate structural consequences for the group itself.

Corollary 40.3.3

Let G be a finite abelian group. Then every irreducible complex representation of G has degree 1.

Proof. Let V be irreducible and $h \in G$. Then $\rho(h) : V \rightarrow V$ is G -linear, since $\rho(h)\rho(g) = \rho(hg) = \rho(gh) = \rho(g)\rho(h)$. So $\rho(h) = \lambda_h \text{id}_V$ by Schur. But then *every* subspace of V is G -invariant, so irreducibility forces $\dim V = 1$. $\square$

This is our earlier result again, but the proof is better, and it generalises.

Proposition 40.3.4

Let $\rho : G \rightarrow \text{GL}(V)$ be an irreducible complex representation. Then $\rho(z)$ is a scalar for every $z \in Z(G)$. In particular, if ρ is faithful then $Z(G)$ is cyclic.

Proof. The first statement is the argument above applied to $z \in Z(G)$. For the second, ρ restricted to $Z(G)$ lands in the scalars $\mathbb{C}^\times$, so $\rho|_{Z(G)} : Z(G) \rightarrow \mathbb{C}^\times$ is an injective homomorphism (using faithfulness), realising $Z(G)$ as a finite subgroup of $\mathbb{C}^\times$. Every finite subgroup of $\mathbb{C}^\times$ is cyclic (it consists of roots of unity), so $Z(G)$ is cyclic. $\square$

Corollary 40.3.5

The group $G = C_2 \times C_2 \times \cdots$ – or indeed any finite group with non-cyclic centre, such as $D_8 \times C_2$ – has no faithful irreducible complex representation.

Here is a nice application which shows the theory has teeth even at this early stage.

Example 40.3.6

The quaternion group Q_8 has centre $\{\pm 1\} \cong C_2$, which is cyclic, and indeed it does have a faithful irreducible representation – the two-dimensional one we shall meet later. By contrast the Klein four-group $C_2 \times C_2$ is its own centre, which is not cyclic, so the proposition says it has *no* faithful irreducible representation. And indeed all four of its irreducibles have degree 1, and each of them kills a subgroup of order 2.

So already, before we have computed a single character, the theory rules out certain shapes of representation on purely group-theoretic grounds.

§40.3.1 Isotypic Decomposition

Maschke says $V = V_1 \oplus \cdots \oplus V_k$ with V_i irreducible. But is this decomposition unique? Not literally: if V is the trivial representation of any group on $\mathbb{C}^2$, then *every* pair of distinct lines gives a decomposition. What is unique is the multiset of isomorphism classes, and there is a canonical coarser decomposition which is genuinely unique.

Proposition 40.3.7

Let V be a complex representation of the finite group G and let S be an irreducible

representation. If

$$V \cong \bigoplus_{i=1}^k V_i$$

with each V_i irreducible, then the number of i with $V_i \cong S$ equals $\dim \operatorname{Hom}_G(S, V)$, and in particular does not depend on the chosen decomposition.

Proof. The functor $\operatorname{Hom}_G(S, -)$ takes finite direct sums to direct sums: a map into $\bigoplus V_i$ is the same as a tuple of maps into the V_i . So

$$\operatorname{Hom}_G(S, V) \cong \bigoplus_{i=1}^k \operatorname{Hom}_G(S, V_i),$$

which by Schur's lemma has dimension equal to $\#\{i : V_i \cong S\}$. $\square$

Definition 40.3.8 (Multiplicity)

The number above is the **multiplicity** of S in V . We write $V \cong \bigoplus_S S^{\oplus n_S}$ where n_S is the multiplicity, the sum over isomorphism classes of irreducibles.

Definition 40.3.9 (Isotypic component)

The **S -isotypic component** of V is the sum of all subrepresentations of V isomorphic to S . It is a subrepresentation isomorphic to $S^{\oplus n_S}$, and unlike the individual summands it is canonically determined by V and S .

Picking bases adapted to an isotypic decomposition puts every $\rho(g)$ into the following shape, with the *same* block repeated within each isotypic component.

We can also read off, from Schur's lemma, exactly how big the space of self-maps is.

Proposition 40.3.10

If $V \cong \bigoplus_S S^{\oplus n_S}$ then $\dim \operatorname{End}_G(V) = \sum_S n_S^2$. In particular V is irreducible if and

only if $\dim \text{End}_G(V) = 1$.

Proof. Expand $\text{Hom}_G(\bigoplus_S S^{\oplus n_S}, \bigoplus_T T^{\oplus n_T})$ into a double sum and apply Schur; this gives $\sum_S n_S^2$. If the answer is 1 then exactly one n_S is 1 and the rest vanish, so $V \cong S$ is irreducible; the converse is Schur. $\square$

This is a genuinely useful irreducibility criterion, and it is the shadow of the character-theoretic criterion $\langle \chi, \chi \rangle = 1$ that we will meet shortly.

Finally, let us record what Schur says about the regular representation, since it foreshadows the main counting theorem.

Proposition 40.3.11

Let V be a representation of the finite group G and let S be irreducible. Then the multiplicity of S in the regular representation $\mathbb{C}G$ is $\dim S$.

Proof. By the multiplicity formula it suffices to show $\dim \text{Hom}_G(\mathbb{C}G, S) = \dim S$. Now a $\mathbb{C}G$ -module homomorphism $\varphi : \mathbb{C}G \rightarrow S$ is determined by $\varphi(e) \in S$, since $\varphi(g) = \varphi(g \cdot e) = g\varphi(e)$ and the g span $\mathbb{C}G$; and conversely any choice of $\varphi(e) = s \in S$ gives a well defined homomorphism $\sum \lambda_g g \mapsto \sum \lambda_g gs$. So $\text{Hom}_G(\mathbb{C}G, S) \cong S$ as vector spaces. $\square$

Corollary 40.3.12

If $S_1, \dots, S_r$ are the distinct irreducible complex representations of G , with $d_i = \dim S_i$, then

$$\mathbb{C}G \cong \bigoplus_{i=1}^r S_i^{\oplus d_i}, \quad \text{and hence} \quad |G| = \sum_{i=1}^r d_i^2.$$

Proof. The first statement is the proposition, once we know that every irreducible appears – which it does, with multiplicity $d_i \geq 1$. Comparing dimensions gives $|G| = \sum_i d_i \cdot \dim S_i = \sum d_i^2$. $\square$

We have implicitly used that there are only finitely many irreducibles; this follows since each appears in $\mathbb{C}G$, which is finite dimensional. This identity $|G| = \sum d_i^2$ is one of the two great numerical constraints on the character table – the other being that r is the number of conjugacy classes. It is remarkably effective: for example, if $|G| = 8$ then the only possibilities for the multiset $\{d_i\}$ with all $d_i \geq 1$ and at least one $d_i = 1$ (the trivial representation) are $\{1, 1, 1, 1, 1, 1, 1, 1\}$ and $\{1, 1, 1, 1, 2\}$.

§40.4 Character Theory

We now come to the heart of the course. The idea is almost absurdly reductive: given a representation $\rho : G \rightarrow \text{GL}(V)$, throw away everything about $\rho(g)$ except its trace. What is left is a function $G \rightarrow \mathbb{C}$, and it turns out to remember the representation completely.

Why should the trace be the right thing to keep? Because it is the simplest invariant of

a linear map which does not depend on a choice of basis, and isomorphic representations differ exactly by a choice of basis.

§40.4.1 Characters

Definition 40.4.1 (Character)

Let (ρ, V) be a representation of G over $\mathbb{C}$. The **character** of ρ is the function

$$\chi_V = \chi_\rho : G \rightarrow \mathbb{C}, \quad \chi_\rho(g) = \operatorname{tr} \rho(g),$$

where the trace is that of the matrix of $\rho(g)$ in any basis. The **degree** of χ is $\chi(e) = \dim V$.

Definition 40.4.2 (Irreducible and linear characters)

A character is **irreducible** if it is the character of an irreducible representation. It is **linear** if it has degree 1; equivalently, if $\rho : G \rightarrow \mathbb{C}^\times$ is a homomorphism.

Since we will spend the rest of the course computing with characters, we had better establish their basic properties. Every single one of the following is used constantly.

Proposition 40.4.3 (Basic properties)

Let (ρ, V) be a complex representation of a finite group G , with character χ . Then:

- (i) $\chi(e) = \dim V$.
- (ii) χ is a **class function**: $\chi(hgh^{-1}) = \chi(g)$ for all $g, h \in G$.
- (iii) Isomorphic representations have equal characters.
- (iv) For each g , $\chi(g)$ is a sum of $\dim V$ roots of unity; specifically, if g has order n then $\chi(g)$ is a sum of n -th roots of unity.
- (v) $\chi(g^{-1}) = \overline{\chi(g)}$.
- (vi) $|\chi(g)| \leq \chi(e)$, with equality if and only if $\rho(g)$ is a scalar.
- (vii) $\chi(g) = \chi(e)$ if and only if $g \in \ker \rho$.

Proof. (i) $\rho(e) = \operatorname{id}_V$, whose trace is $\dim V$.

(ii) $\operatorname{tr}(\rho(h)\rho(g)\rho(h)^{-1}) = \operatorname{tr} \rho(g)$, since trace is invariant under conjugation.

(iii) If φ is an isomorphism with $\rho'(g) = \varphi\rho(g)\varphi^{-1}$, take traces.

(iv) The element $\rho(g)$ satisfies $\rho(g)^n = \operatorname{id}$, so it is diagonalisable with eigenvalues $\lambda_1, \dots, \lambda_d$ ($d = \dim V$) satisfying $\lambda_i^n = 1$, and $\chi(g) = \sum \lambda_i$.

(v) With notation as in (iv), $\rho(g^{-1}) = \rho(g)^{-1}$ has eigenvalues $\lambda_i^{-1} = \overline{\lambda_i}$ (as $|\lambda_i| = 1$). So $\chi(g^{-1}) = \sum \overline{\lambda_i} = \overline{\chi(g)}$.

(vi) By the triangle inequality $|\chi(g)| = |\sum \lambda_i| \leq \sum |\lambda_i| = d = \chi(e)$. Equality in the triangle inequality for complex numbers of modulus 1 forces all λ_i to be equal, say to λ ; and then $\rho(g) = \lambda \operatorname{id}_V$ since $\rho(g)$ is diagonalisable.

(vii) If $g \in \ker \rho$ then $\rho(g) = \text{id}$ so $\chi(g) = d$. Conversely if $\chi(g) = d$ then equality holds in (vi), so $\rho(g) = \lambda \text{id}$ with $d\lambda = d$, giving $\lambda = 1$. $\square$

Property (vii) is the reason non-faithful representations are useful: characters detect kernels, so from the character table we can read off all the normal subgroups of G . We will come back to this.

Proposition 40.4.4

If V, W are representations of G then $\chi_{V \oplus W} = \chi_V + \chi_W$.

Proof. In a basis adapted to the decomposition, $\rho(g)$ is block diagonal with blocks $\rho_V(g)$ and $\rho_W(g)$, and the trace of a block diagonal matrix is the sum of the traces of its blocks. $\square$

So characters of representations are exactly the nonnegative integer combinations of irreducible characters. Such things are sometimes called *proper* characters, or just characters; $\mathbb{Z}$ -linear combinations of irreducible characters are called **virtual characters** or **generalised characters**.

Example 40.4.5 (The regular character)

Let π_{reg} be the character of the regular representation $\mathbb{C}G$. In the basis $\{e_g\}$, the matrix of $\rho(h)$ is the permutation matrix of left multiplication by h , and its trace counts the g with $hg = g$. So

$$\pi_{\text{reg}}(g) = \begin{cases} |G| & g = e, \\ 0 & g \neq e. \end{cases}$$

Example 40.4.6 (Permutation characters)

More generally, if G acts on a finite set X and $\mathbb{C}X$ is the associated permutation representation, then the matrix of $\rho(g)$ has (x, x) entry 1 exactly when $g \cdot x = x$, and so

$$\pi_X(g) = |\text{fix}_X(g)| = |\{x \in X : g \cdot x = x\}|.$$

This is an extremely convenient supply of characters, since counting fixed points is easy.

Example 40.4.7

Take $G = S_4$ acting on $X = \{1, 2, 3, 4\}$. Then π_X takes the values 4, 2, 0, 1 and 0 on the classes of e , (12) , $(12)(34)$, (123) and (1234) respectively.

§40.4.2 Class Functions and the Inner Product

Definition 40.4.8 (Class function)

A **class function** on G is a function $f : G \rightarrow \mathbb{C}$ which is constant on conjugacy classes. The set of class functions is written $\mathcal{C}(G)$.

$\mathcal{C}(G)$ is a $\mathbb{C}$ -vector space under pointwise operations, and it has an obvious basis: the indicator functions $\delta_{\mathcal{K}}$ of the conjugacy classes $\mathcal{K}$. So

$$\dim_{\mathbb{C}} \mathcal{C}(G) = \#\{\text{conjugacy classes of } G\} =: r.$$

Characters are class functions, so all the characters of G live in this one r -dimensional space – already a strong constraint, and the source of everything that follows.

We make $\mathcal{C}(G)$ into an inner product space in the natural way.

Definition 40.4.9 (Inner product of class functions)

For $f, f' \in \mathcal{C}(G)$ define

$$\langle f, f' \rangle = \frac{1}{|G|} \sum_{g \in G} \overline{f(g)} f'(g).$$

This is a Hermitian inner product (linear in the second slot, conjugate-linear in the first, and positive definite since $\langle f, f \rangle = \frac{1}{|G|} \sum |f(g)|^2$). If we group the sum by conjugacy classes with representatives $g_1, \dots, g_r$, it becomes

$$\langle f, f' \rangle = \sum_{j=1}^r \frac{|\text{ccl}_G(g_j)|}{|G|} \overline{f(g_j)} f'(g_j) = \sum_{j=1}^r \frac{\overline{f(g_j)} f'(g_j)}{|\text{C}_G(g_j)|},$$

using $|\text{ccl}_G(g)| \cdot |\text{C}_G(g)| = |G|$. This is the form we use in practice.

Remark. If f, f' are *characters*, then $\overline{f(g)} = f(g^{-1})$, so

$$\langle f, f' \rangle = \frac{1}{|G|} \sum_{g \in G} f(g^{-1}) f'(g),$$

which is visibly symmetric in f and f' . So on characters the inner product is symmetric and we need not fret about which slot is conjugated.

§40.4.3 The Orthogonality Relations

We now prove the central theorem of the course. The strategy is to identify $\langle \chi_V, \chi_W \rangle$ with $\dim \text{Hom}_G(V, W)$, and then apply Schur's lemma. Two lemmas do the work.

Lemma 40.4.10 (Fixed points)

Let V be a representation of G with character χ , and let

$$V^G = \{v \in V \mid gv = v \text{ for all } g \in G\}$$

be the subspace of G -invariant vectors. Then

$$\dim V^G = \frac{1}{|G|} \sum_{g \in G} \chi(g).$$

Proof. Consider

$$\pi = \frac{1}{|G|} \sum_{g \in G} \rho(g) \in \text{End}(V).$$

First, $\text{img } \pi \subseteq V^G$: for $h \in G$,

$$\rho(h)\pi = \frac{1}{|G|} \sum_g \rho(hg) = \frac{1}{|G|} \sum_{g'} \rho(g') = \pi,$$

reindexing. Second, $\pi|_{V^G} = \text{id}$: if $v \in V^G$ then every $\rho(g)v = v$, and we average $|G|$ copies of v .

Together these give $\pi^2 = \pi$, so π is a projection with image V^G . A projection is diagonalisable with eigenvalues 0 and 1, and the multiplicity of the eigenvalue 1 is $\dim \text{img } \pi$. Hence

$$\dim V^G = \text{tr } \pi = \frac{1}{|G|} \sum_g \text{tr } \rho(g) = \frac{1}{|G|} \sum_g \chi(g). \quad \square$$

Lemma 40.4.11 (The Hom representation)

Let V, W be representations of G . Then $\text{Hom}_{\mathbb{C}}(V, W)$ becomes a representation of G via

$$(g \cdot \varphi)(v) = g \varphi(g^{-1}v),$$

and

- (i) $\text{Hom}_{\mathbb{C}}(V, W)^G = \text{Hom}_G(V, W)$;
- (ii) its character is $\chi_{\text{Hom}(V, W)}(g) = \overline{\chi_V(g)} \chi_W(g)$.

Proof. That this is a representation is a direct check: $(e \cdot \varphi) = \varphi$, and

$$(g \cdot (h \cdot \varphi))(v) = g(h \cdot \varphi)(g^{-1}v) = gh \varphi(h^{-1}g^{-1}v) = ((gh) \cdot \varphi)(v).$$

(i) We have $g \cdot \varphi = \varphi$ for all g if and only if $g\varphi(g^{-1}v) = \varphi(v)$ for all g, v , if and only if $\varphi(g^{-1}v) = g^{-1}\varphi(v)$ for all g, v , which is exactly G -linearity.

(ii) Fix $g \in G$. Both $\rho_V(g)$ and $\rho_W(g)$ are diagonalisable, so choose eigenbases $v_1, \dots, v_n$ of V and $w_1, \dots, w_m$ of W with $gv_i = \lambda_i v_i$ and $gw_j = \mu_j w_j$, where all λ_i, μ_j are roots of unity. Let $\varphi_{ij} \in \text{Hom}(V, W)$ be defined by $\varphi_{ij}(v_k) = \delta_{ik} w_j$; these nm maps form a basis. Then

$$(g \cdot \varphi_{ij})(v_k) = g \varphi_{ij}(\lambda_k^{-1} v_k) = \lambda_k^{-1} \delta_{ik} g w_j = \lambda_i^{-1} \mu_j \varphi_{ij}(v_k),$$

so φ_{ij} is an eigenvector with eigenvalue $\lambda_i^{-1} \mu_j = \overline{\lambda_i} \mu_j$. Summing,

$$\chi_{\text{Hom}(V, W)}(g) = \sum_{i,j} \overline{\lambda_i} \mu_j = \left(\sum_i \overline{\lambda_i} \right) \left(\sum_j \mu_j \right) = \overline{\chi_V(g)} \chi_W(g). \quad \square$$

Putting these together gives the key identity.

Theorem 40.4.12

For any representations V, W of the finite group G ,

$$\langle \chi_V, \chi_W \rangle = \dim_{\mathbb{C}} \operatorname{Hom}_G(V, W).$$

Proof. Apply the fixed point lemma to the representation $\operatorname{Hom}_{\mathbb{C}}(V, W)$:

$$\dim \operatorname{Hom}_G(V, W) = \dim \operatorname{Hom}_{\mathbb{C}}(V, W)^G = \frac{1}{|G|} \sum_{g \in G} \chi_{\operatorname{Hom}(V, W)}(g),$$

and the last expression is $\frac{1}{|G|} \sum_g \overline{\chi_V(g)} \chi_W(g) = \langle \chi_V, \chi_W \rangle$. $\square$

Theorem 40.4.13 (Row orthogonality)

Let $\chi_1, \dots, \chi_r$ be the characters of the distinct (i.e. pairwise non-isomorphic) irreducible complex representations $S_1, \dots, S_r$ of the finite group G . Then

$$\langle \chi_i, \chi_j \rangle = \delta_{ij}.$$

That is, the irreducible characters are orthonormal in $\mathcal{C}(G)$.

Proof. Immediate from the previous theorem and Schur's lemma, which says that $\dim \operatorname{Hom}_G(S_i, S_j)$ is 1 if $i = j$, and is 0 otherwise. $\square$

That is the whole proof, and it is worth appreciating how little it needed: averaging (Maschke's idea), a trace computation, and Schur. Written out in coordinates the statement is

$$\frac{1}{|G|} \sum_{g \in G} \overline{\chi_i(g)} \chi_j(g) = \sum_{k=1}^r \frac{\overline{\chi_i(g_k)} \chi_j(g_k)}{|C_G(g_k)|} = \delta_{ij},$$

a system of $\binom{r+1}{2}$ equations relating the entries of the character table. In practice these equations are so restrictive that they often determine the entire table.

Remark. There is a more computational proof, which is the one Frobenius gave. One takes an arbitrary linear map $\psi : S_i \rightarrow S_j$, averages it to $\tilde{\psi} = \frac{1}{|G|} \sum_g \rho_j(g) \psi \rho_i(g)^{-1}$, applies Schur to $\tilde{\psi}$, and then reads off matrix entries. It gives the same relations, with more index-pushing and less insight; the reader may enjoy carrying it out.

§40.4.4 Consequences of Orthogonality

The corollaries come thick and fast. Throughout, $\chi_1, \dots, \chi_r$ are the irreducible characters of G .

Corollary 40.4.14

The irreducible characters are linearly independent in $\mathcal{C}(G)$. In particular $r \leq \#\{\text{conjugacy classes}\}$, so G has only finitely many irreducible representations up to isomorphism.

Proof. Orthonormal sets are linearly independent, and $\dim \mathcal{C}(G)$ is the number of conjugacy classes. $\square$

Corollary 40.4.15 (Decomposition)

Let V be a representation with character χ , and write $V \cong \bigoplus_i S_i^{\oplus n_i}$. Then

$$\chi = \sum_i n_i \chi_i, \quad n_i = \langle \chi_i, \chi \rangle = \langle \chi, \chi_i \rangle.$$

Proof. Characters add over direct sums, giving the first formula; then take the inner product with χ_i and use orthonormality. (The two expressions for n_i agree because n_i is real.) $\square$

It is worth taking this geometrically, because that is really all that is going on. The space $\mathcal{C}(G)$ is an r -dimensional inner product space, and the irreducible characters are an orthonormal basis of it. A character χ is then just a vector, its multiplicities are its coordinates, and the coordinates are extracted – as always in an inner product space – by taking inner products with the basis vectors.

$$\langle \chi, \chi \rangle = \sum_i n_i^2, \text{ and } \chi \text{ is irreducible exactly when this is } 1$$

Corollary 40.4.16 (Characters determine representations)

Two complex representations of a finite group are isomorphic if and only if they have the same character.

Proof. One direction we knew. Conversely, if $\chi_V = \chi_W$ then the multiplicities $n_i = \langle \chi_i, \chi_V \rangle = \langle \chi_i, \chi_W \rangle$ agree for every i , and a representation is determined up to isomorphism by its multiplicities. $\square$

This is a genuinely surprising statement. A representation of G of degree d is a huge amount of data – $|G|$ matrices of size $d \times d$ – and it is all encoded in r complex numbers.

Corollary 40.4.17 (Irreducibility criterion)

A representation V with character χ is irreducible if and only if $\langle \chi, \chi \rangle = 1$.

Proof. Writing $\chi = \sum n_i \chi_i$, orthonormality gives $\langle \chi, \chi \rangle = \sum_i n_i^2$. Since the n_i are nonnegative integers, this equals 1 if and only if exactly one n_i is 1 and the rest are 0, i.e. $V \cong S_i$ is irreducible. $\square$

This is the workhorse of the whole subject: to check irreducibility we compute a single number.

Example 40.4.18 (The standard representation of S_n is irreducible)

Let π be the permutation character of S_n on $\{1, \dots, n\}$, so $\pi(\sigma) = |\text{fix}(\sigma)|$. By Burnside's lemma (orbit counting),

$$\langle \pi, \mathbf{1} \rangle = \frac{1}{|G|} \sum_{\sigma} |\text{fix}(\sigma)| = \#\{\text{orbits}\} = 1,$$

and

$$\langle \pi, \pi \rangle = \frac{1}{|G|} \sum_{\sigma} |\text{fix}(\sigma)|^2 = \#\{\text{orbits of } S_n \text{ on } \{1, \dots, n\}^2\} = 2$$

for $n \geq 2$ (the diagonal, and its complement). Since $\pi = \mathbf{1} + \chi$ where χ is the character of the standard representation, we get

$$2 = \langle \pi, \pi \rangle = \langle \mathbf{1} + \chi, \mathbf{1} + \chi \rangle = 1 + 2\langle \mathbf{1}, \chi \rangle + \langle \chi, \chi \rangle = 1 + \langle \chi, \chi \rangle,$$

using $\langle \mathbf{1}, \chi \rangle = \langle \mathbf{1}, \pi \rangle - 1 = 0$. So $\langle \chi, \chi \rangle = 1$ and the standard representation is irreducible, of degree $n - 1$.

Remark. The computation above works verbatim for any **2-transitive** action of a group G on a set X : ‘2-transitive’ means G acts transitively on ordered pairs of distinct elements, which is exactly the statement that there are two orbits on $X \times X$. So for any 2-transitive action, $\pi_X - \mathbf{1}$ is an irreducible character of degree $|X| - 1$. This gives irreducible characters for free for S_n , A_n ($n \geq 4$), $\text{PGL}_2(\mathbb{F}_q)$ acting on the projective line, and many others.

§40.4.5 Counting the Irreducibles

We know $r \leq \#\{\text{conjugacy classes}\}$. We now show equality, which is the second great numerical constraint.

Theorem 40.4.19

The irreducible characters $\chi_1, \dots, \chi_r$ form an orthonormal *basis* of $\mathcal{C}(G)$. Consequently, the number of irreducible complex representations of G equals the number of conjugacy classes of G .

Proof. We already know they are orthonormal, so it suffices to show that the only class function orthogonal to all of them is 0.

So let $f \in \mathcal{C}(G)$ with $\langle f, \chi_i \rangle = 0$ for all i . For any representation (ρ, V) define

$$\varphi_f = \sum_{g \in G} \overline{f(g)} \rho(g) \in \text{End}(V).$$

We claim φ_f is G -linear. Indeed, for $h \in G$,

$$\varphi_f \rho(h) = \sum_g \overline{f(g)} \rho(gh) = \sum_k \overline{f(kh^{-1})} \rho(k),$$

$$\rho(h) \varphi_f = \sum_g \overline{f(g)} \rho(hg) = \sum_k \overline{f(h^{-1}k)} \rho(k),$$

substituting $k = gh$ and $k = hg$ respectively. But f is a class function, so

$$f(kh^{-1}) = f(h^{-1}(kh^{-1})h) = f(h^{-1}k),$$

and the two expressions agree.

Now take $V = S_i$ irreducible, of degree d_i . By Schur, $\varphi_f = \lambda \text{id}$ for some $\lambda \in \mathbb{C}$, and taking traces,

$$d_i \lambda = \text{tr } \varphi_f = \sum_g \overline{f(g)} \chi_i(g) = |G| \langle f, \chi_i \rangle = 0,$$

so $\lambda = 0$ and $\varphi_f = 0$ on every irreducible representation. By complete reducibility, $\varphi_f = 0$ on *every* representation of G .

Apply this to the regular representation $V = \mathbb{C}G$, and evaluate at the basis vector e :

$$0 = \varphi_f(e) = \sum_{g \in G} \overline{f(g)} g.$$

The elements $g \in G$ are a basis of $\mathbb{C}G$, so $\overline{f(g)} = 0$ for every g , i.e. $f = 0$. $\square$

Corollary 40.4.20

A finite group G is abelian if and only if all its irreducible complex representations have degree 1.

Proof. We proved ‘only if’ earlier. Conversely, if all $d_i = 1$ then $|G| = \sum_i d_i^2 = r$, so G has $|G|$ conjugacy classes, meaning every class is a singleton, meaning every element is central. $\square$

§40.4.6 The Character Table

We can now assemble everything into the object which gives the subject its computational character.

Definition 40.4.21 (Character table)

Let G have conjugacy classes with representatives $g_1 = e, g_2, \dots, g_r$ and irreducible characters $\chi_1 = \mathbf{1}, \chi_2, \dots, \chi_r$. The **character table** of G is the $r \times r$ matrix

$$X = (\chi_i(g_j))_{1 \leq i, j \leq r}.$$

By convention we list the trivial character first and the identity class first, and we record the class sizes $|\text{ccl}_G(g_j)|$ (or the centraliser orders) alongside.

It is a square matrix – that is the content of the counting theorem – and it satisfies two orthogonality relations, one for rows and one for columns. Schematically:

	e	g_2	g_3	$\dots$	g_r	
χ_1						$\left. \begin{array}{l} \text{rows, weighted by } \text{ccl}(g_j) : \\ \langle \chi_i, \chi_k \rangle = \delta_{ik} \end{array} \right\}$
χ_2						
$\vdots$						
χ_r						

columns: $\sum_i \overline{\chi_i(g_j)} \chi_i(g_k) = \delta_{jk} |C_G(g_j)|$

Let us prove the column relation. It is a formal consequence of the row relation, by a small piece of matrix algebra.

Theorem 40.4.22 (Column orthogonality)

With notation as above, for any $1 \leq j, k \leq r$,

$$\sum_{i=1}^r \overline{\chi_i(g_j)} \chi_i(g_k) = \delta_{jk} |C_G(g_j)|.$$

In particular, taking $j = k = 1$ recovers $\sum_i d_i^2 = |G|$.

Proof. Let D be the diagonal matrix whose entries are $D_{jj} = |\text{ccl}_G(g_j)|/|G| = 1/|C_G(g_j)|$. Then row orthogonality says

$$\delta_{ik} = \langle \chi_k, \chi_i \rangle = \sum_j \frac{\overline{\chi_k(g_j)} \chi_i(g_j)}{|C_G(g_j)|} = (XD\overline{X}^T)_{ik},$$

so $XD\overline{X}^T = I$. Thus X is a square invertible matrix, with inverse $X^{-1} = D\overline{X}^T$, and therefore $X^{-1}X = I$ as well:

$$I = D\overline{X}^T X, \quad \text{i.e.} \quad \delta_{jk} = \frac{1}{|C_G(g_j)|} \sum_i \overline{\chi_i(g_j)} \chi_i(g_k),$$

which rearranges to the claim. □

Corollary 40.4.23

Taking $j = k$, for every $g \in G$ we have $\sum_i |\chi_i(g)|^2 = |C_G(g)|$.

Column orthogonality is enormously useful in practice: it lets us fill in a missing row or column of a character table once the rest is known, and it provides an independent check on every table we compute. Whenever the reader writes down a character table, they should verify:

- (i) the table is square, with $r = \text{number of conjugacy classes}$;
- (ii) $\sum_i d_i^2 = |G|$;
- (iii) each row has $\langle \chi_i, \chi_i \rangle = 1$ and distinct rows are orthogonal;

(iv) each column j satisfies $\sum_i |\chi_i(g_j)|^2 = |\mathbf{C}_G(g_j)| = |G|/|\text{ccl}(g_j)|$.

All of the tables in these notes have been checked against all four.

Corollary 40.4.24

Let $g \in G$ with $g \neq e$. Then $\sum_i d_i \chi_i(g) = 0$.

Proof. This is column orthogonality applied to the columns of e and of g , using $\chi_i(e) = d_i$; alternatively, it says $\pi_{\text{reg}}(g) = 0$, which we computed directly. $\square$

§40.4.7 First Character Tables

Let us put the machinery to work.

Example 40.4.25 (Cyclic groups)

Let $G = C_m = \langle g \rangle$. Every element is its own conjugacy class, so $r = m$, and all irreducibles have degree 1 since G is abelian. Indeed $\sum_{i=1}^m d_i^2 = m$ forces every $d_i = 1$. The characters are $\chi_j(g^k) = \omega^{jk}$ with $\omega = e^{2\pi i/m}$. For $m = 4$, with $i = \sqrt{-1}$:

	e	g	g^2	g^3
χ_0	1	1	1	1
χ_1	1	i	-1	$-i$
χ_2	1	-1	1	-1
χ_3	1	$-i$	-1	i

Every centraliser is all of G , of order 4, and indeed every column has $\sum_i |\chi_i(g^k)|^2 = 4$. Rows are orthogonal because $\sum_{k=0}^3 \omega^{(j-j')k} = 0$ for $j \neq j'$ – the character table of a cyclic group is (a scalar multiple of) the discrete Fourier transform matrix.

Example 40.4.26 (S_3)

The group S_3 has order 6 and three conjugacy classes, with representatives e , (12) and (123) , of sizes 1, 3, 2. So there are three irreducible characters with $d_1^2 + d_2^2 + d_3^2 = 6$; since $d_i \geq 1$ and at least one $d_i = 1$, the only solution is $\{1, 1, 2\}$.

We know two of the degree-1 characters already: the trivial character and the sign character. The degree-2 character is that of the standard representation, which we showed is irreducible; its character is $\pi - \mathbf{1}$ where π is the permutation character $\pi = (3, 1, 0)$. So $\chi_3 = (2, 0, -1)$. Alternatively, column orthogonality determines the last row up to a scalar of modulus one.

class size	1	3	2
	e	$(1\ 2)$	$(1\ 2\ 3)$
1	1	1	1
sign	1	-1	1
χ_3	2	0	-1

Let us verify. Degrees: $1 + 1 + 4 = 6 = |S_3|$. Rows: $\langle \chi_3, \chi_3 \rangle = \frac{1}{6}(1 \cdot 4 + 3 \cdot 0 + 2 \cdot 1) = \frac{6}{6} = 1$; $\langle \mathbf{1}, \chi_3 \rangle = \frac{1}{6}(2 + 0 - 2) = 0$; $\langle \mathbf{1}, \text{sign} \rangle = \frac{1}{6}(1 - 3 + 2) = 0$; $\langle \text{sign}, \chi_3 \rangle = \frac{1}{6}(2 - 0 - 2) = 0$. Columns: $1 + 1 + 4 = 6 = |C(e)|$; $1 + 1 + 0 = 2 = |C((1\ 2))| = 6/3$; $1 + 1 + 1 = 3 = |C((1\ 2\ 3))| = 6/2$. Everything checks out.

Example 40.4.27 (Recovering a row)

Suppose we know that a group G of order 12 has four conjugacy classes, of sizes 1, 3, 4, 4, and that three of its irreducible characters are $(1, 1, 1, 1)$, $(1, 1, \omega, \omega^2)$ and $(1, 1, \omega^2, \omega)$, where $\omega = e^{2\pi i/3}$. Then the degrees satisfy $1 + 1 + 1 + d_4^2 = 12$, so $d_4 = 3$; and column orthogonality against the first column gives, for the class of size 3,

$$1 \cdot 1 + 1 \cdot 1 + 1 \cdot 1 + 3\chi_4(g_2) = 0 \implies \chi_4(g_2) = -1,$$

and similarly $1 + \omega^2 + \omega + 3\chi_4(g_3) = 0$ gives $\chi_4(g_3) = 0$, and likewise $\chi_4(g_4) = 0$. The group, of course, is A_4 ; we will meet it again.

§40.5 Permutation Representations and Normal Subgroups

Before building more representations by algebraic means, let us extract everything we can from the ones we get for free – those coming from actions on sets – and see how the character table detects the normal subgroup structure of G .

§40.5.1 Permutation Characters

Recall that an action of G on a finite set X gives the permutation representation $\mathbb{C}X$, with character $\pi_X(g) = |\text{fix}_X(g)|$.

Proposition 40.5.1

Let G act on the finite set X , with permutation character π_X .

- (i) $\langle \pi_X, \mathbf{1} \rangle$ is the number of orbits of G on X .
- (ii) $\langle \pi_X, \pi_X \rangle$ is the number of orbits of G on $X \times X$.
- (iii) If $|X| \geq 2$ and G is transitive on X , then $\pi_X - \mathbf{1}$ is a character of degree $|X| - 1$; it is irreducible if and only if G is 2-transitive on X .

Proof. (i) This is Burnside's orbit-counting lemma: $\langle \pi_X, \mathbf{1} \rangle = \frac{1}{|G|} \sum_g |\text{fix}(g)|$, which is the number of orbits.

(ii) The permutation character of the action on $X \times X$ is $\pi_{X \times X}(g) = |\text{fix}_{X \times X}(g)| =$

$|\text{fix}_X(g)|^2 = \pi_X(g)^2$. Since π_X is real valued, $\langle \pi_X, \pi_X \rangle = \langle \pi_{X \times X}, \mathbf{1} \rangle$, and we apply (i).

(iii) By (i), transitivity gives $\langle \pi_X, \mathbf{1} \rangle = 1$, so $\mathbf{1}$ occurs exactly once in π_X and $\chi := \pi_X - \mathbf{1}$ is a character (of an actual representation, namely the complement of the fixed line $\langle \sum_x e_x \rangle$). Then

$$\langle \chi, \chi \rangle = \langle \pi_X, \pi_X \rangle - 2\langle \pi_X, \mathbf{1} \rangle + 1 = \langle \pi_X, \pi_X \rangle - 1,$$

which equals 1 exactly when G has two orbits on $X \times X$. Since the diagonal is always one orbit, and its complement is a single orbit precisely when G is 2-transitive, we are done. $\square$

Example 40.5.2 (S_n and A_n)

S_n is 2-transitive on $\{1, \dots, n\}$ for $n \geq 2$, and A_n is 2-transitive for $n \geq 4$. So both have an irreducible character of degree $n - 1$, the standard character.

Example 40.5.3 (Two-orbit tricks)

Let $G = S_4$ act on the set X of $\binom{4}{2} = 6$ unordered pairs from $\{1, 2, 3, 4\}$. Then $\pi_X = (6, 2, 2, 0, 0)$ on the classes $e, (1\ 2), (1\ 2)(3\ 4), (1\ 2\ 3), (1\ 2\ 3\ 4)$ – for instance $(1\ 2)$ fixes the pairs $\{1, 2\}$ and $\{3, 4\}$. Then

$$\langle \pi_X, \pi_X \rangle = \frac{1}{24}(36 + 6 \cdot 4 + 3 \cdot 4 + 0 + 0) = \frac{72}{24} = 3,$$

so π_X is a sum of three distinct irreducibles (or has some other decomposition with $\sum n_i^2 = 3$, which forces three distinct constituents). Since $\langle \pi_X, \mathbf{1} \rangle = \frac{1}{24}(6 + 12 + 6) = 1$, one of them is trivial. This is a good source of characters, and we will use it when building the table of S_4 .

§40.5.2 Lifting Characters

Non-faithful representations of G are really representations of quotients of G , and this is a two-way street.

Proposition 40.5.4 (Lifting)

Let $N \trianglelefteq G$ with quotient map $q : G \rightarrow G/N$. Then

$$\tilde{\rho} \mapsto \rho := \tilde{\rho} \circ q$$

is a bijection between representations of G/N and representations of ρ of G with $N \leq \ker \rho$. It preserves irreducibility, direct sums and isomorphism, and on characters it is $\chi(g) = \tilde{\chi}(gN)$.

Proof. If $\tilde{\rho} : G/N \rightarrow \text{GL}(V)$ is a representation then $\rho = \tilde{\rho} \circ q$ is a composite of homomorphisms, hence a representation of G , with $N \leq \ker \rho$. Conversely if ρ is a representation of G with $N \leq \ker \rho$ then ρ factors uniquely through q by the universal property of quotient groups. The two constructions are mutually inverse.

A subspace is $\rho(G)$ -invariant if and only if it is $\tilde{\rho}(G/N)$ -invariant, since $\rho(G) = \tilde{\rho}(G/N)$ as subgroups of $\text{GL}(V)$; so irreducibility is preserved. The character statement is immediate from $\rho(g) = \tilde{\rho}(gN)$. $\square$

$$\begin{array}{ccc}
 G & \xrightarrow{\rho} & \text{GL}(V) \\
 \downarrow q & \nearrow \tilde{\rho} & \\
 G/N & &
 \end{array}
 \quad (\text{exists iff } N \leq \ker \rho)$$

So the character table of G/N sits inside that of G : its rows are exactly those χ_i with $N \leq \ker \chi_i$, and its columns are the classes of G/N , which are the images of the classes of G .

Example 40.5.5 (Lifting from S_3)

S_4 has the normal subgroup $V_4 = \{e, (12)(34), (13)(24), (14)(23)\}$ with $S_4/V_4 \cong S_3$. Lifting the three irreducible characters of S_3 gives three irreducible characters of S_4 , of degrees 1, 1, 2: the trivial character, the sign character, and a degree-2 character taking the value 2 on e and on $(12)(34)$, the value 0 on transpositions and 4-cycles, and -1 on 3-cycles. This is exactly how we shall build the character table of S_4 .

More strikingly, the character table sees *all* the normal subgroups.

Proposition 40.5.6

Let χ be a character of G . Then $\ker \chi := \{g \in G : \chi(g) = \chi(e)\}$ is a normal subgroup of G , namely the kernel of any representation affording χ .

Proof. We proved earlier that $\chi(g) = \chi(e)$ if and only if $\rho(g) = \text{id}$. $\square$

Theorem 40.5.7

Every normal subgroup of G is an intersection of kernels of irreducible characters. Precisely, if $N \trianglelefteq G$ then

$$N = \bigcap \{\ker \chi_i : N \leq \ker \chi_i\}.$$

Proof. The inclusion $\subseteq$ is clear. For the reverse, note that the irreducible characters χ_i with $N \leq \ker \chi_i$ are exactly the lifts of the irreducible characters of G/N . Let g lie in the right hand side; then $\tilde{\chi}(gN) = \tilde{\chi}(N)$ for every irreducible character $\tilde{\chi}$ of G/N . Since the regular representation of G/N is faithful and decomposes into irreducibles containing every irreducible, the intersection of the kernels of all irreducible representations of any finite group is trivial. Hence $gN = N$, i.e. $g \in N$. $\square$

Corollary 40.5.8

A finite group G is simple if and only if for every non-trivial irreducible character

χ_i ($i \neq 1$) and every $g \neq e$, we have $\chi_i(g) \neq \chi_i(e)$.

Proof. If some $\chi_i \neq \mathbf{1}$ has $\chi_i(g) = \chi_i(e)$ with $g \neq e$, then $\ker \chi_i$ is a normal subgroup containing g , and it is proper since χ_i is not trivial (if $\ker \chi_i = G$ then ρ_i is trivial so $\chi_i = d_i \mathbf{1}$, forcing $d_i = 1$ and $\chi_i = \mathbf{1}$). Conversely, if N is a proper nontrivial normal subgroup then by the theorem some χ_i with $i \neq 1$ has $N \leq \ker \chi_i$, and any $g \in N \setminus \{e\}$ works. $\square$

This is a genuinely practical test, and we will use it to confirm that A_5 is simple purely by staring at a 5×5 table.

§40.5.3 Linear Characters and the Derived Subgroup

The degree-1 characters are the easiest to find, and they are exactly accounted for by the abelianisation.

Proposition 40.5.9

Let $G' = [G, G]$ be the derived subgroup. The linear characters of G are precisely the lifts of the (linear) characters of the abelian group G/G' , and there are exactly $|G/G'|$ of them. They form a group under pointwise multiplication, isomorphic to G/G' when G/G' is written multiplicatively (non-canonically).

Proof. A homomorphism $\rho : G \rightarrow \mathbb{C}^\times$ has abelian image, so $G' \leq \ker \rho$, so it is a lift from G/G' . Conversely all such lifts are linear characters. Since G/G' is abelian, all of its irreducible characters are linear and there are $|G/G'|$ of them.

Pointwise product of linear characters is a linear character, and the inverse of χ is $\bar{\chi}$; so they form a group, which is the character group of the finite abelian group G/G' , non-canonically isomorphic to it. $\square$

Example 40.5.10

S_n has $S'_n = A_n$ for $n \geq 2$, so S_n has exactly two linear characters: $\mathbf{1}$ and sign . A_5 is perfect ($A'_5 = A_5$), so its only linear character is the trivial one. And Q_8 has $Q'_8 = \{\pm 1\}$ with quotient $C_2 \times C_2$, so Q_8 has four linear characters.

§40.6 New Characters from Old

We have a good supply of representations coming from group actions, but to fill in a character table we usually need to manufacture more. There are three main constructions – duals, tensor products, and (later) induction – and each has a clean effect on characters.

§40.6.1 Dual Representations

Definition 40.6.1 (Dual representation)

Let (ρ, V) be a representation of G and $V^* = \text{Hom}_{\mathbb{C}}(V, \mathbb{C})$ its dual space. The **dual**

(or **contragredient**) representation is

$$\rho^*(g)(f) = f \circ \rho(g^{-1}), \quad \text{i.e.} \quad (g \cdot f)(v) = f(g^{-1}v).$$

The inverse is essential: without it we would get an antihomomorphism. Note this is the special case $W = \mathbb{C}$ (trivial) of the Hom representation from the proof of orthogonality.

Proposition 40.6.2

$$\chi_{V^*}(g) = \chi_V(g^{-1}) = \overline{\chi_V(g)}.$$

Proof. Choose a basis $v_1, \dots, v_n$ of V of eigenvectors for $\rho(g)$, with $gv_i = \lambda_i v_i$, and let $v_1^*, \dots, v_n^*$ be the dual basis. Then $(g \cdot v_i^*)(v_j) = v_i^*(\lambda_j^{-1} v_j) = \lambda_j^{-1} \delta_{ij}$, so $g \cdot v_i^* = \lambda_i^{-1} v_i^*$. Hence $\chi_{V^*}(g) = \sum_i \lambda_i^{-1} = \chi_V(g^{-1})$, which equals $\overline{\chi_V(g)}$ as the λ_i are roots of unity. $\square$

Definition 40.6.3 (Self-dual)

A representation V is **self-dual** if $V \cong V^*$, equivalently if χ_V is real valued.

Proposition 40.6.4

If every element of G is conjugate to its inverse (a **real** group – for example, any S_n , or any D_{2n}), then every character of G is real valued and every representation is self-dual.

Proof. $\overline{\chi(g)} = \chi(g^{-1}) = \chi(g)$ since χ is a class function and g^{-1} is conjugate to g . $\square$

§40.6.2 Tensor Products

The tensor product is the construction that makes the set of characters into a ring, and it is by far the most productive way of building new irreducibles from known ones.

Recall from *Groups, Rings and Modules* the tensor product $V \otimes W$ of vector spaces: if $v_1, \dots, v_n$ is a basis of V and $w_1, \dots, w_m$ a basis of W , then $V \otimes W$ has basis $\{v_i \otimes w_j\}$, so $\dim(V \otimes W) = \dim V \dim W$, and $\otimes$ is bilinear. Any bilinear map $V \times W \rightarrow U$ factors uniquely through a linear map $V \otimes W \rightarrow U$.

Definition 40.6.5 (Tensor product of representations)

If (ρ, V) and (ρ', W) are representations of G , define $\rho \otimes \rho'$ on $V \otimes W$ by

$$g \cdot (v \otimes w) = (gv) \otimes (gw),$$

extended linearly.

One should check this is well defined: for fixed g , the map $(v, w) \mapsto gv \otimes gw$ is bilinear, so induces a linear map on $V \otimes W$; and $\rho \otimes \rho'(gh) = (\rho \otimes \rho')(g)(\rho \otimes \rho')(h)$ holds on the spanning set of pure tensors.

Proposition 40.6.6

$$\chi_{V \otimes W}(g) = \chi_V(g) \chi_W(g).$$

Proof. Fix g and choose eigenbases (v_i) for $\rho(g)$ with eigenvalues λ_i , and (w_j) for $\rho'(g)$ with eigenvalues μ_j . Then $g \cdot (v_i \otimes w_j) = \lambda_i \mu_j (v_i \otimes w_j)$, so the $v_i \otimes w_j$ form an eigenbasis and

$$\chi_{V \otimes W}(g) = \sum_{i,j} \lambda_i \mu_j = \left(\sum_i \lambda_i \right) \left(\sum_j \mu_j \right) = \chi_V(g) \chi_W(g). \quad \square$$

Remark. Note carefully: this is *not* the same as the representation of $G \times G$ on $V \otimes W$, which we will meet in a moment. Here both factors are acted on by the same g ; this is sometimes called the ‘inner’ tensor product.

Corollary 40.6.7

$\text{Hom}_{\mathbb{C}}(V, W) \cong V^* \otimes W$ as representations of G .

Proof. Both have character $\overline{\chi_V} \chi_W$, and characters determine representations. (One can of course write down the isomorphism $f \otimes w \mapsto (v \mapsto f(v)w)$ directly.) $\square$

Proposition 40.6.8

If χ is a character and λ is a *linear* character, then $\lambda\chi$ is a character, and χ is irreducible if and only if $\lambda\chi$ is.

Proof. $\lambda\chi$ is the character of $L \otimes V$ where L is the one-dimensional space affording λ . Since $|\lambda(g)| = 1$ for all g , we have $\langle \lambda\chi, \lambda\chi \rangle = \frac{1}{|G|} \sum_g |\lambda(g)|^2 |\chi(g)|^2 = \langle \chi, \chi \rangle$, so one is 1 if and only if the other is. $\square$

This is a cheap and very effective way to produce new irreducibles: tensoring the character table of S_n with sign permutes its rows.

The tensor product of two irreducibles is usually *not* irreducible, and decomposing it is a basic computation.

Example 40.6.9

In S_3 , with $\chi_3 = (2, 0, -1)$ the degree-2 character, we have $\chi_3^2 = (4, 0, 1)$. Then

$$\langle \chi_3^2, \mathbf{1} \rangle = \frac{1}{6}(4+0+2) = 1, \quad \langle \chi_3^2, \text{sign} \rangle = \frac{1}{6}(4-0+2) = 1, \quad \langle \chi_3^2, \chi_3 \rangle = \frac{1}{6}(8+0-2) = 1,$$

so $\chi_3 \otimes \chi_3 = \mathbf{1} + \text{sign} + \chi_3$, consistent with degrees $4 = 1 + 1 + 2$.

§40.6.3 Symmetric and Exterior Squares

The decomposition in the last example was not an accident of S_3 : for any V , the space $V \otimes V$ has a canonical decomposition into two pieces, and it is often the fastest way to find new irreducibles.

Let $\tau : V \otimes V \rightarrow V \otimes V$ be the linear map determined by $\tau(v \otimes w) = w \otimes v$ (well defined since $(v, w) \mapsto w \otimes v$ is bilinear). Then $\tau^2 = \text{id}$, and τ is G -linear since g acts diagonally.

Definition 40.6.10 (Symmetric and exterior squares)

Set

$$S^2V = \{x \in V \otimes V : \tau(x) = x\}, \quad \Lambda^2V = \{x \in V \otimes V : \tau(x) = -x\}.$$

These are the **symmetric square** and **exterior square** of V .

Proposition 40.6.11

$V \otimes V = S^2V \oplus \Lambda^2V$ as representations of G . If $v_1, \dots, v_n$ is a basis of V then S^2V has basis $\{v_i v_j := v_i \otimes v_j + v_j \otimes v_i : i \leq j\}$ and Λ^2V has basis $\{v_i \wedge v_j := v_i \otimes v_j - v_j \otimes v_i : i < j\}$, so

$$\dim S^2V = \binom{n+1}{2}, \quad \dim \Lambda^2V = \binom{n}{2}.$$

Proof. Since $\tau^2 = \text{id}$ and we are in characteristic 0, $V \otimes V$ decomposes into the ± 1 eigenspaces of τ via $x = \frac{1}{2}(x + \tau x) + \frac{1}{2}(x - \tau x)$. Both eigenspaces are G -invariant since τ is G -linear. The bases are immediate. $\square$

Proposition 40.6.12

If V has character χ , then

$$\chi_{S^2V}(g) = \frac{1}{2}(\chi(g)^2 + \chi(g^2)), \quad \chi_{\Lambda^2V}(g) = \frac{1}{2}(\chi(g)^2 - \chi(g^2)).$$

Proof. Fix g and take an eigenbasis $v_1, \dots, v_n$ with $gv_i = \lambda_i v_i$. Then $g(v_i v_j) = \lambda_i \lambda_j v_i v_j$ and $g(v_i \wedge v_j) = \lambda_i \lambda_j v_i \wedge v_j$. So

$$\chi_{S^2V}(g) = \sum_{i \leq j} \lambda_i \lambda_j, \quad \chi_{\Lambda^2V}(g) = \sum_{i < j} \lambda_i \lambda_j.$$

Now $\chi(g)^2 = (\sum_i \lambda_i)^2 = \sum_i \lambda_i^2 + 2 \sum_{i < j} \lambda_i \lambda_j$, while $\chi(g^2) = \sum_i \lambda_i^2$ since $g^2 v_i = \lambda_i^2 v_i$. Hence $\sum_{i < j} \lambda_i \lambda_j = \frac{1}{2}(\chi(g)^2 - \chi(g^2))$, and adding $\sum_i \lambda_i^2 = \chi(g^2)$ gives $\sum_{i \leq j} \lambda_i \lambda_j = \frac{1}{2}(\chi(g)^2 + \chi(g^2))$. $\square$

Remark. More generally one can form $S^n V$ and $\Lambda^n V$ for all n , and the reader who has met the tensor algebra will recognise these as the graded pieces of the symmetric and exterior algebras. For this course the squares are what we need, though Λ^n makes an appearance for $\text{SU}(2)$.

Example 40.6.13 (Finding a new irreducible of S_5)

Let $\chi = \pi - 1$ be the standard character of S_5 , of degree 4. We will see later that $\Lambda^2 \chi$ has degree $\binom{4}{2} = 6$ and is irreducible – a character we could not easily have

found by any other elementary means.

§40.6.4 Representations of a Product

Proposition 40.6.14

Let G, H be finite groups. If V is a representation of G and W of H , then $V \otimes W$ is a representation of $G \times H$ via $(g, h) \cdot (v \otimes w) = gv \otimes hw$, with character

$$\chi_{V \otimes W}(g, h) = \chi_V(g)\chi_W(h).$$

Moreover, if V and W are irreducible then so is $V \otimes W$, and every irreducible representation of $G \times H$ arises this way, uniquely.

Proof. The character formula follows exactly as before (diagonalise $\rho_V(g)$ and $\rho_W(h)$ separately). For irreducibility,

$$\langle \chi_V \chi_W, \chi_V \chi_W \rangle_{G \times H} = \frac{1}{|G||H|} \sum_{g, h} |\chi_V(g)|^2 |\chi_W(h)|^2 = \langle \chi_V, \chi_V \rangle_G \langle \chi_W, \chi_W \rangle_H = 1.$$

Distinct pairs give distinct (indeed orthogonal) characters by the same computation. Finally, the conjugacy classes of $G \times H$ are the products of a class of G with a class of H , so there are $r_G r_H$ of them; and we have produced $r_G r_H$ pairwise non-isomorphic irreducibles. Hence there are no others. $\square$

Example 40.6.15

Since $C_6 \cong C_2 \times C_3$, the six characters of C_6 are the products of the two characters of C_2 with the three of C_3 – which is exactly what one sees from $\omega_6 = \omega_2 \omega_3$.

§40.6.5 The Character Ring

We have seen that sums and products of characters are characters. It is convenient to complete this to a ring.

Definition 40.6.16 (Character ring)

The **character ring** (or **representation ring**) of G is

$$R(G) = \left\{ \sum_{i=1}^r n_i \chi_i : n_i \in \mathbb{Z} \right\} \subseteq \mathcal{C}(G),$$

the set of virtual characters, with pointwise addition and multiplication.

Proposition 40.6.17

$R(G)$ is a commutative ring with $1 = \mathbf{1}$, free as a $\mathbb{Z}$ -module with basis $\chi_1, \dots, \chi_r$; and $\chi \in R(G)$ is an irreducible character if and only if $\langle \chi, \chi \rangle = 1$ and $\chi(e) > 0$.

Proof. Closure under multiplication is because $\chi_i\chi_j$ is a genuine character, hence a nonnegative combination of the χ_k . Freeness is linear independence of the χ_i . For the last part, write $\chi = \sum n_i\chi_i$ with $n_i \in \mathbb{Z}$; then $\langle \chi, \chi \rangle = \sum n_i^2 = 1$ forces $\chi = \pm\chi_i$ for a single i , and $\chi(e) = \pm d_i > 0$ picks out the sign. $\square$

This last criterion is used constantly, especially with induced characters: one produces a virtual character by subtracting known constituents, checks its norm is 1, and checks the sign of its degree.

§40.7 Character Tables in Practice

We now have enough theory to compute. This section works out the character tables of a good number of small groups completely; the reader should treat them as templates, since almost every character table computation in this course is one of these arguments in disguise.

The general strategy is always the same.

- (1) Find the conjugacy classes and their sizes. This tells you how many irreducible characters to expect.
- (2) Find the linear characters, by computing G/G' .
- (3) Use $\sum d_i^2 = |G|$ to pin down the remaining degrees, often uniquely.
- (4) Manufacture characters: permutation characters, lifts from quotients, tensor products with linear characters, symmetric and exterior squares, and later induction.
- (5) Test irreducibility with $\langle \chi, \chi \rangle = 1$, and strip off known constituents when it fails.
- (6) If one row is still missing, get it from column orthogonality.
- (7) Check everything.

§40.7.1 Dihedral Groups

Let $G = D_{2n} = \langle r, s \mid r^n = s^2 = e, srs^{-1} = r^{-1} \rangle$, of order $2n$. Note $sr^k s^{-1} = r^{-k}$, so r^k and r^{-k} are always conjugate; and $r^k(sr^j)r^{-k} = sr^{j-2k}$, so the reflections sr^j fall into classes according to j modulo 2.

The case n odd, say $n = 2m + 1$. Then $\gcd(2, n) = 1$, so $j \mapsto j - 2k$ is transitive modulo n and all n reflections are conjugate. The classes are

$$\{e\}, \quad \{r^k, r^{-k}\} \ (1 \leq k \leq m), \quad \{\text{the } n \text{ reflections}\},$$

so there are $m + 2$ of them. Since $srs^{-1}r^{-1} = r^{-2}$ generates $\langle r \rangle$ (as n is odd), $G' = \langle r \rangle$ and $G/G' \cong C_2$: there are exactly two linear characters.

For $1 \leq j \leq m$ define $\rho_j : G \rightarrow \text{GL}_2(\mathbb{C})$ by

$$\rho_j(r) = \begin{pmatrix} \omega^j & 0 \\ 0 & \omega^{-j} \end{pmatrix}, \quad \rho_j(s) = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \omega = e^{2\pi i/n}.$$

One checks the defining relations, so this is a representation, with character $\chi_j(r^k) = \omega^{jk} + \omega^{-jk} = 2 \cos(2\pi jk/n)$ and $\chi_j(sr^k) = 0$. It is irreducible:

$$\langle \chi_j, \chi_j \rangle = \frac{1}{2n} \sum_{k=0}^{n-1} |\omega^{jk} + \omega^{-jk}|^2 = \frac{1}{2n} \sum_{k=0}^{n-1} (2 + \omega^{2jk} + \omega^{-2jk}) = \frac{1}{2n} \cdot 2n = 1,$$

since $\sum_k \omega^{2jk} = 0$ when $n \nmid 2j$, which holds as n is odd and $1 \leq j \leq m$. The χ_j are pairwise distinct, and $1 + 1 + 4m = 4m + 2 = 2n$, so we have them all.

class size	1	2	n
	e	$r^k \quad (1 \leq k \leq m)$	s
1	1	1	1
ε	1	1	-1
$\chi_j \quad (1 \leq j \leq m)$	2	$2 \cos \frac{2\pi jk}{n}$	0

The case n even, say $n = 2m$. Now r^m is central, and the reflections split into two classes $\{sr^{\text{even}}\}$ and $\{sr^{\text{odd}}\}$, each of size m . The classes are

$$\{e\}, \quad \{r^m\}, \quad \{r^k, r^{-k}\} \quad (1 \leq k \leq m-1), \quad \{sr^{2i}\}, \quad \{sr^{2i+1}\},$$

giving $m + 3$ classes. Here $G' = \langle r^2 \rangle$ has index 4, so there are four linear characters, determined by $r \mapsto \pm 1$, $s \mapsto \pm 1$. The same ρ_j as before are irreducible for $1 \leq j \leq m-1$ (the computation is identical; $n \nmid 2j$ still holds), and $4 + 4(m-1) = 4m = 2n$, so again we have everything.

class size	1	1	2	m	m
	e	r^m	$r^k \quad (1 \leq k \leq m-1)$	s	sr
1	1	1	1	1	1
ε_1	1	1	1	-1	-1
ε_2	1	$(-1)^m$	$(-1)^k$	1	-1
ε_3	1	$(-1)^m$	$(-1)^k$	-1	1
$\chi_j \quad (1 \leq j \leq m-1)$	2	$2(-1)^j$	$2 \cos \frac{2\pi jk}{n}$	0	0

Geometrically the χ_j are exactly the characters of the rotation-reflection action of D_{2n} on the plane, but with the rotation sped up by a factor of j : ρ_j realises D_{2n} as the symmetries of an n -gon which has been wrapped j times around itself.

Example 40.7.1 (D_8)

Take $n = 4$, so $m = 2$. The classes are $\{e\}$, $\{r^2\}$, $\{r, r^3\}$, $\{s, r^2s\}$, $\{rs, r^3s\}$ of sizes 1, 1, 2, 2, 2. There is one two-dimensional character, χ_1 , with $\chi_1(e) = 2$, $\chi_1(r^2) = 2(-1)^1 = -2$, $\chi_1(r) = 2 \cos(\pi/2) = 0$, and 0 on both reflection classes.

class size	1	1	2	2	2
	e	r^2	r	s	rs
$\mathbf{1}$	1	1	1	1	1
ε_1	1	1	1	-1	-1
ε_2	1	1	-1	1	-1
ε_3	1	1	-1	-1	1
χ	2	-2	0	0	0

Checks: $1 + 1 + 1 + 1 + 4 = 8 = |D_8|$. $\langle \chi, \chi \rangle = \frac{1}{8}(4 + 4 + 0 + 0 + 0) = 1$. $\langle \mathbf{1}, \chi \rangle = \frac{1}{8}(2 - 2) = 0$, and similarly for the other linear characters. Columns: e gives $1 + 1 + 1 + 1 + 4 = 8 = |C(e)|$; r^2 gives $1 + 1 + 1 + 1 + 4 = 8$, correct since r^2 is central; r gives $1 + 1 + 1 + 1 + 0 = 4 = 8/2$; and likewise for s and rs .

Example 40.7.2 (The quaternion group Q_8)

Let $Q_8 = \{\pm 1, \pm i, \pm j, \pm k\}$ with $i^2 = j^2 = k^2 = ijk = -1$. The classes are $\{1\}, \{-1\}, \{\pm i\}, \{\pm j\}, \{\pm k\}$, of sizes 1, 1, 2, 2, 2. We have $Q'_8 = \{\pm 1\}$ with $Q_8/Q'_8 \cong C_2 \times C_2$, giving four linear characters, and then $8 = 4 \cdot 1 + d^2$ forces one more of degree 2. That degree-2 representation is the obvious one: regard $\mathbb{H} = \mathbb{R}\langle 1, i, j, k \rangle$ inside $M_2(\mathbb{C})$ via

$$1 \mapsto \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad i \mapsto \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}, \quad j \mapsto \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad k \mapsto \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix},$$

whose traces are 2, 0, 0, 0 on $1, i, j, k$ and -2 on -1.

class size	1	1	2	2	2
	1	-1	i	j	k
$\mathbf{1}$	1	1	1	1	1
χ_2	1	1	1	-1	-1
χ_3	1	1	-1	1	-1
χ_4	1	1	-1	-1	1
χ_5	2	-2	0	0	0

The same four checks go through exactly as for D_8 .

Remark (Character tables do not determine groups). Compare the last two tables: they are *identical*. But $D_8 \not\cong Q_8$ – for instance D_8 has five elements of order dividing 2 and Q_8 has two. So the character table, remarkable as it is, does not determine the group.

What distinguishes them is the *squaring* map, which the character table does not record. A convenient way to package this is the **Frobenius–Schur indicator**

$$\iota(\chi) = \frac{1}{|G|} \sum_{g \in G} \chi(g^2),$$

which turns out to be $+1$ if the representation can be written over $\mathbb{R}$, -1 if χ is real valued but the representation cannot, and 0 if χ is not real valued. For the degree-2 character χ of D_8 , every element squares to e except r, r^3 which square to r^2 , so

$$\iota(\chi) = \frac{1}{8}(1 \cdot 2 + 1 \cdot 2 + 2 \cdot (-2) + 2 \cdot 2 + 2 \cdot 2) = \frac{8}{8} = 1,$$

consistent with ρ being the honest rotation-reflection action on $\mathbb{R}^2$. For Q_8 , however, $(\pm i)^2 = (\pm j)^2 = (\pm k)^2 = -1$, so

$$\iota(\chi_5) = \frac{1}{8}(1 \cdot 2 + 1 \cdot 2 + 2 \cdot (-2) + 2 \cdot (-2) + 2 \cdot (-2)) = \frac{-8}{8} = -1,$$

and indeed the two-dimensional representation of Q_8 is quaternionic, not real.

§40.7.2 The Alternating Group A_4

Let $G = A_4$, of order 12, the rotation group of a regular tetrahedron.

The conjugacy classes of S_4 meeting A_4 are those of e , of $(12)(34)$, and of (123) ; the first two remain single A_4 -classes but the class of 3-cycles splits in two, because $C_{S_4}((123)) = \langle (123) \rangle \leq A_4$. So the classes of A_4 are

$$\{e\} \ (1), \quad \{(12)(34), (13)(24), (14)(23)\} \ (3), \quad \text{ccl}((123)) \ (4), \quad \text{ccl}((132)) \ (4),$$

four classes in all. Geometrically the two classes of 3-cycles are the rotations by $+2\pi/3$ and by $-2\pi/3$ about the four 3-fold axes.

Now $A'_4 = V_4$ (the double transpositions together with e), and $A_4/V_4 \cong C_3$. So there are three linear characters, the lifts of the characters of C_3 , and $12 = 1 + 1 + 1 + d_4^2$ gives $d_4 = 3$. The degree-3 character is the standard character $\pi - \mathbf{1}$ of the action on $\{1, 2, 3, 4\}$, with $\pi = (4, 0, 1, 1)$. Writing $\omega = e^{2\pi i/3}$:

class size	1	3	4	4
	e	$(12)(34)$	(123)	(132)
$\mathbf{1}$	1	1	1	1
χ_2	1	1	ω	ω^2
χ_3	1	1	ω^2	ω
χ_4	3	-1	0	0

Checks: degrees $1 + 1 + 1 + 9 = 12$. Rows: $\langle \chi_4, \chi_4 \rangle = \frac{1}{12}(9 + 3 \cdot 1 + 0 + 0) = 1$; $\langle \mathbf{1}, \chi_4 \rangle = \frac{1}{12}(3 - 3) = 0$; $\langle \chi_2, \chi_2 \rangle = \frac{1}{12}(1 + 3 + 4 + 4) = 1$; $\langle \chi_2, \chi_3 \rangle = \frac{1}{12}(1 + 3 + 4\bar{\omega}\omega^2 +$

$4\overline{\omega^2\omega} = \frac{1}{12}(4 + 4\omega + 4\omega^2) = 0$ since $1 + \omega + \omega^2 = 0$; $\langle \mathbf{1}, \chi_2 \rangle = \frac{1}{12}(1 + 3 + 4\omega + 4\omega^2) = 0$. Columns: 12, then $1 + 1 + 1 + 1 = 4 = 12/3$, then $1 + 1 + 1 + 0 = 3 = 12/4$ twice. All correct.

Note the character table shows immediately that A_4 is not simple: $\ker \chi_2 = \{e\} \cup \text{ccl}((1\ 2)(3\ 4)) = V_4$ is a proper nontrivial normal subgroup.

§40.7.3 The Symmetric Group S_4

Let $G = S_4$, of order 24, which is the rotation group of the cube: the four space diagonals are permuted, and this gives an isomorphism onto S_4 .

the 4 space diagonals

The classes are indexed by cycle types: e (size 1), transpositions (size 6), double transpositions (size 3), 3-cycles (size 8), 4-cycles (size 6). Five classes, and $1 + 6 + 3 + 8 + 6 = 24$. Since $S'_4 = A_4$, there are two linear characters $\mathbf{1}$ and sign , and

$$24 = 1 + 1 + d_3^2 + d_4^2 + d_5^2$$

with $d_i \geq 2$; the only solution is $\{2, 3, 3\}$.

We get the two degree-3 characters at once: $\chi_4 = \pi - \mathbf{1}$ is the standard character (irreducible since S_4 is 2-transitive), and $\chi_5 = \text{sign} \cdot \chi_4$ is another, distinct from χ_4 since χ_4 is not zero on transpositions. Here $\pi = (4, 2, 0, 1, 0)$, so $\chi_4 = (3, 1, -1, 0, -1)$ and $\chi_5 = (3, -1, -1, 0, 1)$.

The degree-2 character is the lift of the degree-2 character of $S_4/V_4 \cong S_3$. Under the quotient map, e and the double transpositions go to the identity, transpositions and 4-cycles go to transpositions, and 3-cycles go to 3-cycles. Reading off from the table of S_3 , we get $\chi_3 = (2, 0, 2, -1, 0)$.

class size	1	6	3	8	6
	e	$(1\ 2)$	$(1\ 2)(3\ 4)$	$(1\ 2\ 3)$	$(1\ 2\ 3\ 4)$
$\mathbf{1}$	1	1	1	1	1
sign	1	-1	1	1	-1
χ_3	2	0	2	-1	0
χ_4	3	1	-1	0	-1
χ_5	3	-1	-1	0	1

Let us check this properly.

- Degrees: $1 + 1 + 4 + 9 + 9 = 24 = |S_4|$.

- $\langle \chi_3, \chi_3 \rangle = \frac{1}{24}(1 \cdot 4 + 6 \cdot 0 + 3 \cdot 4 + 8 \cdot 1 + 6 \cdot 0) = \frac{24}{24} = 1.$
- $\langle \chi_4, \chi_4 \rangle = \frac{1}{24}(9 + 6 + 3 + 0 + 6) = \frac{24}{24} = 1$, and by symmetry $\langle \chi_5, \chi_5 \rangle = 1.$
- $\langle \mathbf{1}, \text{sign} \rangle = \frac{1}{24}(1 - 6 + 3 + 8 - 6) = 0;$ $\langle \mathbf{1}, \chi_3 \rangle = \frac{1}{24}(2 + 0 + 6 - 8 + 0) = 0;$
 $\langle \mathbf{1}, \chi_4 \rangle = \frac{1}{24}(3 + 6 - 3 + 0 - 6) = 0;$ $\langle \mathbf{1}, \chi_5 \rangle = \frac{1}{24}(3 - 6 - 3 + 0 + 6) = 0.$
- $\langle \text{sign}, \chi_3 \rangle = \frac{1}{24}(2 - 0 + 6 - 8 - 0) = 0;$ $\langle \text{sign}, \chi_4 \rangle = \frac{1}{24}(3 - 6 - 3 + 0 + 6) = 0;$
 $\langle \text{sign}, \chi_5 \rangle = \frac{1}{24}(3 + 6 - 3 + 0 - 6) = 0.$
- $\langle \chi_3, \chi_4 \rangle = \frac{1}{24}(6 + 0 - 6 + 0 + 0) = 0;$ $\langle \chi_3, \chi_5 \rangle = \frac{1}{24}(6 - 0 - 6 + 0 + 0) = 0;$
 $\langle \chi_4, \chi_5 \rangle = \frac{1}{24}(9 - 6 + 3 + 0 - 6) = 0.$
- Columns: $e: 1 + 1 + 4 + 9 + 9 = 24.$ $(12): 1 + 1 + 0 + 1 + 1 = 4 = 24/6.$ $(12)(34):$
 $1 + 1 + 4 + 1 + 1 = 8 = 24/3.$ $(123): 1 + 1 + 1 + 0 + 0 = 3 = 24/8.$ $(1234):$
 $1 + 1 + 0 + 1 + 1 = 4 = 24/6.$

Every relation holds, so the table is correct.

Remark. As a sanity check on χ_3 : earlier we computed the permutation character of S_4 on the six unordered pairs to be $\pi_X = (6, 2, 2, 0, 0)$, and found $\langle \pi_X, \pi_X \rangle = 3$ with $\langle \pi_X, \mathbf{1} \rangle = 1$. Indeed

$$\pi_X = \mathbf{1} + \chi_3 + \chi_4 = (1, 1, 1, 1, 1) + (2, 0, 2, -1, 0) + (3, 1, -1, 0, -1) = (6, 2, 2, 0, 0). \checkmark$$

§40.7.4 The Alternating Group A_5

Now for the most interesting small example. A_5 has order 60 and is the rotation group of the regular icosahedron (equivalently, of the dodecahedron).

The conjugacy classes of A_5 are those of e , of $(12)(34)$, of (123) , and *two* classes of 5-cycles. (The class of 5-cycles in S_5 has 24 elements and splits, since $C_{S_5}((12345)) = \langle (12345) \rangle \leq A_5$; the classes of $(12)(34)$ and (123) do not split, as (12) and (45) respectively centralise a representative while lying outside A_5 .) Sizes:

$$1, \quad 15, \quad 20, \quad 12, \quad 12, \quad \text{summing to } 60.$$

Geometrically these are: the identity; the 15 rotations by π about the 15 edge-midpoint axes; the 20 rotations by $\pm 2\pi/3$ about the 10 face axes; and the 24 rotations by $\pm 2\pi/5$ and $\pm 4\pi/5$ about the 6 vertex axes, splitting $12 + 12$.

A_5 is perfect, so $\mathbf{1}$ is the only linear character, and $60 = 1 + d_2^2 + d_3^2 + d_4^2 + d_5^2$ with $d_i \geq 2$ and (as we shall prove later) each d_i dividing 60. Let us instead just build characters.

Degree 4. A_5 is 2-transitive on $\{1, \dots, 5\}$, so $\chi_4 := \pi - \mathbf{1}$ is irreducible of degree 4, where $\pi = (5, 1, 2, 0, 0)$. Thus $\chi_4 = (4, 0, 1, -1, -1)$.

Degree 5. Compute the symmetric square. We need $\chi_4(g^2)$: for $g = e$ or a double transposition, $g^2 = e$ so $\chi_4(g^2) = 4$; for a 3-cycle, g^2 is a 3-cycle so $\chi_4(g^2) = 1$; and for a 5-cycle g , g^2 is a 5-cycle in the *other* class, but χ_4 takes the value -1 on both, so $\chi_4(g^2) = -1$. Hence

$$\chi_{S^2}(g) = \frac{1}{2}(\chi_4(g)^2 + \chi_4(g^2)) = (10, 2, 1, 0, 0).$$

Now $\langle \chi_{S^2}, \mathbf{1} \rangle = \frac{1}{60}(10 + 15 \cdot 2 + 20 \cdot 1 + 0 + 0) = 1$ and $\langle \chi_{S^2}, \chi_4 \rangle = \frac{1}{60}(40 + 0 + 20 + 0 + 0) = 1$. So

$$\chi_5 := \chi_{S^2} - \mathbf{1} - \chi_4 = (5, 1, -1, 0, 0),$$

and $\langle \chi_5, \chi_5 \rangle = \frac{1}{60}(25 + 15 + 20 + 0 + 0) = 1$: irreducible, of degree 5.

Degree 3, twice. Compute the exterior square:

$$\chi_{\Lambda^2}(g) = \frac{1}{2}(\chi_4(g)^2 - \chi_4(g^2)) = (6, -2, 0, 1, 1).$$

Then $\langle \chi_{\Lambda^2}, \chi_{\Lambda^2} \rangle = \frac{1}{60}(36 + 15 \cdot 4 + 0 + 12 + 12) = \frac{120}{60} = 2$, so it is a sum of two distinct irreducibles; and it is orthogonal to $\mathbf{1}$ and to χ_4 (check: $\frac{1}{60}(6 - 30 + 0 + 12 + 12) = 0$ and $\frac{1}{60}(24 + 0 + 0 - 12 - 12) = 0$) and to χ_5 (check: $\frac{1}{60}(30 - 30 + 0 + 0 + 0) = 0$). So $\chi_{\Lambda^2} = \chi_2 + \chi_3$ for two new irreducibles of degrees summing to 6; since $60 = 1 + 16 + 25 + d_2^2 + d_3^2$ gives $d_2^2 + d_3^2 = 18$ with $d_2 + d_3 = 6$, we get $d_2 = d_3 = 3$.

To find the entries, write $\chi_2 = (3, a, b, c, c')$ and $\chi_3 = (3, \tilde{a}, \tilde{b}, \tilde{c}, \tilde{c}')$ with $\chi_2 + \chi_3 = (6, -2, 0, 1, 1)$. Column orthogonality gives, for the class of $(12)(34)$ (centraliser order $60/15 = 4$),

$$1 + a^2 + \tilde{a}^2 + 0^2 + 1^2 = 4 \implies a^2 + \tilde{a}^2 = 2, \quad a + \tilde{a} = -2 \implies a = \tilde{a} = -1.$$

For the class of (123) (centraliser order 3): $1 + b^2 + \tilde{b}^2 + 1 + 1 = 3$, so $b = \tilde{b} = 0$. For the class of (12345) (centraliser order 5): $1 + c^2 + \tilde{c}^2 + 1 + 0 = 5$, so $c^2 + \tilde{c}^2 = 3$ while $c + \tilde{c} = 1$; hence $c\tilde{c} = \frac{1}{2}((c + \tilde{c})^2 - (c^2 + \tilde{c}^2)) = -1$, so $c, \tilde{c}$ are the roots of $x^2 - x - 1 = 0$, that is

$$\alpha = \frac{1 + \sqrt{5}}{2}, \quad \beta = \frac{1 - \sqrt{5}}{2}.$$

The same holds on the other class of 5-cycles, with the two values swapped (they must be, or $\chi_2 = \chi_3$).

class size	1	15	20	12	12
	e	$(12)(34)$	(123)	(12345)	(13524)
$\mathbf{1}$	1	1	1	1	1
χ_2	3	-1	0	α	β
χ_3	3	-1	0	β	α
χ_4	4	0	1	-1	-1
χ_5	5	1	-1	0	0

where $\alpha = \frac{1+\sqrt{5}}{2}$ and $\beta = \frac{1-\sqrt{5}}{2}$, so that $\alpha + \beta = 1$, $\alpha\beta = -1$ and $\alpha^2 + \beta^2 = 3$.

Let us verify everything, using these three identities.

- Degrees: $1 + 9 + 9 + 16 + 25 = 60 = |A_5|$.
- $\langle \chi_2, \chi_2 \rangle = \frac{1}{60}(9 + 15 + 0 + 12\alpha^2 + 12\beta^2) = \frac{9+15+36}{60} = 1$; same for χ_3 .
- $\langle \chi_4, \chi_4 \rangle = \frac{1}{60}(16 + 0 + 20 + 12 + 12) = 1$; $\langle \chi_5, \chi_5 \rangle = \frac{1}{60}(25 + 15 + 20 + 0 + 0) = 1$.
- $\langle \chi_2, \chi_3 \rangle = \frac{1}{60}(9 + 15 + 0 + 12\alpha\beta + 12\beta\alpha) = \frac{9+15-24}{60} = 0$.
- $\langle \mathbf{1}, \chi_2 \rangle = \frac{1}{60}(3 - 15 + 0 + 12\alpha + 12\beta) = \frac{3-15+12}{60} = 0$; same for χ_3 .
- $\langle \mathbf{1}, \chi_4 \rangle = \frac{1}{60}(4 + 0 + 20 - 12 - 12) = 0$; $\langle \mathbf{1}, \chi_5 \rangle = \frac{1}{60}(5 + 15 - 20 + 0 + 0) = 0$.
- $\langle \chi_2, \chi_4 \rangle = \frac{1}{60}(12 + 0 + 0 - 12\alpha - 12\beta) = \frac{12-12}{60} = 0$; same for χ_3 .
- $\langle \chi_2, \chi_5 \rangle = \frac{1}{60}(15 - 15 + 0 + 0 + 0) = 0$; same for χ_3 ; $\langle \chi_4, \chi_5 \rangle = \frac{1}{60}(20 + 0 - 20 + 0 + 0) = 0$.
- Columns: e : $1+9+9+16+25 = 60$. $(12)(34)$: $1+1+1+0+1 = 4 = 60/15$. (123) : $1+0+0+1+1 = 3 = 60/20$. Each 5-class: $1+\alpha^2+\beta^2+1+0 = 1+3+1 = 5 = 60/12$.

Finally, the table shows that A_5 is simple: for each $i \neq 1$ and each $g \neq e$ we have $\chi_i(g) \neq \chi_i(e)$, since the entries $-1, 0, \alpha, \beta, 1$ are never equal to $3, 4$ or 5 . So no proper nontrivial normal subgroup exists.

Remark. The appearance of the golden ratio is not a coincidence: the two degree-3 representations are the two ways of realising A_5 as the rotation group of the icosahedron (differing by the outer automorphism of A_5 , which swaps the two classes of 5-cycles), and the trace of a rotation by $2\pi/5$ in $\mathbb{R}^3$ is $1 + 2\cos(2\pi/5) = \frac{1+\sqrt{5}}{2} = \alpha$.

§40.7.5 The Symmetric Group S_5

Finally S_5 , of order 120, which has seven conjugacy classes, indexed by cycle type:

cycle type	1^5	21^3	2^21	31^2	32	41	5
class size	1	10	15	20	20	30	24

These sum to 120, as they must. Since $S'_5 = A_5$ there are two linear characters. Let $\pi = (5, 3, 1, 2, 0, 1, 0)$ be the natural permutation character; the standard character is then

$$\chi_3 = \pi - \mathbf{1} = (4, 2, 0, 1, -1, 0, -1),$$

irreducible by 2-transitivity, and $\chi_4 = \text{sign} \cdot \chi_3 = (4, -2, 0, 1, 1, 0, -1)$ is a second one of degree 4.

For more, take squares of χ_3 . We need the class of g^2 for each g : $e, (12), (12)(34)$ all square into 1^5 ; (123) and $(123)(45)$ square to 3-cycles; (1234) squares to a 2^2 -element; and a 5-cycle squares to a 5-cycle. Hence

$$\chi_3(g^2) = (4, 4, 4, 1, 1, 0, -1),$$

and so

$$\begin{aligned}\chi_{S^2}(g) &= \frac{1}{2}(\chi_3(g)^2 + \chi_3(g^2)) = (10, 4, 2, 1, 1, 0, 0), \\ \chi_{\Lambda^2}(g) &= \frac{1}{2}(\chi_3(g)^2 - \chi_3(g^2)) = (6, 0, -2, 0, 0, 0, 1).\end{aligned}$$

Now $\langle \chi_{\Lambda^2}, \chi_{\Lambda^2} \rangle = \frac{1}{120}(36+0+15 \cdot 4+0+0+0+24) = \frac{120}{120} = 1$, so $\chi_5 := \chi_{\Lambda^2}$ is irreducible of degree 6. (Note $\text{sign} \cdot \chi_5 = \chi_5$: this character is ‘self-associate’.)

For the symmetric square, $\langle \chi_{S^2}, \mathbf{1} \rangle = \frac{1}{120}(10+40+30+20+20+0+0) = 1$ and $\langle \chi_{S^2}, \chi_3 \rangle = \frac{1}{120}(40+80+0+20-20+0+0) = 1$, so

$$\chi_6 := \chi_{S^2} - \mathbf{1} - \chi_3 = (5, 1, 1, -1, 1, -1, 0),$$

with $\langle \chi_6, \chi_6 \rangle = \frac{1}{120}(25+10+15+20+20+30+0) = 1$: irreducible of degree 5. And $\chi_7 = \text{sign} \cdot \chi_6 = (5, -1, 1, -1, -1, 1, 0)$ is a seventh, distinct from χ_6 . Degrees: $1+1+16+16+25+25+36=120$, so we have them all.

class size	1	10	15	20	20	30	24
	e	(1 2)	(1 2)(3 4)	(1 2 3)	(1 2 3)(4 5)	(1 2 3 4)	(1 2 3 4 5)
$\mathbf{1}$	1	1	1	1	1	1	1
sign	1	-1	1	1	-1	-1	1
χ_3	4	2	0	1	-1	0	-1
χ_4	4	-2	0	1	1	0	-1
χ_5	6	0	-2	0	0	0	1
χ_6	5	1	1	-1	1	-1	0
χ_7	5	-1	1	-1	-1	1	0

Verification of the column relations, which is the quickest global check:

$$\begin{aligned}
 e : & \quad 1+1+16+16+36+25+25=120=|C(e)|, \\
 (1\ 2) : & \quad 1+1+4+4+0+1+1=12=120/10, \\
 (1\ 2)(3\ 4) : & \quad 1+1+0+0+4+1+1=8=120/15, \\
 (1\ 2\ 3) : & \quad 1+1+1+1+0+1+1=6=120/20, \\
 (1\ 2\ 3)(4\ 5) : & \quad 1+1+1+1+0+1+1=6=120/20, \\
 (1\ 2\ 3\ 4) : & \quad 1+1+0+0+0+1+1=4=120/30, \\
 (1\ 2\ 3\ 4\ 5) : & \quad 1+1+1+1+1+0+0=5=120/24.
 \end{aligned}$$

And a sample of the row relations: $\langle \chi_3, \chi_4 \rangle = \frac{1}{120}(16-40+0+20-20+0+24)=0$; $\langle \chi_6, \chi_7 \rangle = \frac{1}{120}(25-10+15+20-20-30+0)=0$; $\langle \chi_3, \chi_5 \rangle = \frac{1}{120}(24+0+0+0+0+0-24)=0$; $\langle \chi_5, \chi_6 \rangle = \frac{1}{120}(30+0-30+0+0+0+0)=0$; $\langle \mathbf{1}, \chi_5 \rangle = \frac{1}{120}(6+0-30+0+0+0+24)=0$. (All twenty-one orthogonality relations hold; the reader is invited to spot-check a few more.)

Remark. Notice the shape of the answer: seven irreducible characters, in three ‘associate pairs’ $\{\mathbf{1}, \text{sign}\}$, $\{\chi_3, \chi_4\}$, $\{\chi_6, \chi_7\}$ swapped by tensoring with sign, and one self-associate character χ_5 . There is a beautiful combinatorial explanation in terms of partitions of 5 and their transposes, which we come to in the section on the symmetric group.

§40.8 Restriction and Induction

So far all our constructions have taken place inside a fixed group. We now allow ourselves to move between a group and its subgroups, which turns out to be the single most powerful technique for building character tables of larger groups.

Throughout this section $H \leq G$ is a subgroup of index $n = |G : H|$.

§40.8.1 Restriction

This direction is trivial to define and surprisingly informative.

Definition 40.8.1 (Restriction)

Let (ρ, V) be a representation of G and $H \leq G$. The **restriction** $\text{Res}_H^G V$ (also written $V \downarrow_H$) is the representation of H on the same space V given by $\rho|_H$. On characters, $\text{Res}_H^G \chi$ is just $\chi|_H$.

Restricting an irreducible representation of G to H almost never gives an irreducible representation of H , but the failure is controlled.

Proposition 40.8.2

Let V be an irreducible representation of G with character χ , and write $\text{Res}_H^G \chi = \sum_i c_i \psi_i$ over the irreducible characters ψ_i of H . Then

$$\sum_i c_i^2 = \langle \text{Res}_H^G \chi, \text{Res}_H^G \chi \rangle_H \leq |G : H|,$$

with equality if and only if $\chi(g) = 0$ for every $g \in G \setminus H$.

Proof. We have

$$\langle \chi|_H, \chi|_H \rangle_H = \frac{|G|}{|H|} \cdot \frac{1}{|G|} \sum_{h \in H} |\chi(h)|^2 \leq |G : H| \cdot \frac{1}{|G|} \sum_{g \in G} |\chi(g)|^2 = |G : H|,$$

since $\langle \chi, \chi \rangle_G = 1$. The inequality is an equality exactly when the omitted terms $|\chi(g)|^2$, $g \notin H$, all vanish. $\square$

Corollary 40.8.3

If χ is irreducible of degree d and $H \leq G$ has index n , then $\text{Res}_H^G \chi$ has at most n irreducible constituents counted with multiplicity, and in particular $d \leq n \cdot \max_i \psi_i(1)$.

Example 40.8.4

Restrict the degree-2 character $\chi = (2, 0, -1)$ of S_3 to $H = A_3 = C_3$. We get $\chi|_H = (2, -1, -1)$ on $(e, (1\ 2\ 3), (1\ 3\ 2))$, which is $\omega + \omega^2$ -flavoured: indeed $\chi|_H = \chi_1 + \chi_2$, the two nontrivial characters of C_3 . Here $\langle \chi|_H, \chi|_H \rangle = 2 = |G : H|$, consistent with χ vanishing off A_3 .

§40.8.2 Induction

The other direction is the interesting one: from a representation of H we manufacture a representation of G , of degree multiplied by $|G : H|$.

Choose left coset representatives $g_1 = e, g_2, \dots, g_n$ for H in G , so that $G = \bigsqcup_{i=1}^n g_i H$.

**Definition 40.8.5** (Induced representation)

Let W be a representation of H . The **induced representation** is the vector space

$$\text{Ind}_H^G W = \bigoplus_{i=1}^n g_i \otimes W,$$

where $g_i \otimes W$ is a copy of W labelled by the coset $g_i H$, with G acting as follows: given $g \in G$ and i , write $gg_i = g_j h$ with $h \in H$ (which determines j and h uniquely), and set

$$g \cdot (g_i \otimes w) = g_j \otimes hw.$$

Its degree is $|G : H| \cdot \dim W$.

Remark. Invariantly, $\text{Ind}_H^G W = \mathbb{C}G \otimes_{\mathbb{C}H} W$, the extension of scalars along $\mathbb{C}H \hookrightarrow \mathbb{C}G$; this makes the independence of the choice of coset representatives obvious, and identifies induction as the left adjoint of restriction. Readers who found tensor products of modules congenial in *Groups, Rings and Modules* may prefer this definition; the concrete one above is what we compute with.

One should check this is a representation. If $g'g_j = g_k h'$ then $g'g g_i = g'g_j h = g_k h' h$, so

$$g' \cdot (g \cdot (g_i \otimes w)) = g' \cdot (g_j \otimes hw) = g_k \otimes h'hw = (g'g) \cdot (g_i \otimes w),$$

as required, and the identity acts trivially.

Theorem 40.8.6 (Induced character formula)

Let ψ be the character of a representation W of $H \leq G$. Then the character of $\text{Ind}_H^G W$ is

$$\text{Ind}_H^G \psi(g) = \sum_{\substack{1 \leq i \leq n \\ g_i^{-1} g g_i \in H}} \psi(g_i^{-1} g g_i) = \frac{1}{|H|} \sum_{\substack{x \in G \\ x^{-1} g x \in H}} \psi(x^{-1} g x).$$

In particular $\text{Ind}_H^G \psi(e) = |G : H| \psi(e)$, and $\text{Ind}_H^G \psi(g) = 0$ if no conjugate of g lies in H .

Proof. Write the matrix of g in a basis adapted to the decomposition $\bigoplus_i g_i \otimes W$, as an $n \times n$ array of blocks of size $\dim W$. The action sends the i -th block into the j -th block, where $gg_i \in g_j H$. So the (i, i) diagonal block is nonzero only when $gg_i \in g_i H$, i.e. $g_i^{-1}gg_i \in H$, and then it is the matrix of $\rho_W(g_i^{-1}gg_i)$. Taking traces of the diagonal blocks gives the first formula.

For the second, every $x \in G$ is uniquely $x = g_i h$ with $h \in H$, and

$$x^{-1}gx = h^{-1}(g_i^{-1}gg_i)h,$$

which lies in H if and only if $g_i^{-1}gg_i$ does, and then has the same ψ -value since ψ is a class function on H . So each term of the first sum is repeated exactly $|H|$ times in the second. $\square$

There is a third form of the formula which is often the most efficient for hand computation.

Corollary 40.8.7

Let $g \in G$ and suppose $\text{ccl}_G(g) \cap H$ is the disjoint union of the H -conjugacy classes of $h_1, \dots, h_m$ (possibly $m = 0$). Then

$$\text{Ind}_H^G \psi(g) = |C_G(g)| \sum_{k=1}^m \frac{\psi(h_k)}{|C_H(h_k)|}.$$

Proof. In the sum $\frac{1}{|H|} \sum_{x: x^{-1}gx \in H} \psi(x^{-1}gx)$, group the x by the value of $x^{-1}gx$. For a fixed $h \in \text{ccl}_G(g) \cap H$, the number of x with $x^{-1}gx = h$ is $|C_G(g)|$. So the sum is $\frac{|C_G(g)|}{|H|} \sum_{h \in \text{ccl}_G(g) \cap H} \psi(h)$, and grouping the h into H -classes of sizes $|H|/|C_H(h_k)|$ gives the result. $\square$

§40.8.3 Frobenius Reciprocity

Restriction and induction are adjoint to one another, and this single fact organises everything.

Theorem 40.8.8 (Frobenius reciprocity)

Let $H \leq G$, let ψ be a class function on H and χ a class function on G . Then

$$\langle \text{Res}_H^G \chi, \psi \rangle_H = \langle \chi, \text{Ind}_H^G \psi \rangle_G.$$

Proof. Extend Ind_H^G to all class functions on H by the formula of the theorem above (which makes sense for any class function). Then

$$\langle \chi, \text{Ind}_H^G \psi \rangle_G = \frac{1}{|G|} \sum_{g \in G} \overline{\chi(g)} \cdot \frac{1}{|H|} \sum_{\substack{x \in G \\ x^{-1}gx \in H}} \psi(x^{-1}gx)$$

$$= \frac{1}{|G||H|} \sum_{x \in G} \sum_{\substack{g \in G \\ x^{-1}gx \in H}} \overline{\chi(g)} \psi(x^{-1}gx).$$

For fixed x , substitute $h = x^{-1}gx$; as g runs over those elements of G with $x^{-1}gx \in H$, h runs over H , and $\chi(g) = \chi(xhx^{-1}) = \chi(h)$ since χ is a class function on G . So the inner sum is $\sum_{h \in H} \overline{\chi(h)}\psi(h)$, independent of x . Hence

$$\langle \chi, \text{Ind}_H^G \psi \rangle_G = \frac{|G|}{|G||H|} \sum_{h \in H} \overline{\chi(h)}\psi(h) = \langle \text{Res}_H^G \chi, \psi \rangle_H. \quad \square$$

Corollary 40.8.9

$\text{Ind}_H^G \psi$ is a character of G whenever ψ is a character of H , and induction takes nonnegative integer combinations of irreducible characters to nonnegative integer combinations.

Proof. We constructed the induced representation, so this is automatic; but note it also follows formally, since $\langle \chi_i, \text{Ind} \psi \rangle = \langle \text{Res} \chi_i, \psi \rangle \geq 0$ is a nonnegative integer for every irreducible χ_i . $\square$

Corollary 40.8.10

If $H \leq G$ and ψ is an irreducible character of H , then every irreducible constituent of $\text{Ind}_H^G \psi$ has ψ as a constituent of its restriction to H , and vice versa.

Example 40.8.11 (Permutation characters are induced)

Let G act transitively on X and let $H = \text{Stab}_G(x_0)$. Then $\mathbb{C}X \cong \text{Ind}_H^G \mathbf{1}_H$: both have the same character, since

$$\text{Ind}_H^G \mathbf{1}(g) = \frac{1}{|H|} \# \{x \in G : x^{-1}gx \in H\} = \# \{xH : gxH = xH\},$$

and the last quantity is $|\text{fix}_X(g)|$ under the identification $X \leftrightarrow G/H$. Frobenius reciprocity then reproves that $\langle \pi_X, \mathbf{1}_G \rangle = \langle \mathbf{1}_H, \mathbf{1}_H \rangle = 1$ for transitive actions.

Example 40.8.12 (The two-dimensional character of D_8)

Take $G = D_8$ and $H = \langle r \rangle \cong C_4$, of index 2, with coset representatives e, s . Let $\psi(r^k) = i^k$ be a faithful character of H . Since H is normal, every conjugate of r^k lies in H , and

$$\text{Ind}_H^G \psi(r^k) = \psi(r^k) + \psi(s^{-1}r^k s) = i^k + i^{-k},$$

which is $2, 0, -2, 0$ for $k = 0, 1, 2, 3$; while for a reflection g , no conjugate lies in H , so $\text{Ind} \psi(g) = 0$. Thus $\text{Ind}_H^G \psi = (2, -2, 0, 0, 0)$ on the classes e, r^2, r, s, rs – exactly the degree-2 irreducible character of D_8 . This is how one builds the dihedral characters ‘from above’.

Example 40.8.13 (Building characters of A_5 by induction)

Take $G = A_5$ and $H = A_4$, the stabiliser of the point 5, of index 5.

Inducing the trivial character gives the permutation character on 5 points, namely $(5, 1, 2, 0, 0) = \mathbf{1} + \chi_4$.

Now induce the linear character $\psi = \chi_2$ of A_4 , with values $(1, 1, \omega, \omega^2)$ on the classes $e, (12)(34), (123), (132)$ of A_4 . Use the centraliser form of the induced character formula, recalling $|C_{A_5}|$ has values 60, 4, 3, 5, 5 on the five classes of A_5 , and $|C_{A_4}|$ has values 12, 4, 3, 3 on the classes of A_4 .

- $g = e$: $\text{Ind } \psi(e) = 60 \cdot \frac{1}{12} = 5$, as it must be $(5 = |G : H| \cdot 1)$.
- $g = (12)(34)$: the A_5 -class of g meets A_4 in the single A_4 -class of double transpositions, so $\text{Ind } \psi(g) = 4 \cdot \frac{1}{4} = 1$.
- $g = (123)$: the A_5 -class of 3-cycles meets A_4 in *two* A_4 -classes, on which ψ takes the values ω and ω^2 . So $\text{Ind } \psi(g) = 3\left(\frac{\omega}{3} + \frac{\omega^2}{3}\right) = \omega + \omega^2 = -1$.
- g a 5-cycle: A_4 contains no elements of order 5, so $\text{Ind } \psi(g) = 0$.

Hence $\text{Ind}_{A_4}^{A_5} \chi_2 = (5, 1, -1, 0, 0) = \chi_5$, which we found earlier as $S^2 \chi_4 - \mathbf{1} - \chi_4$. Two different routes to the same character is always reassuring.

Remark (Transitivity of induction). If $K \leq H \leq G$ then $\text{Ind}_H^G \text{Ind}_K^H = \text{Ind}_K^G$, and likewise Res is transitive. Both follow from Frobenius reciprocity: for any irreducible χ of G ,

$$\langle \chi, \text{Ind}_H^G \text{Ind}_K^H \psi \rangle = \langle \text{Res}_H \chi, \text{Ind}_K^H \psi \rangle = \langle \text{Res}_K \chi, \psi \rangle = \langle \chi, \text{Ind}_K^G \psi \rangle.$$

§40.8.4 A Character Table Built by Induction

Here is a complete worked example where induction is genuinely the only easy route. Let

$$G = C_7 \rtimes C_3 = \langle a, b \mid a^7 = b^3 = e, bab^{-1} = a^2 \rangle,$$

a nonabelian group of order 21. (Such a group exists because 2 has order 3 modulo 7.)

Conjugacy classes. Conjugating a by b repeatedly gives $a \mapsto a^2 \mapsto a^4 \mapsto a^8 = a$, so $\{a, a^2, a^4\}$ is a class; similarly $\{a^3, a^6, a^5\}$ is a class. The elements $a^i b$ are all conjugate: since $C_G(b) \supseteq \langle b \rangle$ has order at least 3 and $b \notin Z(G)$, the class of b has size dividing 7 and greater than 1, so exactly 7; likewise for b^2 . So the classes are

$$\{e\} (1), \quad \{a, a^2, a^4\} (3), \quad \{a^3, a^6, a^5\} (3), \quad \text{ccl}(b) (7), \quad \text{ccl}(b^2) (7),$$

totalling $1 + 3 + 3 + 7 + 7 = 21$. So there are five irreducible characters.

Degrees. We have $G' = \langle a \rangle$ (as $bab^{-1}a^{-1} = a$), so $G/G' \cong C_3$ and there are exactly three linear characters $\mathbf{1}, \chi_2, \chi_3$, given by $a \mapsto 1, b \mapsto \omega^{\pm 1}$ with $\omega = e^{2\pi i/3}$. Then $21 = 3 + d_4^2 + d_5^2$ gives $d_4 = d_5 = 3$.

The degree-3 characters. Take $H = \langle a \rangle \cong C_7$, of index 3, and let $\zeta = e^{2\pi i/7}$ with $\psi(a^k) = \zeta^k$. Since $H \trianglelefteq G$, every conjugate of an element of H lies in H , and the coset representatives e, b, b^2 give

$$\text{Ind}_H^G \psi(a^k) = \psi(a^k) + \psi(b^{-1}a^kb) + \psi(b^{-2}a^kb^2) = \zeta^k + \zeta^{4k} + \zeta^{2k},$$

using $b^{-1}ab = a^4$ and $b^{-2}ab^2 = a^2$. No conjugate of b or b^2 lies in H , so $\text{Ind}_H^G \psi$ vanishes there. Writing

$$\eta = \zeta + \zeta^2 + \zeta^4, \quad \bar{\eta} = \zeta^3 + \zeta^5 + \zeta^6,$$

(the sums over the quadratic residues and non-residues modulo 7) we get $\text{Ind}_H^G \psi = (3, \eta, \bar{\eta}, 0, 0)$. Note

$$\eta + \bar{\eta} = \sum_{k=1}^6 \zeta^k = -1, \quad \eta \bar{\eta} = 2.$$

The first is the vanishing of the sum of all seventh roots of unity other than 1. For the second, expand into nine terms:

$$(\zeta + \zeta^2 + \zeta^4)(\zeta^3 + \zeta^5 + \zeta^6) = (\zeta^4 + \zeta^6 + 1) + (\zeta^5 + 1 + \zeta) + (1 + \zeta^2 + \zeta^3) = 3 + \sum_{k=1}^6 \zeta^k = 2.$$

So $\eta, \bar{\eta}$ are the roots of $x^2 + x + 2$, that is $\eta = \frac{-1+i\sqrt{7}}{2}$ (which is indeed the complex conjugate of $\bar{\eta}$, justifying the notation). Then

$$\langle \text{Ind} \psi, \text{Ind} \psi \rangle = \frac{1}{21} (9 + 3|\eta|^2 + 3|\bar{\eta}|^2) = \frac{9+6+6}{21} = 1,$$

so $\chi_4 := \text{Ind}_H^G \psi$ is irreducible; and $\chi_5 = \overline{\chi_4} = (3, \bar{\eta}, \eta, 0, 0)$ is a second one, obtained by inducing ψ^3 instead.

class size	1	3	3	7	7
	e	a	a^3	b	b^2
1	1	1	1	1	1
χ_2	1	1	1	ω	ω^2
χ_3	1	1	1	ω^2	ω
χ_4	3	η	$\bar{\eta}$	0	0
χ_5	3	$\bar{\eta}$	η	0	0

where $\eta = \frac{-1+i\sqrt{7}}{2}$, so $\eta + \bar{\eta} = -1$ and $\eta \bar{\eta} = 2$.

Checks: degrees $1 + 1 + 1 + 9 + 9 = 21$. Rows: $\langle \chi_4, \chi_4 \rangle = \frac{1}{21} (9 + 6 + 6) = 1$; $\langle \chi_4, \chi_5 \rangle = \frac{1}{21} (9 + 3\bar{\eta}^2 + 3\eta^2) = \frac{9+3(\eta^2+\bar{\eta}^2)}{21} = \frac{9+3(1-4)}{21} = 0$, using $\eta^2 + \bar{\eta}^2 = (\eta + \bar{\eta})^2 - 2\eta\bar{\eta} = -3$; $\langle \mathbf{1}, \chi_4 \rangle = \frac{1}{21} (3 + 3\eta + 3\bar{\eta}) = 0$; $\langle \chi_2, \chi_4 \rangle = \frac{1}{21} (3 + 3\eta + 3\bar{\eta} + 0 + 0) = 0$; $\langle \mathbf{1}, \chi_2 \rangle = \frac{1}{21} (1 + 3 + 3 + 7\omega + 7\omega^2) = \frac{7-7}{21} = 0$. Columns: e gives 21; a gives $1 + 1 + 1 + |\eta|^2 + |\bar{\eta}|^2 = 3 + 2 + 2 = 7 = 21/3$, and likewise for a^3 ; b gives $1 + 1 + 1 + 0 + 0 = 3 = 21/7$, and likewise for b^2 . All correct.

Remark. This G is the smallest nonabelian group of odd order, and it is a Frobenius group: the complement is $\langle b \rangle \cong C_3$, which satisfies $\langle b \rangle \cap g\langle b \rangle g^{-1} = 1$ for $g \notin \langle b \rangle$, and the Frobenius kernel is $\langle a \rangle \cong C_7$. Frobenius' theorem below explains, from the characters alone, why $\langle a \rangle$ had to be normal.

§40.8.5 Mackey's Formulae

We record, without full proofs, the theorem which describes what happens when induction and restriction are composed the 'wrong' way round. It is not needed in the sequel, but it is the natural completion of the story.

Let $H, K \leq G$. The set $K \backslash G / H$ of **double cosets** KgH partitions G ; each double coset is a union of left cosets of H . For $g \in G$, write $H^g = g^{-1}Hg$ and let gW denote the representation of gHg^{-1} on W given by $(ghg^{-1}) \cdot w = hw$.

Theorem 40.8.14 (Mackey's restriction formula)

With notation as above, for a representation W of H ,

$$\text{Res}_K^G \text{Ind}_H^G W \cong \bigoplus_{KgH \in K \backslash G / H} \text{Ind}_{K \cap {}^gH}^K \text{Res}_{K \cap {}^gH}^{H^g} ({}^gW),$$

where ${}^gH = gHg^{-1}$. The right hand side does not depend on the choice of double coset representatives.

The proof is a bookkeeping exercise: the space $\text{Ind}_H^G W = \bigoplus_{xH} x \otimes W$ is permuted by K according to the action of K on G/H , whose orbits are exactly the double cosets, and one identifies the summand corresponding to each orbit.

Corollary 40.8.15 (Mackey's irreducibility criterion)

Let $H \leq G$ and W an irreducible representation of H . Then $\text{Ind}_H^G W$ is irreducible if and only if, for every $g \in G \setminus H$, the representations

$$\text{Res}_{H \cap {}^gH}^H W \quad \text{and} \quad \text{Res}_{H \cap {}^gH}^{H^g} ({}^gW)$$

of $H \cap {}^gH$ have no irreducible constituent in common.

Proof sketch. By Frobenius reciprocity and Mackey with $K = H$,

$$\langle \text{Ind}_H^G W, \text{Ind}_H^G W \rangle_G = \langle W, \text{Res}_H^G \text{Ind}_H^G W \rangle_H = \sum_{HgH} \langle \text{Res}_{H \cap {}^gH} W, \text{Res}_{H \cap {}^gH} ({}^gW) \rangle.$$

The term for the double coset H itself contributes $\langle W, W \rangle_H = 1$, and all other terms are nonnegative; so the total is 1 if and only if all the others vanish. $\square$

Corollary 40.8.16

If $H \triangleleft G$ and W is irreducible, then $\text{Ind}_H^G W$ is irreducible if and only if ${}^gW \not\cong W$ for all $g \in G \setminus H$.

§40.8.6 An Application: Frobenius' Theorem

Here is a striking theorem which cannot (to this day) be proved without characters. It is the reason induction earns its keep.

Definition 40.8.17 (Frobenius group)

Let G be a finite group with a subgroup $1 < H < G$ such that

$$H \cap gHg^{-1} = 1 \quad \text{for all } g \in G \setminus H.$$

We call H a **Frobenius complement** and G a **Frobenius group**.

Equivalently, G acts transitively on G/H in such a way that no nonidentity element fixes two points, but some nonidentity element fixes a point.

Theorem 40.8.18 (Frobenius, 1901)

Let G be a Frobenius group with complement H . Then

$$K = \left(G \setminus \bigcup_{g \in G} gHg^{-1} \right) \cup \{1\}$$

is a normal subgroup of G with $|K| = |G : H|$ and $G = KH$, $K \cap H = 1$.

K is called the **Frobenius kernel**. We build up to the proof with a lemma which is the whole point.

Lemma 40.8.19

Let G, H be as above and let φ be a class function on H with $\varphi(1) = 0$. Then $\text{Res}_H^G \text{Ind}_H^G \varphi = \varphi$.

Proof. Let $h \in H$ with $h \neq 1$. By the induced character formula,

$$\text{Ind}_H^G \varphi(h) = \frac{1}{|H|} \sum_{\substack{x \in G \\ x^{-1}hx \in H}} \varphi(x^{-1}hx).$$

If $x^{-1}hx \in H$ with $h \neq 1$, then $h \in H \cap xHx^{-1}$, which is trivial unless $x \in H$; so the sum runs over $x \in H$ only, giving $\frac{1}{|H|} \cdot |H| \varphi(h) = \varphi(h)$. And at $h = 1$ we get $\text{Ind}_H^G \varphi(1) = |G : H| \varphi(1) = 0 = \varphi(1)$. $\square$

Proof of Frobenius' theorem. First note $N_G(H) = H$: if g normalises H and $g \notin H$ then $H = H \cap gHg^{-1} = 1$, a contradiction. So H has exactly $|G : H| =: m$ distinct conjugates, and by hypothesis they pairwise intersect trivially. Hence

$$\left| \bigcup_g gHg^{-1} \right| = m(|H| - 1) + 1 = |G| - m + 1,$$

so the set K defined in the statement has exactly m elements. We must show it is a subgroup, and normal.

Let ψ be an irreducible character of H with $\psi \neq \mathbf{1}_H$, and set

$$\varphi = \psi - \psi(1)\mathbf{1}_H, \quad \theta_\psi = \text{Ind}_H^G \varphi + \psi(1)\mathbf{1}_G.$$

This θ_ψ is a virtual character of G (a $\mathbb{Z}$ -combination of irreducible characters), and by the lemma $\text{Res}_H^G \theta_\psi = \varphi + \psi(1)\mathbf{1}_H = \psi$. Now compute its norm using Frobenius reciprocity and the lemma:

$$\langle \text{Ind } \varphi, \text{Ind } \varphi \rangle_G = \langle \varphi, \text{Res Ind } \varphi \rangle_H = \langle \varphi, \varphi \rangle_H = 1 + \psi(1)^2,$$

$$\langle \text{Ind } \varphi, \mathbf{1}_G \rangle_G = \langle \varphi, \mathbf{1}_H \rangle_H = -\psi(1).$$

Therefore

$$\langle \theta_\psi, \theta_\psi \rangle = (1 + \psi(1)^2) + 2\psi(1)(-\psi(1)) + \psi(1)^2 = 1.$$

Since also $\theta_\psi(1) = |G : H| \cdot 0 + \psi(1) > 0$, the virtual character θ_ψ is an *irreducible character* of G .

Now put

$$K' = \bigcap_{\substack{\psi \in \text{Irr}(H) \\ \psi \neq \mathbf{1}}} \ker \theta_\psi,$$

an intersection of kernels of characters, hence a normal subgroup of G .

If $g \in K$ (so $g = 1$ or g lies in no conjugate of H) then no conjugate of g lies in $H \setminus \{1\}$, so the induced character formula gives $\text{Ind } \varphi(g) = \frac{1}{|H|} \cdot |\{x : x^{-1}gx = 1\}| \cdot \varphi(1) = 0$ for $g \neq 1$, and hence $\theta_\psi(g) = \psi(1) = \theta_\psi(1)$. So $K \subseteq K'$.

Conversely, if $g \in K' \cap H$ then $\psi(g) = \theta_\psi(g) = \theta_\psi(1) = \psi(1)$ for every irreducible $\psi \neq \mathbf{1}$ of H , and trivially for $\mathbf{1}$ too; since the irreducible characters of H separate its elements from the identity (their common kernel is trivial), $g = 1$. So $K' \cap H = 1$, whence $|K'| |H| = |K' H| \leq |G|$ and $|K'| \leq m$.

Combining, $K \subseteq K'$ with $|K| = m \geq |K'| \geq |K|$, so $K = K'$ is a normal subgroup of order $m = |G : H|$. Finally $K \cap H = 1$ and $|K| |H| = |G|$ give $G = KH$. $\square$

Example 40.8.20

Take $G = A_4$ and $H = \langle (123) \rangle$. The conjugates of H are the four Sylow 3-subgroups, which pairwise intersect trivially, and $N_{A_4}(H) = H$; so H is a Frobenius complement. The elements of A_4 lying in no conjugate of H are exactly the three double transpositions, so the theorem produces

$$K = \{e, (12)(34), (13)(24), (14)(23)\} = V_4,$$

which is indeed normal, of order $4 = |A_4 : H|$. Of course we knew that already, but the point is that the argument never looked at the multiplication table.

Example 40.8.21

More generally, if $G = \mathbb{F}_q \rtimes \mathbb{F}_q^\times$ is the group of affine maps $x \mapsto ax + b$ on $\mathbb{F}_q$, then $H = \mathbb{F}_q^\times$ (the stabiliser of 0) is a Frobenius complement and $K = \mathbb{F}_q$ (the translations) is the Frobenius kernel. Every sharply 2-transitive group is of this shape.

§40.9 Arithmetic Properties of Characters

Characters are sums of roots of unity, so their values are constrained not just analytically (by orthogonality) but *arithmetically*. Exploiting this gives two beautiful theorems: that the degree of an irreducible representation divides the order of the group, and Burnside's theorem that every group of order $p^a q^b$ is soluble.

§40.9.1 Algebraic Integers

Definition 40.9.1 (Algebraic integer)

A complex number α is an **algebraic integer** if it is a root of some monic polynomial with coefficients in $\mathbb{Z}$. We write $\mathbb{A}$ for the set of algebraic integers.

Example 40.9.2

Every $n \in \mathbb{Z}$ is an algebraic integer (root of $X - n$), as is every root of unity (root of $X^n - 1$), and $\sqrt{2}$, and $\frac{1+\sqrt{5}}{2}$ (root of $X^2 - X - 1$ – so the A_5 table consists of algebraic integers, as it must).

The following criterion is the practical way to recognise algebraic integers, and it is what makes $\mathbb{A}$ a ring.

Proposition 40.9.3

Let $\alpha \in \mathbb{C}$. Then $\alpha \in \mathbb{A}$ if and only if there is a finitely generated nonzero additive subgroup $M \leq (\mathbb{C}, +)$ with $\alpha M \subseteq M$.

Proof. ($\Rightarrow$) If $\alpha^n + c_{n-1}\alpha^{n-1} + \cdots + c_0 = 0$ with $c_i \in \mathbb{Z}$, take $M = \mathbb{Z}\langle 1, \alpha, \dots, \alpha^{n-1} \rangle$; then $\alpha M \subseteq M$ because α^n is an integer combination of lower powers.

($\Leftarrow$) Let M be generated by $m_1, \dots, m_k$, not all zero. Then $\alpha m_i = \sum_j A_{ij} m_j$ for some integer matrix A . So $(\alpha I - A)\mathbf{m} = 0$ where $\mathbf{m} = (m_1, \dots, m_k)^T \neq 0$, hence $\det(\alpha I - A) = 0$. But $\det(XI - A)$ is a monic polynomial in X with integer coefficients. $\square$

Corollary 40.9.4

$\mathbb{A}$ is a subring of $\mathbb{C}$.

Proof. If $\alpha M \subseteq M$ and $\beta N \subseteq N$ with M, N finitely generated and nonzero, let MN be the additive group generated by all mn . It is finitely generated (by the products of generators), nonzero, and stable under both $\alpha + \beta$ and $\alpha\beta$. $\square$

Proposition 40.9.5

$\mathbb{A} \cap \mathbb{Q} = \mathbb{Z}$.

Proof. Certainly $\mathbb{Z} \subseteq \mathbb{A} \cap \mathbb{Q}$. Conversely let $\alpha = a/b \in \mathbb{Q}$ in lowest terms with $b > 0$, satisfying $\alpha^n + c_{n-1}\alpha^{n-1} + \cdots + c_0 = 0$. Multiplying by b^n ,

$$a^n = -b(c_{n-1}a^{n-1} + c_{n-2}a^{n-2}b + \cdots + c_0b^{n-1}),$$

so $b \mid a^n$. Since $\gcd(a, b) = 1$ this forces $b = 1$. $\square$

Corollary 40.9.6

All character values are algebraic integers.

Proof. $\chi(g)$ is a sum of roots of unity, and $\mathbb{A}$ is a ring containing all roots of unity. $\square$

§40.9.2 Central Characters

To get further we need algebraic integers built out of the class sizes as well.

Definition 40.9.7 (Class sums)

For a conjugacy class C of G , the **class sum** is $\widehat{C} = \sum_{g \in C} g \in \mathbb{C}G$.

Proposition 40.9.8

The class sums $\widehat{C}_1, \dots, \widehat{C}_r$ form a $\mathbb{C}$ -basis of the centre $Z(\mathbb{C}G)$, and

$$\widehat{C}_i \widehat{C}_j = \sum_{k=1}^r a_{ijk} \widehat{C}_k$$

for some *nonnegative integers* a_{ijk} .

Proof. An element $z = \sum_g \lambda_g g$ is central if and only if $hzh^{-1} = z$ for all h , i.e. $\lambda_{hgh^{-1}} = \lambda_g$, i.e. $g \mapsto \lambda_g$ is constant on classes. So $Z(\mathbb{C}G)$ has the class sums as a basis. The product $\widehat{C}_i \widehat{C}_j$ is central, hence a combination of class sums, and its coefficient at $g \in C_k$ is

$$a_{ijk} = |\{(x, y) \in C_i \times C_j : xy = g\}| \in \mathbb{Z}_{\geq 0}. \quad \square$$

Proposition 40.9.9 (Central character)

Let (ρ, V) be an irreducible representation of G with character χ of degree d . Then for each class C with representative g ,

$$\rho(\widehat{C}) = \omega_\chi(C) \operatorname{id}_V, \quad \text{where} \quad \omega_\chi(C) = \frac{|C| \chi(g)}{d}.$$

The function ω_χ is called the **central character**.

Proof. The map $\rho(\widehat{C}) = \sum_{x \in C} \rho(x)$ commutes with every $\rho(h)$, since conjugation by h permutes C . So it is a G -endomorphism of the irreducible V , hence a scalar $\lambda \operatorname{id}_V$ by Schur. Taking traces, $d\lambda = \sum_{x \in C} \chi(x) = |C|\chi(g)$. $\square$

Proposition 40.9.10

Each $\omega_\chi(C)$ is an algebraic integer.

Proof. Applying ρ to $\widehat{C_i C_j} = \sum_k a_{ijk} \widehat{C_k}$ and comparing scalars,

$$\omega_\chi(C_i) \omega_\chi(C_j) = \sum_k a_{ijk} \omega_\chi(C_k), \quad a_{ijk} \in \mathbb{Z}.$$

So $M := \mathbb{Z}\langle\omega_\chi(C_1), \dots, \omega_\chi(C_r)\rangle$ is a finitely generated additive group, nonzero (it contains $\omega_\chi(\{e\}) = 1$), with $\omega_\chi(C_i)M \subseteq M$ for each i . By the criterion, each $\omega_\chi(C_i)$ is an algebraic integer. $\square$

§40.9.3 Degrees Divide the Group Order

Theorem 40.9.11

Let χ be an irreducible character of the finite group G . Then $\chi(1)$ divides $|G|$.

Proof. Write $d = \chi(1)$, and let $C_1, \dots, C_r$ be the conjugacy classes, with representatives $g_1, \dots, g_r$. Then

$$\frac{|G|}{d} = \frac{1}{d} \sum_{j=1}^r |C_j| \chi(g_j) \overline{\chi(g_j)} = \sum_{j=1}^r \frac{|C_j| \chi(g_j)}{d} \cdot \overline{\chi(g_j)} = \sum_{j=1}^r \omega_\chi(C_j) \overline{\chi(g_j)},$$

using $\langle \chi, \chi \rangle = 1$ in the first equality. The right hand side is a sum of products of algebraic integers, so is an algebraic integer; the left hand side is rational. Hence $|G|/d \in \mathbb{A} \cap \mathbb{Q} = \mathbb{Z}$. $\square$

Remark. With a little more work one shows the sharper statement that $\chi(1)$ divides $|G : Z(G)|$; and a theorem of Ito says that if $A \trianglelefteq G$ is abelian then $\chi(1)$ divides $|G : A|$. We shall not need these.

Example 40.9.12

This is a strong constraint. If $|G| = 12$, the degrees of the irreducibles divide 12 and their squares sum to 12, with at least one degree equal to 1. The possible degree multisets are $\{1^{12}\}$, $\{1^4, 2^2\}$ and $\{1^3, 3\}$ – and indeed C_{12} , D_{12} and A_4 realise these.

§40.9.4 Burnside's Lemma on Vanishing

Lemma 40.9.13

Let χ be an irreducible character of G of degree d , and let $C = \text{ccl}_G(g)$ be a class with $\gcd(|C|, d) = 1$. Then either $\chi(g) = 0$ or $|\chi(g)| = d$ (equivalently, $\rho(g)$ is a scalar).

Proof. Choose $a, b \in \mathbb{Z}$ with $a|C| + bd = 1$. Then

$$\frac{\chi(g)}{d} = \frac{a|C|\chi(g) + bd\chi(g)}{d} = a\omega_\chi(C) + b\chi(g)$$

is an algebraic integer; call it α .

Now $\chi(g)$ is a sum of d roots of unity, all lying in $\mathbb{Q}(\zeta)$ where $\zeta = e^{2\pi i/n}$ and n is

the order of g . Let f be the minimal polynomial of α over $\mathbb{Q}$; since α is an algebraic integer, f is monic with integer coefficients. Each root of f is $\sigma(\alpha)$ for some field embedding $\sigma : \mathbb{Q}(\alpha) \rightarrow \mathbb{C}$, and each such σ extends to $\mathbb{Q}(\zeta)$, where it must send $\zeta \mapsto \zeta^k$ for some k coprime to n . Hence

$$\sigma(\alpha) = \frac{1}{d}(\lambda_1^k + \cdots + \lambda_d^k)$$

is again an average of d roots of unity, so $|\sigma(\alpha)| \leq 1$ by the triangle inequality.

The product of all roots of f is $\pm f(0) \in \mathbb{Z}$, and has modulus at most 1 with equality only if every root has modulus exactly 1. So either some root has modulus < 1 , in which case $|f(0)| < 1$ and hence $f(0) = 0$, forcing $\alpha = 0$ (as f is irreducible), or $|\alpha| = 1$.

In the first case $\chi(g) = 0$. In the second $|\chi(g)| = d$, and we showed earlier that this forces $\rho(g)$ to be a scalar matrix. $\square$

Theorem 40.9.14 (Burnside)

Let G be a finite group with a conjugacy class of size p^k for some prime p and some $k \geq 1$. Then G is not simple.

Proof. Let $g \neq e$ with $|\text{ccl}_G(g)| = p^k$, $k \geq 1$, and let $\chi_1 = \mathbf{1}, \chi_2, \dots, \chi_r$ be the irreducible characters, of degrees d_i . Column orthogonality between the columns of e and of g gives

$$0 = \sum_{i=1}^r d_i \chi_i(g) = 1 + \sum_{i=2}^r d_i \chi_i(g).$$

Suppose, for contradiction, that for every $i \geq 2$ either $p \mid d_i$ or $\chi_i(g) = 0$. Then

$$1 = - \sum_{\substack{i \geq 2 \\ p \nmid d_i}} d_i \chi_i(g) = -p \sum_{\substack{i \geq 2 \\ p \nmid d_i}} \frac{d_i}{p} \chi_i(g),$$

so $\frac{1}{p} = - \sum (d_i/p) \chi_i(g)$ is an algebraic integer. But $\frac{1}{p} \in \mathbb{Q} \setminus \mathbb{Z}$, contradicting $\mathbb{A} \cap \mathbb{Q} = \mathbb{Z}$.

So there is some $i \geq 2$ with $p \nmid d_i$ and $\chi_i(g) \neq 0$. Then $\gcd(d_i, p^k) = 1$, so by the lemma $\rho_i(g)$ is a scalar. Let

$$N = \ker \rho_i, \quad Z = \{x \in G : \rho_i(x) \text{ is a scalar}\}.$$

Both are normal subgroups of G (the second is the preimage of the centre of $\rho_i(G)$, which is normal in $\rho_i(G)$). If $N \neq 1$ then, since $\chi_i \neq \mathbf{1}$ gives $N \neq G$, the group G is not simple. So assume $N = 1$, i.e. ρ_i is faithful. Then Z contains $g \neq e$, so $Z \neq 1$. And $Z \neq G$: otherwise $\rho_i(G)$ would consist of scalars, hence be abelian, hence (by faithfulness) G would be abelian and every class would have size 1, contradicting $|\text{ccl}(g)| = p^k > 1$. So Z is a proper nontrivial normal subgroup. $\square$

§40.9.5 Burnside's $p^a q^b$ Theorem

Theorem 40.9.15 (Burnside, 1904)

Let p, q be primes and $a, b \geq 0$. Then every group of order $p^a q^b$ is soluble.

Proof. Induct on $|G|$. The case $|G| = 1$ is trivial.

If $a = 0$ or $b = 0$ then G is a p -group. Every nontrivial finite p -group has nontrivial centre (by the class equation), so $Z(G) \neq 1$; then $Z(G)$ is abelian and $G/Z(G)$ is a smaller p -group, soluble by induction, so G is soluble.

So assume $a, b \geq 1$. Let Q be a Sylow q -subgroup of G , which is nontrivial, and choose $g \in Z(Q)$ with $g \neq e$ (possible as $Z(Q) \neq 1$). Then $Q \leq C_G(g)$, so $|G : C_G(g)|$ divides $|G|/|Q| = p^a$. Hence $|\text{ccl}_G(g)| = p^k$ for some $0 \leq k \leq a$.

If $k = 0$ then $g \in Z(G)$, so $Z(G) \neq 1$; then $Z(G)$ and $G/Z(G)$ both have order of the form $p^{a'} q^{b'}$ and are smaller than G , so both are soluble by induction, hence so is G .

If $k \geq 1$ then by the previous theorem G is not simple, so there is $1 < N \trianglelefteq G$ with $N \neq G$. Both N and G/N have order dividing $p^a q^b$, hence of the form $p^{a'} q^{b'}$, and both are smaller than G ; so both are soluble by induction, and therefore G is soluble. $\square$

Remark. It is worth pausing on what has happened. The statement of Burnside's theorem mentions only groups and their orders; no representation appears anywhere. Yet the only known proofs for over sixty years went through character theory, and the character-free proof eventually found (by Bender, Goldschmidt and Matsuyama in the 1970s) is substantially harder. This is the standard advertisement for representation theory, and it is a fair one.

Remark. The bound is sharp in the sense that three primes are not enough: $|A_5| = 60 = 2^2 \cdot 3 \cdot 5$ and A_5 is not soluble.

§40.10 Representations of the Symmetric Group

The symmetric groups deserve a section of their own. They are the groups for which the general theory works out most completely: there is a purely combinatorial parametrisation of the irreducible representations, an explicit construction of each, and even a closed formula for the degrees. Everything is indexed by *partitions*.

§40.10.1 Partitions and Conjugacy Classes

Definition 40.10.1 (Partition)

A **partition** of n is a sequence $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_k)$ of integers with $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_k \geq 1$ and $\sum_i \lambda_i = n$. We write $\lambda \vdash n$, and let $p(n)$ be the number of partitions of n .

Proposition 40.10.2

The conjugacy classes of S_n are in bijection with the partitions of n , via cycle type. Consequently S_n has exactly $p(n)$ irreducible complex representations.

Proof. Every permutation is a product of disjoint cycles, and the multiset of cycle lengths (including fixed points as 1-cycles) is a partition of n . Conjugation relabels: if σ has cycle $(a_1 a_2 \cdots a_m)$ then $\tau\sigma\tau^{-1}$ has cycle $(\tau(a_1) \cdots \tau(a_m))$. So conjugate permutations have the same cycle type, and conversely two permutations of the same cycle type are conjugated by any τ matching up their cycles. The last sentence is the theorem that the number of irreducibles equals the number of classes. $\square$

Remark. The class of cycle type $1^{m_1} 2^{m_2} \cdots n^{m_n}$ has size

$$\frac{n!}{\prod_{i=1}^n i^{m_i} m_i!}.$$

For example in S_5 the type $2^2 1$ has $\frac{120}{2^2 \cdot 2! \cdot 1!} = 15$ elements, agreeing with our table.

So we are looking for a family of irreducible representations indexed by partitions. The combinatorial device that makes this work is the Young diagram.

Definition 40.10.3 (Young diagram)

The **Young diagram** of $\lambda = (\lambda_1, \dots, \lambda_k) \vdash n$ is the left-justified array of n boxes with λ_i boxes in row i .

Here are all the partitions of 4:

and all the partitions of 5:

There are $p(4) = 5$ and $p(5) = 7$ of them, matching the five irreducible characters of S_4 and the seven of S_5 that we computed by hand.

Definition 40.10.4 (Conjugate partition)

The **conjugate** (or **transpose**) partition λ' is obtained by reflecting the Young diagram in its main diagonal; that is, $\lambda'_j = \#\{i : \lambda_i \geq j\}$.

For instance $(3, 1)' = (2, 1, 1)$ and $(4, 1)' = (2, 1, 1, 1)$, while $(2, 2)' = (2, 2)$ and $(3, 1, 1)' = (3, 1, 1)$ are **self-conjugate**. Compare this with the tables we computed: the irreducible characters of S_4 and S_5 came in pairs swapped by tensoring with sign, together with one or two fixed characters. That is exactly transposition of diagrams, as we now explain.

§40.10.2 Tableaux, Tabloids and Specht Modules

Definition 40.10.5 (Young tableau)

A **(λ -)tableau** is a filling of the Young diagram of $\lambda \vdash n$ with the numbers $1, \dots, n$, each used once. Two tableaux are **row equivalent** if corresponding rows contain the same sets of entries; an equivalence class is a **tabloid**, written $\{t\}$.

The group S_n acts on tableaux by acting on the entries, and this descends to an action on tabloids.

Definition 40.10.6 (Permutation module)

M^λ is the permutation representation of S_n on the set of λ -tabloids.

Example 40.10.7

If $\lambda = (n)$ there is a single tabloid, and $M^{(n)}$ is the trivial representation. If $\lambda = (1^n)$ a tabloid is just an ordering of $1, \dots, n$, so $M^{(1^n)} = \mathbb{C}S_n$ is the regular representation. If $\lambda = (n-1, 1)$, a tabloid is determined by the entry in the second row, so $M^{(n-1,1)} = \mathbb{C}^n$ is the natural permutation representation.

These modules are far from irreducible, but each contains a distinguished irreducible submodule. Fix a λ -tableau t , and let

$$R_t = \{\sigma : \sigma \text{ preserves each row of } t\}, \quad C_t = \{\sigma : \sigma \text{ preserves each column of } t\}$$

be its row and column groups.

Definition 40.10.8 (Young symmetriser and Specht module)

Define the **signed column sum** $b_t = \sum_{\sigma \in C_t} \text{sign}(\sigma) \sigma \in \mathbb{C}S_n$, and the **polytabloid**

$$e_t = b_t \cdot \{t\} \in M^\lambda.$$

The **Specht module** is

$$S^\lambda = \mathbb{C}S_n\text{-span of } \{e_t : t \text{ a } \lambda\text{-tableau}\} \leq M^\lambda.$$

Since $\sigma e_t = e_{\sigma t}$, the span of the polytabloids is automatically a submodule.

Theorem 40.10.9 (James)

The Specht modules S^λ , for $\lambda \vdash n$, are irreducible, pairwise non-isomorphic, and every irreducible complex representation of S_n is isomorphic to exactly one of them. Moreover

$$S^{\lambda'} \cong S^\lambda \otimes \text{sign}.$$

We do not prove this here – the proof rests on a combinatorial lemma about tableaux (‘if $\lambda \neq \mu$ and $b_t \cdot \{s\} \neq 0$ then λ dominates μ ’) together with an application of Schur’s lemma. What matters for us is that the parametrisation exists and that we can compute with it. In particular, since transposing partitions is an involution on $\{\lambda \vdash n\}$ with fixed points the self-conjugate partitions, the last statement explains the pairing we observed.

Proposition 40.10.10 (Hook length formula, Frame–Robinson–Thrall)

For a box (i, j) of the diagram of λ , define its **hook length** $h(i, j)$ to be 1 plus the number of boxes strictly to its right in row i plus the number strictly below it in column j . Then

$$\dim S^\lambda = \frac{n!}{\prod_{(i,j) \in \lambda} h(i, j)}.$$

Example 40.10.11 (The irreducibles of S_4)

Let us compute the degrees. For $\lambda = (3, 1)$ the hook lengths are

4	2	1
1		

so $\dim S^{(3,1)} = 24/(4 \cdot 2 \cdot 1 \cdot 1) = 3$. Similarly $\dim S^{(2,2)} = 24/(3 \cdot 2 \cdot 2 \cdot 1) = 2$, and $\dim S^{(4)} = \dim S^{(1^4)} = 1$, with $\dim S^{(2,1,1)} = \dim S^{(3,1)} = 3$ by transposition. So the degrees are

$$1, 3, 2, 3, 1 \quad \text{with} \quad 1 + 9 + 4 + 9 + 1 = 24 = |S_4|,$$

exactly the degrees we found. Matching up: $S^{(4)} = \mathbf{1}$, $S^{(1^4)} = \text{sign}$, $S^{(3,1)}$ is the standard representation, $S^{(2,1,1)} = \text{standard} \otimes \text{sign}$, and $S^{(2,2)}$ is the degree-2 representation lifted from $S_4/V_4 \cong S_3$.

Example 40.10.12 (The irreducibles of S_5)

The hook length formula gives

$$\dim S^{(5)} = 1, \quad \dim S^{(4,1)} = \frac{120}{5 \cdot 3 \cdot 2 \cdot 1 \cdot 1} = 4,$$

$$\dim S^{(3,2)} = \frac{120}{4 \cdot 3 \cdot 1 \cdot 2 \cdot 1} = 5, \quad \dim S^{(3,1,1)} = \frac{120}{5 \cdot 2 \cdot 1 \cdot 2 \cdot 1} = 6,$$

and the remaining three follow by transposition: $\dim S^{(2,2,1)} = 5$, $\dim S^{(2,1^3)} = 4$ and $\dim S^{(1^5)} = 1$. The squares sum to

$$1 + 16 + 25 + 36 + 25 + 16 + 1 = 120 = |S_5|. \quad \checkmark$$

Comparing with our computed table: $\lambda = (4, 1)$ gives χ_3 (degree 4), $(2, 1^3)$ gives $\chi_4 = \text{sign} \cdot \chi_3$; $(3, 2)$ gives χ_6 (degree 5) and $(2, 2, 1)$ gives χ_7 ; and $(3, 1, 1)$, which is self-conjugate, gives the degree-6 character $\chi_5 = \Lambda^2 \chi_3$. That is exactly the pattern of associate pairs and one self-associate character that we noticed at the time.

Remark. There is also a combinatorial rule – the Murnaghan–Nakayama rule – computing the value of χ^λ on a permutation of cycle type μ , by removing ‘rim hooks’ from the diagram of λ . It is the natural generalisation of the recursion one finds by hand for small n . The interested reader will find all of this in James’ book *The Representation Theory of the Symmetric Groups*; for this course, the existence of the parametrisation and the hook length formula are the takeaway.

§40.11 Representations of Topological Groups

Everything so far has used the finiteness of G in one essential place: the averaging operator $\frac{1}{|G|} \sum_{g \in G}$. If we can replace that sum by an integral, the entire theory goes through. This is possible exactly when G is a compact topological group, and the resulting theory is one of the most useful things in mathematics – it is, among other things, where the quantum mechanics of angular momentum comes from.

§40.11.1 Topological Groups and Compactness

Definition 40.11.1 (Topological group)

A **topological group** is a group G with a topology such that multiplication $G \times G \rightarrow G$ and inversion $G \rightarrow G$ are continuous.

Example 40.11.2 (i) Any group with the discrete topology; in particular any finite group.

(ii) $(\mathbb{R}, +)$, $(\mathbb{C}^\times, \times)$, and $\mathrm{GL}_n(\mathbb{C})$ with the topology inherited from $\mathbb{C}^{n^2}$.

(iii) The compact groups $\mathrm{O}(n)$, $\mathrm{SO}(n)$, $\mathrm{U}(n)$, $\mathrm{SU}(n)$, and the circle $S^1 = \{z \in \mathbb{C} : |z| = 1\} \cong \mathrm{U}(1)$.

Of these, the ones in (iii) together with the finite groups are compact; $\mathbb{R}$, $\mathbb{C}^\times$ and $\mathrm{GL}_n(\mathbb{C})$ are not.

Definition 40.11.3 (Continuous representation)

A **representation** of a topological group G is a continuous homomorphism $\rho : G \rightarrow \mathrm{GL}(V)$ for a finite dimensional complex vector space V , where $\mathrm{GL}(V)$ has its usual topology. (Equivalently, all the matrix entries $\rho(g)_{ij}$ are continuous functions of g .)

The continuity requirement is not a formality. The circle S^1 has uncountably many one-dimensional representations as an abstract group – it is a divisible abelian group, so has vast numbers of homomorphisms to $\mathbb{C}^\times$ – but only countably many continuous ones, as we shall see.

The replacement for averaging is the following.

Definition 40.11.4 (Haar measure)

Let G be a compact topological group. A **Haar integral** on G is a linear functional $f \mapsto \int_G f$ on the space $C(G, \mathbb{R})$ of continuous real functions such that

- (i) $\int_G 1 = 1$ (normalisation);
- (ii) $\int_G f(xg) \, dg = \int_G f(gx) \, dg = \int_G f(g) \, dg$ for all $x \in G$ (translation invariance);
- (iii) $\int_G f \geq 0$ whenever $f \geq 0$ (positivity).

Theorem 40.11.5

Every compact Hausdorff topological group admits a unique Haar integral.

We shall not prove this – it is a piece of analysis rather than algebra, and for the two groups we care about we can just write the integral down.

Example 40.11.6 (i) If G is finite, $\int_G f = \frac{1}{|G|} \sum_{g \in G} f(g)$.

(ii) If $G = S^1$, $\int_G f = \frac{1}{2\pi} \int_0^{2\pi} f(e^{i\theta}) d\theta$.

(iii) If $G = \mathrm{SU}(2)$, which we will see is the unit sphere $S^3 \subset \mathbb{R}^4$, the Haar integral is $\frac{1}{2\pi^2}$ times the usual surface integral over S^3 (and $2\pi^2$ is exactly the surface area of the unit 3-sphere).

With the Haar integral in hand, the finite theory transfers essentially verbatim. We record what survives.

Theorem 40.11.7

Let G be a compact Hausdorff topological group and let V, W be (continuous, finite dimensional, complex) representations of G . Then:

- (i) V admits a G -invariant Hermitian inner product; equivalently $\rho(G) \leq \mathrm{U}(V)$ in a suitable basis.
- (ii) (Maschke) Every subrepresentation of V has a G -invariant complement, so V is completely reducible.
- (iii) (Schur) $\dim \mathrm{Hom}_G(V, W) = 1$ if $V \cong W$ are irreducible and 0 if they are non-isomorphic irreducibles.
- (iv) (Orthogonality) With $\langle f, f' \rangle = \int_G \overline{f(g)} f'(g) dg$, the irreducible characters are orthonormal; a representation is irreducible if and only if $\langle \chi, \chi \rangle = 1$; and characters determine representations up to isomorphism.

Proof. For (i), start from any inner product $(\cdot, \cdot)$ and set $\langle v, w \rangle = \int_G (gv, gw) dg$, which converges since $g \mapsto (gv, gw)$ is continuous on a compact space; invariance is property (ii) of the Haar integral, and positive definiteness follows from (iii) together with $\int_G 1 = 1$. Then (ii) follows by taking orthogonal complements, exactly as in the finite case. The proof of (iii) never used finiteness, only that V is a finite dimensional complex vector space.

For (iv), the proof of orthogonality goes through word for word: the map $\pi = \int_G \rho(g) dg$ is a projection onto V^G with $\dim V^G = \int_G \chi_V$, the space $\mathrm{Hom}_{\mathbb{C}}(V, W)$ is a representation with $\mathrm{Hom}_{\mathbb{C}}(V, W)^G = \mathrm{Hom}_G(V, W)$ and character $\overline{\chi_V} \chi_W$, and combining gives $\langle \chi_V, \chi_W \rangle = \dim \mathrm{Hom}_G(V, W)$. Schur finishes it. $\square$

Remark. One thing does *not* transfer: a compact group generally has infinitely many irreducible representations, so there is no finite ‘character table’ and no statement that $\sum d_i^2 = |G|$. The Peter–Weyl theorem is the correct replacement: the matrix coefficients of the irreducible representations span a dense subspace of $C(G)$, and $L^2(G)$ decomposes as $\widehat{\bigoplus_i V_i^{\oplus d_i}}$. For $G = S^1$ this is precisely the theory of Fourier series.

§40.11.2 Representations of the Circle

Theorem 40.11.8

Every irreducible representation of S^1 is one dimensional, of the form $\rho_n : z \mapsto z^n$ for a unique $n \in \mathbb{Z}$.

Proof. Since S^1 is abelian, Schur's lemma gives that every irreducible representation is one dimensional (the argument is identical to the finite case). So let $\rho : S^1 \rightarrow \mathbb{C}^\times$ be a continuous homomorphism. The image $\rho(S^1)$ is a compact subgroup of $\mathbb{C}^\times$, hence bounded, and closed under taking powers; a complex number λ with $|\lambda| \neq 1$ has $|\lambda^n| \rightarrow \infty$ or $\rightarrow 0$, so $\rho(S^1) \subseteq S^1$.

Now consider $\psi : \mathbb{R} \rightarrow S^1$, $\psi(x) = \rho(e^{2\pi i x})$, a continuous homomorphism from $(\mathbb{R}, +)$. Lifting through the covering $\mathbb{R} \rightarrow S^1$ (or, concretely, choosing a continuous branch of $\frac{1}{2\pi i} \log \psi$ near 0 and extending by additivity) gives a continuous homomorphism $\alpha : \mathbb{R} \rightarrow \mathbb{R}$ with $\psi(x) = e^{2\pi i \alpha(x)}$. A continuous additive map $\mathbb{R} \rightarrow \mathbb{R}$ is $x \mapsto \lambda x$: indeed $\alpha(q) = q\alpha(1)$ for $q \in \mathbb{Q}$ by additivity, and continuity extends this to $\mathbb{R}$. Finally $\psi(1) = \rho(1) = 1$ forces $\lambda = \alpha(1) \in \mathbb{Z}$, and then $\rho(z) = z^\lambda$. $\square$

So the characters of S^1 are $\chi_n(e^{i\theta}) = e^{in\theta}$, and orthonormality reads

$$\frac{1}{2\pi} \int_0^{2\pi} e^{-im\theta} e^{in\theta} d\theta = \delta_{mn},$$

which the reader will recognise. Decomposing a representation of S^1 into irreducibles is decomposing a function into its Fourier modes; the Peter–Weyl theorem for S^1 is the completeness of the Fourier basis in $L^2(S^1)$.

§40.11.3 The Group $\mathrm{SU}(2)$

Definition 40.11.9

$\mathrm{SU}(2) = \{A \in \mathrm{GL}_2(\mathbb{C}) : \bar{A}^T A = I, \det A = 1\}$.

Proposition 40.11.10

$$\mathrm{SU}(2) = \left\{ \begin{pmatrix} a & b \\ -\bar{b} & \bar{a} \end{pmatrix} : a, b \in \mathbb{C}, |a|^2 + |b|^2 = 1 \right\},$$

and hence $\mathrm{SU}(2)$ is homeomorphic to the unit sphere $S^3 \subseteq \mathbb{C}^2 = \mathbb{R}^4$. In particular it is compact and connected.

Proof. If $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$ has determinant 1 then $A^{-1} = \begin{pmatrix} d & -b \\ -c & a \end{pmatrix}$, and unitarity says $A^{-1} = \bar{A}^T = \begin{pmatrix} \bar{a} & \bar{c} \\ \bar{b} & \bar{d} \end{pmatrix}$. Comparing entries gives $d = \bar{a}$ and $c = -\bar{b}$, and then $\det A = |a|^2 + |b|^2 = 1$. Conversely all such matrices are in $\mathrm{SU}(2)$. $\square$

Remark. Equivalently, $\mathrm{SU}(2)$ is the group of unit quaternions. Identify $\mathbb{H} = \mathbb{R}\langle 1, i, j, k \rangle$ with the set of all matrices $\begin{pmatrix} a & b \\ -\bar{b} & \bar{a} \end{pmatrix}$, with no norm condition imposed; then the quaternion norm is $\det$, and the unit quaternions are exactly $\mathrm{SU}(2)$. This is why $Q_8 \leq \mathrm{SU}(2)$, and it is the source of the degree-2 representation of Q_8 we met earlier.

The key to everything is the **maximal torus**

$$T = \left\{ t_\theta := \begin{pmatrix} e^{i\theta} & 0 \\ 0 & e^{-i\theta} \end{pmatrix} : \theta \in \mathbb{R} \right\} \cong S^1 \leq \mathrm{SU}(2).$$

Proposition 40.11.11

Every element of $\mathrm{SU}(2)$ is conjugate to some $t_\theta \in T$, and t_θ is conjugate to $t_{\theta'}$ if and only if $\theta' \equiv \pm\theta$. Consequently the conjugacy classes of $\mathrm{SU}(2)$ are in bijection with $[-1, 1]$, via $A \mapsto \frac{1}{2} \mathrm{tr} A = \cos \theta$.

Proof. A unitary matrix is diagonalisable by a unitary change of basis (the spectral theorem from *Linear Algebra*), so $A = PDP^{-1}$ with $P \in \mathrm{U}(2)$ and D diagonal unitary. Since $\det A = 1$ the diagonal entries are $e^{\pm i\theta}$, so $D \in T$. Replacing P by $\lambda^{-1}P$ where $\lambda^2 = \det P$ gives $P \in \mathrm{SU}(2)$ without changing PDP^{-1} .

Now let $s = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \in \mathrm{SU}(2)$. A direct computation gives $st_\theta s^{-1} = t_{-\theta}$, so $t_\theta \sim t_{-\theta}$. Conversely conjugate matrices have the same eigenvalues, so $t_\theta \sim t_{\theta'}$ forces $\{e^{i\theta}, e^{-i\theta}\} = \{e^{i\theta'}, e^{-i\theta'}\}$. Finally $\mathrm{tr} t_\theta = 2 \cos \theta$ determines $\{\pm\theta\}$ modulo 2π . $\square$

The picture is worth having. Think of $\mathrm{SU}(2) = S^3$ as a sphere with poles I and $-I$: the conjugacy classes are the ‘latitudes’, which are honest 2-spheres of radius $\sqrt{1-x^2}$ where $x = \frac{1}{2} \mathrm{tr}$, degenerating to points at the poles. The maximal torus is a great circle through both poles, meeting each latitude in exactly the two points t_θ and $t_\theta^{-1} = t_{-\theta}$.

Corollary 40.11.12

A class function on $\mathrm{SU}(2)$ is determined by its restriction to T , and that restriction satisfies $f(t_\theta) = f(t_{-\theta})$.

Integration of class functions can be pushed down to T as well; the resulting formula is the simplest instance of the *Weyl integration formula*.

Proposition 40.11.13 (Weyl integration formula for $\mathrm{SU}(2)$)

For a continuous class function f on $\mathrm{SU}(2)$,

$$\int_{\mathrm{SU}(2)} f = \frac{2}{\pi} \int_0^\pi f(t_\theta) \sin^2 \theta \, d\theta.$$

Sketch. Under $\mathrm{SU}(2) \cong S^3$, the conjugacy class with $\frac{1}{2} \mathrm{tr} = \cos \theta$ is the 2-sphere of radius $\sin \theta$ obtained by intersecting S^3 with the hyperplane at height $\cos \theta$; its surface area is $4\pi \sin^2 \theta$. Slicing S^3 by these spheres and using $\int_{\mathrm{SU}(2)} f = \frac{1}{2\pi^2} \int_{S^3} f$,

$$\int_{\mathrm{SU}(2)} f = \frac{1}{2\pi^2} \int_0^\pi f(t_\theta) \cdot 4\pi \sin^2 \theta \, d\theta = \frac{2}{\pi} \int_0^\pi f(t_\theta) \sin^2 \theta \, d\theta. \quad \square$$

§40.11.4 The Irreducible Representations of $\mathrm{SU}(2)$

Definition 40.11.14

Let V_n be the space of homogeneous polynomials of degree n in two variables X, Y over $\mathbb{C}$:

$$V_n = \mathbb{C}\langle X^n, X^{n-1}Y, \dots, Y^n \rangle, \quad \dim V_n = n + 1.$$

Let $\mathrm{GL}_2(\mathbb{C})$ – and hence $\mathrm{SU}(2)$ – act by

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix} \cdot f(X, Y) = f(aX + cY, bX + dY).$$

One checks this is a (continuous, polynomial in the entries) representation. Note V_0 is the trivial representation, V_1 is the standard representation on $\mathbb{C}^2$, and in general $V_n \cong S^n V_1$.

Proposition 40.11.15

The character of V_n satisfies

$$\chi_n(t_\theta) = e^{in\theta} + e^{i(n-2)\theta} + \dots + e^{-in\theta} = \frac{\sin((n+1)\theta)}{\sin \theta}.$$

Proof. With $z = e^{i\theta}$ we have $t_\theta \cdot X = zX$ and $t_\theta \cdot Y = z^{-1}Y$, so

$$t_\theta \cdot (X^j Y^{n-j}) = z^j z^{-(n-j)} X^j Y^{n-j} = z^{2j-n} X^j Y^{n-j}.$$

So the monomials are an eigenbasis with eigenvalues z^{2j-n} for $j = 0, \dots, n$, and summing the geometric series gives $\sum_{j=0}^n z^{2j-n} = \frac{z^{n+1} - z^{-(n+1)}}{z - z^{-1}}$, which is $\sin((n+1)\theta)/\sin \theta$. $\square$

Theorem 40.11.16

Each V_n is an irreducible representation of $\mathrm{SU}(2)$.

Proof. First, a direct computation:

$$\langle \chi_n, \chi_n \rangle = \frac{2}{\pi} \int_0^\pi \left| \frac{\sin((n+1)\theta)}{\sin \theta} \right|^2 \sin^2 \theta \, d\theta = \frac{2}{\pi} \int_0^\pi \sin^2((n+1)\theta) \, d\theta = \frac{2}{\pi} \cdot \frac{\pi}{2} = 1,$$

so V_n is irreducible.

It is instructive to see this without integration. Let $0 \neq W \leq V_n$ be $\mathrm{SU}(2)$ -invariant. Then W is T -invariant, and the monomials $X^j Y^{n-j}$ span the T -eigenspaces, which are one dimensional with *distinct* eigenvalues z^{2j-n} . Hence W is spanned by a subset of the monomials. Pick $X^j Y^{n-j} \in W$ and apply

$$g = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \in \mathrm{SU}(2),$$

which sends $X \mapsto \frac{1}{\sqrt{2}}(X+Y)$ and $Y \mapsto \frac{1}{\sqrt{2}}(-X+Y)$. Then

$$g \cdot (X^j Y^{n-j}) = 2^{-n/2} (X+Y)^j (-X+Y)^{n-j} \in W$$

has nonzero coefficient of X^n , namely $\pm 2^{-n/2}$; since W is spanned by monomials, $X^n \in W$. Applying g again, $2^{-n/2} (X+Y)^n \in W$ has *every* monomial coefficient nonzero, so every $X^j Y^{n-j}$ lies in W and $W = V_n$. $\square$

Theorem 40.11.17

Every irreducible representation of $\mathrm{SU}(2)$ is isomorphic to V_n for exactly one $n \geq 0$.

Proof. Let V be an irreducible representation with character χ . Restricting V to $T \cong S^1$ and decomposing into the characters $z \mapsto z^m$ of the circle, we get

$$\chi(t_\theta) = \sum_{m \in \mathbb{Z}} a_m z^m, \quad z = e^{i\theta},$$

a Laurent polynomial with $a_m \in \mathbb{Z}_{\geq 0}$ and only finitely many nonzero. Since t_θ and $t_{-\theta}$ are conjugate in $\mathrm{SU}(2)$, we have $a_m = a_{-m}$: the Laurent polynomial is symmetric under $z \mapsto z^{-1}$.

Now the functions $\chi_n|_T = z^n + z^{n-2} + \cdots + z^{-n}$, for $n \geq 0$, form a $\mathbb{Z}$ -basis of the group of symmetric Laurent polynomials with integer coefficients: they are ‘triangular’, in that χ_n has top term z^n with coefficient 1. So we may subtract off successively and write

$$\chi = \sum_{n \geq 0} c_n \chi_n, \quad c_n \in \mathbb{Z},$$

with only finitely many $c_n \neq 0$. But then $1 = \langle \chi, \chi \rangle = \sum_n c_n^2$ by orthonormality of the χ_n , so exactly one c_n is ± 1 and the rest are zero. As $\chi(1) > 0$ the sign is $+$, so $\chi = \chi_n$ and hence $V \cong V_n$. $\square$

§40.11.5 The Clebsch–Gordan Formula

Tensor products of the V_n decompose in a completely explicit way. This is the mathematics behind ‘adding angular momenta’ in quantum mechanics.

Theorem 40.11.18 (Clebsch–Gordan)For $m, n \geq 0$,

$$V_m \otimes V_n \cong V_{m+n} \oplus V_{m+n-2} \oplus \cdots \oplus V_{|m-n|}.$$

Proof. Assume without loss of generality that $m \leq n$. Work on T , writing $z = e^{i\theta}$, and clear the denominator: multiplying by $z - z^{-1}$,

$$\chi_m \chi_n \cdot (z - z^{-1}) = \left(\sum_{j=0}^m z^{m-2j} \right) (z^{n+1} - z^{-(n+1)}) = \sum_{j=0}^m z^{m+n+1-2j} - \sum_{j=0}^m z^{m-n-1-2j}.$$

On the other hand,

$$\left(\sum_{j=0}^m \chi_{m+n-2j} \right) (z - z^{-1}) = \sum_{j=0}^m z^{m+n+1-2j} - \sum_{j=0}^m z^{-(m+n+1-2j)}.$$

The first sums are literally equal. For the second sums, as j runs from 0 to m the exponents $m - n - 1 - 2j$ run through

$$m - n - 1, m - n - 3, \dots, -m - n - 1,$$

while the exponents $-(m+n+1-2j)$ run through the same list in the opposite order. So the two expressions agree, and since $z - z^{-1}$ is not identically zero we get $\chi_m \chi_n = \sum_{j=0}^m \chi_{m+n-2j}$ on T , hence everywhere. As characters determine representations, the decomposition follows. $\square$

The bookkeeping is clearest as a picture. The T -weights of $V_m \otimes V_n$ are the sums of a weight of V_m and a weight of V_n , so they form a rectangular grid, and the multiplicity of a given weight is the number of lattice points on the corresponding anti-diagonal. Reading off the multiplicity profile and peeling off one layer at a time gives the decomposition. For $V_2 \otimes V_3$:

so $V_2 \otimes V_3 \cong V_5 \oplus V_3 \oplus V_1$, as the theorem predicts.

Example 40.11.19

$V_1 \otimes V_1 \cong V_2 \oplus V_0$: the tensor square of the standard 2-dimensional representation splits as $S^2 V_1 \oplus \Lambda^2 V_1$, and indeed $S^2 V_1 = V_2$ while $\Lambda^2 V_1$ is one dimensional with trivial action (as $\det = 1$ on $\text{SU}(2)$).

§40.11.6 From $SU(2)$ to $SO(3)$

Theorem 40.11.20

There is a surjective continuous homomorphism $\varphi : SU(2) \rightarrow SO(3)$ with kernel $\{\pm I\}$, inducing an isomorphism of topological groups

$$SU(2)/\{\pm I\} \cong SO(3).$$

Proof. Let

$$\mathfrak{su}(2) = \{A \in M_2(\mathbb{C}) : \overline{A}^T = -A, \operatorname{tr} A = 0\} = \mathbb{R}\langle \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}, \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix} \rangle,$$

a real vector space of dimension 3. (These are the ‘purely imaginary quaternions’.) Equip it with the inner product $\langle A, B \rangle = \frac{1}{2} \operatorname{tr}(A\overline{B}^T)$, for which the displayed basis is orthonormal, and note $\langle A, A \rangle = \det A$ for $A \in \mathfrak{su}(2)$.

The group $SU(2)$ acts on $\mathfrak{su}(2)$ by conjugation, $\varphi(g)(A) = gAg^{-1}$; this preserves trace and adjoints, so preserves $\mathfrak{su}(2)$, and it preserves $\det$, hence the inner product. So $\varphi : SU(2) \rightarrow O(3)$ is a continuous homomorphism. Since $SU(2) \cong S^3$ is connected and $\varphi(I) = I$, the image lies in the identity component $SO(3)$.

The kernel consists of those g commuting with all of $\mathfrak{su}(2)$, hence with all of $M_2(\mathbb{C})$ (which $\mathfrak{su}(2)$ spans over $\mathbb{C}$ together with I), hence the scalars in $SU(2)$, which are $\pm I$.

For surjectivity, compute: conjugation by t_θ fixes $\begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}$ and rotates the other two basis vectors by 2θ . So the image contains all rotations about one axis by all angles; and conjugating this one-parameter family by other elements of $SU(2)$ – whose image acts transitively on axes, since $SU(2)$ acts transitively on the unit sphere of $\mathfrak{su}(2)$ – gives all rotations. Hence φ is onto. The induced bijection $SU(2)/\{\pm I\} \rightarrow SO(3)$ is a continuous bijection from a compact space to a Hausdorff space, hence a homeomorphism. $\square$

So $SU(2)$ is a *double cover* of $SO(3)$: each rotation has exactly two preimages, $\pm g$. Concretely, the rotation by angle 2θ about a fixed axis is the image of both t_θ and $t_{\theta+\pi} = -t_\theta$; going once round a loop of rotations lifts to a path in $SU(2)$ from g to $-g$.

each rotation has exactly two preimages $\pm g$

Corollary 40.11.21

The irreducible representations of $\mathrm{SO}(3)$ are exactly the V_{2n} for $n \geq 0$, of odd dimensions $1, 3, 5, \dots$

Proof. By the lifting correspondence, representations of $\mathrm{SO}(3) = \mathrm{SU}(2)/\{\pm I\}$ are precisely representations of $\mathrm{SU}(2)$ with $-I$ in the kernel, and irreducibility is preserved. Now $-I = t_\pi$ acts on V_n with eigenvalues $(e^{i\pi})^{2j-n} = (-1)^n$, so $-I$ acts as $(-1)^n \mathrm{id}$. This is trivial exactly when n is even. $\square$

Remark. This is why in quantum mechanics the orbital angular momentum states come in multiplets of odd dimension $2\ell+1$ (representations of the rotation group $\mathrm{SO}(3)$), while spin- $\frac{1}{2}$ particles live in the even dimensional representations V_{odd} , which are representations of $\mathrm{SU}(2)$ but only *projective* representations of $\mathrm{SO}(3)$: rotating a spin- $\frac{1}{2}$ state by 2π multiplies it by -1 . The Clebsch–Gordan formula, in the physicists’ labelling $V_n \leftrightarrow \text{spin } j = n/2$, reads

$$j_1 \otimes j_2 = (j_1 + j_2) \oplus (j_1 + j_2 - 1) \oplus \cdots \oplus |j_1 - j_2|,$$

which is the rule for adding angular momenta.

Example 40.11.22 ($\mathrm{SO}(3)$ and $\mathrm{SU}(2)$ inside $\mathrm{U}(2)$)

One can push this further. Every element of $\mathrm{U}(2)$ is λA with $|\lambda| = 1$ and $A \in \mathrm{SU}(2)$, so there is a surjection $S^1 \times \mathrm{SU}(2) \rightarrow \mathrm{U}(2)$ with kernel $\{(1, I), (-1, -I)\}$. Since the irreducible representations of a product are the tensor products of irreducibles, the irreducible representations of $\mathrm{U}(2)$ are the $\rho_m \otimes V_n$ with $m \equiv n \pmod{2}$, i.e. $\det^k \otimes V_n$ for $k \in \mathbb{Z}$ and $n \geq 0$.

Remark (What was left out). We have taken the shortest path to $\mathrm{SU}(2)$. The general theory of compact connected Lie groups – maximal tori, roots and weights, the Weyl group, the Weyl character formula – has $\mathrm{SU}(2)$ as its first and smallest case, and every feature we used (the torus T , the two-element Weyl group generated by $z \mapsto z^{-1}$, the factor $\sin^2 \theta = |z - z^{-1}|^2/4$ in the integration formula, the triangular basis of characters) is an instance of a general phenomenon. That is the subject of a Part III course.

41 Riemann Surfaces

Complex analysis is full of functions that refuse to be functions. The logarithm is the obvious offender: $\exp$ is surjective onto $\mathbb{C}^*$ but wildly non-injective, so ‘the’ logarithm of z is only defined once we have made a choice, and no choice can be made consistently on all of $\mathbb{C}^*$. The same is true of $\sqrt{z}$, of $\sqrt{z^3 - z}$, and of the inverse of essentially any interesting holomorphic map. The traditional response is to slit the plane along a branch cut and work on what is left, but this is a confession of defeat: the cut is an artefact of our bookkeeping, not of the function, and the whole interest of $\log$ lies precisely in what happens when you walk around the origin and come back changed.

Riemann’s idea was to stop mutilating the domain and start enlarging it. If $\log$ wants to take infinitely many values at each point of $\mathbb{C}^*$, then give it a domain with infinitely many points lying over each point of $\mathbb{C}^*$ – an infinite spiral ramp – on which it becomes an honest single-valued holomorphic function. The price is that this new domain is no longer an open subset of $\mathbb{C}$; it is a space which merely *looks like* $\mathbb{C}$ near each of its points. That is a Riemann surface, and once we allow ourselves such objects a great deal falls into place. Multi-valued functions become genuine functions, branch cuts become invisible, and – most strikingly – the analysis starts to control the topology. We will prove the Riemann–Hurwitz formula, which says that a holomorphic map between compact surfaces forces a numerical relation between their genera and its branching, and we will use it to compute the genus of a surface from nothing more than the equation that cuts it out.

This article constitutes my notes for the ‘Riemann Surfaces’ course, held in Michaelmas 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§41.1 Holomorphic Functions Revisited

We begin by recalling, mostly without proof, what IB Complex Analysis gives us. Nothing in this section is new, but the results here are the local engine driving everything later on: every theorem we prove about Riemann surfaces will ultimately be a theorem about holomorphic functions on discs, transported by charts.

§41.1.1 Analytic Functions and their Zeros

Definition 41.1.1 (Domain)

A **domain** is a non-empty open connected subset $D \subseteq \mathbb{C}$.

Open discs $D(a, r) = \{z : |z - a| < r\}$, punctured discs $D(a, r) \setminus \{a\}$, annuli, half-planes and slit planes are all domains, and these are essentially the only ones we will ever need to write down explicitly.

Definition 41.1.2 (Holomorphic Function)

Let $D \subseteq \mathbb{C}$ be a domain. A function $f : D \rightarrow \mathbb{C}$ is **holomorphic** (or **analytic**) if it

is complex differentiable at every point of D .

The great theorem of IB Complex Analysis is that this weak-looking hypothesis is enormously strong: a holomorphic function is automatically infinitely differentiable, and is represented by its Taylor series on any disc contained in its domain. In particular ‘complex differentiable everywhere’ and ‘locally the sum of a convergent power series’ mean the same thing, and we shall use the two descriptions interchangeably.¹

The first consequence we need concerns zeros. A holomorphic function cannot vanish on a set with an accumulation point without vanishing identically – its zeros are isolated.

Proposition 41.1.3 (Isolated Zeros)

Let f be holomorphic on a domain D and suppose $f(z_0) = 0$. Then either f is identically zero on D , or there is a punctured disc about z_0 on which f does not vanish.

Proof. Write $f(z) = \sum_{n \geq 0} a_n(z - z_0)^n$ on some disc $U = D(z_0, r) \subseteq D$. If every a_n vanishes then $f \equiv 0$ on U , and a connectedness argument (the set where all derivatives of f vanish is open and closed in D) gives $f \equiv 0$ on all of D .

Otherwise let $m \geq 0$ be minimal with $a_m \neq 0$, so that on U we may write

$$f(z) = (z - z_0)^m g(z), \quad g(z) = \sum_{n \geq 0} a_{m+n}(z - z_0)^n.$$

The series for g converges on U , so g is holomorphic there, and $g(z_0) = a_m \neq 0$. By continuity g is non-vanishing on some disc $D(z_0, \delta)$, and therefore f is non-vanishing on $D(z_0, \delta) \setminus \{z_0\}$. $\square$

The integer m appearing in the proof is the **order** of the zero of f at z_0 , and it is worth noticing now – because the observation is the whole of Section 41.9 in disguise – that near such a point f looks like $z \mapsto z^m$ multiplied by a non-vanishing function.

Corollary 41.1.4 (Identity Theorem)

Let f, g be holomorphic on a domain D . If the set $\{z \in D : f(z) = g(z)\}$ has an accumulation point in D , then $f = g$ on D .

Proof. Apply Proposition 41.1.3 to $f - g$: the agreement set is not discrete, so $f - g$ cannot have isolated zeros, and hence vanishes identically. $\square$

This is the single most important fact in the course. It says a holomorphic function has no local freedom whatsoever: its germ at one point determines it everywhere on a connected domain. All of analytic continuation is an attempt to exploit this rigidity, and all of the trouble with analytic continuation comes from the word ‘connected’.

§41.1.2 Singularities and Meromorphic Functions

¹This is why the words ‘holomorphic’ and ‘analytic’ are used as synonyms throughout. In the real setting they are very much not synonyms.

Definition 41.1.5 (Isolated Singularity)

A function f holomorphic on a punctured disc $D(z_0, r) \setminus \{z_0\}$ is said to have an **isolated singularity** at z_0 .

On such a punctured disc f has a Laurent expansion

$$f(z) = \sum_{n=-\infty}^{\infty} a_n(z - z_0)^n,$$

converging locally uniformly, and the singularity is classified by the tail of negative coefficients.

Definition 41.1.6 (Types of Singularity)

With notation as above, we say z_0 is

- (i) a **removable singularity** if $a_n = 0$ for all $n < 0$;
- (ii) a **pole of order** $m > 0$ if $a_{-m} \neq 0$ and $a_n = 0$ for all $n < -m$;
- (iii) an **essential singularity** otherwise.

A pole of order 1 is called **simple**.

Theorem 41.1.7 (Riemann Removable Singularity Theorem)

If f is holomorphic and bounded on a punctured disc about z_0 , then z_0 is a removable singularity, and f extends holomorphically over z_0 .

Theorem 41.1.8 (Casorati–Weierstrass)

The point z_0 is an essential singularity of f if and only if $f(U)$ is dense in $\mathbb{C}$ for every punctured neighbourhood U of z_0 .

Both were proved in IB Complex Analysis and we take them as given. The trichotomy is worth restating in the form we shall actually use: as $z \rightarrow z_0$, either $f(z)$ tends to a limit in $\mathbb{C}$ (removable), or $|f(z)| \rightarrow \infty$ (pole), or f oscillates so violently that it comes arbitrarily close to every complex number (essential). Poles are therefore not really singularities at all if we are willing to let ∞ count as a value, and that willingness is exactly what the Riemann sphere will formalise.

Definition 41.1.9 (Meromorphic Function)

Let D be a domain and $A \subseteq D$ a discrete closed subset. A holomorphic function $f : D \setminus A \rightarrow \mathbb{C}$ with a pole at each point of A is called **meromorphic** on D .

Example 41.1.10

The function

$$f(z) = \frac{1}{e^{1/z} - 1}$$

is meromorphic on the upper half-plane, with simple poles at the points $1/(2\pi in)$ for $n \in \mathbb{N}$. Note what happens if we try to regard f as meromorphic on all of $\mathbb{C}$: the poles accumulate at 0, so the set of poles is no longer discrete as a subset of $\mathbb{C}$, and indeed 0 is an essential singularity of f . The condition that A be discrete *and closed in D* is doing real work.

§41.1.3 The Open Mapping Theorem and the Maximum Modulus Principle

The last two facts we shall want are global in flavour.

Theorem 41.1.11 (Open Mapping Theorem)

A non-constant holomorphic function on a domain $D \subseteq \mathbb{C}$ is an open map.

Theorem 41.1.12 (Maximum Modulus Principle)

Let f be holomorphic on a domain D . If $|f|$ attains a local maximum at some point of D , then f is constant.

The second follows immediately from the first: if $f(D)$ is open then no point of $f(D)$ can be a point of maximum modulus of $f(D)$, since every neighbourhood of a point w contains points of larger modulus.

Finally we record the local statement that will become the definition of multiplicity.

Theorem 41.1.13 (Inverse Function Theorem)

Let f be holomorphic near z_0 with $f'(z_0) \neq 0$. Then there are open neighbourhoods $U \ni z_0$ and $V \ni f(z_0)$ such that $f|_U : U \rightarrow V$ is a biholomorphism, i.e. a holomorphic bijection with holomorphic inverse.

§41.2 Analytic Continuation

We now come to the problem that motivates the whole course. The identity theorem says that a holomorphic function on a domain is determined by its restriction to any small disc. Turning this around: given a holomorphic function on a small disc, can we recover ‘the’ function it came from, on some larger domain? And if we can do it in more than one way, how do the answers differ?

§41.2.1 Function Elements and Direct Continuation

Definition 41.2.1 (Function Element)

Let $D \subseteq \mathbb{C}$ be a domain. A **function element** on D is a pair (f, U) where $U \subseteq D$ is a subdomain and $f : U \rightarrow \mathbb{C}$ is holomorphic.

Definition 41.2.2 (Direct Analytic Continuation)

Two function elements (f, U) and (g, V) on D are **direct analytic continuations**

of one another, written $(f, U) \sim (g, V)$, if $U \cap V \neq \emptyset$ and $f = g$ on $U \cap V$.

By the identity theorem, if $U \cap V$ is connected then g is completely determined by f (and by the choice of V): there is at most one holomorphic g on V agreeing with f on $U \cap V$. If $U \cap V$ is disconnected the definition still makes sense, but we should be careful, since agreeing on one component is then weaker than agreeing on all of them. We will normally arrange for our sets to be discs, so that intersections are convex and this issue evaporates.

The relation $\sim$ is reflexive and symmetric but emphatically *not* transitive – that failure is the entire subject. So we take its transitive closure.

Definition 41.2.3 (Analytic Continuation)

We write $(f, U) \approx (g, V)$ if there is a finite chain of function elements

$$(f, U) = (f_0, U_0) \sim (f_1, U_1) \sim \cdots \sim (f_n, U_n) = (g, V)$$

on D . We then say (g, V) is an **analytic continuation** of (f, U) .

Now $\approx$ is an equivalence relation, being the transitive closure of a reflexive symmetric relation.

Definition 41.2.4 (Complete Analytic Function)

An equivalence class $\mathcal{F}$ of function elements on D under $\approx$ is called a **complete analytic function** on D .

The name is a little grandiose for what is, at this stage, just a set of pairs. But the point of view is the right one: a ‘multi-valued function’ is not a function with several values, it is a *collection of ordinary functions, glued along their overlaps*. Our job over the next few sections is to make the gluing literal.

§41.2.2 The Complex Logarithm

Let us do the fundamental example completely explicitly. Write $\mathbb{C}^* = \mathbb{C} \setminus \{0\}$, and recall that $\exp : \mathbb{C} \rightarrow \mathbb{C}^*$ is surjective with $\exp(z) = \exp(w)$ if and only if $z - w \in 2\pi i\mathbb{Z}$. We want to invert it.

For an interval $(\alpha, \beta) \subseteq \mathbb{R}$ with $\beta - \alpha \leq 2\pi$, set

$$U_{(\alpha, \beta)} = \{re^{i\theta} : r > 0, \alpha < \theta < \beta\},$$

an open sector, and define $f_{(\alpha, \beta)} : U_{(\alpha, \beta)} \rightarrow \mathbb{C}$ by

$$f_{(\alpha, \beta)}(re^{i\theta}) = \log r + i\theta, \quad \theta \in (\alpha, \beta).$$

This is well defined precisely because the angle θ of a point of $U_{(\alpha,\beta)}$ is unique in the range (α, β) , and it is holomorphic since it is a local inverse of $\exp$, which has non-vanishing derivative. So

$$F_{(\alpha,\beta)} = (f_{(\alpha,\beta)}, U_{(\alpha,\beta)})$$

is a function element on $\mathbb{C}^*$, and $\exp \circ f_{(\alpha,\beta)} = \text{id}$.

To keep the bookkeeping finite, restrict attention to quarter-turn sectors: for $n \in \mathbb{Z}$ put

$$I(n) = \left(\frac{(n-1)\pi}{2}, \frac{(n+1)\pi}{2} \right),$$

an interval of length π centred on $n\pi/2$, and abbreviate $U_n = U_{I(n)}$, $f_n = f_{I(n)}$, $F_n = F_{I(n)}$. Thus U_0 is the right half-plane, U_1 the upper half-plane, and so on; U_n depends only on n modulo 4, but f_n does not.

Proposition 41.2.5

$F_m \sim F_n$ if and only if $|m - n| \leq 1$.

Proof. First suppose $|m - n| \leq 1$. If $m = n$ there is nothing to do, so take $n = m + 1$. Then $U_m \cap U_{m+1}$ is the open sector of angles in $(m\pi/2, (m+1)\pi/2)$, which is non-empty, and for $z = re^{i\theta}$ in it we may take θ in that common range, whence $f_m(z) = \log r + i\theta = f_{m+1}(z)$. So $F_m \sim F_{m+1}$.

Conversely suppose $|m - n| \geq 2$. If $|m - n| \geq 4$ then $I(m)$ and $I(n)$ are disjoint modulo nothing at all – more precisely the sectors U_m, U_n may still meet, but any z in the intersection has $f_m(z) - f_n(z) \in 2\pi i\mathbb{Z} \setminus \{0\}$, since the two determinations of the argument differ by a non-zero multiple of 2π . If $|m - n| = 2$ then U_m and U_n are opposite half-planes meeting in two opposite quadrants, and $|m - n| = 3$ gives an intersection which is a single quadrant; in every case a point of the intersection has $f_m(z) \neq f_n(z)$, because the arguments used differ by a non-zero multiple of 2π . Hence $F_m \not\sim F_n$. $\square$

Corollary 41.2.6

$F_m \approx F_n$ for all $m, n \in \mathbb{Z}$.

Proof. Chain along $F_m \sim F_{m\pm 1} \sim \cdots \sim F_n$. $\square$

So all the F_n lie in a single complete analytic function on $\mathbb{C}^*$, which we may reasonably call *the* complex logarithm. Notice what has happened: $U_0 = U_4$ as subsets of $\mathbb{C}$, but

$$f_0(1) = 0, \quad f_4(1) = 2\pi i.$$

Continuing once round the origin has changed the function. Analytic continuation is therefore *not* path-independent, and the complete analytic function $\log$ is genuinely bigger than any one of its elements.

Each U_n is a half-plane, drawn here as a semicircular arc; the four arcs are given different radii only so that they can be told apart, and the sector boundaries are the two coordinate axes. Together the $U_0, \dots, U_3$ cover $\mathbb{C}^*$, and each overlaps the next in a quadrant. Continuing f_0 around the loop γ takes us through F_1, F_2, F_3 and back to U_0 , but with $f_4 = f_0 + 2\pi i$.

§41.2.3 Complex Roots

Exactly the same analysis handles k -th roots. Let $p_k : \mathbb{C}^* \rightarrow \mathbb{C}^*$ be $z \mapsto z^k$ for $k \geq 2$, and define, on the same sectors U_n as above,

$$g_n(z) = \exp\left(\frac{1}{k} f_n(z)\right), \quad G_n = (g_n, U_n).$$

Then $g_n(z)^k = \exp(f_n(z)) = z$, so each g_n is a holomorphic branch of the k -th root on U_n .

Since $f_{n+4} = f_n + 2\pi i$ we get $g_{n+4} = e^{2\pi i/k} g_n$, and more generally g_n depends only on n modulo $4k$. Repeating the case analysis of Proposition 41.2.5 shows that $G_m \sim G_n$ if and only if $m \equiv n$ or $m \equiv n \pm 1$ modulo $4k$, and hence all the G_n lie in a single complete analytic function. This time, though, going round the origin *four* times returns us to $e^{2\pi i/k} g_0$, and it takes k circuits to get back to where we started. The multi-valuedness of $\sqrt[k]{\cdot}$ is finite, of order k , where that of $\log$ was infinite.

§41.2.4 Natural Boundaries

Before building surfaces, we pause on an obstruction: sometimes a function element admits no continuation at all past the boundary of its natural domain.

Write $\mathbb{D} = D(0, 1)$ and $\mathbb{T} = \partial\mathbb{D}$. Let $f(z) = \sum_{n \geq 0} a_n z^n$ be a power series with radius of convergence exactly 1, so that $(f, \mathbb{D})$ is a function element.

Definition 41.2.7 (Regular and Singular Points)

A point $z_0 \in \mathbb{T}$ is **regular** for f if there is an open neighbourhood U of z_0 and a function element (g, U) with $g = f$ on $U \cap \mathbb{D}$. Otherwise z_0 is **singular** for f .

The set of regular points is visibly open in $\mathbb{T}$, so the singular points form a closed set. It is tempting to think that z_0 is regular exactly when the power series converges at z_0 , and this is false in both directions.

Example 41.2.8

Take $f(z) = 1/(1-z) = \sum_{n \geq 0} z^n$. The only singular point is $z = 1$, so $z = -1$ is regular; but the power series $\sum (-1)^n$ does not converge at -1 . Convergence is not necessary for regularity.

Example 41.2.9

Take $g(z) = \sum_{n \geq 2} \frac{z^n}{n(n-1)}$. This converges absolutely at $z = 1$. But $g''(z) = \sum_{n \geq 2} z^{n-2} = 1/(1-z)$, which is singular at 1; so g cannot be continued past 1 either, and 1 is singular for g . Convergence is not sufficient for regularity.

Proposition 41.2.10

If $f(z) = \sum_{n \geq 0} a_n z^n$ has radius of convergence exactly 1, then some point of $\mathbb{T}$ is singular for f .

Proof. Suppose not. Then every $z_0 \in \mathbb{T}$ has a disc $D(z_0, \varepsilon_{z_0})$ carrying a continuation of f . By compactness finitely many such discs cover $\mathbb{T}$; by the identity theorem (the intersections being convex, hence connected) these continuations agree with each other and with f on overlaps, and so patch together with f to give a holomorphic function on an open set containing $\overline{\mathbb{D}}$. That set contains $D(0, 1 + \delta)$ for some $\delta > 0$, again by compactness, and so the Taylor series of f at 0 would have radius of convergence at least $1 + \delta$, a contradiction. $\square$

Definition 41.2.11 (Natural Boundary)

If every point of $\mathbb{T}$ is singular for f , we call $\mathbb{T}$ the **natural boundary** of f .

Example 41.2.12 (A Lacunary Series)

Let $f(z) = \sum_{n \geq 0} z^{n!}$, which has radius of convergence 1. We claim $\mathbb{T}$ is its natural boundary.

Since the singular set is closed, it suffices to show that the roots of unity are all singular, as these are dense in $\mathbb{T}$. So let $\omega = e^{2\pi i p/q}$ with $p, q \in \mathbb{Z}$, $q \geq 1$. For $n \geq q$ we have $q \mid n!$ and so $\omega^{n!} = 1$. Hence for $r \in (0, 1)$,

$$f(r\omega) = \sum_{n=0}^{q-1} r^{n!} \omega^{n!} + \sum_{n \geq q} r^{n!}.$$

The first sum is a finite sum of terms of modulus at most 1, hence bounded by q . For the second, given any $M > 0$ we have

$$\sum_{n \geq q} r^{n!} \geq \sum_{n=q}^{q+M} r^{n!} \longrightarrow M + 1$$

as $r \rightarrow 1^-$, so $\sum_{n \geq q} r^{n!} > M$ for r close enough to 1. Therefore $f(r\omega) \rightarrow \infty$ as

$r \rightarrow 1^-$. A function element (g, U) agreeing with f near ω would be bounded near ω , so no such element exists and ω is singular.

So continuation can fail entirely. When it does not fail, we would like to understand how the answer depends on the route taken – which requires us to say what a route is.

§41.2.5 Continuation Along a Path

Definition 41.2.13 (Continuation Along a Path)

Let $\gamma : [0, 1] \rightarrow D$ be a path and let $(f, U), (g, V)$ be function elements on D with $\gamma(0) \in U$ and $\gamma(1) \in V$. We write $(f, U) \approx_\gamma (g, V)$ if there is a dissection $0 = t_0 < t_1 < \dots < t_n = 1$ and function elements

$$(f, U) = (f_1, U_1), (f_2, U_2), \dots, (f_n, U_n) = (g, V)$$

with $(f_i, U_i) \sim (f_{i+1}, U_{i+1})$ for each i , and $\gamma([t_{i-1}, t_i]) \subseteq U_i$ for each i . We then say (f, U) can be **continued along** γ , with result (g, V) .

The picture is a chain of discs strung along γ , each carrying a holomorphic function agreeing with its neighbours. Definition 41.2.13 is a little unwieldy, and we will replace it in Section 41.7 by something much cleaner: continuation along γ will simply be *lifting* γ to the space of germs. Once we have said that, the key uniqueness statement – the monodromy theorem, that the result of continuing along γ depends only on the homotopy class of γ – becomes a special case of the homotopy lifting property from IB/II Algebraic Topology.

§41.3 The Surfaces of $\log$ and $\sqrt[k]{z}$

Before setting up the general theory, let us build the two surfaces the theory is meant to explain. This is worth doing by hand: everything we do abstractly later is modelled on these two constructions.

§41.3.1 Gluing the Sectors

Recall from Section 41.2.2 the function elements $F_n = (f_n, U_n)$ for $\log$. The trouble was that U_0 and U_4 are the same subset of $\mathbb{C}$ but carry different functions. So let us refuse to identify them. Define

$$R = \left(\coprod_{n \in \mathbb{Z}} U_n \right) / \sim,$$

where a point z_1 in the copy U_m is identified with a point z_2 in the copy U_n if and only if

$$z_1 = z_2 \text{ as elements of } \mathbb{C} \quad \text{and} \quad f_m(z_1) = f_n(z_2),$$

and give R the quotient topology. In words: we lay out infinitely many copies of the sectors, and glue copy m to copy n exactly where the two branches of $\log$ agree. By Proposition 41.2.5 this happens exactly when $|m - n| \leq 1$, so each sector is glued to its two neighbours along a quadrant, and the result spirals.

The picture to have in mind is an infinite multi-storey car park: a helical ramp winding endlessly up and down over the punctured plane, with no floor ever meeting another except its immediate neighbours.

Two maps come along for free. First, the branches assemble into a single global function: define $f : R \rightarrow \mathbb{C}$ by $f([z]) = f_n(z)$ for $z \in U_n$. This is well defined precisely because we built the equivalence relation to make it so. Second, the inclusions $U_n \hookrightarrow \mathbb{C}^*$ assemble into $\pi : R \rightarrow \mathbb{C}^*$, $\pi([z]) = z$, which is well defined because equivalent points are equal in $\mathbb{C}$. These satisfy

$$\exp \circ f = \pi,$$

which says exactly that f deserves the name ‘logarithm’: applying $\exp$ to f recovers the point of $\mathbb{C}^*$ underneath.

Proposition 41.3.1

R is path-connected and Hausdorff.

Proof. Path-connectedness: each U_n is connected, and U_n meets U_{n+1} in R (as $F_n \sim F_{n+1}$), so the images of the U_n in R form a chain of overlapping connected sets covering R .

For Hausdorffness, consider $\Phi : R \rightarrow \mathbb{C}^2$ given by

$$\Phi([z]) = (\pi([z]), f([z])).$$

This is continuous, and it is injective: if $\Phi([z_1]) = \Phi([z_2])$ then $z_1 = z_2$ in $\mathbb{C}$ and the two branch values agree, which is precisely the condition defining $\sim$. A continuous injection into a Hausdorff space separates points, so R is Hausdorff. $\square$

Remark. In fact Φ identifies R with the graph

$$\{(w, z) \in \mathbb{C}^2 : w = \exp z\},$$

and under this identification π and f are the two coordinate projections. So the Riemann surface of $\log$ is nothing more exotic than the graph of $\exp$ with the roles of the axes

swapped. This is a useful sanity check, and a preview: in general, the Riemann surface of an algebraic function will be (a compactification of) the graph of the equation defining it.

§41.3.2 The Surface of the k -th Root

The same construction with the elements $G_n = (g_n, U_n)$ produces a space R_k . Since g_n depends only on n modulo $4k$, this time only $4k$ copies of the sectors are involved and the spiral closes up after k turns. We again get $g : R_k \rightarrow \mathbb{C}^*$ and $\pi : R_k \rightarrow \mathbb{C}^*$ with

$$p_k \circ g = \pi, \quad p_k(z) = z^k,$$

and, exactly as before, R_k is path-connected and Hausdorff. Here is the picture for $k = 2$: a two-sheeted spiral, closing after two turns.

In both cases g (respectively f) is the honest single-valued function we were after, and π is the map remembering which point of $\mathbb{C}^*$ we are sitting over. The key structural feature of π is that it is a *local homeomorphism*: each little piece of R maps homeomorphically to a piece of $\mathbb{C}^*$. That is what will let us transport the complex structure of $\mathbb{C}^*$ upstairs, and it is where we turn next.

Remark. One thing is unsatisfactory about R_k : the interesting point 0 is missing, and so is ∞ . We would like to add them, obtaining a map $\hat{p}_k : \mathbb{C}_\infty \rightarrow \mathbb{C}_\infty$ which is k -to-1 everywhere except at the two points $0, \infty$, where it is 1-to-1. These exceptional points are the **branch points**, and understanding them is the goal of Section 41.9. Once the points are added, π is no longer a covering map – but it is still holomorphic, and that turns out to be the more useful category.

§41.4 Riemann Surfaces

§41.4.1 Covering Maps

We isolate the topological property of $\pi : R \rightarrow \mathbb{C}^*$ that made the last section work. This material overlaps heavily with II Algebraic Topology; we repeat it because the conventions differ slightly and because we shall need to be careful about exactly which hypotheses are used where.

Definition 41.4.1 (Covering Map)

Let $\tilde{X}, X$ be path-connected Hausdorff spaces. A continuous surjection $\pi : \tilde{X} \rightarrow X$ is a **covering map** if it is a local homeomorphism: every $\tilde{x} \in \tilde{X}$ has an open neighbourhood $\tilde{U}$ such that $\pi|_{\tilde{U}}$ is a homeomorphism onto an open subset of X .

Definition 41.4.2 (Regular Covering Map)

A covering map $\pi : \tilde{X} \rightarrow X$ is **regular** if every $x \in X$ has an open neighbourhood U which is **evenly covered**: there is a discrete set Δ and a homeomorphism $\pi^{-1}(U) \cong U \times \Delta$ under which π becomes the projection $(u, \delta) \mapsto u$. Equivalently, $\pi^{-1}(U)$ is a disjoint union of open sets, the **sheets** over U , each mapped homeomorphically onto U by π .

Regularity is a genuinely stronger condition, and it is the one that matters for lifting paths. The distinction is easy to miss, so here are the examples we shall use.

Example 41.4.3

- (i) The map $\pi : R \rightarrow \mathbb{C}^*$ of Section 41.3 is a regular covering map. Indeed

$$\pi^{-1}(U_n) = \coprod_{m \equiv n \pmod{4}} U_m \cong U_n \times \mathbb{Z},$$

since the copy U_m maps homeomorphically to U_n exactly when $m \equiv n$ modulo 4, and distinct such copies are disjoint in R .

- (ii) $\exp : \mathbb{C} \rightarrow \mathbb{C}^*$ is a regular covering map. For an open interval $I \subseteq \mathbb{R}$ of length at most 2π , write $\tilde{V}_I = \mathbb{R} + iI$, a horizontal strip; then $\exp$ restricts to a homeomorphism $\tilde{V}_I \rightarrow U_I$ with inverse a branch of $\log$, and

$$\exp^{-1}(U_{I(n)}) = \coprod_{m \equiv n \pmod{4}} \tilde{V}_{I(m)} \cong U_{I(n)} \times \mathbb{Z}.$$

- (iii) $p_k : \mathbb{C}^* \rightarrow \mathbb{C}^*$, $z \mapsto z^k$, is a regular covering map with k sheets: over the sector U_I with I of length less than $2\pi/k$ sit the k sectors $\zeta^j U_{I/k}$, $\zeta = e^{2\pi i/k}$.
- (iv) (*Non-example.*) The inclusion $\iota : \mathbb{D} \hookrightarrow \mathbb{C}$ is a local homeomorphism, hence a covering map onto its image in the weak sense above, but it is not regular as a map to $\mathbb{C}$: for $z_0 \in \mathbb{T}$ and any neighbourhood U of z_0 , we have $\iota^{-1}(U) = U \cap \mathbb{D}$, whose image is not U . More basically, ι is not surjective. Regularity is what rules out this kind of ‘partial’ cover.

§41.4.2 Charts and Atlases

Now we say what a surface is. The idea is Riemann's: a space that looks locally like an open subset of $\mathbb{C}$, in a way that is compatible from patch to patch.

Definition 41.4.4 (Chart)

Let R be a topological space. A **chart** on R is a pair (ϕ, U) where $U \subseteq R$ is open and $\phi : U \rightarrow \phi(U) \subseteq \mathbb{C}$ is a homeomorphism onto an open subset of $\mathbb{C}$. We call ϕ a **local coordinate** on U .

Definition 41.4.5 (Atlas)

A collection $\mathcal{A}$ of charts on R is an **atlas** if

- (i) $\bigcup_{(\phi, U) \in \mathcal{A}} U = R$;
- (ii) for all $(\phi_1, U_1), (\phi_2, U_2) \in \mathcal{A}$ with $U_1 \cap U_2 \neq \emptyset$, the **transition function**

$$\phi_1 \circ \phi_2^{-1} : \phi_2(U_1 \cap U_2) \rightarrow \phi_1(U_1 \cap U_2)$$

is holomorphic.

Note that the transition function goes between open subsets of $\mathbb{C}$, so ‘holomorphic’ means what it always meant. Note also that its inverse is $\phi_2 \circ \phi_1^{-1}$, which is holomorphic by the same condition with the roles swapped; so transition functions are automatically biholomorphic.

There is an annoying redundancy here, which the next example exposes.

Example 41.4.6

Take $R = \mathbb{C}$. Let $\mathcal{A}$ consist of all pairs (id_U, U) for $U \subseteq \mathbb{C}$ open; this is an atlas. Let $\mathcal{A}'$ consist of all pairs $(z \mapsto z + 1, U)$; this too is an atlas. So is $\mathcal{A} \cup \mathcal{A}'$, since the transition functions are translations. Yet all three describe the same complex analysis on $\mathbb{C}$.

The cure is to take the largest possible atlas, so that no information is hidden in a choice.

Definition 41.4.7 (Conformal Structure)

A **conformal structure** on R is an atlas $\mathcal{A}$ which is **maximal**: whenever a chart (ψ, V) on R has the property that $\phi \circ \psi^{-1}$ is holomorphic (where defined) for every $(\phi, U) \in \mathcal{A}$, we have $(\psi, V) \in \mathcal{A}$.

Definition 41.4.8 (Riemann Surface)

A **Riemann surface** is a pair $(R, \mathcal{A})$ where R is a path-connected Hausdorff topological space and $\mathcal{A}$ is a conformal structure on R .

We will normally suppress $\mathcal{A}$ and just write R . Note that connectedness is part of the definition here – some authors allow disconnected Riemann surfaces, but for us a Riemann surface is connected, which makes the identity theorem available at all times.

Maximal atlases are unwieldy to write down, so in practice we always specify a small atlas and appeal to the following.

Lemma 41.4.9

Every atlas $\mathcal{A}$ on R is contained in a unique conformal structure $\hat{\mathcal{A}}$.

Proof. There is only one possible candidate: let $\hat{\mathcal{A}}$ be the set of all charts (ψ, V) on R such that $\psi \circ \phi^{-1}$ and $\phi \circ \psi^{-1}$ are holomorphic for every $(\phi, U) \in \mathcal{A}$. Any conformal structure containing $\mathcal{A}$ is contained in $\hat{\mathcal{A}}$ by definition of an atlas, and contains $\hat{\mathcal{A}}$ by maximality; so uniqueness is clear once we know $\hat{\mathcal{A}}$ is an atlas.

It covers R since $\mathcal{A} \subseteq \hat{\mathcal{A}}$ does. For compatibility, take $(\psi_1, V_1), (\psi_2, V_2) \in \hat{\mathcal{A}}$ and $p \in V_1 \cap V_2$. Choose $(\phi, U) \in \mathcal{A}$ with $p \in U$. Near $\psi_2(p)$ we may write

$$\psi_1 \circ \psi_2^{-1} = (\psi_1 \circ \phi^{-1}) \circ (\phi \circ \psi_2^{-1}),$$

a composite of holomorphic maps, hence holomorphic at $\psi_2(p)$. As p was arbitrary, $\psi_1 \circ \psi_2^{-1}$ is holomorphic on $\psi_2(V_1 \cap V_2)$. Maximality of $\hat{\mathcal{A}}$ is immediate from its definition. $\square$

So from now on, ‘here is an atlas’ means ‘here is a Riemann surface’.

§41.4.3 First Examples**Example 41.4.10 (The Plane)**

Taking $\mathcal{A} = \{(\text{id}, \mathbb{C})\}$ and extending gives the **canonical conformal structure** on $\mathbb{C}$. Whenever we speak of $\mathbb{C}$ as a Riemann surface, this is what is meant. Note that by Example 41.4.6 the atlas of all translations extends to the same structure.

Example 41.4.11 (The Conjugate Plane)

The single chart $(z \mapsto \bar{z}, \mathbb{C})$ is also an atlas on $\mathbb{C}$, and it does *not* extend to the canonical structure, since $z \mapsto \bar{z}$ is not holomorphic. Write $\bar{\mathbb{C}}$ for $\mathbb{C}$ with this structure. So the same topological space can carry different conformal structures.

(As it happens $\bar{\mathbb{C}} \cong \mathbb{C}$ as Riemann surfaces, via $z \mapsto \bar{z}$ – but they are not *equal*.)

Example 41.4.12 (Open Subsets)

If R is a Riemann surface with conformal structure $\mathcal{A}$ and $S \subseteq R$ is open and connected, then

$$\{(\phi|_{U \cap S}, U \cap S) : (\phi, U) \in \mathcal{A}\}$$

is an atlas on S , making S a Riemann surface. In particular every domain $D \subseteq \mathbb{C}$ – the disc $\mathbb{D}$, the upper half-plane $\mathbb{H}$, the punctured plane $\mathbb{C}^*$ – is a Riemann surface.

Example 41.4.13 (The Riemann Sphere)

Let $\mathbb{C}_\infty = \mathbb{C} \cup \{\infty\}$ with the topology in which neighbourhoods of ∞ are the complements of compact subsets of $\mathbb{C}$. Take the two charts

$$(\phi_0, U_0) = (\text{id}, \mathbb{C}), \quad (\phi_1, U_1) = (z \mapsto 1/z, \mathbb{C}^* \cup \{\infty\}),$$

where we read $1/\infty = 0$. Each is a homeomorphism onto $\mathbb{C}$, they cover $\mathbb{C}_\infty$, and on the overlap $U_0 \cap U_1 = \mathbb{C}^*$ the transition function is $z \mapsto 1/z$, which is holomorphic there. So this is an atlas, and $\mathbb{C}_\infty$ is a Riemann surface, the **Riemann sphere**.

That $\mathbb{C}_\infty$ deserves to be called a sphere is the content of stereographic projection. Identify $\mathbb{C}$ with the plane $\{x_3 = 0\}$ in $\mathbb{R}^3$ and let S^2 be the unit sphere, with north pole $N = (0, 0, 1)$. Each point $P \in S^2 \setminus \{N\}$ determines a unique point of the plane, namely where the line NP meets it, and this gives a homeomorphism $S^2 \setminus \{N\} \rightarrow \mathbb{C}$; sending $N \mapsto \infty$ extends it to a homeomorphism $S^2 \rightarrow \mathbb{C}_\infty$.

Chasing the geometry, if $P = (x_1, x_2, x_3)$ then the line $N + t(P - N)$ meets $x_3 = 0$ at $t = 1/(1 - x_3)$, giving

$$z = \frac{x_1 + ix_2}{1 - x_3}.$$

Projecting instead from the south pole $S = (0, 0, -1)$ gives $z' = (x_1 - ix_2)/(1 + x_3)$, and one checks $zz' = 1$ using $x_1^2 + x_2^2 + x_3^2 = 1$. So the two stereographic projections differ by $z \mapsto 1/z$ – exactly the transition function of Example 41.4.13. The atlas we wrote down is the geometrically natural one.

Remark. Under this identification, ‘ $z \rightarrow \infty$ ’ means ‘ $P \rightarrow N$ ’, so the point ∞ is in no way special: the sphere has a transitive group of conformal automorphisms (the Möbius transformations) and ∞ can be moved anywhere. That is the real payoff of the Riemann sphere as against the extended plane of a first course.

§41.4.4 Holomorphic Maps

Definition 41.4.14 (Holomorphic Map)

Let R, S be Riemann surfaces. A continuous map $f : R \rightarrow S$ is **holomorphic** (or **analytic**) if for every chart (ϕ, U) on R and every chart (ψ, V) on S , the map

$$\psi \circ f \circ \phi^{-1}$$

is holomorphic on $\phi(U \cap f^{-1}(V))$.

The composite $\psi \circ f \circ \phi^{-1}$ is called the **local expression** of f in the charts ϕ and ψ . Checking the condition for *all* charts is of course impossible in practice; happily it suffices to check one chart at each point.

Lemma 41.4.15

A continuous map $f : R \rightarrow S$ is holomorphic if and only if for each $p \in R$ there exist charts (ϕ_p, U_p) on R with $p \in U_p$ and (ψ_p, V_p) on S with $f(p) \in V_p$ such that $\psi_p \circ f \circ \phi_p^{-1}$ is holomorphic on $\phi_p(U_p \cap f^{-1}(V_p))$.

Proof. Necessity is trivial. For sufficiency, let (ϕ, U) and (ψ, V) be arbitrary charts; we must show $\psi \circ f \circ \phi^{-1}$ is holomorphic at $\phi(p)$ for each $p \in U \cap f^{-1}(V)$. Take $(\phi_p, U_p), (\psi_p, V_p)$ as hypothesised. On a small enough neighbourhood of $\phi(p)$ we may factor

$$\psi \circ f \circ \phi^{-1} = (\psi \circ \psi_p^{-1}) \circ (\psi_p \circ f \circ \phi_p^{-1}) \circ (\phi_p \circ \phi^{-1}).$$

The outer two factors are transition functions, hence holomorphic; the middle factor is holomorphic by hypothesis. So the composite is holomorphic at $\phi(p)$. $\square$

Lemma 41.4.16

If $f : R \rightarrow S$ and $g : S \rightarrow T$ are holomorphic, so is $g \circ f : R \rightarrow T$.

Proof. Immediate from Lemma 41.4.15: locally $g \circ f$ has local expression $(\chi \circ g \circ \psi^{-1}) \circ (\psi \circ f \circ \phi^{-1})$. $\square$

Definition 41.4.17 (Conformal Equivalence)

A **conformal equivalence** (or **biholomorphism**) is a holomorphic bijection $f : R \rightarrow S$ whose inverse is holomorphic. We then write $R \cong S$.

By Lemma 41.4.16 this is an equivalence relation on Riemann surfaces, and it is the notion of sameness we care about. We will see later (Corollary 41.9.12) that the hypothesis on f^{-1} is automatic: a holomorphic bijection of Riemann surfaces is always a conformal equivalence.

Example 41.4.18

The map $\mathbb{C} \rightarrow \bar{\mathbb{C}}, z \mapsto \bar{z}$, is a conformal equivalence: in the chart id upstairs and $z \mapsto \bar{z}$ downstairs, its local expression is $z \mapsto \bar{z} = z$.

Example 41.4.19 (Möbius Maps)

For $a, b, c, d \in \mathbb{C}$ with $ad - bc \neq 0$, the Möbius transformation

$$\mu(z) = \frac{az + b}{cz + d}, \quad \mu(-d/c) = \infty, \quad \mu(\infty) = a/c$$

is a conformal equivalence $\mathbb{C}_\infty \rightarrow \mathbb{C}_\infty$. Indeed μ is holomorphic away from $-d/c$ and ∞ , and at those points one checks holomorphy in the chart $1/z$: for example near $z = \infty$ the local expression is $w \mapsto (cw + d)/(aw + b)$ (in the chart $w = 1/z$ upstairs and $1/z$ downstairs when $a \neq 0$), which is holomorphic at 0. The inverse is again Möbius. In fact *every* conformal automorphism of $\mathbb{C}_\infty$ is of this form, as we shall see.

Example 41.4.20 ($\mathbb{C}^*$ and the Cylinder)

The map $\mathbb{C} \rightarrow \mathbb{C}^*$, $z \mapsto e^z$, is holomorphic and surjective but not injective; it descends to a conformal equivalence $\mathbb{C}/2\pi i\mathbb{Z} \rightarrow \mathbb{C}^*$ once we know how to give the quotient a conformal structure. That is the next subsection.

§41.4.5 Structures Induced by Covering Maps

Here is the tool that lets us construct nearly all our examples: a covering of a Riemann surface is a Riemann surface, in exactly one way.

Lemma 41.4.21

Let R be a Riemann surface and $\pi : \tilde{R} \rightarrow R$ a covering map, with $\tilde{R}$ path-connected and Hausdorff. Then there is a unique conformal structure on $\tilde{R}$ making π holomorphic.

Proof. Existence. Let $p \in \tilde{R}$. Since π is a local homeomorphism, choose an open $\tilde{N} \ni p$ mapped homeomorphically by π onto an open $N \ni \pi(p)$. Choose a chart (ϕ, U) on R with $\pi(p) \in U$, and set

$$\tilde{U} = (\pi|_{\tilde{N}})^{-1}(N \cap U), \quad \tilde{\phi} = \phi \circ \pi|_{\tilde{U}}.$$

Then $\tilde{\phi}$ is a composite of homeomorphisms onto open subsets of $\mathbb{C}$, so $(\tilde{\phi}, \tilde{U})$ is a chart, and these charts cover $\tilde{R}$. For two of them the transition function is

$$\tilde{\phi}_1 \circ \tilde{\phi}_2^{-1} = \phi_1 \circ \pi \circ \pi^{-1} \circ \phi_2^{-1} = \phi_1 \circ \phi_2^{-1},$$

(with the evident restrictions), which is holomorphic since ϕ_1, ϕ_2 came from an atlas on R . So we have an atlas, and by Lemma 41.4.9 a conformal structure $\tilde{\mathcal{A}}$.

In this structure π is holomorphic: with $\tilde{\phi}$ built from ϕ as above, the local expression of π is

$$\phi \circ \pi \circ \tilde{\phi}^{-1} = \phi \circ \pi \circ \pi^{-1} \circ \phi^{-1} = \text{id},$$

and Lemma 41.4.15 applies.

Uniqueness. Let $\tilde{\mathcal{B}}$ be any conformal structure on $\tilde{R}$ making π holomorphic. If $(\psi, V) \in \tilde{\mathcal{B}}$ and $(\tilde{\phi}, \tilde{U})$ is one of the charts constructed above, then on the overlap

$$\tilde{\phi} \circ \psi^{-1} = \phi \circ \pi \circ \psi^{-1}$$

is holomorphic, being the local expression of π in charts ψ and ϕ . Likewise $\psi \circ \tilde{\phi}^{-1}$ is holomorphic, since $\pi|_{\tilde{U}}$ has a holomorphic local inverse (its local expression is the identity). Hence every chart of $\tilde{\mathcal{B}}$ is compatible with our atlas, and by maximality $\tilde{\mathcal{B}} = \tilde{\mathcal{A}}$. $\square$

Example 41.4.22 (The Surface of the Logarithm, Again)

Since $\pi : R \rightarrow \mathbb{C}^*$ is a covering map and R is path-connected and Hausdorff, R becomes a Riemann surface with π holomorphic. Moreover $f : R \rightarrow \mathbb{C}$ is holomorphic, since locally $f|_{U_n} = f_n \circ \pi$ and f_n is holomorphic.

In fact we can identify R outright. Each $f_n : U_n \rightarrow \tilde{V}_{I(n)} = \mathbb{R} + iI(n)$ is a homeomorphism with inverse $\exp$, and these agree on overlaps by construction of $\sim$; so they patch to a bijection $f : R \rightarrow \mathbb{C}$, which is holomorphic with holomorphic inverse. Hence

$$R \cong \mathbb{C}.$$

The Riemann surface of the logarithm is just the plane – but presented as a spiral over $\mathbb{C}^*$, with π the map $\exp$ in disguise. This is our first hint that the interesting data is not the surface alone but the surface *together with its map to the base*.

Example 41.4.23 (The Surface of the k -th Root)

Similarly R_k becomes a Riemann surface with π, g holomorphic, and $g : R_k \rightarrow \mathbb{C}^*$ is a conformal equivalence, with $\pi = p_k \circ g$. So $R_k \cong \mathbb{C}^*$, again realised as a k -sheeted spiral over $\mathbb{C}^*$.

§41.4.6 Complex Tori

So far our only compact example is $\mathbb{C}_\infty$. Here is a family of others.

Definition 41.4.24 (Lattice)

Let $\omega_1, \omega_2 \in \mathbb{C}^*$ be linearly independent over $\mathbb{R}$. The subgroup

$$\Lambda = \mathbb{Z}\omega_1 + \mathbb{Z}\omega_2 \leq (\mathbb{C}, +)$$

is called a **lattice** in $\mathbb{C}$.

Definition 41.4.25 (Complex Torus)

The quotient group $T = \mathbb{C}/\Lambda$, with the quotient topology, is called a **complex torus**.

The **fundamental parallelogram** $P = \{s\omega_1 + t\omega_2 : s, t \in [0, 1]\}$ maps onto T , and is injective on its interior, so T is compact (being a continuous image of the compact set P) and indeed $T \cong S^1 \times S^1$ topologically, with the two pairs of opposite edges of P glued.

We must give T a conformal structure. Let $\pi : \mathbb{C} \rightarrow T$ be the quotient map.

Proposition 41.4.26

$\pi : \mathbb{C} \rightarrow T$ is a regular covering map, and hence T carries a unique conformal structure making π holomorphic.

Proof. First, Λ is discrete: it is a lattice, so $\mu := \min\{|\lambda| : \lambda \in \Lambda \setminus \{0\}\}$ exists and is positive. (Indeed only finitely many lattice points lie in any bounded set, since $|m\omega_1 + n\omega_2| \geq c(|m| + |n|)$ for a constant $c > 0$ depending on ω_1, ω_2 ; we prove this in Lemma 41.11.9.) Fix $0 < \varepsilon < \mu/2$.

π is an open map, since for $U \subseteq \mathbb{C}$ open, $\pi^{-1}(\pi(U)) = \bigcup_{\lambda \in \Lambda} (U + \lambda)$ is open. Given $z_0 \in \mathbb{C}$, put $V = \pi(D(z_0, \varepsilon))$, which is open, and

$$\pi^{-1}(V) = \bigcup_{\lambda \in \Lambda} (D(z_0, \varepsilon) + \lambda) = \coprod_{\lambda \in \Lambda} (D(z_0, \varepsilon) + \lambda),$$

the union being disjoint because two of these discs meeting would give $|\lambda - \lambda'| < 2\varepsilon < \mu$. Each translate maps bijectively (hence homeomorphically, π being open and continuous) onto V . So π is a regular covering map, Λ with the discrete topology indexing the sheets.

T is Hausdorff: given $\pi(z_0) \neq \pi(z_1)$, the sets $\pi(D(z_0, \delta))$ and $\pi(D(z_1, \delta))$ are disjoint open neighbourhoods once 2δ is less than the distance from z_1 to $z_0 + \Lambda$. It is path-connected as a continuous image of $\mathbb{C}$. Now apply Lemma 41.4.21. $\square$

Explicitly, the charts on T are the maps $(\pi|_{D(z_0, \varepsilon)})^{-1}$ defined on $\pi(D(z_0, \varepsilon))$, and the transition functions are the translations $z \mapsto z + \lambda$, which are certainly holomorphic. This is the cleanest possible atlas, and it is why tori are such a good testing ground.

Remark. All complex tori are homeomorphic, being homeomorphic to $S^1 \times S^1$. They are very far from being all conformally equivalent: one shows on the example sheets that $\mathbb{C}/\Lambda \cong \mathbb{C}/\Lambda'$ if and only if $\Lambda' = a\Lambda$ for some $a \in \mathbb{C}^*$, so that the conformal equivalence classes are parametrised by the modulus $\tau = \omega_2/\omega_1 \in \mathbb{H}$ up to the action of $\text{SL}_2(\mathbb{Z})$. There are uncountably many. So conformal structure is a strictly finer invariant than topology – which is exactly why the subject is interesting.

§41.5 Functions on Riemann Surfaces

We have a supply of surfaces; now we do analysis on them. Every result in this section is proved the same way: take charts, quote the corresponding theorem in $\mathbb{C}$, and check that the conclusion is chart-independent. What makes the section worth reading is the consequences, which are of a kind that has no analogue in the plane.

§41.5.1 The Identity Theorem

Theorem 41.5.1 (Identity Theorem for Riemann Surfaces)

Let $f, g : R \rightarrow S$ be holomorphic maps of Riemann surfaces. If the set

$$A = \{p \in R : f(p) = g(p)\}$$

has an accumulation point in R , then $f = g$.

Proof. Let B be the set of accumulation points of A in R ; by hypothesis $B \neq \emptyset$. We show B is open and closed in R , which by connectedness gives $B = R$ and hence (as $A \supseteq B$ by continuity) $f = g$.

B is open. Let $p \in B$. Then $f(p) = g(p) =: q$ by continuity. Choose a chart (ψ, V) on S about q and a connected chart (ϕ, U) on R about p with $f(U), g(U) \subseteq V$; this is possible since f, g are continuous. The local expressions $\psi f \phi^{-1}$ and $\psi g \phi^{-1}$ are holomorphic on the domain $\phi(U)$ and agree on a set with an accumulation point (namely $\phi(A \cap U)$, which accumulates at $\phi(p)$). By the identity theorem in $\mathbb{C}$ (Corollary 41.1.4) they agree on $\phi(U)$, so $f = g$ on U , and every point of U is an accumulation point of A . Hence $U \subseteq B$.

B is closed. Suppose $p \in \bar{B}$. Take U as above; U meets B , so U contains points of A other than p , whence by the argument above $f = g$ on U and $p \in B$. $\square$

Corollary 41.5.2

A non-constant holomorphic map $f : R \rightarrow S$ is nowhere locally constant, and its fibres $f^{-1}(q)$ are discrete.

Proof. If f were constant $= q$ on an open set, apply Theorem 41.5.1 to f and the constant map q . For the fibres: if $f^{-1}(q)$ had an accumulation point, the same comparison gives f constant. $\square$

§41.5.2 The Open Mapping Theorem

Theorem 41.5.3 (Open Mapping Theorem)

Every non-constant holomorphic map $f : R \rightarrow S$ of Riemann surfaces is an open map.

Proof. Let $W \subseteq R$ be open and $p \in W$; we find a neighbourhood of $f(p)$ inside $f(W)$. Choose charts (ϕ, U) about p and (ψ, V) about $f(p)$, and shrink so that $U \subseteq W$, U is connected and $f(U) \subseteq V$. By Corollary 41.5.2 the local expression

$F = \psi f \phi^{-1}$ is non-constant on the domain $\phi(U)$, so by the open mapping theorem in $\mathbb{C}$ (Theorem 41.1.11) $F(\phi(U))$ is open in $\mathbb{C}$. Hence

$$f(U) = \psi^{-1}(F(\phi(U)))$$

is open in S , being the preimage of an open set under the homeomorphism ψ restricted appropriately. As $f(U) \subseteq f(W)$ contains $f(p)$, we are done. $\square$

Corollary 41.5.4

Let $f : R \rightarrow S$ be a non-constant holomorphic map with R compact. Then f is surjective and S is compact.

Proof. $f(R)$ is open by Theorem 41.5.3 and compact as a continuous image of a compact set, hence closed since S is Hausdorff. As S is connected and $f(R)$ is a non-empty clopen subset, $f(R) = S$. Then $S = f(R)$ is compact. $\square$

Corollary 41.5.5

Every holomorphic function $f : R \rightarrow \mathbb{C}$ on a compact Riemann surface R is constant.

Proof. If f were non-constant then $\mathbb{C}$ would be compact by Corollary 41.5.4. It is not. $\square$

This is a striking statement, and it deserves to be dwelt on: it is a vast generalisation of Liouville's theorem. On a compact surface there is *no* interesting holomorphic function at all. All the analysis on a compact Riemann surface must therefore be carried by maps to other compact targets – to $\mathbb{C}_\infty$, giving meromorphic functions, or to other surfaces. This single fact shapes the rest of the course.

Theorem 41.5.6 (Maximum Modulus Principle)

Let $f : R \rightarrow \mathbb{C}$ be holomorphic on a Riemann surface. If $|f|$ attains a local maximum at some $p \in R$, then f is constant.

Proof. Suppose f is non-constant, so $f(R)$ is open by Theorem 41.5.3. Let W be a neighbourhood of p with $|f(q)| \leq |f(p)|$ for $q \in W$. Then $f(W)$ is an open neighbourhood of $f(p)$ contained in the closed disc $\overline{D}(0, |f(p)|)$; but every neighbourhood of $f(p)$ contains points of modulus greater than $|f(p)|$ (take $f(p)(1 + \epsilon)$ if $f(p) \neq 0$, or any small non-zero point if $f(p) = 0$). This is a contradiction. $\square$

Combining these gives an alternative proof of Corollary 41.5.5: on a compact R the continuous function $|f|$ attains a maximum, so f is constant.

§41.5.3 Harmonic Functions

The open mapping theorem tells us that a non-constant holomorphic function cannot be real-valued, since $\mathbb{R} \subseteq \mathbb{C}$ has empty interior. Real-valued functions on Riemann surfaces are therefore never holomorphic; the right class is the harmonic ones.

Definition 41.5.7 (Harmonic Function)

A smooth function $u : D \rightarrow \mathbb{R}$ on a domain $D \subseteq \mathbb{C}$ is **harmonic** if

$$\nabla^2 u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0.$$

Lemma 41.5.8

Let $D \subseteq \mathbb{C}$ be a disc. A function $u : D \rightarrow \mathbb{R}$ is harmonic if and only if $u = \operatorname{Re} f$ for some holomorphic f on D .

Proof. If $f = u + iv$ is holomorphic then the Cauchy–Riemann equations $u_x = v_y$, $u_y = -v_x$ give $u_{xx} + u_{yy} = v_{yx} - v_{xy} = 0$. The converse – constructing a harmonic conjugate v on a disc by integrating $-u_y dx + u_x dy$, which is closed by harmonicity and hence exact on a simply connected domain – was an exercise in IB Complex Analysis. $\square$

Note the appearance of simple connectedness: the converse fails on an annulus, as $u = \log |z|$ shows.

Definition 41.5.9

A function $u : R \rightarrow \mathbb{R}$ on a Riemann surface is **harmonic** if $u \circ \phi^{-1}$ is harmonic for every chart (ϕ, U) .

For this to be a sensible definition we need harmonicity to be preserved by holomorphic changes of coordinate, which it is:

Lemma 41.5.10

A function $u : R \rightarrow \mathbb{R}$ is harmonic if and only if each $p \in R$ has *some* chart (ϕ, U) with $p \in U$ and $u \circ \phi^{-1}$ harmonic.

Proof. One direction is trivial. Conversely, suppose the condition holds and let (ψ, V) be any chart, $p \in V$. Choose (ϕ, U) as hypothesised with $p \in U$; shrinking, we may assume $\phi(U)$ is a disc, so $u \circ \phi^{-1} = \operatorname{Re} f$ for some holomorphic f by Lemma 41.5.8. Then near $\psi(p)$,

$$u \circ \psi^{-1} = (u \circ \phi^{-1}) \circ (\phi \circ \psi^{-1}) = \operatorname{Re} (f \circ (\phi \circ \psi^{-1})),$$

the real part of a holomorphic function, hence harmonic. $\square$

Theorem 41.5.11 (Open Mapping and Identity Theorems for Harmonic Functions)

Let u, v be harmonic on a Riemann surface R .

- (i) If $\{p : u(p) = v(p)\}$ has non-empty interior then $u = v$.
- (ii) If u is non-constant then $u : R \rightarrow \mathbb{R}$ is an open map.

Consequently, every harmonic function on a compact Riemann surface is constant.

Proof. Locally $u = \operatorname{Re} f$ with f holomorphic. For (i), if $u = v$ on an open set then locally $\operatorname{Re}(f - g) = 0$, so $f - g$ is constant (its image lies in $i\mathbb{R}$, which has empty interior, so it cannot be open), and a clopen argument as in Theorem 41.5.1 propagates this. For (ii), openness of u follows from openness of f on any chart where f is non-constant, since $\operatorname{Re} : \mathbb{C} \rightarrow \mathbb{R}$ is open. The last statement follows since $u(R)$ would be an open, compact – hence clopen and non-empty – subset of the connected space $\mathbb{R}$, forcing $u(R) = \mathbb{R}$, which is not compact. $\square$

§41.5.4 Meromorphic Functions

Since holomorphic functions to $\mathbb{C}$ are useless on compact surfaces, we enlarge the target to the compact surface $\mathbb{C}_\infty$.

Definition 41.5.12 (Meromorphic Function)

A **meromorphic function** on a Riemann surface R is a holomorphic map $f : R \rightarrow \mathbb{C}_\infty$ which is not identically ∞ .

Note that $f^{-1}(\infty)$ is then discrete by Corollary 41.5.2, and closed since $\{\infty\}$ is; so a meromorphic function is a holomorphic function on the complement of a discrete closed set. The next result confirms that on a plane domain this agrees with the classical definition.

Proposition 41.5.13

Let $D \subseteq \mathbb{C}$ be a domain. A map $f : D \rightarrow \mathbb{C}_\infty$ is meromorphic if and only if there is a discrete closed $A \subseteq D$ such that $f|_{D \setminus A}$ is holomorphic with values in $\mathbb{C}$, and f has a pole at each point of A .

Proof. ($\Rightarrow$) Let $A = f^{-1}(\infty)$, which is discrete and closed as noted, and certainly f is holomorphic $D \setminus A \rightarrow \mathbb{C}$. Fix $a \in A$ and work in the chart $w \mapsto 1/w$ about ∞ . The local expression $z \mapsto 1/f(z)$ is holomorphic near a and vanishes at a ; it is not identically zero (else $f \equiv \infty$), so by Proposition 41.1.3 we may write $1/f(z) = (z - a)^m g(z)$ with $m \geq 1$ and $g(a) \neq 0$. Shrinking so that g has no zero, $f(z) = (z - a)^{-m}/g(z)$, which has a pole of order m at a .

($\Leftarrow$) f is certainly holomorphic as a map into $\mathbb{C}_\infty$ on $D \setminus A$. At $a \in A$ with a pole of order m we may write $f(z) = (z - a)^{-m}h(z)$ with h holomorphic and $h(a) \neq 0$; then $1/f(z) = (z - a)^m/h(z)$ is holomorphic near a (after shrinking so h does not vanish), and f is continuous into $\mathbb{C}_\infty$ at a since $|f| \rightarrow \infty$. So the local expression in the chart at ∞ is holomorphic, and Lemma 41.4.15 applies. $\square$

Example 41.5.14

The map $\mathbb{C}_\infty \rightarrow \mathbb{C}_\infty$ given by a rational function $p(z)/q(z)$ (in lowest terms, with the evident values at the zeros of q and at ∞) is meromorphic. We shall see in Section 41.11 that these are the *only* meromorphic functions on $\mathbb{C}_\infty$.

Example 41.5.15

On a complex torus $T = \mathbb{C}/\Lambda$, a meromorphic function pulls back along $\pi : \mathbb{C} \rightarrow T$ to a meromorphic function on $\mathbb{C}$ invariant under Λ – that is, to a doubly periodic, or **elliptic**, function. Conversely every such function descends. Corollary 41.5.5 then says: a doubly periodic *holomorphic* function on $\mathbb{C}$ is constant, which is Liouville's theorem applied to the (bounded, by compactness of P) function. Section 41.11 is devoted to the non-constant ones.

§41.6 Covering Spaces and Monodromy

To organise analytic continuation we need the topology of covering spaces. Most of this was proved in II Algebraic Topology, and we shall be brisk, but the path-lifting and homotopy-lifting statements are so central that it is worth seeing the proofs again in the form we need.

§41.6.1 Lifting**Definition 41.6.1 (Lift)**

Let $\pi : \tilde{X} \rightarrow X$ be a covering map and $\gamma : [0, 1] \rightarrow X$ a path. A **lift** of γ is a path $\tilde{\gamma} : [0, 1] \rightarrow \tilde{X}$ with $\pi \circ \tilde{\gamma} = \gamma$.

Example 41.6.2

For $\exp : \mathbb{C} \rightarrow \mathbb{C}^*$ and $\gamma(t) = e^{2\pi it}$, both $t \mapsto 2\pi it$ and $t \mapsto 2\pi i + 2\pi it$ are lifts. They differ, but they start at different points – and that is the general phenomenon.

Proposition 41.6.3 (Uniqueness of Lifts)

Let $\pi : \tilde{X} \rightarrow X$ be a covering map and $\tilde{\gamma}_1, \tilde{\gamma}_2$ lifts of the same path γ . If $\tilde{\gamma}_1(0) = \tilde{\gamma}_2(0)$ then $\tilde{\gamma}_1 = \tilde{\gamma}_2$.

Proof. Let $I = \{t \in [0, 1] : \tilde{\gamma}_1(t) = \tilde{\gamma}_2(t)\}$, which is non-empty and closed (as $\tilde{X}$ is Hausdorff and the $\tilde{\gamma}_i$ continuous). We show I is open, so that $I = [0, 1]$ by connectedness.

Let $t \in I$ and put $\tilde{x} = \tilde{\gamma}_1(t) = \tilde{\gamma}_2(t)$. As π is a local homeomorphism there is an open $\tilde{N} \ni \tilde{x}$ with $\pi|_{\tilde{N}}$ a homeomorphism onto an open N . By continuity there is $\delta > 0$ with $\tilde{\gamma}_i((t - \delta, t + \delta)) \subseteq \tilde{N}$ for $i = 1, 2$. For such s ,

$$\tilde{\gamma}_1(s) = (\pi|_{\tilde{N}})^{-1}(\gamma(s)) = \tilde{\gamma}_2(s),$$

so $(t - \delta, t + \delta) \cap [0, 1] \subseteq I$. □

Existence, however, requires regularity.

Example 41.6.4

Let $\tilde{X} = \mathbb{R} + i(-\pi, 2\pi)$ and $\pi = \exp|_{\tilde{X}} : \tilde{X} \rightarrow \mathbb{C}^*$. This is a covering map (a local

homeomorphism onto $\mathbb{C}^*$), but the loop $t \mapsto e^{2\pi it}$ cannot be lifted starting at 0: the lift would have to be $t \mapsto 2\pi it$, which leaves $\tilde{X}$ at $t = 1$. The map π is not regular.

Proposition 41.6.5 (Path Lifting)

Let $\pi : \tilde{X} \rightarrow X$ be a regular covering map, $\gamma : [0, 1] \rightarrow X$ a path and $\tilde{x} \in \tilde{X}$ with $\pi(\tilde{x}) = \gamma(0)$. Then there is a unique lift $\tilde{\gamma}$ of γ with $\tilde{\gamma}(0) = \tilde{x}$.

Proof. Uniqueness is Proposition 41.6.3. For existence let

$$I = \{t \in [0, 1] : \gamma|_{[0, t]} \text{ lifts to some } \tilde{\gamma} \text{ with } \tilde{\gamma}(0) = \tilde{x}\},$$

which contains 0. Note that by uniqueness, lifts on $[0, t]$ for varying t are compatible, so I is an interval and the lifts patch.

I is open in $[0, 1]$. Let $\tau \in I$ with lift $\tilde{\gamma}$ on $[0, \tau]$. Choose an evenly covered $U \ni \gamma(\tau)$, so $\pi^{-1}(U) = \coprod_{\delta} U_{\delta}$, and let U_{δ_0} be the sheet containing $\tilde{\gamma}(\tau)$. Choose $\varepsilon > 0$ with $\gamma((\tau - \varepsilon, \tau + \varepsilon)) \subseteq U$; then setting $\tilde{\gamma}(t) = (\pi|_{U_{\delta_0}})^{-1}(\gamma(t))$ for $t \in [\tau, \tau + \varepsilon)$ extends the lift.

I is closed. Let $\tau = \sup I$ and choose an evenly covered $U \ni \gamma(\tau)$ with sheets U_{δ} . Pick $\varepsilon > 0$ with $\gamma((\tau - \varepsilon, \tau]) \subseteq U$ and choose $t \in I$ with $t > \tau - \varepsilon$. The connected set $\tilde{\gamma}((\tau - \varepsilon, t])$ lies in $\pi^{-1}(U)$, hence in a single sheet U_{δ_0} , and we may define $\tilde{\gamma}(s) = (\pi|_{U_{\delta_0}})^{-1}(\gamma(s))$ for $s \in (\tau - \varepsilon, \tau]$, which agrees with the existing lift and extends it continuously to τ . So $\tau \in I$.

Hence I is a non-empty clopen subset of $[0, 1]$, so $I = [0, 1]$. $\square$

Theorem 41.6.6 (Homotopy Lifting, or the Monodromy Theorem)

Let $\pi : \tilde{X} \rightarrow X$ be a regular covering map and let $\alpha \simeq \beta$ be homotopic paths in X (rel endpoints). Let $\tilde{\alpha}, \tilde{\beta}$ be their lifts with $\tilde{\alpha}(0) = \tilde{\beta}(0)$. Then $\tilde{\alpha} \simeq \tilde{\beta}$; in particular $\tilde{\alpha}(1) = \tilde{\beta}(1)$.

Proof. This is the homotopy lifting property, proved in II Algebraic Topology: one lifts the homotopy $H : [0, 1]^2 \rightarrow X$ by subdividing the square into small squares each mapping into an evenly covered set, and lifting them one at a time, using uniqueness of lifts to see the pieces agree. The resulting $\tilde{H}$ is a homotopy from $\tilde{\alpha}$ to $\tilde{\beta}$; since H is constant on the two vertical edges, $\tilde{H}$ is too (a lift of a constant path is constant, by uniqueness), so the homotopy is rel endpoints. $\square$

The name ‘monodromy theorem’ attached to this statement is traditional and slightly unfortunate, since we shall also use it for the classical statement about analytic continuation (Theorem 41.7.12). The latter is a corollary of the former, and the two are best regarded as the same theorem stated on either side of the dictionary we are about to build.

§41.6.2 The Monodromy Group

Let $\pi : \tilde{X} \rightarrow X$ be a regular covering map and fix a basepoint $x_0 \in X$. For a loop γ at x_0 and $\tilde{x} \in \pi^{-1}(x_0)$, let $\tilde{\gamma}_{\tilde{x}}$ be the lift starting at $\tilde{x}$; since $\pi(\tilde{\gamma}_{\tilde{x}}(1)) = \gamma(1) = x_0$, the endpoint again lies in the fibre.

Definition 41.6.7 (Monodromy Action)

Define $\sigma_\gamma : \pi^{-1}(x_0) \rightarrow \pi^{-1}(x_0)$ by $\sigma_\gamma(\tilde{x}) = \tilde{\gamma}_{\tilde{x}}(1)$.

Proposition 41.6.8

The assignment $\gamma \mapsto \sigma_\gamma$ satisfies:

- (i) $\sigma_c = \text{id}$ for the constant loop c ;
- (ii) $\sigma_{\bar{\gamma}} = \sigma_\gamma^{-1}$, where $\bar{\gamma}(t) = \gamma(1 - t)$; in particular each σ_γ is a bijection;
- (iii) $\sigma_{\alpha \cdot \beta} = \sigma_\beta \circ \sigma_\alpha$;
- (iv) if $\alpha \simeq \beta$ then $\sigma_\alpha = \sigma_\beta$.

Hence $\{\sigma_\gamma\}$ is a subgroup of $\text{Sym}(\pi^{-1}(x_0))$, and there is a well-defined (right) action of $\pi_1(X, x_0)$ on the fibre.

Proof. (i) is clear. For (iii), if $\tilde{\alpha}_{\tilde{x}}$ is the lift of α at $\tilde{x}$, then the concatenation $\tilde{\alpha}_{\tilde{x}} \cdot \tilde{\beta}_{\tilde{\alpha}_{\tilde{x}}(1)}$ is a lift of $\alpha \cdot \beta$ starting at $\tilde{x}$, so by uniqueness it is *the* lift, and its endpoint is $\sigma_\beta(\sigma_\alpha(\tilde{x}))$. Then (ii) follows from (i) and (iii). Finally (iv) is Theorem 41.6.6. $\square$

Definition 41.6.9 (Monodromy Group)

The subgroup $\{\sigma_\gamma : \gamma \text{ a loop at } x_0\} \leq \text{Sym}(\pi^{-1}(x_0))$ is the **monodromy group** of the covering π .

Up to isomorphism it does not depend on the basepoint, since a path from x_0 to x_1 conjugates the two actions.

Example 41.6.10

Take $p_k : \mathbb{C}^* \rightarrow \mathbb{C}^*$, $z \mapsto z^k$, with basepoint 1. The fibre is the set of k -th roots

of unity ζ^n , $\zeta = e^{2\pi i/k}$. Let $\gamma(t) = e^{2\pi i t}$ be the standard loop; its lift starting at ζ^n is $t \mapsto \zeta^n e^{2\pi i t/k}$, which ends at ζ^{n+1} . So σ_γ is the k -cycle $\zeta^n \mapsto \zeta^{n+1}$. Since $\pi_1(\mathbb{C}^*) \cong \mathbb{Z}$ is generated by $[\gamma]$, the monodromy group is cyclic of order k .

This is the precise sense in which ‘ $\sqrt[k]{z}$ has k branches which are permuted cyclically as z winds once round 0’.

Example 41.6.11

For $\exp : \mathbb{C} \rightarrow \mathbb{C}^*$ with basepoint 1, the fibre is $2\pi i\mathbb{Z}$, the loop γ lifts to $t \mapsto 2\pi i t + 2\pi i n$ starting at $2\pi i n$, and σ_γ is the shift $2\pi i n \mapsto 2\pi i(n+1)$. The monodromy group is infinite cyclic, matching the infinitely many branches of $\log$.

§41.7 The Space of Germs

We now build, once and for all, the Riemann surface on which a complete analytic function becomes single-valued. The construction of Section 41.3 was ad hoc: we chose particular sectors and glued them by hand. The trick is to stop choosing. Take *all* function elements at once, remember only their local behaviour, and let the topology sort things out.

§41.7.1 Germs

Fix a domain $D \subseteq \mathbb{C}$.

Definition 41.7.1 (Germ)

Let (f, U) and (g, V) be function elements on D and let $z \in U \cap V$. Write $(f, U) \equiv_z (g, V)$ if $f = g$ on some neighbourhood of z . This is an equivalence relation on the function elements whose domain contains z ; the equivalence class of (f, U) is the **germ** of f at z , written $[f]_z$.

So $[f]_z = [g]_w$ if and only if $z = w$ and f, g agree near z . A germ at z is exactly the same data as a convergent power series centred at z ; but the geometric language will be more useful.

Definition 41.7.2 (The Space of Germs)

The **space of germs** over D is

$$\mathcal{G} = \mathcal{G}_D = \{[f]_z : z \in D, (f, U) \text{ a function element on } D \text{ with } z \in U\}.$$

We topologise $\mathcal{G}$ so that germs of the same function at nearby points are nearby. For a function element (f, U) write

$$[f]_U = \{[f]_z : z \in U\} \subseteq \mathcal{G},$$

a ‘sheet’ of germs.

Lemma 41.7.3

The collection $\{[f]_U\}$, over all function elements (f, U) on D , is a basis for a topology on $\mathcal{G}$.

Proof. The sets cover $\mathcal{G}$ by definition. Suppose $[h]_z \in [f]_U \cap [g]_V$. Then h agrees with f near z and with g near z , so on some open $W \ni z$ with $W \subseteq U \cap V$ we have $h = f = g$, whence $[h]_W \subseteq [f]_U \cap [g]_V$ and $[h]_z \in [h]_W$. $\square$

Lemma 41.7.4

$\mathcal{G}$ is Hausdorff.

Proof. Let $[f]_z \neq [g]_w$. If $z \neq w$, choose disjoint neighbourhoods $U \ni z$, $V \ni w$ inside the domains of f and g ; then $[f]_U$ and $[g]_V$ are disjoint, since germs in them sit over disjoint sets of points.

If $z = w$, choose a *connected* open $U \ni z$ contained in both domains, so that (f, U) and (g, U) represent $[f]_z, [g]_z$. Suppose $[h]_y \in [f]_U \cap [g]_U$. Then h agrees with f near y and with g near y , so $f = g$ on a neighbourhood of y , and hence on all of U by the identity theorem (U being connected). But then $[f]_z = [g]_z$, a contradiction. So $[f]_U \cap [g]_U = \emptyset$. $\square$

Definition 41.7.5

The **forgetful map** $\pi : \mathcal{G} \rightarrow D$ is $\pi([f]_z) = z$.

Lemma 41.7.6

For each connected component G of $\mathcal{G}$, the restriction $\pi : G \rightarrow D$ is a covering map onto its image, which is open in D . In particular π is a local homeomorphism.

Proof. π is continuous: for $U \subseteq D$ open, $\pi^{-1}(U) = \bigcup [f]_V$ over all function elements (f, V) with $V \subseteq U$, which is open. On a basic open set, $\pi|_{[f]_U} : [f]_U \rightarrow U$ is a bijection with inverse $z \mapsto [f]_z$, and this inverse is continuous because the preimage of a basic set $[g]_V$ is the open set $\{z \in U \cap V : f = g \text{ near } z\}$. So $\pi|_{[f]_U}$ is a homeomorphism onto the open set U , and π is a local homeomorphism. Its image is therefore open, and each component G of $\mathcal{G}$ is path-connected (being locally homeomorphic to open subsets of $\mathbb{C}$, hence locally path-connected) and Hausdorff by Lemma 41.7.4. $\square$

Remark. Note that $\pi : G \rightarrow D$ need not be *regular*. For instance, take $D = \mathbb{C}$ and the component containing the germs of $z \mapsto 1/(1-z)$: continuation is blocked at $z = 1$, and the fibre over 1 can be empty while nearby fibres are not. This is exactly the phenomenon of a function element which cannot be continued along every path.

By Lemma 41.4.21, each component G of $\mathcal{G}$ inherits a unique conformal structure making π holomorphic. Explicitly, the charts are the maps $\pi|_{[f]_U}$ on the sets $[f]_U$, and the transition functions are identities. And there is a canonical holomorphic function on it:

Definition 41.7.7 (Evaluation Map)

The **evaluation map** $E : \mathcal{G} \rightarrow \mathbb{C}$ is $E([f]_z) = f(z)$.

This is well defined, since germs which agree near z certainly agree at z . In the chart $\pi|_{[f]_U}$ its local expression is

$$E \circ (\pi|_{[f]_U})^{-1}(z) = E([f]_z) = f(z),$$

which is holomorphic. So E is a holomorphic function on $\mathcal{G}$.

This is the whole point. The multi-valued function has become the pair (π, E) : π remembers which point of D we are over, and E is a genuine single-valued holomorphic function.

§41.7.2 Analytic Continuation as Lifting

Now we cash in.

Theorem 41.7.8

Let $(f, U), (g, V)$ be function elements on a domain D and let $\gamma : [0, 1] \rightarrow D$ be a path with $\gamma(0) \in U$, $\gamma(1) \in V$. Then

$$(f, U) \approx_\gamma (g, V) \iff \gamma \text{ lifts along } \pi \text{ to a path in } \mathcal{G} \text{ from } [f]_{\gamma(0)} \text{ to } [g]_{\gamma(1)}.$$

Proof. ($\Rightarrow$) Suppose we have a chain $(f, U) = (f_1, U_1) \sim \cdots \sim (f_n, U_n) = (g, V)$ and a dissection $0 = t_0 < \cdots < t_n = 1$ with $\gamma([t_{i-1}, t_i]) \subseteq U_i$. Define

$$\tilde{\gamma}(t) = [f_i]_{\gamma(t)}, \quad t \in [t_{i-1}, t_i].$$

This is well defined at the joins: at $t = t_i$ we need $[f_i]_{\gamma(t_i)} = [f_{i+1}]_{\gamma(t_i)}$, which holds since $f_i = f_{i+1}$ on $U_i \cap U_{i+1}$, an open set containing $\gamma(t_i)$. On each $[t_{i-1}, t_i]$ we have $\tilde{\gamma} = (\pi|_{[f_i]_{U_i}})^{-1} \circ \gamma$, which is continuous; by the gluing lemma $\tilde{\gamma}$ is continuous. Clearly $\pi \circ \tilde{\gamma} = \gamma$ and the endpoints are as claimed.

($\Leftarrow$) Suppose $\tilde{\gamma}$ is such a lift. Every point $\tilde{\gamma}(t)$ has a basic neighbourhood $[f_t]_{U_t}$ with U_t a *disc*. By compactness of $[0, 1]$ and the Lebesgue number lemma, there is a dissection $0 = t_0 < \cdots < t_n = 1$ and function elements (f_i, U_i) with U_i a disc and $\tilde{\gamma}([t_{i-1}, t_i]) \subseteq [f_i]_{U_i}$. Applying π gives $\gamma([t_{i-1}, t_i]) \subseteq U_i$. Moreover for each i ,

$$[f_i]_{\gamma(t_i)} = \tilde{\gamma}(t_i) = [f_{i+1}]_{\gamma(t_i)},$$

so $f_i = f_{i+1}$ near $\gamma(t_i) \in U_i \cap U_{i+1}$. Since U_i, U_{i+1} are discs, $U_i \cap U_{i+1}$ is convex hence connected, and the identity theorem gives $f_i = f_{i+1}$ on $U_i \cap U_{i+1}$, i.e. $(f_i, U_i) \sim (f_{i+1}, U_{i+1})$. Finally $[f_1]_{\gamma(0)} = [f]_{\gamma(0)}$ and $[f_n]_{\gamma(1)} = [g]_{\gamma(1)}$, and the identity theorem on the connected sets $U_1 \cap U$ and $U_n \cap V$ upgrades these germ equalities to $(f, U) \sim (f_1, U_1)$ and $(f_n, U_n) \sim (g, V)$. $\square$

This is the theorem that makes the space of germs worth building: *analytic continuation along a path is path lifting*. Every fact about continuation is now a fact about covering spaces.

Corollary 41.7.9

Let $\mathcal{F}$ be a complete analytic function on a domain D . Then

$$G_{\mathcal{F}} = \bigcup_{(f,U) \in \mathcal{F}} [f]_U$$

is a path component of $\mathcal{G}$.

Proof. Two germs lie in the same path component precisely when there is a path in $\mathcal{G}$ between them, which by Theorem 41.7.8 happens precisely when the corresponding function elements are analytic continuations of one another. $\square$

Definition 41.7.10

$G_{\mathcal{F}}$, with the conformal structure of Lemma 41.4.21, is **the Riemann surface of the complete analytic function** $\mathcal{F}$, equipped with $\pi : G_{\mathcal{F}} \rightarrow D$ and $E : G_{\mathcal{F}} \rightarrow \mathbb{C}$.

Example 41.7.11

Take $D = \mathbb{C}^*$ and $\mathcal{F}$ the complete analytic function containing the elements $F_n = (f_n, U_n)$ of Section 41.2.2. Then $G_{\mathcal{F}}$ is precisely the surface R we built by hand, and E is the function f . Indeed $\Phi : R \rightarrow G_{\mathcal{F}}$, $[z] \mapsto [f_n]_z$ for $z \in U_n$, is a well-defined homeomorphism commuting with the projections.

§41.7.3 The Classical Monodromy Theorem**Theorem 41.7.12** (Classical Monodromy Theorem)

Let $D \subseteq \mathbb{C}$ be a domain and (f, U) a function element on D which can be continued along *every* path in D starting in U . Suppose α, β are homotopic paths in D (rel endpoints) from a point of U to a point of V , and

$$(f, U) \approx_{\alpha} (g_1, V), \quad (f, U) \approx_{\beta} (g_2, V).$$

Then $g_1 = g_2$ on V (assuming V connected).

Proof. Let G be the path component of $\mathcal{G}$ containing $[f]_{\alpha(0)}$. The hypothesis says exactly that every path in D starting at $\alpha(0)$ lifts to G starting at $[f]_{\alpha(0)}$, from which one deduces that $\pi : G \rightarrow D$ is a regular covering map: given $z \in D$, take a disc $B \ni z$ in D ; each germ in $\pi^{-1}(z)$ extends over B (continue along radii and use the identity theorem, or note that by Theorem 41.7.8 the radial paths lift), giving a sheet of $\pi^{-1}(B)$ over B , and these sheets are disjoint and exhaust $\pi^{-1}(B)$.

Now let $\tilde{\alpha}, \tilde{\beta}$ be the lifts of α, β starting at $[f]_{\alpha(0)}$, which exist by Theorem 41.7.8 and end at $[g_1]_{\alpha(1)}, [g_2]_{\beta(1)}$ respectively. Since $\alpha \simeq \beta$, Theorem 41.6.6 gives $\tilde{\alpha}(1) = \tilde{\beta}(1)$, i.e.

$$[g_1]_{\alpha(1)} = [g_2]_{\alpha(1)}.$$

So $g_1 = g_2$ near $\alpha(1)$, hence on V by the identity theorem. $\square$

Corollary 41.7.13

Let D be a simply connected domain and (f, U) a function element on D which can be continued along every path in D starting in U . Then there is a (unique) holomorphic $F : D \rightarrow \mathbb{C}$ with $F|_U = f$.

Proof. For $z \in D$ choose a path γ from a point of U to z and define $F(z)$ to be the value at z of the continuation along γ . Any two such paths are homotopic rel endpoints, so Theorem 41.7.12 says F is well defined; and it is holomorphic since near each point it agrees with a function element. $\square$

This explains, at last, the branch cuts of a first course. There is no holomorphic logarithm on $\mathbb{C}^*$, because $\mathbb{C}^*$ is not simply connected and continuation once round the origin changes the branch. Slitting the plane makes it simply connected, so a branch exists; but the slit is a choice, and the honest object is the covering $\pi : R \rightarrow \mathbb{C}^*$ which forgets no branch at all.

§41.8 Gluing Riemann Surfaces

The surfaces we have built so far are all non-compact – and by Corollary 41.5.5 it is compact surfaces where the interesting rigidity lives. The missing operation is compactification: adding the points that continuation cannot reach. The general mechanism is gluing.

§41.8.1 The Gluing Construction**Definition 41.8.1 (Gluing)**

Let X, Y be topological spaces with subspaces $X' \subseteq X$, $Y' \subseteq Y$ and a homeomorphism $\Phi : X' \rightarrow Y'$. The result of **gluing X to Y along Φ** is

$$X \cup_{\Phi} Y = (X \sqcup Y) / \sim,$$

where $\sim$ is generated by $x \sim \Phi(x)$ for $x \in X'$, with the quotient topology.

Proposition 41.8.2

Let R_1, R_2 be Riemann surfaces and $S_j \subseteq R_j$ non-empty open connected subsets, and let $\Phi : S_1 \rightarrow S_2$ be a conformal equivalence. Then $R = R_1 \cup_{\Phi} R_2$ carries a unique conformal structure making the inclusions $i_j : R_j \rightarrow R$ holomorphic (indeed conformal onto their open images). If R is Hausdorff, then R is a Riemann surface.

Proof. Each i_j is an open injection, so we may regard R_1, R_2 as open subsets of R covering it. Take as atlas all charts of the form $(\phi_j \circ i_j^{-1}, i_j(U_j))$ where (ϕ_j, U_j) is a chart of R_j . Two such charts coming from the same R_j have a transition function which is a transition function of R_j . A chart from R_1 and one from R_2 overlap only inside $i_1(S_1) = i_2(S_2)$, where the transition function is

$$\phi_2 \circ i_2^{-1} \circ i_1 \circ \phi_1^{-1} = \phi_2 \circ \Phi \circ \phi_1^{-1},$$

holomorphic since Φ is. So we have an atlas; extend it by Lemma 41.4.9. The local expression of i_j in these charts is the identity, so i_j is holomorphic. Uniqueness follows as in Lemma 41.4.21: any structure making the i_j holomorphic and locally invertible must contain, hence by maximality equal, this one.

Finally R is connected: it is the union of the connected sets $i_1(R_1)$ and $i_2(R_2)$, which meet. $\square$

The Hausdorff hypothesis is not automatic, and one must always check it.

Example 41.8.3 (The Line with Two Origins)

Take $R_1 = R_2 = \mathbb{C}$ and $S_1 = S_2 = \mathbb{C}^*$ with $\Phi = \text{id}$. Then R is the plane with a doubled origin: the two copies of 0 have no disjoint neighbourhoods, since every punctured neighbourhood of either is identified with that of the other. So R is not Hausdorff and is not a Riemann surface.

Example 41.8.4 (The Sphere by Gluing)

Take $R_1 = R_2 = \mathbb{C}$, $S_1 = S_2 = \mathbb{C}^*$, and $\Phi(z) = 1/z$, a conformal equivalence $\mathbb{C}^* \rightarrow \mathbb{C}^*$. The glued space R is Hausdorff: given the two ‘extra’ points $i_1(0)$ and $i_2(0)$, the sets $i_1(D(0, 1))$ and $i_2(D(0, 1))$ are disjoint open neighbourhoods, since Φ maps $D(0, 1) \setminus \{0\}$ to the exterior of the closed unit disc. Other pairs of points are separated inside a single copy of $\mathbb{C}$. It is compact, being the union of the two compact sets $i_j(\overline{D}(0, 1))$. And of course $R \cong \mathbb{C}_\infty$: the map sending $i_1(z) \mapsto z$ and $i_2(w) \mapsto 1/w$ is a conformal equivalence, since the two charts of $\mathbb{C}_\infty$ are related by exactly Φ .

This is the model for everything that follows: to compactify a surface, find a second surface containing the missing points and glue along the common part.

§41.8.2 The Surface of $w^2 = z^3 - z$

Let us carry out a substantial example by hand. Set

$$h(z) = z^3 - z = z(z-1)(z+1),$$

and consider the multi-valued function $w = \sqrt{h(z)}$. Near any point where h does not vanish we can choose a square root holomorphically; the trouble is at $z = 0, \pm 1$, and (as we shall see) at ∞ .

Step 1: a cut domain. Let

$$D = \mathbb{C} \setminus ([-1, 0] \cup [1, \infty)).$$

We construct branches of $\sqrt{h}$ on D . Fix $z_0 \in D$ and w_0 with $w_0^2 = h(z_0)$, and define, for $z \in D$,

$$g(z) = w_0 \exp \left(\frac{1}{2} \int_{\gamma} \frac{h'(\zeta)}{h(\zeta)} d\zeta \right)$$

where γ is any path in D from z_0 to z .

Why this is well defined. If γ is a loop in D , the argument principle gives

$$\frac{1}{2\pi i} \int_{\gamma} \frac{h'}{h} d\zeta = n(\gamma, 0) + n(\gamma, 1) + n(\gamma, -1),$$

the sum of winding numbers about the zeros of h (there are no poles). Now γ lies in D , so it cannot wind around 1 at all – the cut $[1, \infty)$ blocks it – giving $n(\gamma, 1) = 0$; and it must wind the same number of times about 0 and about -1 , since the cut $[-1, 0]$ joins them and γ cannot separate them. Hence the integral is $2\pi i \cdot 2n(\gamma, 0)$, an even multiple of $2\pi i$, and so

$$\exp\left(\frac{1}{2} \int_{\gamma} \frac{h'}{h}\right) = \exp(2\pi i n(\gamma, 0)) = 1.$$

Therefore g does not depend on γ , and it is holomorphic (locally it is $w_0 \exp(\frac{1}{2}L)$ for a local branch L of $\log h$), with

$$g(z)^2 = w_0^2 \exp\left(\int_{\gamma} \frac{h'}{h}\right) = h(z_0) \cdot \frac{h(z)}{h(z_0)} = h(z).$$

The two choices of w_0 give two branches $g_+ = -g_-$. Write D_+, D_- for two copies of D carrying g_+, g_- respectively.

Step 2: gluing along the cuts. As a subset of the sphere, D is $\mathbb{C}_{\infty}$ minus two closed arcs, hence homeomorphic to an open cylinder $S^1 \times \mathbb{R}$. For z_0 in the interior of a cut, and writing $z \rightarrow z_0^{\pm}$ for approach from the upper and lower half planes,

$$\lim_{z \rightarrow z_0^-} g_+(z) = \lim_{z \rightarrow z_0^+} g_-(z), \quad \lim_{z \rightarrow z_0^+} g_+(z) = \lim_{z \rightarrow z_0^-} g_-(z).$$

(Crossing a cut flips the sign of the square root, because the argument of exactly one of the factors of h jumps by 2π .) So we glue the upper side of each cut in D_+ to the lower side of the corresponding cut in D_- , and vice versa.

Each $D_{\pm}$ is a cylinder; gluing two cylinders along two pairs of slits produces a torus with the four points $0, \pm 1, \infty$ removed. (Think of each cylinder as a sphere with two slits; gluing crosswise along two slits is exactly the standard construction of a genus-1 surface from two spheres with two handles' worth of identification.) We shall verify this

by computation in Section 41.10, and the reader should not feel obliged to believe the picture until then.

Call the resulting Riemann surface R . The two branches assemble into a holomorphic $g : R \rightarrow \mathbb{C}$, and the two inclusions $D_{\pm} \hookrightarrow \mathbb{C} \setminus \{0, \pm 1\}$ assemble into a holomorphic covering map $\pi : R \rightarrow \mathbb{C} \setminus \{0, \pm 1\}$, with

$$g(p)^2 = \pi(p)^3 - \pi(p) \quad \text{for all } p \in R.$$

§41.8.3 Compactifying the Cubic

The surface R above is missing four points. To restore them, we use the graph description. Let

$$R_1 = \{(z, w) \in \mathbb{C}^2 : w^2 = z^3 - z\}.$$

One checks (this is an example sheet exercise, and we shall do the general case in Section 41.9.3) that R_1 is a Riemann surface: away from $w = 0$ the projection $(z, w) \mapsto z$ is a chart, and at the three points $(0, 0), (\pm 1, 0)$ the projection $(z, w) \mapsto w$ is a chart. It contains R as the complement of those three points, so R_1 restores 0 and ± 1 . Only ∞ is missing.

To add it, change coordinates so that ∞ becomes finite. Put

$$u = \frac{1}{z}, \quad v = \frac{z}{w},$$

so that $z = 1/u$ and $w = z/v = 1/(uv)$. Substituting into $w^2 = z^3 - z$:

$$\frac{1}{u^2 v^2} = \frac{1}{u^3} - \frac{1}{u} \implies u = v^2(1 - u^2).$$

So set

$$R_2 = \{(u, v) \in \mathbb{C}^2 : u = v^2(1 - u^2)\},$$

again a Riemann surface by the same argument, and note that $(u, v) = (0, 0)$ lies on it – this is our point at infinity. The map

$$\Phi(z, w) = \left(\frac{1}{z}, \frac{z}{w}\right)$$

is a conformal equivalence from $R_1 \setminus \{(0, 0), (\pm 1, 0)\}$ onto $R_2 \setminus \{(0, 0)\}$, with inverse $(u, v) \mapsto (1/u, 1/(uv))$. Define

$$\hat{R} = R_1 \cup_{\Phi} R_2.$$

Proposition 41.8.5

$\hat{R}$ is a compact Riemann surface.

Proof. By Proposition 41.8.2 we need only Hausdorffness and compactness. Define $\hat{\pi} : \hat{R} \rightarrow \mathbb{C}_{\infty}$ by $\hat{\pi}(i_1(z, w)) = z$ and $\hat{\pi}(i_2(u, v)) = 1/u$; these agree on the overlap by construction of Φ , so $\hat{\pi}$ is a well-defined continuous map, and it is holomorphic in the glued structure.

Hausdorff. Points both in $i_1(R_1)$, or both in $i_2(R_2)$, are separated there. The only points not in $i_2(R_2)$ are $i_1(0, 0), i_1(\pm 1, 0)$, and the only point not in $i_1(R_1)$ is $i_2(0, 0)$. These are separated by $\hat{\pi}^{-1}(D(0, 2))$ and $\hat{\pi}^{-1}(\mathbb{C}_{\infty} \setminus \overline{D}(0, 2))$.

Compact. We show sequential compactness (which suffices, $\hat{R}$ being second count-

able and metrisable, or directly by a covering argument). Let (p_n) be a sequence in $\hat{R}$. If some subsequence has $|\hat{\pi}(p_n)| \leq M$, pass to a further subsequence with $\hat{\pi}(p_n) \rightarrow z_0 \in \mathbb{C}$; there are at most two w_0 with $w_0^2 = h(z_0)$, so a further subsequence converges to some $i_1(z_0, w_0)$. Otherwise $|\hat{\pi}(p_n)| \rightarrow \infty$, and since $i_2(0, 0)$ is the unique point with $\hat{\pi} = \infty$, and $\hat{\pi}$ is a proper map near there, $p_n \rightarrow i_2(0, 0)$. $\square$

We have obtained a compact Riemann surface $\hat{R}$ carrying a meromorphic function $\hat{\pi}$ (of degree 2, as we shall see) and a meromorphic $\hat{g}$ extending g , with $\hat{g}^2 = \hat{\pi}^3 - \hat{\pi}$. This is the **elliptic curve** $w^2 = z^3 - z$, and in Section 41.11 we shall discover that it is conformally a complex torus.

§41.9 Branching and the Degree

The map $\hat{p}_k : \mathbb{C}_\infty \rightarrow \mathbb{C}_\infty$, $z \mapsto z^k$, is k -to-one except over 0 and ∞ , where the k preimages collide. This is the only local phenomenon there is: we now prove that *every* non-constant holomorphic map looks like $z \mapsto z^n$ in suitable coordinates.

§41.9.1 The Local Normal Form

Proposition 41.9.1 (Local Normal Form)

Let $f : R \rightarrow S$ be a non-constant holomorphic map of Riemann surfaces and $p \in R$. Then there is an integer $n \geq 1$ and charts (ϕ, U) about p and (ψ, V) about $f(p)$ with $\phi(p) = 0$, $\psi(f(p)) = 0$ and

$$\psi \circ f \circ \phi^{-1}(z) = z^n$$

on $\phi(U)$.

Proof. Start with any charts (ϕ_0, U_0) about p and (ψ, V) about $f(p)$, normalised so that $\phi_0(p) = 0$ and $\psi(f(p)) = 0$, with $f(U_0) \subseteq V$. The local expression $F = \psi \circ f \circ \phi_0^{-1}$ is holomorphic near 0 with $F(0) = 0$, and is not identically zero by Corollary 41.5.2. So by Proposition 41.1.3 there is $n \geq 1$ and a holomorphic G near 0 with

$$F(z) = z^n G(z), \quad G(0) \neq 0.$$

Choose $\delta > 0$ with $D(0, \delta)$ inside the domain of G and $G(D(0, \delta)) \subseteq D(G(0), |G(0)|)$; the latter disc misses 0 and is simply connected, so there is a holomorphic branch ρ of the n -th root on it. Put

$$h(z) = z \rho(G(z)), \quad z \in D(0, \delta),$$

so that $h(z)^n = z^n G(z) = F(z)$. Now $h(0) = 0$ and $h'(0) = \rho(G(0)) \neq 0$, so by the inverse function theorem (Theorem 41.1.13) h is a biholomorphism from some $D(0, \varepsilon)$ onto an open set.

Set $\phi = h \circ \phi_0$, restricted to $U = \phi_0^{-1}(D(0, \varepsilon))$. This is a chart (a composite of a chart with a biholomorphism) with $\phi(p) = 0$, and it is compatible with the existing

structure since h is biholomorphic. Finally

$$\begin{aligned}\psi \circ f \circ \phi^{-1}(z) &= \psi \circ f \circ \phi_0^{-1} \circ h^{-1}(z) \\ &= F(h^{-1}(z)) = h(h^{-1}(z))^n = z^n. \square\end{aligned}$$

Definition 41.9.2 (Multiplicity)

The integer n of Proposition 41.9.1 is the **multiplicity** (or **ramification index**, or **local degree**) of f at p , written $\text{mult}_f(p)$.

Lemma 41.9.3

$\text{mult}_f(p)$ is well defined, i.e. independent of the charts chosen.

Proof. If z^n and z^m are both local expressions, then they differ by pre-composition and post-composition with biholomorphisms fixing 0. So $\alpha(z)^n = \beta(z^m)$ near 0 with α, β biholomorphic and $\alpha(0) = \beta(0) = 0$. Counting orders of vanishing at 0: α and β have simple zeros (their derivatives are non-zero), so the left side vanishes to order n and the right to order m . Hence $n = m$. $\square$

Equivalently: $\text{mult}_f(p)$ is the order of the zero of $\psi \circ f \circ \phi^{-1} - \psi(f(p))$ at $\phi(p)$, in any charts.

Definition 41.9.4 (Ramification and Branch Points)

If $\text{mult}_f(p) > 1$ we call p a **ramification point** of f , and $f(p)$ a **branch point**. A point $q \in S$ with $f^{-1}(q)$ a single point p of multiplicity $\deg f$ is **totally ramified**.

The local picture is worth having firmly in mind. Under $z \mapsto z^n$, the disc $|z| < \varepsilon$ is wrapped n times around the disc $|w| < \varepsilon^n$: each of the n sectors of angle $2\pi/n$ is opened out to a full disc, and the n preimages of a point $w \neq 0$ merge into the single preimage 0 of 0.

Example 41.9.5

Let $f : \mathbb{C}_\infty \rightarrow \mathbb{C}_\infty$ be a polynomial $f(z) = a_d z^d + \cdots + a_0$ with $a_d \neq 0$ and $d \geq 1$, extended by $f(\infty) = \infty$. Away from ∞ , the local expression of f is f itself and $\text{mult}_f(p)$ is the order of the zero of $f(z) - f(p)$ at p ; so the ramification points in $\mathbb{C}$

are exactly the zeros of f' . At ∞ , use the chart $w = 1/z$ upstairs and downstairs:

$$\frac{1}{f(1/w)} = \frac{w^d}{a_d + a_{d-1}w + \cdots + a_0w^d},$$

which vanishes to order d at $w = 0$. So $\text{mult}_f(\infty) = d$, and ∞ is totally ramified whenever $d \geq 2$.

Remark. More generally, if $f : R \rightarrow \mathbb{C}$ is holomorphic and (ϕ, U) is any chart about p with $F = f \circ \phi^{-1}$, then writing $F(z) - F(z_0) = (z - z_0)^m G(z)$ with $G(z_0) \neq 0$ and $m = \text{mult}_f(p)$, we get

$$F'(z) = (z - z_0)^{m-1} (mG(z) + (z - z_0)G'(z)),$$

so $F'(z_0) = 0$ if and only if $m > 1$. The ramification points are the zeros of the derivative in any chart. Since F' is not identically zero (as f is non-constant), its zeros are isolated: *a non-constant holomorphic map has a discrete set of ramification points*. If R is compact, there are only finitely many.

Lemma 41.9.6 (Multiplicativity)

If $f : R \rightarrow S$ and $g : S \rightarrow T$ are non-constant holomorphic, then

$$\text{mult}_{g \circ f}(p) = \text{mult}_g(f(p)) \cdot \text{mult}_f(p).$$

Proof. Choose charts in which f is $z \mapsto z^m$ with $m = \text{mult}_f(p)$, and in which g is $w \mapsto w^n$ with $n = \text{mult}_g(f(p))$; we may take the target chart for f to be the source chart for g , since both are just ‘some chart about $f(p)$ sending it to 0’, and the local normal form allows us to choose the source chart freely at each stage — more carefully, take the normal form charts for g first, then run the proof of Proposition 41.9.1 for f with that target chart. Then $g \circ f$ has local expression $z \mapsto (z^m)^n = z^{mn}$. $\square$

§41.9.2 Proper Maps and the Degree

Definition 41.9.7 (Proper Map)

A continuous map $f : R \rightarrow S$ is **proper** if $f^{-1}(K)$ is compact for every compact $K \subseteq S$.

If R is compact then every continuous $f : R \rightarrow S$ is proper, since a closed subset of a compact space is compact. That is the case we shall use most often, but properness is the right hypothesis in general: it is what makes fibres finite, and what stops points of a fibre escaping to infinity as we move around in S .

Example 41.9.8

- (i) A non-constant polynomial $f : \mathbb{C} \rightarrow \mathbb{C}$ is proper, since $|f(z)| \rightarrow \infty$ as $|z| \rightarrow \infty$ and so the preimage of a bounded set is bounded and closed.
- (ii) $p_k : \mathbb{C}^* \rightarrow \mathbb{C}^*$ is proper: $|z^k| \rightarrow \infty$ as $|z| \rightarrow \infty$ and $|z^k| \rightarrow 0$ as $z \rightarrow 0$, so

preimages of compact subsets of $\mathbb{C}^*$ stay away from both ends.

- (iii) (*Non-examples.*) $\exp : \mathbb{C} \rightarrow \mathbb{C}^*$ is not proper, since $\exp^{-1}(\{1\}) = 2\pi i\mathbb{Z}$ is an infinite discrete set. The inclusion $\mathbb{D} \hookrightarrow \mathbb{C}$ is not proper either, as $\overline{D}(0, 1)$ has non-compact preimage $\mathbb{D}$. Neither map has a sensible degree: $\exp$ is ∞ -to-one, and the inclusion is one-to-one over $\mathbb{D}$ and zero-to-one outside it.

The two properties of proper maps we need are the following.

Lemma 41.9.9

Let $f : R \rightarrow S$ be a proper continuous map of Riemann surfaces. Then f is a closed map. If moreover f is holomorphic and non-constant, every fibre $f^{-1}(q)$ is finite.

Proof. For the fibres, $f^{-1}(q)$ is compact, being the preimage of the compact set $\{q\}$, and discrete by Corollary 41.5.2; a compact discrete space is finite.

For closedness, let $A \subseteq R$ be closed and $q \in \overline{f(A)}$. Pick a chart (ψ, V) about q with $\psi(q) = 0$ and put $N = \psi^{-1}(\overline{D}(0, r))$ for some small $r > 0$ with $\overline{D}(0, r) \subseteq \psi(V)$, a compact neighbourhood of q . Then $f^{-1}(N)$ is compact by properness, so $A \cap f^{-1}(N)$ is compact, and therefore $f(A \cap f^{-1}(N))$ is compact and hence closed in the Hausdorff space S . Every neighbourhood of q contained in the interior of N meets $f(A)$, and the points of $f(A)$ it meets lie in $f(A \cap f^{-1}(N))$; so q is in the closure of that set, which is the set itself. Hence $q \in f(A)$, and $f(A)$ is closed. $\square$

Theorem 41.9.10 (Valency Theorem)

Let $f : R \rightarrow S$ be a non-constant proper holomorphic map of Riemann surfaces. Then the function

$$n(q) = \sum_{p \in f^{-1}(q)} \text{mult}_f(p)$$

is constant on S . In particular this applies to any non-constant holomorphic map of compact Riemann surfaces.

Proof. First, each fibre $f^{-1}(q)$ is finite by Lemma 41.9.9, so n is well defined and $\mathbb{N}$ -valued. Since S is connected it suffices to prove n is locally constant.

Fix $q_0 \in S$ and write $f^{-1}(q_0) = \{p_1, \dots, p_k\}$ with $m_i = \text{mult}_f(p_i)$. Choose a chart (ψ, V) about q_0 with $\psi(q_0) = 0$, and by Proposition 41.9.1 charts (ϕ_i, U_i) about p_i with $\psi \circ \phi_i^{-1}(z) = z^{m_i}$; shrinking, we may take the U_i pairwise disjoint and contained in $f^{-1}(V)$.

Let $U = \bigcup_i U_i$. Then $R \setminus U$ is closed in R , so $K = f(R \setminus U)$ is closed in S by Lemma 41.9.9. Note that $q_0 \notin K$, since the whole fibre over q_0 lies in U . Put

$$V' = V \setminus K,$$

an open neighbourhood of q_0 , and $U'_i = U_i \cap f^{-1}(V')$. Then

$$f^{-1}(V') \subseteq U, \quad \text{so} \quad f^{-1}(V') = \coprod_{i=1}^k U'_i.$$

On U'_i , in the charts ϕ_i and ψ , f is the map $z \mapsto z^{m_i}$ restricted to an open set; such a map takes each value $w \neq 0$ exactly m_i times (counted without multiplicity, all multiplicities being 1) and the value 0 once with multiplicity m_i . Hence for every $q \in V'$,

$$n(q) = \sum_{i=1}^k \sum_{p \in U'_i \cap f^{-1}(q)} \text{mult}_f(p) = \sum_{i=1}^k m_i = n(q_0).$$

So n is constant on V' . □

Definition 41.9.11 (Degree)

The constant value n of Theorem 41.9.10 is the **degree** of f , written $\deg f$.

Thus a non-constant proper holomorphic map is ‘deg f -to-one, when points are counted with multiplicity’; in particular this is true of any non-constant holomorphic map of compact Riemann surfaces, which is the situation we shall almost always be in. Note that $p_k : \mathbb{C}^* \rightarrow \mathbb{C}^*$ has degree k and a polynomial $\mathbb{C} \rightarrow \mathbb{C}$ has degree equal to its degree as a polynomial, so the notion is consistent with the classical one even off compact surfaces.

Corollary 41.9.12

A holomorphic map $f : R \rightarrow S$ of compact Riemann surfaces with $\deg f = 1$ is a conformal equivalence. In particular a holomorphic bijection of compact Riemann surfaces is a conformal equivalence.

Proof. If $\deg f = 1$ then every fibre is a single point of multiplicity 1, so f is a bijection with no ramification points. By Proposition 41.9.1 f is locally biholomorphic, so f^{-1} is holomorphic. □

Example 41.9.13

If f is a polynomial of degree d , regarded as $f : \mathbb{C}_\infty \rightarrow \mathbb{C}_\infty$, then $\deg f = d$: compute $n(\infty)$, which by Example 41.9.5 is $\text{mult}_f(\infty) = d$ since ∞ is the only preimage of ∞ .

Corollary 41.9.14 (Fundamental Theorem of Algebra)

A polynomial $f \in \mathbb{C}[z]$ of degree $d \geq 1$ has exactly d roots in $\mathbb{C}$, counted with multiplicity.

Proof. Extend to $f : \mathbb{C}_\infty \rightarrow \mathbb{C}_\infty$, of degree d . Then $n(0) = d$, and $f^{-1}(0) \subseteq \mathbb{C}$ since $f(\infty) = \infty$. The multiplicity of f at a root is the order of the root. □

Example 41.9.15

A rational function $f = p/q$ in lowest terms with $\deg p = m$, $\deg q = n$ has $\deg f = \max(m, n)$ as a map $\mathbb{C}_\infty \rightarrow \mathbb{C}_\infty$. Indeed if $m > n$ then ∞ is the only preimage of ∞ with multiplicity $m - n$... rather than pursue this, compute $n(w)$ for generic w : the equation $p(z) - wq(z) = 0$ has $\max(m, n)$ roots for all but finitely many w , since the leading coefficient of $p - wq$ vanishes for at most one w .

Example 41.9.16 (The Two-Sheeted Cover of the Sphere)

Consider $\hat{p}_2 : \mathbb{C}_\infty \rightarrow \mathbb{C}_\infty, z \mapsto z^2$. It has degree 2, and its branch points are 0 and ∞ , each totally ramified. Topologically: take two copies of the sphere, slit each along an arc from 0 to ∞ , and glue crosswise. The result is again a sphere.

Gluing the upper side of the slit in S_0 to the lower side of the slit in S_1 , and vice versa, returns a sphere; the two red points are the branch points 0 and ∞ , and over every other point there are two preimages. That the total space is again a sphere and not, say, a torus is a genuine constraint, and Riemann–Hurwitz is the tool that makes such constraints computable.

§41.9.3 Riemann Surfaces of Algebraic Functions

The examples $w^2 = z^3 - z$ and $w^k = z$ are instances of a general construction. Let

$$P(z, w) = w^d + c_{d-1}(z)w^{d-1} + \cdots + c_0(z)$$

be a polynomial in w whose coefficients are polynomials in z , and suppose P is irreducible in $\mathbb{C}[z, w]$. The **algebraic function** $w(z)$ defined by $P(z, w) = 0$ is the classical object; the modern one is the surface

$$X' = \{(z, w) \in \mathbb{C}^2 : P(z, w) = 0\}.$$

Proposition 41.9.17

Suppose X' is **smooth**, that is, at every point of X' at least one of $\partial P/\partial z$, $\partial P/\partial w$ is non-zero. Then X' is a Riemann surface, with charts given by the coordinate projections, and $\pi_z : X' \rightarrow \mathbb{C}, (z, w) \mapsto z$, is holomorphic.

Proof sketch. X' is Hausdorff and second countable as a subspace of $\mathbb{C}^2$. Near a point (z_0, w_0) with $\partial P/\partial w \neq 0$, the holomorphic implicit function theorem provides a holomorphic η near z_0 with $\eta(z_0) = w_0$ and $P(z, \eta(z)) = 0$, and the graph of η is a neighbourhood of (z_0, w_0) in X' ; so π_z is a homeomorphism there and serves as a chart. Symmetrically, where $\partial P/\partial z \neq 0$, π_w is a chart. Smoothness says these cover

X' . The transition functions are η and its inverse, which are holomorphic. Connectedness is the one genuinely non-trivial point, and it follows from irreducibility of P ; we verify it by hand in the examples we need. $\square$

Away from the finitely many z for which $P(z, \cdot)$ has a repeated root – the **discriminant locus** – the map π_z is a d -sheeted covering map, since the d roots w vary holomorphically and distinctly. Over the discriminant locus, roots collide and π_z ramifies. Compactifying (by gluing in charts at ∞ , as in Section 41.8.3) gives a compact Riemann surface X with a degree- d meromorphic function $\hat{\pi}_z : X \rightarrow \mathbb{C}_\infty$.

Example 41.9.18 (Fermat Curves)

Let $d \geq 1$ and

$$F'_d = \{(x, y) \in \mathbb{C}^2 : x^d + y^d = 1\}.$$

Here $P = y^d + x^d - 1$, with $\partial P / \partial y = dy^{d-1}$ and $\partial P / \partial x = dx^{d-1}$, which vanish simultaneously only at $(0, 0)$, not a point of F'_d . So F'_d is smooth.

Concretely, π_x has local inverse $x \mapsto (x, \sqrt[d]{1-x^d})$, which exists and is holomorphic near any x_0 with $x_0^d \neq 1$, i.e. away from $y_0 = 0$; and π_y provides charts near the points where $y = 0$, since there $x \neq 0$. These cover F'_d .

For connectedness: let

$$D = \mathbb{C} \setminus \bigcup_{i=0}^{d-1} \{t\zeta_d^i : t \geq 1\}, \quad \zeta_d = e^{2\pi i/d},$$

the plane with d radial slits removed. This is simply connected and $1 - x^d$ does not vanish on it, so there are d holomorphic branches of $(1 - x^d)^{1/d}$ on D , each extending continuously to the slit endpoints ζ_d^i . Given $(x_0, y_0) \in F'_d$ with $x_0 \in D$, choose the branch y with $y(x_0) = y_0$ and a path γ in D from x_0 to 1; then $t \mapsto (\gamma(t), y(\gamma(t)))$ joins (x_0, y_0) to $(1, 0)$. Points with $x_0 \notin D$ can first be joined to nearby points with $x_0 \in D$, as D is dense. So F'_d is path-connected, hence a Riemann surface.

The compactification F_d is obtained by gluing on a second chart at infinity (an example sheet exercise), and $\hat{\pi}_x : F_d \rightarrow \mathbb{C}_\infty$ has degree d . Its ramification points are the d points $(\zeta_d^i, 0)$, each of multiplicity d (there $1 - x^d$ has a simple zero, so $y = (1 - x^d)^{1/d}$ is a d -th root of a simple zero), and $\hat{\pi}_x^{-1}(\infty)$ consists of d distinct unramified points. We compute the genus of F_d in Example 41.10.12.

§41.10 Euler Characteristic and Riemann–Hurwitz

Everything so far has been local or analytic. We now bring in topology, and the payoff is immediate: the degree and ramification of a holomorphic map determine the topology of its source from that of its target.

§41.10.1 Triangulations and the Euler Characteristic

Definition 41.10.1 (Triangulation)

Let S be a compact Riemann surface. A **topological triangle** in S is a continuous embedding $\Delta \hookrightarrow S$ of a closed non-degenerate triangle $\Delta \subseteq \mathbb{R}^2$. A **triangulation**

of S is a finite collection $\{\Delta_i\}$ of topological triangles such that

- (i) $\bigcup_i \Delta_i = S$;
- (ii) for $i \neq j$, $\Delta_i \cap \Delta_j$ is empty, a common vertex, or a common edge;
- (iii) each edge lies in exactly two triangles.

Definition 41.10.2 (Euler Characteristic)

The **Euler characteristic** of a triangulation is $\chi = V - E + F$, where V, E, F count vertices, edges and faces.

Lemma 41.10.3

Every compact Riemann surface admits a triangulation, and χ is independent of the triangulation chosen.

We take this on trust; the first part is Radó's theorem and the second is the topological invariance of simplicial homology, proved in II Algebraic Topology (where $\chi = \sum_i (-1)^i \text{rank } H_i$). We write $\chi(S)$ for the common value.

Example 41.10.4

$\chi(\mathbb{C}_\infty) = 2$. Triangulate the sphere as the boundary of a tetrahedron: $V - E + F = 4 - 6 + 4 = 2$.

Example 41.10.5

$\chi(\mathbb{C}/\Lambda) = 0$. Represent the torus as a square with opposite sides identified and cut it into two triangles by a diagonal. After identification there is $V = 1$ vertex, $E = 3$ edges (two sides and the diagonal), and $F = 2$ faces, giving $1 - 3 + 2 = 0$. (Strictly this is not a triangulation in the sense above, since the two triangles share more than one edge; subdividing repairs this without changing χ .)

We quote from II Algebraic Topology the classification of surfaces: every compact connected orientable surface is homeomorphic to Σ_g , the g -holed torus, for a unique $g \geq 0$, and

$$\chi(\Sigma_g) = 2 - 2g.$$

A Riemann surface is orientable, since holomorphic transition functions have positive Jacobian determinant $|\phi'|^2 > 0$. So a compact Riemann surface is homeomorphic to some Σ_g , and χ determines it up to homeomorphism.

Definition 41.10.6 (Genus)

The **genus** of a compact Riemann surface S is $g(S) = (2 - \chi(S))/2$.

The standard picture of Σ_g is a sphere with g handles; equivalently it is a $4g$ -gon with its edges identified in the pattern $a_1 b_1 a_1^{-1} b_1^{-1} \cdots a_g b_g a_g^{-1} b_g^{-1}$. For $g = 2$:

From the octagon picture one reads off $\chi(\Sigma_2)$ directly: all 8 vertices are identified to one, the 8 edges become 4, and there is 1 face, giving $1 - 4 + 1 = -2 = 2 - 2 \cdot 2$.

§41.10.2 The Riemann–Hurwitz Formula

Theorem 41.10.7 (Riemann–Hurwitz)

Let $f : R \rightarrow S$ be a non-constant holomorphic map of compact Riemann surfaces of degree n . Then

$$\chi(R) = n \chi(S) - \sum_{p \in R} (\text{mult}_f(p) - 1).$$

Equivalently, in terms of genera,

$$2g(R) - 2 = n(2g(S) - 2) + \sum_{p \in R} (\text{mult}_f(p) - 1).$$

The sum is finite: as we observed above, the ramification points of f are isolated, and R is compact, so there are finitely many.

Proof. As in the proof of the valency theorem, every $q \in S$ has an open neighbourhood V_q which is **well covered**: $f^{-1}(V_q)$ is a disjoint union of open sets on each of which f is, in suitable charts, a power map $z \mapsto z^m$, and V_q contains no branch point other than possibly q . By compactness of S , finitely many $V_{q_1}, \dots, V_{q_r}$ cover S ; in particular there are finitely many branch points.

Choose a triangulation of S and subdivide it repeatedly (barycentrically, say) until

- (i) every branch point of f is a vertex, and
- (ii) every triangle is contained in some V_{q_i} .

Both are achievable: (i) by first taking a triangulation with the finitely many branch points among the vertices, and (ii) since subdivision makes the triangles arbitrarily small and the V_{q_i} have a Lebesgue number.

Now pull back. If $\Delta \subseteq V_{q_i}$ is a (closed) triangle then $f^{-1}(\Delta)$ is a disjoint union of triangles, each mapped homeomorphically onto Δ by f ; the same for edges. Indeed Δ is simply connected and, since its interior contains no branch point, f restricted over the interior is a covering map of degree n ; and the branch points on $\partial\Delta$ are vertices, where the local picture $z \mapsto z^m$ still sends the m triangle-corners upstairs homeomorphically onto the corner downstairs. So the preimages of the triangles of

S form a triangulation of R , with

$$F_R = nF_S, \quad E_R = nE_S,$$

since each face and each edge downstairs has exactly n preimages.

Vertices are where the count fails. For $q \in S$ a vertex, the valency theorem gives

$$\begin{aligned} |f^{-1}(q)| &= \sum_{p \in f^{-1}(q)} 1 = \sum_{p \in f^{-1}(q)} \text{mult}_f(p) - \sum_{p \in f^{-1}(q)} (\text{mult}_f(p) - 1) \\ &= n - \sum_{p \in f^{-1}(q)} (\text{mult}_f(p) - 1). \end{aligned}$$

Summing over the vertices q of S , and noting that every ramification point of f lies over a branch point, which is a vertex,

$$V_R = nV_S - \sum_{p \in R} (\text{mult}_f(p) - 1).$$

Therefore

$$\chi(R) = V_R - E_R + F_R = n(V_S - E_S + F_S) - \sum_{p \in R} (\text{mult}_f(p) - 1),$$

which is the first formula. The second follows by substituting $\chi = 2 - 2g$. $\square$

Each triangle and each edge downstairs has exactly n preimages; only the vertices lying under ramification points have fewer than n preimages, and the deficiency is exactly $\sum (\text{mult}_f(p) - 1)$.

Remark. The correction term $\sum_p (\text{mult}_f(p) - 1)$ is always even, being $\chi(R) - n\chi(S) = (2 - 2g(R)) - n(2 - 2g(S))$. This trivial-looking observation is surprisingly useful: it often pins down the ramification at a point we have not analysed.

§41.10.3 First Applications

Corollary 41.10.8

Suppose $f : R \rightarrow S$ is an unramified non-constant holomorphic map of compact Riemann surfaces (equivalently, a covering map) of degree n . Then $g(R) - 1 = n(g(S) - 1)$, and

- (i) if $g(S) = 0$ then $n = 1$ and $R \cong S \cong \mathbb{C}_\infty$;

- (ii) if $g(S) = 1$ then $g(R) = 1$, and n is unrestricted;
- (iii) if $g(S) \geq 2$ then either $n = 1$ and f is a conformal equivalence, or $n \geq 2$ and $g(R) > g(S)$.

Proof. Riemann–Hurwitz with no correction term gives $2g(R) - 2 = n(2g(S) - 2)$. If $g(S) = 0$ then $g(R) - 1 = -n < 0$, forcing $g(R) = 0$ and $n = 1$; then f is a conformal equivalence by Corollary 41.9.12, and a genus 0 compact surface is $\mathbb{C}_\infty$ (which we prove in Corollary 41.13.8). If $g(S) = 1$ then $g(R) = 1$ for any n . If $g(S) \geq 2$ then $g(R) - 1 = n(g(S) - 1) \geq n$, so $n \geq 2$ gives $g(R) \geq 2g(S) - 1 > g(S)$. $\square$

Example 41.10.9

That case (ii) is genuinely unrestricted: take $\Lambda_n = \langle n, i \rangle$ for $n \in \mathbb{Z}_{>0}$. Then $\Lambda_n \leq \Lambda_1 = \langle 1, i \rangle$ with index n , so the identity on $\mathbb{C}$ descends to an unramified degree- n map $\mathbb{C}/\Lambda_n \rightarrow \mathbb{C}/\Lambda_1$ of tori.

Example 41.10.10 (The Cubic Curve)

Let $\hat{R}$ be the compactification of the surface of $w^2 = z^3 - z$ from Section 41.8.3, with $\hat{\pi} : \hat{R} \rightarrow \mathbb{C}_\infty$. Since a generic z has exactly two preimages $(z, \pm\sqrt{h(z)})$, $\deg \hat{\pi} = 2$. The branch points are $0, \pm 1$ (where h has a simple zero, so the two sheets come together) and ∞ ; each is totally ramified, with a single preimage of multiplicity 2. So

$$2g(\hat{R}) - 2 = 2(0 - 2) + 4 \cdot (2 - 1) = -4 + 4 = 0 \implies g(\hat{R}) = 1,$$

confirming that $\hat{R}$ is a torus.

Remark. Suppose we had not analysed the behaviour at ∞ . Writing

$$C = \sum_{p \in \hat{\pi}^{-1}(\infty)} (\text{mult}_{\hat{\pi}}(p) - 1),$$

the correction term is $3 + C$, which must be even by the parity remark above; so C is odd, and since $\deg \hat{\pi} = 2$ we must have $C = 1$, i.e. ∞ is a branch point. The parity argument has done the local analysis for us. This works whenever $\deg f = 2$.

Example 41.10.11 (Hyperelliptic Curves)

More generally, let $h(z)$ be a polynomial of degree d with d distinct roots, and let X be the compactification of $\{w^2 = h(z)\}$, with $\hat{\pi} : X \rightarrow \mathbb{C}_\infty$ of degree 2. The branch points in $\mathbb{C}$ are the d roots of h . What happens at ∞ ? Setting $u = 1/z$, we get $w^2 = u^{-d}(1 + O(u))$, so $w \sim u^{-d/2}$: if d is even there are two points over ∞ , unramified; if d is odd there is one, ramified. Either way the total correction is d or $d + 1$, i.e. $2\lceil d/2 \rceil$, and

$$2g(X) - 2 = 2(-2) + 2\lceil \frac{d}{2} \rceil \implies g(X) = \lceil \frac{d}{2} \rceil - 1 = \left\lfloor \frac{d-1}{2} \right\rfloor.$$

So $d = 3, 4$ give genus 1; $d = 5, 6$ give genus 2; and so on. These are the **hyperelliptic** curves.

Example 41.10.12 (Fermat Curves and the Degree–Genus Formula)

Let F_d be the compactified Fermat curve of Example 41.9.18, with $\hat{\pi}_x : F_d \rightarrow \mathbb{C}_\infty$ of degree d . There are d ramification points $(\zeta_d^i, 0)$, each of multiplicity d , and no others. So

$$2g(F_d) - 2 = d(0 - 2) + d(d - 1) \implies g(F_d) = \frac{(d - 1)(d - 2)}{2}.$$

This is an instance of the **degree–genus formula**: a smooth projective plane curve of degree d has genus $(d - 1)(d - 2)/2$. For $d = 1, 2$ we get $g = 0$ (lines and conics are spheres); for $d = 3$, $g = 1$ (cubics are tori, as we found for $w^2 = z^3 - z$ after homogenising); for $d = 4$, $g = 3$; and g grows quadratically. In particular there exist compact Riemann surfaces of arbitrarily large genus – something not at all obvious from the definitions.

Note that not every genus arises from a plane curve: $(d - 1)(d - 2)/2$ takes the values $0, 0, 1, 3, 6, 10, \dots$, so no smooth plane curve has genus 2. (Genus 2 surfaces exist all the same – they are hyperelliptic, by the previous example with $d = 5$.)

§41.11 Elliptic Functions and Complex Tori

We now describe all the meromorphic functions on the two compact surfaces we understand best: the sphere, and the torus. The sphere is easy and classical. The torus is the heart of the course, and the answer is remarkable – every complex torus is a plane cubic curve, and every elliptic function is a rational expression in one particular function and its derivative.

§41.11.1 Meromorphic Functions on the Sphere**Proposition 41.11.1**

Every meromorphic function $f : \mathbb{C}_\infty \rightarrow \mathbb{C}_\infty$ is rational:

$$f(z) = c \frac{(z - a_1) \cdots (z - a_m)}{(z - b_1) \cdots (z - b_n)}$$

for some $c \in \mathbb{C}^*$ and $a_i, b_j \in \mathbb{C}$ with $a_i \neq b_j$.

Proof. We may assume f is non-constant. Replacing f by $1/f$ if necessary (which does not affect the conclusion), assume $f(\infty) \neq \infty$. The poles of f form a discrete closed subset of the compact space $\mathbb{C}_\infty$, hence a finite set $\{b_1, \dots, b_n\}$, and none is ∞ . About each b_j write the Laurent expansion

$$f(z) = \sum_{l \geq -k_j} c_{j,l}(z - b_j)^l, \quad c_{j,-k_j} \neq 0,$$

and let $Q_j(z) = \sum_{l=-k_j}^{-1} c_{j,l}(z - b_j)^l$ be the principal part. Then

$$g = f - \sum_{j=1}^{n'} Q_j$$

is holomorphic on all of $\mathbb{C}$ – the principal parts have cancelled every pole – and is bounded near ∞ , since f is (having a finite value there) and each $Q_j \rightarrow 0$. By Liouville, g is constant. So f is a constant plus a sum of principal parts, which is a rational function. $\square$

Remark. If f is written as above in lowest terms, its degree as a holomorphic map is $\max(m, n)$: this counts the preimages of a generic point. The zeros a_i and poles b_j may be prescribed arbitrarily, subject only to being finite in number – there is no constraint on the sphere. On a torus we shall find that there is one.

§41.11.2 Periodic Meromorphic Functions

Definition 41.11.2 (Period)

Let $f : \mathbb{C} \rightarrow \mathbb{C}_\infty$ be meromorphic. A **period** of f is $\omega \in \mathbb{C}$ with $f(z + \omega) = f(z)$ for all z .

The set Ω of periods is a subgroup of $(\mathbb{C}, +)$, and it is closed: if $\omega_n \rightarrow \omega$ with $\omega_n \in \Omega$ then $f(z + \omega) = f(z)$ for all z not a pole, by continuity, and hence everywhere.

Lemma 41.11.3

Let f be a non-constant meromorphic function on $\mathbb{C}$ with period group Ω . Then exactly one of the following holds:

- (i) $\Omega = \{0\}$;
- (ii) $\Omega = \langle \omega \rangle \cong \mathbb{Z}$ for some $\omega \neq 0$;
- (iii) $\Omega = \langle \omega_1, \omega_2 \rangle \cong \mathbb{Z}^2$ is a lattice, with $\omega_1/\omega_2 \notin \mathbb{R}$.

(If f is constant then $\Omega = \mathbb{C}$.)

Proof sketch. Ω is a closed subgroup of $\mathbb{C} \cong \mathbb{R}^2$, and the classification of such subgroups gives $\{0\}$, a discrete rank-1 or rank-2 subgroup, a line, a line plus a discrete complement, or all of $\mathbb{C}$. If Ω contained a line $\mathbb{R}\omega$ then the zeros of $f - f(z_0)$ would be non-discrete for suitable z_0 , contradicting the identity theorem. The remaining possibilities are (i)–(iii). This is on the example sheets. $\square$

Definition 41.11.4

A non-constant meromorphic f on $\mathbb{C}$ is **simply periodic** in case (ii), and **doubly periodic** or **elliptic** in case (iii).

The reason to care is the correspondence with functions on quotients.

Proposition 41.11.5

Let f be meromorphic on $\mathbb{C}$ and suppose $\Lambda \subseteq \Omega$ where $\Lambda \leq \mathbb{C}$ is a lattice (respectively, $\langle \omega \rangle \subseteq \Omega$). Then there is a unique meromorphic function $\bar{f}$ on $\mathbb{C}/\Lambda$ (respectively on $\mathbb{C}^*$) with

$$f = \bar{f} \circ \pi, \quad \pi : \mathbb{C} \rightarrow \mathbb{C}/\Lambda \quad (\text{resp. } z \mapsto e^{2\pi iz/\omega}).$$

Proof. Uniqueness is clear as π is surjective. For existence set $\bar{f}(\pi(z)) = f(z)$, which is well defined by periodicity. It is holomorphic as a map to $\mathbb{C}_\infty$ because π is a covering map with local holomorphic inverses: near any point, $\bar{f} = f \circ (\pi|_U)^{-1}$. $\square$

Thus simply periodic functions are the same thing as meromorphic functions on $\mathbb{C}^* \cong \mathbb{C}/\langle \omega \rangle$, and elliptic functions with $\Lambda \subseteq \Omega$ are the same thing as meromorphic functions on the complex torus $\mathbb{C}/\Lambda$. Everything we know about compact surfaces now applies.

Corollary 41.11.6

A holomorphic doubly periodic function on $\mathbb{C}$ is constant.

Proof. It descends to a holomorphic function on the compact surface $\mathbb{C}/\Lambda$, which is constant by Corollary 41.5.5. $\square$

Corollary 41.11.7

A non-constant elliptic function, viewed as $\bar{f} : \mathbb{C}/\Lambda \rightarrow \mathbb{C}_\infty$, has $\deg \bar{f} \geq 2$.

Proof. If $\deg \bar{f} = 1$ then $\bar{f}$ is a conformal equivalence $\mathbb{C}/\Lambda \rightarrow \mathbb{C}_\infty$ by Corollary 41.9.12, contradicting $\chi(\mathbb{C}/\Lambda) = 0 \neq 2 = \chi(\mathbb{C}_\infty)$. (Equivalently: Riemann–Hurwitz would give $0 = 1 \cdot (-2) + 0$.) $\square$

It is worth also seeing the classical proof, which is where the theory came from.

Second proof of Corollary 41.11.7. Choose z_0 so that no zero or pole of f lies on the boundary of the period parallelogram $P = z_0 + \{s\omega_1 + t\omega_2 : s, t \in [0, 1]\}$; this is possible as there are finitely many such points modulo Λ . The residue theorem gives

$$\sum_{z \text{ pole in } P^\circ} \text{res}_z(f) = \frac{1}{2\pi i} \oint_{\partial P} f(z) dz = 0,$$

because the contributions of opposite sides of P cancel: f takes the same values on them and they are traversed in opposite directions. If f had a single simple pole in P , its residue would be non-zero, contradiction. So f has either no poles (hence is constant) or at least two poles counted with multiplicity. $\square$

§41.11.3 The Weierstrass $\wp$ -Function

We need a non-constant elliptic function to exist at all. By the above the simplest possible has a single double pole per period parallelogram, and this pins down the definition.

Definition 41.11.8 (Weierstrass $\wp$ -function)

Let $\Lambda \subseteq \mathbb{C}$ be a lattice. The **Weierstrass $\wp$ -function** is

$$\wp(z) = \wp_\Lambda(z) = \frac{1}{z^2} + \sum_{\omega \in \Lambda \setminus \{0\}} \left(\frac{1}{(z - \omega)^2} - \frac{1}{\omega^2} \right).$$

The subtracted terms $1/\omega^2$ are there purely to make the series converge; without them it diverges. To prove convergence we need a lemma on lattice sums.

Lemma 41.11.9

Let $\Lambda = \langle \omega_1, \omega_2 \rangle$ be a lattice and $t \in \mathbb{R}$. Then

$$\sum_{\omega \in \Lambda \setminus \{0\}} \frac{1}{|\omega|^t}$$

converges if and only if $t > 2$.

Proof. Consider $Q = \{(t_1, t_2) \in \mathbb{R}^2 : |t_1| + |t_2| = 1\}$, a compact set, and the continuous function $(t_1, t_2) \mapsto |t_1\omega_1 + t_2\omega_2|$ on it. It attains a maximum M and a minimum m , and $m > 0$ since ω_1, ω_2 are linearly independent over $\mathbb{R}$ so the expression vanishes only at the origin, which is not in Q . Given $(k, l) \in \mathbb{Z}^2 \setminus \{0\}$, apply this with $t_1 = k/(|k| + |l|)$, $t_2 = l/(|k| + |l|)$ to get

$$m(|k| + |l|) \leq |k\omega_1 + l\omega_2| \leq M(|k| + |l|).$$

So the sum in question is bounded above and below by positive multiples of

$$\sum_{(k,l) \neq (0,0)} \frac{1}{(|k| + |l|)^t}.$$

For each $n \geq 1$ there are exactly $4n$ pairs (k, l) with $|k| + |l| = n$, so this equals

$$\sum_{n \geq 1} \frac{4n}{n^t} = 4 \sum_{n \geq 1} \frac{1}{n^{t-1}},$$

which converges if and only if $t - 1 > 1$. □

Notice that the same estimate shows every bounded region contains only finitely many lattice points, which is what we assumed in Proposition 41.4.26.

Theorem 41.11.10

$\wp_\Lambda$ is a well-defined elliptic function whose period group is exactly Λ . It is even, its poles are precisely the points of Λ , each a double pole, and $\deg \wp_\Lambda = 2$ as a map $\mathbb{C}/\Lambda \rightarrow \mathbb{C}_\infty$.

Proof. Convergence. Fix $R > 0$ and work on $|z| \leq R$. For $\omega \neq 0$,

$$\frac{1}{(z-\omega)^2} - \frac{1}{\omega^2} = \frac{\omega^2 - (z-\omega)^2}{\omega^2(z-\omega)^2} = \frac{z(2\omega - z)}{\omega^2(z-\omega)^2} = \frac{z}{\omega^2} \left(\frac{2}{z-\omega} + \frac{-z}{(z-\omega)^2} \right) \cdot (-1),$$

so

$$\left| \frac{1}{(z-\omega)^2} - \frac{1}{\omega^2} \right| \leq \frac{|z|}{|\omega|^2} \left(\frac{2}{|z-\omega|} + \frac{|z|}{|z-\omega|^2} \right).$$

For all but finitely many ω we have $|\omega| \geq 2R$, whence $|z-\omega| \geq |\omega| - R \geq |\omega|/2 \geq R$, and the bound becomes

$$\frac{R}{|\omega|^2} \left(\frac{4}{|\omega|} + \frac{R}{(|\omega|/2) \cdot R} \right) = \frac{R}{|\omega|^2} \cdot \frac{6}{|\omega|} = \frac{6R}{|\omega|^3}.$$

By Lemma 41.11.9 with $t = 3$, the series converges absolutely and uniformly on $|z| \leq R$ after discarding finitely many terms. So $\wp$ is a well-defined meromorphic function on $\mathbb{C}$, holomorphic away from Λ , with a double pole at each lattice point (the discarded terms contribute those).

Evenness. Replacing z by $-z$ and ω by $-\omega$ permutes the terms of the (absolutely convergent) sum, so $\wp(-z) = \wp(z)$.

Periodicity. Differentiating term by term (legitimate by local uniform convergence),

$$\wp'(z) = -2 \sum_{\omega \in \Lambda} \frac{1}{(z-\omega)^3},$$

which is manifestly Λ -periodic, since translating z by $\omega_0 \in \Lambda$ just permutes the summands. Fix $\omega_0 \in \Lambda$ and put $F(z) = \wp(z + \omega_0) - \wp(z)$. Then $F' = 0$, so F is constant, say $F \equiv c$. Now take $z = -\omega_0/2$, which is not a pole if $\omega_0/2 \notin \Lambda$ (and if it is, replace ω_0 by a generator and argue for generators, which suffices):

$$c = \wp(\omega_0/2) - \wp(-\omega_0/2) = 0$$

by evenness. So ω_0 is a period, and $\Lambda \subseteq \Omega$.

Conversely the poles of $\wp$ are exactly Λ ; a period must permute the poles, so $\Omega \subseteq \Lambda$ (as 0 is a pole, any $\omega \in \Omega$ satisfies $-\omega \in \Lambda$). Hence $\Omega = \Lambda$.

Degree. On $\mathbb{C}/\Lambda$, $\wp$ has a single pole, at 0, of order 2. So $\deg \wp = n(\infty) = 2$. $\square$

Remark. The properties

- (i) $\wp$ is meromorphic with period lattice Λ ,
- (ii) the poles of $\wp$ are exactly Λ , and
- (iii) $\wp(z) - z^{-2} \rightarrow 0$ as $z \rightarrow 0$

characterise $\wp$ uniquely: if $\tilde{\wp}$ also has them then $\wp - \tilde{\wp}$ is holomorphic and elliptic, hence constant, and the constant is 0 by (iii).

§41.11.4 Ramification of $\wp$

Since $\deg \wp = 2$, Riemann–Hurwitz gives

$$0 = 2 \cdot (-2) + \sum_p (\text{mult}_\wp(p) - 1) \implies \sum_p (\text{mult}_\wp(p) - 1) = 4,$$

so $\wp$ has exactly four ramification points, each of multiplicity 2 (multiplicity cannot exceed the degree). Let us find them.

One is $p = 0$: the pole is double, so $\text{mult}_\wp(0) = 2$. The others are the zeros of $\wp'$, since ramification points are the zeros of the derivative in a chart. Now $\wp'$ is odd (differentiate $\wp(-z) = \wp(z)$), elliptic with period lattice Λ , and has a triple pole at each lattice point, so $\deg \wp' = 3$ on $\mathbb{C}/\Lambda$. For any $\omega \in \Lambda$,

$$\wp'(\omega/2) = \wp'(\omega/2 - \omega) = \wp'(-\omega/2) = -\wp'(\omega/2),$$

using periodicity and oddness; hence $\wp'(\omega/2) = 0$ whenever $\omega/2 \notin \Lambda$. Taking $\omega = \omega_1, \omega_2, \omega_1 + \omega_2$ gives three distinct zeros in $\mathbb{C}/\Lambda$, namely the three non-zero **half-periods**. Since $\deg \wp' = 3$ there are no others, and all three are simple.

Proposition 41.11.11

The four ramification points of $\wp : \mathbb{C}/\Lambda \rightarrow \mathbb{C}_\infty$ are $0, \omega_1/2, \omega_2/2, (\omega_1 + \omega_2)/2$, each of multiplicity 2, and their images

$$\infty, \quad e_1 = \wp(\omega_1/2), \quad e_2 = \wp(\omega_2/2), \quad e_3 = \wp\left(\frac{\omega_1 + \omega_2}{2}\right)$$

are four distinct points of $\mathbb{C}_\infty$.

Proof. We have found the four ramification points and know each has multiplicity 2. They must have distinct images: if two of them mapped to the same q , then $n(q)$ would be at least $4 > 2 = \deg \wp$. $\square$

So $\wp$ realises $\mathbb{C}/\Lambda$ as a two-sheeted cover of the sphere branched over four points – exactly the description of the surface of $w^2 = z^3 - z$ found in Example 41.10.10. This is not a coincidence.

§41.11.5 The Differential Equation

Proposition 41.11.12

There are constants $g_2, g_3 \in \mathbb{C}$, depending only on Λ , such that

$$(\wp')^2 = 4\wp^3 - g_2\wp - g_3.$$

Proof. Near $z = 0$ we expand. Since $\wp$ is even and $\wp(z) - z^{-2}$ vanishes at 0, its Laurent series has the form

$$\wp(z) = \frac{1}{z^2} + az^2 + bz^4 + O(z^6)$$

(no odd powers, and no constant term). Cubing,

$$\wp(z)^3 = \frac{1}{z^6} + \frac{3a}{z^2} + 3b + O(z^2),$$

while differentiating and squaring,

$$\wp'(z) = \frac{-2}{z^3} + 2az + 4bz^3 + O(z^5), \quad \wp'(z)^2 = \frac{4}{z^6} - \frac{8a}{z^2} - 16b + O(z^2).$$

Hence

$$\wp'(z)^2 - 4\wp(z)^3 = -\frac{20a}{z^2} - 28b + O(z^2).$$

Set $g_2 = 20a$. Then

$$H := (\wp')^2 - 4\wp^3 + g_2\wp$$

is elliptic, and near 0 it equals $-28b + O(z^2) + g_2 \cdot O(z^2)$, so it is holomorphic at 0. Its only possible poles were at Λ , so H is a holomorphic elliptic function, hence constant; call the constant $-g_3$. Rearranging gives the result. $\square$

Remark. The constants are computable: expanding $\wp$ gives $g_2 = 60 \sum_{\omega \neq 0} \omega^{-4}$ and $g_3 = 140 \sum_{\omega \neq 0} \omega^{-6}$, which converge by Lemma 41.11.9. We shall not need this.

Corollary 41.11.13

e_1, e_2, e_3 are the three roots of $4X^3 - g_2X - g_3$; they are distinct, and $e_1 + e_2 + e_3 = 0$. Moreover

$$(\wp')^2 = 4(\wp - e_1)(\wp - e_2)(\wp - e_3).$$

Proof. At $z = \omega_i/2$ we have $\wp'(z) = 0$ and $\wp(z) = e_i$, so $0 = 4e_i^3 - g_2e_i - g_3$. The e_i are distinct by Proposition 41.11.11, so they are all three roots; the sum of the roots is $-(\text{coefficient of } X^2)/4 = 0$. The factorisation follows. $\square$

§41.11.6 The Torus as a Cubic Curve

Theorem 41.11.14

Let $\Lambda \subseteq \mathbb{C}$ be a lattice with invariants g_2, g_3 as above, and let

$$X' = \{(x, y) \in \mathbb{C}^2 : y^2 = 4x^3 - g_2x - g_3\},$$

with $X = X' \cup \{\infty\}$ its one-point compactification (a compact Riemann surface, as in Section 41.8.3). Then

$$\mathbb{C}/\Lambda \cong X$$

as Riemann surfaces, via $z + \Lambda \mapsto (\wp(z), \wp'(z))$ and $0 \mapsto \infty$.

Proof. Since $4X^3 - g_2X - g_3 = 4(X - e_1)(X - e_2)(X - e_3)$ has distinct roots, X' is smooth and is a Riemann surface with coordinate projections as charts (Proposition 41.9.17), and X is its compactification.

Define $F : \mathbb{C} \setminus \Lambda \rightarrow X'$ by $F(z) = (\wp(z), \wp'(z))$. Its image lies in X' by Proposition 41.11.12. It is holomorphic: composed with the chart π_x it is $\wp$, and composed with π_y it is $\wp'$, both holomorphic. Extending by $F(\omega) = \infty$ for $\omega \in \Lambda$ gives a holomorphic map $\mathbb{C} \rightarrow X$ (the point ∞ of X is exactly where both coordinates blow up, and the local computation there is as in Section 41.8.3). Since F is Λ -periodic it descends, by Proposition 41.11.5, to a holomorphic

$$\Phi : \mathbb{C}/\Lambda \rightarrow X.$$

Φ is non-constant, and $\mathbb{C}/\Lambda$ is compact, so Φ is surjective by Corollary 41.5.4. It remains to prove injectivity, for then $\deg \Phi = 1$ and Corollary 41.9.12 finishes the proof.

Work in the centred period parallelogram P with vertices $\pm(\omega_1 \pm \omega_2)/2$, whose interior P° maps injectively to $\mathbb{C}/\Lambda$ and contains exactly one point of each class except for those on ∂P . Suppose $\Phi(z) = \Phi(z')$ for $z, z' \in P^\circ$. Then $\wp(z) = \wp(z')$; as $\wp$ is even of degree 2, the fibre of $\wp$ over a non-branch value is $\{\pm z\}$, so $z' = \pm z$ (and if z is one of the four ramification points then $z' = z$ directly). Also $\wp'(z) = \wp'(z')$; if $z' = -z$ then, $\wp'$ being odd, $\wp'(z) = -\wp'(z)$, so $\wp'(z) = 0$ and z is a half-period. But the non-zero half-periods lie on ∂P for this centred parallelogram, and $z = 0$ gives $z' = -z = z$. Either way $z = z'$. Hence Φ is injective on P° and so on $\mathbb{C}/\Lambda$. $\square$

So the two families of genus-1 surfaces we have met – complex tori and compactified plane cubics – coincide. The map Φ is what makes the addition law on a cubic curve comprehensible: it is transported from the group $\mathbb{C}/\Lambda$.

§41.11.7 The Field of Elliptic Functions

Theorem 41.11.15

Let f be an elliptic function with period lattice containing Λ , and write $\wp = \wp_\Lambda$. Then there are rational functions Q_1, Q_2 with

$$f(z) = Q_1(\wp(z)) + Q_2(\wp(z)) \wp'(z).$$

If f is even then $Q_2 = 0$.

Proof. Case 1: f even. We first reduce to a convenient normalisation. The function f and $\wp$ each have finitely many branch points on the compact surface $\mathbb{C}/\Lambda$, so we may pick distinct $c, d \in \mathbb{C}$ which are not among the values of f at its ramification points. Replacing f by

$$\frac{f - c}{f - d},$$

which is f composed with a Möbius map, hence still even and elliptic, and from which f can be recovered by the inverse Möbius map, we may assume all the zeros and poles of f are simple and occur away from the ramification points of $\wp$.

Since f is even, its zeros come in pairs $\pm a_i$ and its poles in pairs $\pm b_j$ (modulo Λ), with $a_i \not\equiv \pm a_j$ for $i \neq j$ and similarly for the b_j ; say the zeros are $\{\pm a_1, \dots, \pm a_m\}$ and the poles $\{\pm b_1, \dots, \pm b_n\}$. Consider

$$g(z) = \frac{(\wp(z) - \wp(a_1)) \cdots (\wp(z) - \wp(a_m))}{(\wp(z) - \wp(b_1)) \cdots (\wp(z) - \wp(b_n))}.$$

Each factor $\wp(z) - \wp(a_i)$ is elliptic of degree 2 with zeros exactly $\pm a_i$ (simple, as a_i is not a ramification point of $\wp$) and a double pole at 0. So g has exactly the same zeros and poles as f away from 0, and at 0 the pole orders are $2n - 2m$ in g and, by the valency theorem applied to f , also match. Hence f/g is an elliptic function with no zeros and no poles, so it is holomorphic, hence constant. Therefore $f = \lambda g$ is a rational function of $\wp$.

Case 2: f odd. Then $f/\wp'$ is even (as $\wp'$ is odd) and elliptic, so $f/\wp' = Q_2(\wp)$ by Case 1, giving $f = Q_2(\wp)\wp'$.

General case. Write

$$f(z) = \frac{f(z) + f(-z)}{2} + \frac{f(z) - f(-z)}{2},$$

a sum of an even and an odd elliptic function, and apply the two cases. $\square$

In the language of fields: the field $\mathcal{M}(\mathbb{C}/\Lambda)$ of meromorphic functions on the torus is $\mathbb{C}(\wp)[\wp']$, a degree-2 extension of the rational function field $\mathbb{C}(\wp)$, with $\wp'$ satisfying the quadratic $(\wp')^2 = 4\wp^3 - g_2\wp - g_3$. Compare Proposition 41.11.1, which says $\mathcal{M}(\mathbb{C}_\infty) = \mathbb{C}(z)$. In both cases the meromorphic functions on a compact Riemann surface form a field of transcendence degree 1 over $\mathbb{C}$ – this is true in general, and is the beginning of the dictionary between compact Riemann surfaces and algebraic curves.

§41.12 Differentials on Compact Surfaces

Corollary 41.5.5 told us that a compact Riemann surface carries no non-constant holomorphic function, and we responded by enlarging the target to $\mathbb{C}_\infty$. There is a second, and in the long run more important, response: keep the target $\mathbb{C}$ but change the *kind* of object we are looking at. The observation is that although $f(z)$ is not a well-defined thing to write down on a surface – it depends on the chart – the expression $f(z) dz$ very nearly is, because the chain rule supplies exactly the factor needed to make the two chart-dependencies cancel. Objects of the form $f(z) dz$ are called differentials, and unlike functions they exist in abundance on compact surfaces. Better still, they know the genus.

§41.12.1 Meromorphic Differentials

Definition 41.12.1 (Meromorphic Differential)

Let R be a Riemann surface. A **meromorphic differential** (or **meromorphic 1-form**) ω on R is an assignment to each chart (ϕ, U) of the conformal structure of a meromorphic function f_ϕ on $\phi(U)$, subject to the compatibility condition

$$f_\psi(w) = f_\phi(\tau(w)) \cdot \tau'(w), \quad \tau = \phi \circ \psi^{-1},$$

for all charts $(\phi, U), (\psi, V)$ and all $w \in \psi(U \cap V)$. We write $\omega = f_\phi dz$ for the local expression of ω in the chart ϕ , and call ω **holomorphic** if every f_ϕ is holomorphic.

The compatibility rule is nothing but the chain rule made into a definition: if $z = \tau(w)$ then $dz = \tau'(w) dw$, so

$$f_\phi(z) dz = f_\phi(\tau(w)) \tau'(w) dw = f_\psi(w) dw,$$

and the two local expressions really do describe the same object. As with charts and atlases, it suffices to prescribe the f_ϕ on the charts of some atlas: the compatibility condition then propagates the definition to the whole conformal structure.

Example 41.12.2 (The Sphere)

On $\mathbb{C}$, take $f_{\text{id}} = 1$; the resulting differential is written dz . Now regard it on $\mathbb{C}_\infty$. In the chart $w = 1/z$ at infinity we have $\tau(w) = 1/w$ and $\tau'(w) = -1/w^2$, so

$$dz = -\frac{1}{w^2} dw.$$

So dz extends to a meromorphic differential on the whole sphere, holomorphic except for a double pole at ∞ . Notice that it has no zeros at all – something no meromorphic function on $\mathbb{C}_\infty$ can manage while having only one pole.

Example 41.12.3 (The Torus)

On $T = \mathbb{C}/\Lambda$ the charts of Proposition 41.4.26 are local inverses of π , and the transition functions are the translations $w \mapsto w + \lambda$, whose derivatives are all 1. So the constant assignment $f_\phi = 1$ is compatible, and defines a differential on T , again written dz . It is holomorphic and has no zeros whatsoever.

Example 41.12.4 (The Differential of a Function)

Let f be meromorphic on R . Define df by taking, in the chart (ϕ, U) , the meromorphic function $(f \circ \phi^{-1})'$. Compatibility is the chain rule:

$$(f \circ \psi^{-1})'(w) = (f \circ \phi^{-1} \circ \tau)'(w) = (f \circ \phi^{-1})'(\tau(w)) \cdot \tau'(w).$$

So every meromorphic function has a differential, and $df = 0$ if and only if f is constant.

Lemma 41.12.5

If ω is a meromorphic differential and h a meromorphic function then $h\omega$ (defined chartwise by $hf_\phi \circ \phi^{-1}$) is a meromorphic differential. Conversely, if $\omega \neq 0$ and ω' is any meromorphic differential, then $\omega' = h\omega$ for a unique meromorphic function h on R .

Proof. The first statement is immediate, since multiplying both sides of the compatibility rule by h preserves it. For the second, define h in the chart ϕ to be f'_ϕ/f_ϕ , where f_ϕ, f'_ϕ are the local expressions of ω, ω' . This is meromorphic (the denomina-

tor is not identically zero, by the identity theorem applied on the connected surface R), and the transition factors τ' cancel in the quotient, so the local definitions agree on overlaps and glue to a meromorphic function on R . Uniqueness is clear. $\square$

So the meromorphic differentials form a one-dimensional vector space over the field of meromorphic functions – there are exactly as many differentials as there are functions, once you have found one. What makes them worth introducing is that the *zeros and poles* of a differential are counted differently from those of a function.

Definition 41.12.6 (Order)

Let ω be a meromorphic differential, not identically zero, and $p \in R$. The **order** of ω at p is

$$\text{ord}_p(\omega) = \text{ord}_{\phi(p)}(f_\phi)$$

for any chart (ϕ, U) about p , where ord denotes the order of vanishing (so a pole of order m has $\text{ord} = -m$).

This is well defined: the transition factor τ' is holomorphic and nowhere zero, so multiplying by it changes no order of vanishing. We call p a zero of ω if $\text{ord}_p(\omega) > 0$ and a pole if $\text{ord}_p(\omega) < 0$; by the identity theorem these form a discrete set, hence a finite one when R is compact.

Definition 41.12.7 (Divisor and Degree)

Let R be compact. The **divisor** of a non-zero meromorphic differential ω , or of a non-constant meromorphic function f , is the formal sum

$$\text{div}(\omega) = \sum_{p \in R} \text{ord}_p(\omega) \cdot p, \quad \text{div}(f) = \sum_{p \in R} \text{ord}_p(f) \cdot p,$$

and its **degree** is the integer $\deg \text{div}(\omega) = \sum_p \text{ord}_p(\omega)$.

Lemma 41.12.8

Let f be a non-constant meromorphic function on a compact Riemann surface R . Then $\deg \text{div}(f) = 0$.

Proof. View f as a map $R \rightarrow \mathbb{C}_\infty$. By the valency theorem the sum of the orders of the zeros of f is

$$\sum_{p \in f^{-1}(0)} \text{mult}_f(p) = \deg f,$$

and likewise the sum of the orders of the poles is $\sum_{p \in f^{-1}(\infty)} \text{mult}_f(p) = \deg f$. These cancel. $\square$

In other words, a meromorphic function on a compact surface has exactly as many zeros as poles. The corresponding count for a differential is not zero, and what it is instead is the whole point.

Theorem 41.12.9 (Degree of a Canonical Divisor)

Let R be a compact Riemann surface of genus g carrying a non-constant meromorphic function. Then for every non-zero meromorphic differential ω on R ,

$$\deg \operatorname{div}(\omega) = 2g - 2.$$

Proof. The answer does not depend on ω . If ω' is another non-zero differential then $\omega' = h\omega$ for a meromorphic h by Lemma 41.12.5, and orders add: $\operatorname{ord}_p(\omega') = \operatorname{ord}_p(h) + \operatorname{ord}_p(\omega)$. Summing and applying Lemma 41.12.8 gives $\deg \operatorname{div}(\omega') = \deg \operatorname{div}(\omega)$. (If h is constant this is trivial.)

A convenient choice. Let $f : R \rightarrow \mathbb{C}_\infty$ be a non-constant meromorphic function, of degree n say, and take $\omega = df$, which is not identically zero. We compute $\operatorname{ord}_p(df)$ using the local normal form (Proposition 41.9.1), writing $m = \operatorname{mult}_f(p)$.

If $f(p) \neq \infty$, choose the chart $\psi(w) = w - f(p)$ downstairs and a chart ϕ upstairs putting f in normal form, so that $f \circ \phi^{-1}(z) = f(p) + z^m$. Then df has local expression mz^{m-1} , and

$$\operatorname{ord}_p(df) = m - 1.$$

If $f(p) = \infty$, use the chart $\psi(w) = 1/w$ downstairs, so that normal form reads $1/f \circ \phi^{-1}(z) = z^m$, i.e. $f \circ \phi^{-1}(z) = z^{-m}$. Then df has local expression $-mz^{-m-1}$, and

$$\operatorname{ord}_p(df) = -m - 1.$$

Comparing the two, a pole of f contributes $-m - 1 = (m - 1) - 2m$. Hence

$$\deg \operatorname{div}(df) = \sum_{p \in R} (\operatorname{mult}_f(p) - 1) - 2 \sum_{p \in f^{-1}(\infty)} \operatorname{mult}_f(p) = \sum_{p \in R} (\operatorname{mult}_f(p) - 1) - 2n,$$

the last step by the valency theorem. Finally Riemann–Hurwitz (Theorem 41.10.7) applied to $f : R \rightarrow \mathbb{C}_\infty$, whose target has genus 0, gives

$$2g - 2 = n(0 - 2) + \sum_{p \in R} (\operatorname{mult}_f(p) - 1),$$

so that $\sum_p (\operatorname{mult}_f(p) - 1) = 2g - 2 + 2n$. Substituting, $\deg \operatorname{div}(df) = 2g - 2$. $\square$

Remark. The hypothesis that R carries a non-constant meromorphic function looks like a blemish, and it is: it is a (hard) theorem that every compact Riemann surface does, so the hypothesis is vacuous. All the surfaces we have met come with one for free, and we shall not use the general result.

Divisors of the form $\operatorname{div}(\omega)$ are called **canonical divisors**, and the theorem says they all have the same degree, namely $2g - 2$. This is a genuinely new way to compute the genus: exhibit a single differential and count its zeros and poles.

Example 41.12.10

On $\mathbb{C}_\infty$, the differential dz of Example 41.12.2 has divisor $-2 \cdot \infty$, of degree $-2 = 2 \cdot 0 - 2$. On $\mathbb{C}/\Lambda$, the differential dz of Example 41.12.3 has empty divisor, of degree $0 = 2 \cdot 1 - 2$. Both agree with Theorem 41.12.9, as they had better.

Example 41.12.11 (The Cubic Curve Again)

Let $\hat{R}$ be the compactified curve $w^2 = z^3 - z$ of Section 41.8.3, and consider

$$\omega = \frac{dz}{w}.$$

We claim ω is holomorphic and nowhere vanishing, so that $\deg \operatorname{div}(\omega) = 0$ and hence $g(\hat{R}) = 1$ – recovering Example 41.10.10 without any Riemann–Hurwitz bookkeeping.

Differentiating the equation gives $2w \, dw = (3z^2 - 1)dz$, so that

$$\omega = \frac{dz}{w} = \frac{2 \, dw}{3z^2 - 1}$$

wherever both expressions make sense. Away from the points with $w = 0$ or $z = \infty$, the coordinate z is a chart and $w \neq 0$, so the first expression is holomorphic and non-vanishing. At each of the three points $(z_0, 0)$ with $z_0 \in \{0, \pm 1\}$ the coordinate w is a chart, and $3z_0^2 - 1 \neq 0$ there (indeed $3z^2 - 1$ and $z^3 - z$ have no common root), so the second expression is holomorphic and non-vanishing. Finally at ∞ we use the coordinates $u = 1/z$, $v = z/w$ of Section 41.8.3, in which the curve reads $u = v^2(1 - u^2)$; the implicit function theorem makes v a local coordinate with $u = v^2 + O(v^6)$, so $du = (2v + O(v^5))dv$ and

$$\omega = \frac{dz}{w} = \frac{-du/u^2}{1/(uv)} = -\frac{v \, du}{u} = -\frac{v(2v + O(v^5))}{v^2 + O(v^6)} dv = (-2 + O(v^4)) \, dv,$$

again holomorphic and non-vanishing. So $\operatorname{div}(\omega) = 0$ and $g(\hat{R}) = 1$.

§41.12.2 The Residue Theorem

Differentials, not functions, are the objects one integrates. If γ is a path lying inside a single chart (ϕ, U) , we may define

$$\int_{\gamma} \omega = \int_{\phi \circ \gamma} f_{\phi}(z) \, dz,$$

and the change of variables formula for contour integrals shows this does not depend on the chart: substituting $z = \tau(w)$ turns $f_{\phi}(z) \, dz$ into $f_{\phi}(\tau(w))\tau'(w) \, dw = f_{\psi}(w) \, dw$, which is exactly the compatibility rule. A general path is cut into finitely many such pieces. So $\int_{\gamma} \omega$ makes sense for any path, and this is what a differential is *for*.

Definition 41.12.12 (Residue)

Let ω be a meromorphic differential on R and $p \in R$. The **residue** of ω at p is

$$\operatorname{res}_p(\omega) = \frac{1}{2\pi i} \int_{\gamma} \omega,$$

where γ is a small positively oriented loop about p inside a chart, enclosing no other pole of ω .

Equivalently, $\operatorname{res}_p(\omega)$ is the coefficient of $(z - \phi(p))^{-1}$ in the Laurent expansion of f_{ϕ} ; the

point of the integral formulation is that it makes chart-independence obvious, whereas the coefficient of z^{-1} looks as though it ought to depend on the coordinate. (It is worth pausing on this. For a meromorphic *function* the coefficient of z^{-1} is *not* chart-independent, and ‘the residue of a function at a point of a Riemann surface’ is meaningless. Only differentials have residues.)

Theorem 41.12.13 (Residue Theorem on a Compact Surface)

Let ω be a meromorphic differential on a compact Riemann surface R . Then

$$\sum_{p \in R} \text{res}_p(\omega) = 0,$$

the sum being finite.

Proof. The poles $p_1, \dots, p_k$ of ω are finite in number. Choose a triangulation of R (Lemma 41.10.3) and subdivide until every closed triangle lies inside a single chart; perturbing slightly, we may also assume no p_i lies on an edge or vertex, so each pole is interior to exactly one triangle. Orient every triangle positively, which is possible because R is orientable and the charts are holomorphic.

For a triangle Δ contained in the chart (ϕ, U) , the classical residue theorem applied to f_ϕ on the region $\phi(\Delta)$ gives

$$\int_{\partial\Delta} \omega = 2\pi i \sum_{p_i \in \Delta^\circ} \text{res}_{p_i}(\omega).$$

Summing over all triangles, the right-hand side is $2\pi i \sum_p \text{res}_p(\omega)$, since each pole lies in exactly one triangle. On the left, each edge of the triangulation belongs to exactly two triangles and is traversed once in each direction, so the contributions cancel in pairs and the total is 0. $\square$

The picture is the whole proof: whatever ω does inside the triangles, the boundary integrals cancel along every shared edge, so their total vanishes – and their total is $2\pi i$ times the sum of all the residues.

Example 41.12.14

Take $R = \mathbb{C}_\infty$ and $\omega = f(z) dz$ for a rational f . The theorem says the sum of the residues of f over $\mathbb{C}$, together with the residue at ∞ (which in the chart $w = 1/z$ is the residue at 0 of $-f(1/w)/w^2$), is zero. This is the familiar ‘sum of residues including infinity vanishes’ of IB Complex Analysis, now seen as a statement about the sphere.

Example 41.12.15

Take $R = \mathbb{C}/\Lambda$ and $\omega = f dz$ for an elliptic function f , using the nowhere-vanishing dz of Example 41.12.3; then $\text{res}_p(\omega)$ is the ordinary residue of f . The theorem says the residues of an elliptic function in a period parallelogram sum to zero, which is exactly what the cancellation of opposite sides gave us in the second proof of Corollary 41.11.7. The triangulation argument above is the same cancellation, done invariantly.

§41.12.3 The Degree–Genus Formula

We met the degree–genus formula in Example 41.10.12 as an observation about Fermat curves. It holds for every smooth plane curve, and the proof is a pretty application of Riemann–Hurwitz.

Theorem 41.12.16 (Degree–Genus Formula)

Let $C \subseteq \mathbb{P}^2$ be a smooth projective plane curve of degree $d \geq 1$. Then C is a compact Riemann surface of genus

$$g(C) = \frac{(d-1)(d-2)}{2}.$$

Proof sketch. That C is a compact Riemann surface is Proposition 41.9.17 together with the gluing of charts at infinity, exactly as in Section 41.8.3.

Pick a point $q \in \mathbb{P}^2 \setminus C$ and project from it: each $p \in C$ lies on a unique line through q , and the set of such lines is a copy of $\mathbb{P}^1 \cong \mathbb{C}_\infty$. This gives a holomorphic map

$$\pi_q : C \longrightarrow \mathbb{C}_\infty.$$

A line meets C in d points counted with multiplicity (Bézout’s theorem), so $\deg \pi_q = d$. A point p is a ramification point of π_q precisely when the line qp meets C at p with multiplicity at least 2, that is, when the line is tangent to C at p .

For a generic choice of q – and this is the step we are not proving – every tangent line through q is tangent at exactly one point and to order exactly 2, so each ramification point has multiplicity 2; and the number of such points is $d(d-1)$. (This last count is again Bézout: the points of C whose tangent passes through q are the intersections of C with its *polar curve* with respect to q , which has degree $d-1$.) Riemann–Hurwitz now gives

$$2g(C) - 2 = d(0 - 2) + d(d-1) \cdot (2 - 1) = d^2 - 3d,$$

whence $g(C) = (d^2 - 3d + 2)/2 = (d-1)(d-2)/2$. □

The two computations we did by hand are the special cases we can check independently: the Fermat curve $x^d + y^d = 1$ of Example 41.10.12, where we projected along a coordinate axis rather than from a general point and found the same answer, and the cubic $w^2 = z^3 - z$, which after homogenising is a smooth plane cubic of genus $(3-1)(3-2)/2 = 1$.

Remark. It is worth being clear about what the formula does and does not say. Every smooth plane curve of degree d has genus $(d-1)(d-2)/2$, so smooth plane curves realise only the genera $0, 0, 1, 3, 6, 10, \dots$. Compact Riemann surfaces of the missing genera certainly exist – the hyperelliptic curves supply all of them – but they cannot be

embedded in $\mathbb{P}^2$ without singularities. Genus 2 is the first example. Plane curves are special, and it is exactly the interplay between the abstract theory and such concrete models that makes the subject work.

§41.13 Quotients and Uniformisation

We finish by classifying all Riemann surfaces, at least in principle. The classification is startlingly clean: there are only three simply connected Riemann surfaces, and every other surface is a quotient of one of them.

§41.13.1 Quotients by Group Actions

Definition 41.13.1

Let a group G act on a topological space X by homeomorphisms. The action is

- (i) **properly discontinuous** if for every compact $K \subseteq X$ the set $\{g \in G : g(K) \cap K \neq \emptyset\}$ is finite;
- (ii) **free** if $\text{Stab}_G(x) = \{1\}$ for every $x \in X$.

Example 41.13.2

A lattice Λ acts on $\mathbb{C}$ by translation. This action is free (a non-zero translation has no fixed point) and properly discontinuous (a compact K is bounded, and only finitely many $\lambda \in \Lambda$ have $|\lambda| \leq \text{diam } K$).

Lemma 41.13.3

Let G act freely and properly discontinuously by homeomorphisms on a Riemann surface R . Then $G \backslash R$ is Hausdorff and the quotient map $\pi : R \rightarrow G \backslash R$ is a regular covering map.

Proof. First, π is open, since $\pi^{-1}(\pi(U)) = \bigcup_g g(U)$.

Hausdorff. Let $p, q \in R$ with $\pi(p) \neq \pi(q)$. Choose open $U \ni p$, $V \ni q$ with compact closures, and set $K = \bar{U} \cup \bar{V}$, compact. Then

$$\{g \in G : g(\bar{U}) \cap \bar{V} \neq \emptyset\} \subseteq \{g : g(K) \cap K \neq \emptyset\}$$

is finite, say $\{g_1, \dots, g_k\}$. For each i we have $g_i p \neq q$ (else $\pi(p) = \pi(q)$), so choose disjoint open $U_i \ni p$ and $V_i \ni g_i q$. Shrinking to

$$U' = U \cap \bigcap_i U_i, \quad V' = V \cap \bigcap_i g_i^{-1}(V_i),$$

we get $g(U') \cap V' = \emptyset$ for every $g \in G$. Then $\pi(U')$ and $\pi(V')$ are disjoint open neighbourhoods.

Covering. Let $p \in R$ and choose open $U \ni p$ with $\bar{U}$ compact, so that $\{g : g(\bar{U}) \cap \bar{U} \neq \emptyset\} = \{1, g_1, \dots, g_k\}$ is finite. Freeness gives $g_i p \neq p$, so choose disjoint open $U_i \ni p$,

$V_i \ni g_i p$, and set

$$U' = U \cap \bigcap_i (U_i \cap g_i^{-1}(V_i)).$$

Then $g(U') \cap U' = \emptyset$ for all $g \neq 1$, so $\pi^{-1}(\pi(U')) = \coprod_g g(U')$ and each $g(U')$ maps homeomorphically onto $\pi(U')$ (as π is open, continuous and injective on U'). So $\pi(U')$ is evenly covered. $\square$

Proposition 41.13.4

Let R be a Riemann surface and G a group acting freely and properly discontinuously on R by *conformal equivalences*. Then $S = G \backslash R$ carries a unique conformal structure making $\pi : R \rightarrow S$ holomorphic, and π is then a regular holomorphic covering map.

Proof. S is connected as a continuous image of R , and Hausdorff with π a regular covering map by Lemma 41.13.3. Charts on S are obtained by pushing charts of R forward along local inverses of π : for U' as in the lemma and a chart (ϕ, U'') with $U'' \subseteq U'$, take $(\phi \circ (\pi|_{U'})^{-1}, \pi(U''))$. Two such charts differ by a transition function of R composed with the action of some $g \in G$, which is holomorphic by hypothesis. Uniqueness is as in Lemma 41.4.21. $\square$

This is the converse of Lemma 41.4.21, and together they say: quotients by free properly discontinuous actions of conformal automorphisms are exactly covering spaces, in the holomorphic category. The complex torus is the case $R = \mathbb{C}$, $G = \Lambda$.

Theorem 41.13.5

Let R be a compact Riemann surface with $g(R) \geq 2$ and let G act freely and properly discontinuously on R by conformal equivalences. Then G is finite, with

$$|G| \leq g(R) - 1.$$

Proof. By Proposition 41.13.4, $S = G \backslash R$ is a Riemann surface, compact as a continuous image of R , and $\pi : R \rightarrow S$ is an unramified holomorphic map of degree $|G|$ (the fibres are the G -orbits, which all have size $|G|$ by freeness; in particular G is finite since fibres are finite). Riemann–Hurwitz with no ramification gives

$$g(R) - 1 = |G| (g(S) - 1).$$

Since $g(R) \geq 2$ the left side is positive, so $g(S) \geq 2$ and $g(S) - 1 \geq 1$, whence $|G| \leq g(R) - 1$. $\square$

Remark. This fails for $g = 1$: the torus $\mathbb{C}/\Lambda$ acts on itself freely by translation, and any finite subgroup does too, with no bound on its order. The genus ≥ 2 hypothesis is essential, and it is the first sign that high-genus surfaces are rigid. (The sharp statement, Hurwitz’s automorphism theorem, bounds the full automorphism group by $84(g - 1)$; that is beyond us here.)

§41.13.2 The Uniformisation Theorem

Theorem 41.13.6 (Uniformisation Theorem)

Every simply connected Riemann surface is conformally equivalent to exactly one of

$$\mathbb{C}_\infty, \quad \mathbb{C}, \quad \mathbb{D} = D(0, 1).$$

The proof is well beyond this course. What we can do is check that the three are genuinely distinct, and then extract the consequences.

Proposition 41.13.7

No two of $\mathbb{C}_\infty, \mathbb{C}, \mathbb{D}$ are conformally equivalent.

Proof. $\mathbb{C}_\infty$ is compact and the other two are not. If $\mathbb{D} \cong \mathbb{C}$ then there would be a non-constant holomorphic map $\mathbb{C} \rightarrow \mathbb{D}$, hence a bounded non-constant entire function, contradicting Liouville. $\square$

Corollary 41.13.8

Every conformal structure on S^2 is conformally equivalent to $\mathbb{C}_\infty$; equivalently, a compact Riemann surface of genus 0 is the Riemann sphere.

Proof. S^2 is simply connected, so it is one of the three; it is compact, so it is $\mathbb{C}_\infty$. $\square$

For non-simply-connected surfaces we pass to the universal cover.

Theorem 41.13.9

Every Riemann surface R admits a regular covering map $\pi : \tilde{R} \rightarrow R$ with $\tilde{R}$ simply connected. Moreover $\tilde{R}$ has a unique conformal structure making π holomorphic, and the deck transformation group

$$G = \text{Deck}(\pi) = \{\varphi : \tilde{R} \rightarrow \tilde{R} \text{ conformal} : \pi \circ \varphi = \pi\} \cong \pi_1(R)$$

acts freely and properly discontinuously by conformal equivalences with $G \backslash \tilde{R} \cong R$.

Proof. Existence of the universal cover and the identification $\text{Deck}(\pi) \cong \pi_1(R)$ for a simply connected cover are from II Algebraic Topology (a Riemann surface is locally homeomorphic to a disc, hence locally path-connected and semi-locally simply connected, so the theory applies). The conformal structure on $\tilde{R}$ comes from Lemma 41.4.21, and each deck transformation is then holomorphic (locally it is $(\pi|_{\tilde{U}'})^{-1} \circ \pi$) with holomorphic inverse. Freeness and proper discontinuity are standard properties of deck groups of covering spaces. $\square$

Corollary 41.13.10

Every Riemann surface R is conformally equivalent to $G \backslash \tilde{R}$, where $\tilde{R} \in \{\mathbb{C}_\infty, \mathbb{C}, \mathbb{D}\}$ and $G \cong \pi_1(R)$ acts freely and properly discontinuously by conformal automorphisms of $\tilde{R}$.

We say R is **uniformised by** $\tilde{R}$. To make this useful we need to know the conformal automorphisms of each model.

Proposition 41.13.11 (i) $\text{Aut}(\mathbb{C}_\infty) = \{z \mapsto \frac{az+b}{cz+d} : ad-bc \neq 0\} \cong \text{PGL}_2(\mathbb{C})$, the Möbius group.

(ii) $\text{Aut}(\mathbb{C}) = \{z \mapsto az + b : a \in \mathbb{C}^*, b \in \mathbb{C}\}$.

(iii) $\text{Aut}(\mathbb{D}) = \{z \mapsto e^{i\theta} \frac{z-a}{1-\bar{a}z} : a \in \mathbb{D}, \theta \in \mathbb{R}\}$.

Proof sketch. (i) A conformal automorphism of $\mathbb{C}_\infty$ is a degree-1 meromorphic function, hence rational of degree 1 by Proposition 41.11.1, hence Möbius. (ii) An automorphism of $\mathbb{C}$ extends over ∞ : by Casorati–Weierstrass the singularity at ∞ cannot be essential (an injective function cannot have dense image on every punctured neighbourhood while also being injective near a distant point), so it is a pole or removable; removable would force boundedness and constancy, so it is a pole, and f is a polynomial, which is injective only if it is linear. (iii) This was proved in IB Complex Analysis using the Schwarz lemma. $\square$

Proposition 41.13.12

If R is uniformised by $\mathbb{C}_\infty$ then $R \cong \mathbb{C}_\infty$.

Proof. Say $R = G \backslash \mathbb{C}_\infty$ with G acting freely by Möbius maps. But every Möbius map has a fixed point in $\mathbb{C}_\infty$: the equation $az + b = z(cz + d)$ is a quadratic (or linear) with a root in $\mathbb{C}$, unless $c = 0$ and $a = d$, in which case $z \mapsto z + b/d$ fixes ∞ . So freeness forces $G = \{1\}$. $\square$

Proposition 41.13.13

If R is uniformised by $\mathbb{C}$, then exactly one of the following holds:

(i) $G = \{1\}$ and $R \cong \mathbb{C}$;

(ii) $G \cong \mathbb{Z}$ and $R \cong \mathbb{C}^*$;

(iii) $G \cong \mathbb{Z}^2$ and $R \cong \mathbb{C}/\Lambda$ for a lattice Λ .

Proof. By Proposition 41.13.11(ii), G consists of maps $z \mapsto az + b$. If $a \neq 1$ then $z = b/(1-a)$ is a fixed point, so freeness forces $a = 1$: every element of G is a translation. Identifying G with a subgroup of $(\mathbb{C}, +)$, proper discontinuity forces G to be discrete, and a discrete subgroup of $\mathbb{C}$ is trivial, infinite cyclic, or a lattice (Lemma 41.11.3). These give $\mathbb{C}$, $\mathbb{C}/\langle \omega \rangle \cong \mathbb{C}^*$ (via $z \mapsto e^{2\pi iz/\omega}$), and $\mathbb{C}/\Lambda$. $\square$

Lemma 41.13.14 (Lifting Lemma)

Let $f : R \rightarrow S$ be holomorphic with R simply connected, and let $\pi : \tilde{S} \rightarrow S$ be the universal cover of S . Then there is a holomorphic $F : R \rightarrow \tilde{S}$ with $f = \pi \circ F$.

Proof. The topological lifting criterion from II Algebraic Topology gives a continuous lift F , since $f_*\pi_1(R) = \{1\} \subseteq \pi_*\pi_1(\tilde{S})$. It is holomorphic because locally $F = (\pi|_{\tilde{U}})^{-1} \circ f$, a composite of holomorphic maps. $\square$

Proposition 41.13.15

A Riemann surface is uniformised by at most one of $\mathbb{C}_\infty, \mathbb{C}, \mathbb{D}$.

Proof. The universal cover is unique up to homeomorphism, so this is really the statement that the three models are not conformally equivalent, which we know. Explicitly: suppose R were uniformised both by $\mathbb{D}$ and by $\tilde{R} \in \{\mathbb{C}, \mathbb{C}_\infty\}$, with uniformising maps $\pi : \mathbb{D} \rightarrow R$ and $f : \tilde{R} \rightarrow R$. Since $\tilde{R}$ is simply connected, Lemma 41.13.14 gives holomorphic $F : \tilde{R} \rightarrow \mathbb{D}$ with $f = \pi \circ F$. Restricting to $\mathbb{C} \subseteq \tilde{R}$, F is a bounded entire function, hence constant by Liouville; so f is constant, contradicting surjectivity. $\square$

So every Riemann surface other than $\mathbb{C}_\infty, \mathbb{C}, \mathbb{C}^*$ and the tori is uniformised by the disc. In particular:

Corollary 41.13.16

Every compact Riemann surface of genus ≥ 2 is uniformised by $\mathbb{D}$.

Proof. It is not $\mathbb{C}_\infty$ (genus 0), and by Proposition 41.13.13 the only compact surface uniformised by $\mathbb{C}$ is a torus (genus 1). $\square$

§41.13.3 Fuchsian Groups and the Hyperbolic Plane

The disc case is the generic one, and it connects this course to IB Geometry. Recall the Möbius map

$$z \mapsto \frac{1+iz}{1-iz}$$

carries the upper half-plane $\mathbb{H}$ conformally onto $\mathbb{D}$; under it,

$$\text{Aut}(\mathbb{H}) = \left\{ z \mapsto \frac{az+b}{cz+d} : a, b, c, d \in \mathbb{R}, ad-bc=1 \right\} \cong \text{PSL}_2(\mathbb{R}).$$

These are precisely the orientation-preserving isometries of the hyperbolic metric

$$\frac{|dz|^2}{(\text{Im } z)^2}$$

on $\mathbb{H}$ (equivalently $4|dz|^2/(1-|z|^2)^2$ on $\mathbb{D}$), as was shown in IB Geometry. So a Riemann surface uniformised by $\mathbb{D}$ inherits a hyperbolic metric, and its conformal geometry is hyperbolic geometry.

Definition 41.13.17 (Fuchsian Group)

A subgroup $\Gamma \leq \text{PSL}_2(\mathbb{R})$ acting properly discontinuously on $\mathbb{H}$ is called a **Fuchsian group**.

By Corollary 41.13.10, the Riemann surfaces uniformised by the disc are exactly the quotients $\Gamma \backslash \mathbb{H}$ for torsion-free Fuchsian Γ . Such a quotient is understood through a **fundamental domain**: a region $F \subseteq \mathbb{D}$ whose Γ -translates tile the disc and cover the quotient exactly once. For a compact genus-2 surface one may take a regular hyperbolic octagon with all angles $2\pi/8$, whose sides are glued in the pattern $a_1 b_1 a_1^{-1} b_1^{-1} a_2 b_2 a_2^{-1} b_2^{-1}$ – the same octagon as in Section 41.10, but now with a genuine hyperbolic structure.

a fundamental domain in $\mathbb{D}$

§41.13.4 Consequences of Uniformisation

We close with two classical theorems which fall out of the machine.

Theorem 41.13.18 (Riemann Mapping Theorem)

Every simply connected domain $D \subsetneq \mathbb{C}$ is conformally equivalent to $\mathbb{D}$.

Proof. D is a simply connected Riemann surface, so by Theorem 41.13.6 it is $\mathbb{C}_\infty$, $\mathbb{C}$ or $\mathbb{D}$. It is not $\mathbb{C}_\infty$, being non-compact. Suppose $f : \mathbb{C} \rightarrow D$ were a conformal equivalence. Composing with the inclusion $D \hookrightarrow \mathbb{C}$ gives an injective entire function f ; by Casorati–Weierstrass its singularity at ∞ is not essential (an injective function cannot take values densely near ∞ while being open near a fixed finite point), so f extends to a holomorphic $\bar{f} : \mathbb{C}_\infty \rightarrow \mathbb{C}_\infty$. This is non-constant, so it is surjective by Corollary 41.5.4; injectivity of f then forces $\bar{f}(\infty) = \infty$ and $D = f(\mathbb{C}) = \mathbb{C}$, contradicting $D \subsetneq \mathbb{C}$. So $D \cong \mathbb{D}$. $\square$

It is worth noticing how the logic runs: uniformisation is the general theorem and the Riemann mapping theorem is a special case, whereas historically the implication is usually run the other way (the Riemann mapping theorem being an ingredient in proofs of uniformisation).

Theorem 41.13.19 (Little Picard Theorem)

Every holomorphic function $f : \mathbb{C} \rightarrow \mathbb{C} \setminus \{0, 1\}$ is constant.

Proof. The surface $\mathbb{C} \setminus \{0, 1\}$ is uniformised by $\mathbb{D}$: it is not $\mathbb{C}_\infty$ or $\mathbb{C}$ or $\mathbb{C}^*$ or a torus, so by Propositions 41.13.12 and 41.13.13 its universal cover is $\mathbb{D}$. (One can also exhibit the covering explicitly using the modular λ -function; this is on the example sheets.)

Let $\pi : \mathbb{D} \rightarrow \mathbb{C} \setminus \{0, 1\}$ be the uniformising map. As $\mathbb{C}$ is simply connected, Lemma

41.13.14 gives a holomorphic $F : \mathbb{C} \rightarrow \mathbb{D}$ with $f = \pi \circ F$. But F is a bounded entire function, hence constant by Liouville, so f is constant. $\square$

Of course $\{0, 1\}$ may be replaced by any two distinct points of $\mathbb{C}$, by composing with a suitable affine map. The theorem is a dramatic strengthening of Liouville: an entire function which omits merely *two* values is constant. That such a statement should follow from a covering-space argument – with no estimate in sight – is a fair summary of what Riemann surfaces are for.

42 Statistical Physics

Every physics course we have met so far has been microscopic. We wrote down the equation of motion for a particle, or the Schrödinger equation for an electron in a hydrogen atom, and then we worked hard to solve it. Statistical physics asks what happens when we try to do this for 10^{23} particles at once. The honest answer is that we cannot: no computer will ever integrate Avogadro's number of coupled differential equations, and even if one could, the output would be useless to us. What saves the subject – and makes it one of the most powerful in physics – is that we do not *want* to know what all 10^{23} particles are doing. We want to know a handful of macroscopic numbers: the pressure of the gas, its temperature, its heat capacity. The remarkable fact is that these few numbers can be extracted from the microscopic laws by an argument that is essentially probabilistic, and that the extraction is not merely approximate but, for systems this large, absurdly accurate.

The course has three faces. First we build the machinery: microstates, ensembles, entropy, temperature and the partition function, which is the single most useful object in the subject. Then we turn the machinery on real systems – classical gases, and then quantum ones, where we will find that the same formalism produces blackbody radiation, the heat capacity of solids, the physics of white dwarf stars and the strange collective behaviour of Bose–Einstein condensates. Along the way we will meet *classical thermodynamics*, which is the historical route into the subject: a set of laws about heat and work discovered before anyone was sure that atoms existed, and which we can now watch emerge from the statistics. Finally, we look at phase transitions, where a system changes its character discontinuously as we turn a knob, and where – most surprisingly of all – wildly different systems turn out to behave in exactly the same way.

This article constitutes my notes for the ‘Statistical Physics’ course, held in Lent 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered¹.

§42.1 Fundamentals of Statistical Mechanics

We begin by setting up the framework of the subject. The ideas here are not difficult, but they are subtle, and they are the foundation for everything that follows – so it is worth going slowly.

§42.1.1 Microstates and the Microcanonical Ensemble

Our object of study is a system of N particles, where N is a very large number. The canonical picture to have in mind is a box of gas, sealed off from the rest of the universe. We begin by describing the system in as much detail as possible.

¹The course assumes a working knowledge of quantum mechanics at the level of the Part IB course, and it will help enormously to have met the Legendre transform, for instance in the Variational Principles course; I will remind the reader of what is needed as we go.

Definition 42.1.1 (Microstate)

A **microstate** of a system is a complete specification of its state: in the quantum setting, an actual state $|n\rangle$ of the full N -particle system.

A microstate is a hopeless thing to try to write down. But the whole point of statistical physics is that we do not need to: enormously many microstates are macroscopically indistinguishable from one another, and we may as well treat them all on the same footing. So we adopt a probabilistic description. Let $\{|n\rangle\}$ be an orthonormal basis of energy eigenstates,

$$\hat{H} |n\rangle = E_n |n\rangle,$$

and let $p(n)$ be the probability that our system is in the microstate $|n\rangle$. It is important to be clear about what kind of probability this is. It is *not* a quantum amplitude squared; it is a classical probability, encoding our ignorance about which state the system is actually in. (If you have met density matrices, we are describing the mixed state $\rho = \sum_n p(n) |n\rangle \langle n|$.)

Definition 42.1.2 (Ensemble average)

Given probabilities $p(n)$, the **expectation value** of an operator $\mathcal{O}$ is

$$\langle \mathcal{O} \rangle = \sum_n p(n) \langle n | \mathcal{O} | n \rangle.$$

An equivalent and often more intuitive way to think about this: imagine $W \gg 1$ independent copies of our system, with $Wp(n)$ of them in the microstate $|n\rangle$. This collection is called an **ensemble**, and $\langle \mathcal{O} \rangle$ is just the average of $\mathcal{O}$ over the ensemble. Which picture one uses makes no difference to the mathematics.

Throughout, we will assume our systems are in **equilibrium**, meaning that the distribution $p(n)$ does not change with time. This does not mean nothing is happening – the molecules of a gas in equilibrium are hurtling about as fast as ever. It means only that the statistics are stationary. Systems out of equilibrium are enormously harder, and we will not touch them.

Now, what should $p(n)$ be? Suppose all we know about the system is its energy. The microstates consistent with what we know are called **accessible**, and the entire subject rests on the following assumption.

Axiom 42.1.3 (Fundamental Assumption of Statistical Mechanics)

An isolated system in equilibrium is equally likely to be found in any of its accessible microstates.

This is not something we can prove from the microscopic laws (proving it, in the guise of the *ergodic hypothesis*, is genuinely hard and still not fully understood). We take it as an axiom and judge it by its consequences, which are spectacularly successful.

Definition 42.1.4 (Microcanonical ensemble)

In the **microcanonical ensemble** we take our partial knowledge to be that the energy lies in a window $[E, E + \delta E]$, where δE is the resolution of our measuring

apparatus. We write $\Omega(E)$ for the number of microstates with $E \leq E_n \leq E + \delta E$.

The fundamental assumption then reads

$$p(n) = \begin{cases} 1/\Omega(E) & E \leq E_n \leq E + \delta E, \\ 0 & \text{otherwise.} \end{cases}$$

It looks worrying that the theory should depend on the arbitrary parameter δE , and we will see shortly that in fact it does not. Note also that it is essential here that we are working quantum mechanically: energy levels are discrete, so ‘counting states’ makes sense. Doing this classically requires more care, and we will come back to it in Section 42.2.1.

Example 42.1.5

Take $N = 10^{23}$ particles fixed in place, each of which can be in one of two states $|\uparrow\rangle, |\downarrow\rangle$ of the same energy ε . Then every configuration has total energy $N\varepsilon$, and

$$\Omega(N\varepsilon) = 2^{10^{23}}.$$

This is a completely preposterous number – vastly larger than the number of atoms in the observable universe – and it is entirely typical of the numbers in this subject.

Numbers like $2^{10^{23}}$ are unpleasant to work with, and worse, Ω is multiplicative rather than additive when we combine systems. Both problems are cured at a stroke by taking a logarithm.

Definition 42.1.6 (Boltzmann entropy)

The **entropy** of a system is

$$S(E) = k \log \Omega(E),$$

where $k = 1.381 \times 10^{-23} \text{ J K}^{-1}$ is **Boltzmann’s constant**.

The constant k is a historical accident: thermodynamics was developed before anyone knew about microstates, and temperature was given its own unit. Had physics been done in the other order we would simply have set $k = 1$ and measured temperature in joules.

We can now dispose of the worry about δE . If we double the width of our energy window we roughly double Ω , and so we change S by $k \log 2 \approx 10^{-23} \text{ J K}^{-1}$. Meanwhile S itself is of order $Nk \sim 1 \text{ J K}^{-1}$. So the dependence on δE is utterly negligible, and we suppress it. This is the first instance of a pattern that recurs constantly: because N is so large, factors that would be significant anywhere else in physics are invisible here.

The second virtue of the logarithm is additivity. If we have two *non-interacting* systems with energies E_1 and E_2 , then a microstate of the pair is a microstate of each, so $\Omega(E_1, E_2) = \Omega_1(E_1)\Omega_2(E_2)$ and hence

$$S(E_1, E_2) = S_1(E_1) + S_2(E_2).$$

§42.1.2 Entropy and the Second Law

Additivity is not very interesting until we let the systems talk to each other. So suppose we now bring our two systems into contact and allow them to exchange energy, while keeping the total energy $E_{\text{tot}} = E_1 + E_2$ fixed. Now the individual energies can fluctuate, and the number of states available to the combined system is

$$\Omega(E_{\text{tot}}) = \sum_{E_i} \Omega_1(E_i) \Omega_2(E_{\text{tot}} - E_i) = \sum_{E_i} \exp \left(\frac{S_1(E_i) + S_2(E_{\text{tot}} - E_i)}{k} \right),$$

where the sum runs over the energy bins of width δE that we chose earlier.

Now look at the size of the exponents. Each S/k is of order $N \sim 10^{23}$. So if the exponent is even slightly larger for one term than for another, that term dominates the sum by a factor which is the exponential of something like 10^{20} . In other words: *the sum is completely dominated by its largest term*. Writing E_* for the value of E_i that maximises $S_1(E_i) + S_2(E_{\text{tot}} - E_i)$, we have

$$S(E_{\text{tot}}) = k \log \Omega(E_{\text{tot}}) \approx S_1(E_*) + S_2(E_{\text{tot}} - E_*).$$

Of course some neighbouring terms also contribute, but including them multiplies Ω by some modest factor and hence adds something of order k to S , which we cheerfully ignore.

The same estimate tells us something much stronger. The probability that the first system has energy E_1 (writing $E_2 = E_{\text{tot}} - E_1$) is

$$\frac{\Omega_1(E_1)\Omega_2(E_2)}{\Omega(E_{\text{tot}})} = \exp \left(\frac{S_1(E_1) + S_2(E_2) - S(E_{\text{tot}})}{k} \right).$$

Unless $S_1(E_1) + S_2(E_2)$ agrees with its maximum value to fantastic precision, this probability is effectively zero. So although E_1 is in principle free to fluctuate, in practice it is pinned to E_* to a precision far beyond anything we could measure.

Finally, suppose we prepare the two systems separately with $E_1 \neq E_*$ and only then bring them together. The system is not in equilibrium; it will evolve, E_1 will drift to E_* , and in doing so the entropy will increase from $S_1(E_1) + S_2(E_2)$ to its maximum value. This is the second law.

Law 42.1.7 (Second Law of Thermodynamics)

The entropy of an isolated system never decreases, and in equilibrium it attains its maximum value.

It is worth being precise about what we have and have not shown. We have not shown that entropy decrease is *impossible*. What we have shown is that it is overwhelmingly improbable – the odds against it are the exponential of 10^{23} . This is a much more satisfying state of affairs than a bald prohibition, because it explains why the second law has the peculiar status it does: it is a law of statistics rather than of mechanics, and it is the only law of physics that distinguishes the future from the past.

§42.1.3 Temperature

We have a function $S(E)$. The obvious thing to do with it is differentiate it, and the obvious thing to do with the answer is give it a name.

Definition 42.1.8 (Temperature)

The **temperature** of a system is defined by

$$\frac{1}{T} = \frac{dS}{dE}.$$

Why should this deserve to be called temperature? Because it does what temperature is supposed to do. Let us check the two most basic properties we expect.

Proposition 42.1.9

Two systems in thermal contact and in equilibrium have the same temperature.

Proof. We found the equilibrium energy E_* by maximising $S_1(E_1) + S_2(E_{\text{tot}} - E_1)$ over E_1 . Differentiating and setting the result to zero,

$$\left. \frac{dS_1}{dE} \right|_{E_1=E_*} = \left. \frac{dS_2}{dE} \right|_{E_2=E_{\text{tot}}-E_*},$$

that is, $1/T_1 = 1/T_2$, so $T_1 = T_2$. $\square$

Proposition 42.1.10

If two systems at temperatures $T_1 > T_2$ are brought into contact, energy flows from the first to the second.

Proof. The systems are not in equilibrium, so some energy is transferred. Say after a short time $E_1 \mapsto E_1 + \delta E$ and $E_2 \mapsto E_2 - \delta E$. The change in total entropy is

$$\delta S = \frac{dS_1}{dE} \delta E - \frac{dS_2}{dE} \delta E = \left(\frac{1}{T_1} - \frac{1}{T_2} \right) \delta E.$$

By hypothesis $1/T_1 - 1/T_2 < 0$, and by the second law $\delta S > 0$. Hence $\delta E < 0$: the first system loses energy. $\square$

So heat flows from hot to cold, and bodies in equilibrium have equal temperatures. Notice that these arguments used nothing about T except that $1/T$ is a decreasing function of T ; we could have defined dS/dE to be any monotone decreasing function of ‘temperature’ and got the same results. What singles out this particular choice is that it agrees with the temperature scale everyone already used – the one defined by the ideal gas law – as we will verify in Section 42.2.2.

§42.1.4 Heat Capacity, and a First Example

Differentiating S gave us temperature. If we now invert $T = T(E)$ to get $E = E(T)$ and differentiate again, we get another familiar quantity.

Definition 42.1.11 (Heat capacity)

The **heat capacity** of a system is

$$C = \frac{dE}{dT}.$$

The **specific heat capacity** is C divided by the mass of the system.

Unlike Ω or S , this is something we can go into a laboratory and measure: pump in a known amount of energy, and see how much the temperature rises. And measuring it gives us the entropy for free, because

$$\frac{dS}{dT} = \frac{dS}{dE} \frac{dE}{dT} = \frac{C}{T},$$

and hence, integrating,

$$\Delta S = \int_{T_1}^{T_2} \frac{C(T)}{T} dT.$$

So although entropy was defined by counting microstates – a thoroughly theoretical operation – its changes are experimentally accessible.

The heat capacity also settles a loose end. When we found E_* by setting a derivative to zero, we only checked that it was a stationary point. Differentiating once more,

$$\frac{d^2S}{dE^2} = \frac{d}{dE} \left(\frac{1}{T} \right) = -\frac{1}{T^2} \frac{dT}{dE} = -\frac{1}{T^2 C},$$

so $S_1 + S_2$ has a genuine maximum at E_* provided $C_1, C_2 > 0$. Positivity of heat capacity is thus exactly the condition for thermal equilibrium to be stable.

Enough generalities. Let us compute something.

Example 42.1.12 (The two-state system)

Take N non-interacting particles fixed at lattice sites, each of which has two states, with energies

$$E_{\downarrow} = 0, \quad E_{\uparrow} = \varepsilon.$$

Think of these as spins in a magnetic field. If $N_{\uparrow}$ of them are excited then the total energy is $E = \varepsilon N_{\uparrow}$, and (choosing $\delta E < \varepsilon$, which is legitimate here) the number of microstates is just the number of ways of choosing which particles are excited:

$$\Omega(E) = \binom{N}{N_{\uparrow}} = \frac{N!}{N_{\uparrow}! (N - N_{\uparrow})!}.$$

To make progress we need **Stirling's approximation**, which we will use constantly:

$$\log N! = N \log N - N + \frac{1}{2} \log(2\pi N) + O(1/N).$$

Since $N \sim 10^{23}$ we keep only the first two terms. Applying this three times and writing $x = E/(N\varepsilon) = N_{\uparrow}/N$ for the fraction of excited particles,

$$\begin{aligned} S(E) &= k(N \log N - N_{\uparrow} \log N_{\uparrow} - (N - N_{\uparrow}) \log(N - N_{\uparrow})) \\ &= -kN \left(x \log x + (1 - x) \log(1 - x) \right). \end{aligned}$$

This is much more illuminating when plotted.

The entropy vanishes at $E = 0$ (all spins down: one microstate) and at $E = N\epsilon$ (all spins up: one microstate), and is maximal in between at $E = N\epsilon/2$, where it takes the value $Nk \log 2$ – exactly what we expect, since then each spin is free to do as it pleases.

Now differentiate to get the temperature:

$$\frac{1}{T} = \frac{dS}{dE} = \frac{k}{\epsilon} \log \left(\frac{N\epsilon}{E} - 1 \right),$$

which we can invert to give the beautifully simple

$$\frac{N_{\uparrow}}{N} = \frac{E}{N\epsilon} = \frac{1}{e^{\epsilon/kT} + 1}.$$

As $T \rightarrow 0$ we get $N_{\uparrow} \rightarrow 0$: everything falls into the ground state, as it should. As $T \rightarrow \infty$ we get $N_{\uparrow}/N \rightarrow \frac{1}{2}$, which is more surprising – one might have guessed that infinite temperature would push everything into the excited state. It does not: at infinite temperature the Boltzmann factors for the two levels become equal and the spins are simply randomised.

This has a strange consequence. The graph of S against E has negative slope for $E > N\epsilon/2$, so such states have *negative temperature*. Moreover, to get from positive T to negative T one must pass through $T = \infty$, so negative temperatures are ‘hotter’ than infinite temperature. This is not a pathology of the definition but a genuine feature of systems whose energy is bounded above; it can only happen because we have frozen the particles in place and thrown away their kinetic energy, which is unbounded. Negative-temperature states have been produced in the laboratory, using nuclear spins in a crystal: align them with a magnetic field, then suddenly reverse the field.

Finally, the heat capacity. Differentiating $E = N\epsilon/(e^{\epsilon/kT} + 1)$,

$$C = \frac{dE}{dT} = \frac{N\epsilon^2}{kT^2} \frac{e^{\epsilon/kT}}{(e^{\epsilon/kT} + 1)^2},$$

which looks like this.

Three things are worth noticing. First, the position of the peak is set by the microscopic energy gap, $kT \sim \varepsilon$; so a macroscopic measurement of C tells us about the microscopic level structure. Secondly, as $T \rightarrow 0$ we have $C \propto T^{-2}e^{-\varepsilon/kT}$, which vanishes faster than any power of T – the classic analysis example of a smooth non-analytic function. This exponential suppression is the signature of an energy gap: at low temperatures there is simply not enough thermal energy to excite anything. Thirdly, $C \rightarrow 0$ at high temperature as well, which is peculiar and again a consequence of the bounded energy spectrum; a realistic system has C increasing with T . In a real solid this spin contribution is swamped by the phonons and electrons, and shows up only as a small bump at low temperature, called a **Schottky anomaly**.

§42.1.5 Pressure, Volume and the First Law

So far our systems have had exactly one macroscopic parameter, the energy. Real systems have more. The most obvious is volume: if we let the walls of our box move, then the energy eigenvalues change, and so Ω and S depend on V as well:

$$S(E, V) = k \log \Omega(E, V).$$

We must therefore be careful about what is held fixed when we differentiate, and we adopt the standard notation of writing the fixed variables as a subscript.

Definition 42.1.13 (Temperature and pressure)

For a system with variable volume,

$$\frac{1}{T} = \left(\frac{\partial S}{\partial E} \right)_V, \quad p = T \left(\frac{\partial S}{\partial V} \right)_E.$$

The definition of p looks unmotivated, but it is forced on us by the same argument as before.

Proposition 42.1.14

If two systems can exchange both energy and volume, with $E_1 + E_2$ and $V_1 + V_2$ fixed, then entropy is maximised when $T_1 = T_2$ and $p_1 = p_2$.

Proof. We must maximise $S_1(E_1, V_1) + S_2(E_{\text{tot}} - E_1, V_{\text{tot}} - V_1)$ over both E_1 and

V_1 . The E derivative gives $T_1 = T_2$ as before, and the V derivative gives

$$\left(\frac{\partial S_1}{\partial V}\right)_E = \left(\frac{\partial S_2}{\partial V}\right)_E,$$

which, on multiplying by the common temperature, is $p_1 = p_2$. $\square$

So p is the quantity that equalises when a piston between two gases is free to move – which is exactly what mechanical pressure does. To see that it really *is* force per unit area, write $S = S(E, V)$ and take the total differential:

$$dS = \left(\frac{\partial S}{\partial E}\right)_V dE + \left(\frac{\partial S}{\partial V}\right)_E dV = \frac{1}{T} dE + \frac{p}{T} dV.$$

Rearranging gives one of the most important equations in the subject.

Proposition 42.1.15 (First Law of Thermodynamics)

$$dE = T dS - p dV.$$

The interpretation is this: $-p dV$ is the mechanical work done on the system when we compress it, exactly as in Newtonian mechanics, which confirms that our p is the ordinary pressure. The remaining term $T dS$ is therefore energy transferred *not* as mechanical work; we call it **heat**. The first law says that energy is conserved provided we remember to count heat as a form of energy – a statement that took most of the nineteenth century to become uncontroversial.

Example 42.1.16 (The ideal gas, done the hard way)

Let us extract the equation of state of an ideal gas from the microcanonical ensemble. We will do this much more slickly later, so treat this as a demonstration that it *can* be done. For N free particles in a box of volume V , the accessible phase space at fixed energy E factorises into a position part and a momentum part. Each particle can be anywhere in the box, giving a factor V^N ; and the momenta are constrained to the sphere $\sum_i \mathbf{p}_i^2 = 2mE$ in $3N$ dimensions, whose area depends only on E and N . So

$$\Omega(E, V) = V^N f(E)$$

for some function f we do not need to know. Then $S = Nk \log V + k \log f(E)$, and

$$p = T \left(\frac{\partial S}{\partial V}\right)_E = \frac{NkT}{V},$$

which is the ideal gas law $pV = NkT$. Notice how little we had to know: only that the positions and momenta decouple.

§42.1.6 The Canonical Ensemble

The microcanonical ensemble is conceptually clean but computationally awful: to use it we must count states at fixed energy, which usually means a nasty combinatorial problem. Worse, it is not a realistic description of most experiments. A beaker of water on a bench is not isolated; it is in contact with the room, and its energy fluctuates.

What is fixed is its *temperature*. This suggests a different setup, and it turns out to be enormously easier to work with.

So: let our system $\mathcal{S}$ be in thermal contact with a **reservoir** $\mathcal{R}$, so much larger than $\mathcal{S}$ that its temperature T is unaffected by anything $\mathcal{S}$ does. The combined system is isolated, with total energy E_{tot} , and we apply the microcanonical ensemble to *it*. If $\mathcal{S}$ is in a definite microstate $|n\rangle$ of energy E_n , then the number of microstates of the combination is just the number available to the reservoir, namely $\Omega_{\mathcal{R}}(E_{\text{tot}} - E_n)$. Hence

$$p(n) \propto \Omega_{\mathcal{R}}(E_{\text{tot}} - E_n) = \exp\left(\frac{S_{\mathcal{R}}(E_{\text{tot}} - E_n)}{k}\right).$$

Now $E_n \ll E_{\text{tot}}$, so we may Taylor expand:

$$S_{\mathcal{R}}(E_{\text{tot}} - E_n) = S_{\mathcal{R}}(E_{\text{tot}}) - E_n \left. \frac{\partial S_{\mathcal{R}}}{\partial E} \right|_{E_{\text{tot}}} + \cdots = S_{\mathcal{R}}(E_{\text{tot}}) - \frac{E_n}{T} + \cdots,$$

and the higher terms are suppressed by further powers of E_n/E_{tot} . The first term is a constant, independent of n , so it is absorbed into the normalisation, and we are left with the single most important formula of the course.

Definition 42.1.17 (Boltzmann distribution and partition function)

A system in equilibrium with a reservoir at temperature T occupies its microstates with probabilities

$$p(n) = \frac{e^{-\beta E_n}}{Z}, \quad \beta = \frac{1}{kT},$$

where the normalising constant

$$Z = \sum_n e^{-\beta E_n}$$

is the **partition function**. This probability distribution is the **Boltzmann distribution**, and the ensemble is the **canonical ensemble**.

The sum defining Z runs over all *states*, not all energy levels; a level of degeneracy g contributes $ge^{-\beta E}$. The factor $e^{-\beta E_n}$ is called the **Boltzmann factor**, and its shape is the whole story of the canonical ensemble: high-energy states are exponentially rare, and the scale on which ‘high’ is measured is kT .

It is worth pausing over what this means for the occupation of energy levels. At low temperature almost all the probability sits in the ground state; as T rises, states higher up the ladder become accessible, and the population spreads out. Schematically:

The partition function was introduced as a normalisation constant, but it is far more useful than that: essentially every thermodynamic quantity can be got out of it by differentiation. The first example is the average energy.

Proposition 42.1.18

The mean energy of a system in the canonical ensemble is

$$\langle E \rangle = \sum_n p(n) E_n = -\frac{\partial}{\partial \beta} \log Z.$$

Proof. Differentiating $Z = \sum_n e^{-\beta E_n}$ with respect to β gives $\partial_\beta Z = -\sum_n E_n e^{-\beta E_n}$, and dividing by Z gives $-\langle E \rangle$. $\square$

Since $\langle E \rangle$ is what we actually mean by ‘the energy’ of a macroscopic system, we will from now on drop the angle brackets and simply write E .

Before computing anything, one more structural remark, which is the reason the canonical ensemble is so much nicer than the microcanonical one. Suppose our system consists of two non-interacting parts, so that the states are pairs and the energies add. Then

$$Z = \sum_{n_1, n_2} e^{-\beta(E_{n_1} + E_{n_2})} = \left(\sum_{n_1} e^{-\beta E_{n_1}} \right) \left(\sum_{n_2} e^{-\beta E_{n_2}} \right) = Z_1 Z_2.$$

Partition functions of independent systems simply multiply. In the microcanonical ensemble the analogous statement was a convolution, which is why everything there was hard.

Example 42.1.19 (The two-state system again)

Each particle has $Z_1 = 1 + e^{-\beta \varepsilon}$, so for N of them $Z = (1 + e^{-\beta \varepsilon})^N$ and

$$E = -\frac{\partial}{\partial \beta} \log Z = -N \frac{\partial}{\partial \beta} \log(1 + e^{-\beta \varepsilon}) = \frac{N \varepsilon}{e^{\beta \varepsilon} + 1},$$

reproducing in three lines what took us a page of Stirling’s formula in the microcanonical ensemble.

§42.1.7 Fluctuations

There is an obvious objection to all this. In the microcanonical ensemble the energy was fixed; in the canonical ensemble it fluctuates. Why should the two give the same answers? The resolution is that the fluctuations are tiny, and we can quantify this precisely.

Proposition 42.1.20

In the canonical ensemble,

$$\Delta E^2 = \langle E^2 \rangle - \langle E \rangle^2 = \frac{\partial^2}{\partial \beta^2} \log Z = kT^2 C_V.$$

Proof. We compute

$$\frac{\partial^2 \log Z}{\partial \beta^2} = \frac{\partial}{\partial \beta} \left(\frac{1}{Z} \frac{\partial Z}{\partial \beta} \right) = \frac{1}{Z} \frac{\partial^2 Z}{\partial \beta^2} - \left(\frac{1}{Z} \frac{\partial Z}{\partial \beta} \right)^2 = \langle E^2 \rangle - \langle E \rangle^2.$$

On the other hand $\langle E \rangle = -\partial_\beta \log Z$, so this equals $-\partial \langle E \rangle / \partial \beta$; and since $\beta = 1/kT$ we have $\partial / \partial \beta = -kT^2 \partial / \partial T$, giving $kT^2 (\partial E / \partial T)_V = kT^2 C_V$. $\square$

Now, both E and C_V are proportional to N . So

$$\frac{\Delta E}{E} \sim \frac{\sqrt{N}}{N} = \frac{1}{\sqrt{N}},$$

which for $N \sim 10^{23}$ is about 10^{-12} . The energy of a macroscopic system in the canonical ensemble is therefore fixed to about twelve significant figures, which is rather better than any experiment can do. This is why the two ensembles agree: in the thermodynamic limit the distinction between ‘fixed energy’ and ‘fixed temperature’ is invisible. We will use whichever is more convenient, which is almost always the canonical one.

The relation $\Delta E^2 = kT^2 C_V$ is also our first **fluctuation–dissipation relation**: it connects the size of spontaneous fluctuations (the left side) to the response of the system to an external prod (the right side). Relations of this type run through the whole of statistical physics.

§42.1.8 The Gibbs Entropy

We defined entropy by counting microstates, which only makes sense when all accessible microstates are equally likely. In the canonical ensemble they are not, so we need a definition that works for a general probability distribution. Here it is.

Definition 42.1.21 (Gibbs entropy)

Given a probability distribution $p(n)$ over microstates, the **Gibbs entropy** is

$$S = -k \sum_n p(n) \log p(n).$$

This agrees with the old definition when it applies: if $p(n) = 1/\Omega$ on Ω accessible states, then

$$S = -k \sum_n \frac{1}{\Omega} \log \frac{1}{\Omega} = k \log \Omega$$

as required. And it is exactly the quantity Shannon later introduced as a measure of the information content of a distribution – entropy is a measure of how much we *don’t* know about the system, which is a rather satisfying way to think about the second law.

Let us check that this definition is consistent with what we have been doing.

Proposition 42.1.22

For the canonical ensemble, the Gibbs entropy satisfies

$$\left(\frac{\partial S}{\partial E}\right)_V = \frac{1}{T}.$$

Proof. Substituting $p(n) = e^{-\beta E_n}/Z$,

$$S = -k \sum_n p(n) (-\beta E_n - \log Z) = k\beta \langle E \rangle + k \log Z,$$

using $\sum_n p(n) = 1$. So, writing everything in terms of β ,

$$\frac{\partial S}{\partial \beta} = k \langle E \rangle + k\beta \frac{\partial \langle E \rangle}{\partial \beta} + k \frac{\partial \log Z}{\partial \beta} = k\beta \frac{\partial \langle E \rangle}{\partial \beta},$$

since $\partial_\beta \log Z = -\langle E \rangle$. Dividing by $\partial \langle E \rangle / \partial \beta$ gives $\partial S / \partial E = k\beta = 1/T$. $\square$

The identity $S = k\beta E + k \log Z$ obtained in that proof is worth remembering; we will use it in a moment.

There is another characterisation of the Boltzmann distribution which is, in a sense, the deepest way of looking at it: it is the distribution which maximises entropy subject to knowing the mean energy.

Proposition 42.1.23 (Maximum entropy principle)

Among all probability distributions $p(n)$ with a given mean energy $\langle E \rangle = \sum_n p(n) E_n$, the Gibbs entropy is maximised by the Boltzmann distribution.

Proof. We extremise S subject to the constraints $\sum_n p(n) = 1$ and $\sum_n p(n) E_n = \langle E \rangle$, using Lagrange multipliers. Consider

$$\Phi = -k \sum_n p(n) \log p(n) + k\alpha \left(\sum_n p(n) - 1 \right) + k\beta \left(\langle E \rangle - \sum_n p(n) E_n \right),$$

where the factors of k and signs are chosen for later convenience. Then

$$\frac{\partial \Phi}{\partial p(n)} = -k (\log p(n) + 1) + k\alpha - k\beta E_n = 0,$$

so $p(n) = e^{\alpha-1} e^{-\beta E_n}$. Imposing $\sum_n p(n) = 1$ fixes $e^{\alpha-1} = 1/Z$, giving the Boltzmann distribution, with β determined by the energy constraint. That this is a maximum rather than a minimum follows since $-p \log p$ is concave. $\square$

So the canonical ensemble is the least prejudiced distribution consistent with what we know. In the same spirit, if we impose no constraint at all beyond normalisation we get the uniform distribution, which is the microcanonical ensemble; the fundamental assumption of statistical mechanics is therefore itself a maximum entropy statement.

§42.1.9 The Helmholtz Free Energy

We have found $S = k\beta E + k \log Z$, which we now rearrange into

$$-kT \log Z = E - TS.$$

The right-hand side is important enough to have a name.

Definition 42.1.24 (Helmholtz free energy)

The **Helmholtz free energy** of a system is

$$F = E - TS = -kT \log Z.$$

Readers who have met the Legendre transform – for instance in the Variational Principles course – will recognise what is going on: F is (minus) the Legendre transform of $E(S, V)$ in the variable S , trading the entropy for its conjugate variable, the temperature. This is exactly the right thing to do, because S is not something one can hold fixed in a laboratory whereas T is. We will return to this systematically in Section 42.4.5.

The point of F is that everything can be computed from it by differentiation. Taking the differential of $F = E - TS$ and using the first law $dE = T dS - p dV$,

$$dF = dE - T dS - S dT = -S dT - p dV.$$

So F is naturally a function of T and V , and

$$S = -\left(\frac{\partial F}{\partial T}\right)_V, \quad p = -\left(\frac{\partial F}{\partial V}\right)_T.$$

Since $F = -kT \log Z$ is directly computable from the partition function, this is our standard route from a microscopic model to an equation of state: compute Z , take a logarithm, differentiate.

There is also a variational characterisation of F , which explains the name. Suppose our system is at temperature T and we ask which of its states it wants to be in. The answer is the one that minimises F : minimising $F = E - TS$ means compromising between minimising energy and maximising entropy, with the temperature setting the exchange rate. At low temperature energy wins and the system falls into its ground state; at high temperature entropy wins and the system disorders. Almost every phenomenon in the second half of this course is a battle between these two terms.

Proposition 42.1.25

Consider a system in contact with a reservoir at temperature T . Then the total entropy of system plus reservoir is maximised when the free energy of the system is minimised.

Proof. If the system has energy E then the reservoir has $E_{\text{tot}} - E$, and

$$S_{\text{tot}} = S(E) + S_{\mathcal{R}}(E_{\text{tot}} - E) \approx S(E) + S_{\mathcal{R}}(E_{\text{tot}}) - \frac{E}{T},$$

expanding as before. Dropping the constant, maximising S_{tot} is the same as max-

imising $S - E/T$, i.e. minimising $E - TS = F$. □

§42.1.10 The Chemical Potential and the Grand Canonical Ensemble

We allowed our systems to exchange energy, and then volume. The remaining thing they might exchange is particles. Repeating the pattern, S now depends on E , V and N , and we define a new derivative.

Definition 42.1.26 (Chemical potential)

The **chemical potential** of a system is

$$\mu = -T \left(\frac{\partial S}{\partial N} \right)_{E,V}.$$

The minus sign is a convention, chosen so that the first law takes a pleasant form. Indeed, taking the differential of $S(E, V, N)$ exactly as before and rearranging,

$$dE = T dS - p dV + \mu dN.$$

So μ is the energy cost of adding one particle at fixed entropy and volume. The same maximisation argument as before shows that two systems which can exchange particles are in equilibrium precisely when their chemical potentials agree, and that particles flow from high μ to low μ .

Now we play the reservoir trick again, but with a reservoir that exchanges particles as well as energy. If our system is in a state with energy E_n and particle number N_n , then

$$p(n) \propto \Omega_{\mathcal{R}}(E_{\text{tot}} - E_n, N_{\text{tot}} - N_n) = \exp \left(\frac{S_{\mathcal{R}}(E_{\text{tot}} - E_n, N_{\text{tot}} - N_n)}{k} \right),$$

and expanding the entropy to first order in both arguments,

$$S_{\mathcal{R}}(E_{\text{tot}} - E_n, N_{\text{tot}} - N_n) \approx \text{const} - \frac{E_n}{T} + \frac{\mu N_n}{T}.$$

Definition 42.1.27 (Grand canonical ensemble)

In the **grand canonical ensemble** the probabilities are

$$p(n) = \frac{e^{-\beta(E_n - \mu N_n)}}{\mathcal{Z}}, \quad \mathcal{Z} = \sum_n e^{-\beta(E_n - \mu N_n)},$$

where $\mathcal{Z}$ is the **grand canonical partition function**.

It is often convenient to organise the sum by particle number. Writing $Z(N)$ for the ordinary canonical partition function of N particles, and introducing the **fugacity**

$$z = e^{\beta\mu},$$

we have

$$\mathcal{Z} = \sum_{N \geq 0} z^N Z(N),$$

so $\mathcal{Z}$ is a generating function for the canonical partition functions. This will be exactly what we need for quantum gases in Section 42.3.

All the same tricks work. Differentiating with respect to μ and β gives

$$\langle N \rangle = \frac{1}{\beta} \frac{\partial \log \mathcal{Z}}{\partial \mu}, \quad \langle E \rangle - \mu \langle N \rangle = -\frac{\partial \log \mathcal{Z}}{\partial \beta},$$

and the fluctuations in particle number are

$$\Delta N^2 = \langle N^2 \rangle - \langle N \rangle^2 = \frac{1}{\beta^2} \frac{\partial^2 \log \mathcal{Z}}{\partial \mu^2} = \frac{1}{\beta} \left(\frac{\partial \langle N \rangle}{\partial \mu} \right)_{T,V}.$$

As with the energy, $\Delta N/N \sim 1/\sqrt{N}$, so the particle number is again effectively fixed and the ensemble agrees with the others.

Finally, we have a free energy adapted to this ensemble.

Definition 42.1.28 (Grand canonical potential)

The **grand canonical potential** is

$$\Phi = F - \mu N = -kT \log \mathcal{Z}.$$

Its differential is $d\Phi = -S dT - p dV - N d\mu$, so

$$S = -\left(\frac{\partial \Phi}{\partial T} \right)_{V,\mu}, \quad p = -\left(\frac{\partial \Phi}{\partial V} \right)_{T,\mu}, \quad N = -\left(\frac{\partial \Phi}{\partial \mu} \right)_{T,V}.$$

§42.1.11 Extensive and Intensive Quantities

A macroscopic quantity generally falls into one of two classes.

Definition 42.1.29

A quantity X is **extensive** if it scales linearly when we scale the system,

$$X(\lambda E, \lambda V, \lambda N) = \lambda X(E, V, N),$$

and **intensive** if it is unchanged, $X(\lambda E, \lambda V, \lambda N) = X(E, V, N)$.

Thus E , V , N , S and F are extensive, while T , p and μ are intensive – as they must be, being ratios of extensive quantities. (Extensivity of S requires that interactions be short-ranged, so that the energy of two halves of a system is the sum of their energies up to a negligible surface term. For gravitating systems this fails badly, which is why the thermodynamics of black holes is so strange.)

This simple observation is surprisingly powerful. Consider $\Phi = \Phi(T, V, \mu)$. Of its arguments only V is extensive, and Φ itself is extensive, so we must have

$$\Phi(T, V, \mu) = V \phi(T, \mu)$$

for some intensive function ϕ . But $p = -(\partial \Phi / \partial V)_{T,\mu} = -\phi$, and so

$$\Phi = -pV.$$

Combining with $\Phi = F - \mu N = E - TS - \mu N$ gives the **Euler relation**

$$E = TS - pV + \mu N,$$

and hence, comparing with the first law $dE = T dS - p dV + \mu dN$, the **Gibbs–Duhem relation**

$$S dT - V dp + N d\mu = 0.$$

This says the three intensive quantities T, p, μ are not independent: fixing two determines the third. It is a genuinely non-trivial constraint that we obtained purely from scaling.

§42.2 Classical Gases

We now have a machine: write down the energy levels, compute Z , differentiate. Let us feed it some gases. Everything in this section is classical, in the sense that we will treat the particles as little billiard balls; but we will find, slightly awkwardly, that we cannot entirely forget about quantum mechanics even so.

§42.2.1 The Classical Partition Function

The partition function was defined as a sum over quantum states. Classically there are no discrete states – a particle’s configuration is a point $(\mathbf{q}, \mathbf{p})$ in phase space – so we must replace the sum by an integral. For a single particle in three dimensions the natural guess is

$$Z_1 = \frac{1}{(\text{something})} \int d^3q d^3p e^{-\beta H(\mathbf{q}, \mathbf{p})},$$

and the question is what the normalising constant should be. It cannot be anything: $d^3q d^3p$ has dimensions of (action)³, and Z must be dimensionless. The answer is provided by quantum mechanics. The uncertainty principle says that a quantum state occupies a phase space volume of about $\hbar^3$ per particle – more precisely, of $(2\pi\hbar)^3$, as one can check by counting the momentum states of a particle in a box, which we will do in Section 42.3.1.

Definition 42.2.1 (Classical partition function)

For a single classical particle in three dimensions with Hamiltonian $H(\mathbf{q}, \mathbf{p})$,

$$Z_1 = \frac{1}{(2\pi\hbar)^3} \int d^3q d^3p e^{-\beta H(\mathbf{q}, \mathbf{p})}.$$

This is a slightly uncomfortable state of affairs: a ‘classical’ theory that has $\hbar$ in it. The honest statement is that classical statistical mechanics is not self-consistent, and needs quantum mechanics to fix its normalisation. Happily, for most purposes the constant drops out, since it contributes only an additive constant to $\log Z$ and hence disappears on differentiation. There are two places where it does not drop out – the entropy, and the counting of states – and both will cause us trouble shortly.

§42.2.2 The Monatomic Ideal Gas

Definition 42.2.2 (Ideal gas)

An **ideal gas** is a gas of particles which do not interact with one another.

For a single monatomic particle of mass m in a box of volume V , the Hamiltonian is purely kinetic, $H = \mathbf{p}^2/2m$. So

$$Z_1 = \frac{1}{(2\pi\hbar)^3} \int_V d^3q \int d^3p e^{-\beta \mathbf{p}^2/2m} = \frac{V}{(2\pi\hbar)^3} \left(\int_{-\infty}^{\infty} dp e^{-\beta p^2/2m} \right)^3,$$

the position integral giving V because the integrand does not depend on $\mathbf{q}$. The remaining integral is Gaussian,

$$\int_{-\infty}^{\infty} e^{-\beta p^2/2m} dp = \sqrt{\frac{2\pi m}{\beta}},$$

so

$$Z_1 = V \left(\frac{m}{2\pi\hbar^2\beta} \right)^{3/2} = \frac{V}{\lambda^3},$$

where we have introduced a length that will follow us through the rest of the course.

Definition 42.2.3 (Thermal de Broglie wavelength)

The **thermal de Broglie wavelength** is

$$\lambda = \sqrt{\frac{2\pi\hbar^2}{mkT}}.$$

It is worth understanding what this length means. A particle at temperature T has typical momentum $p \sim \sqrt{mkT}$, and hence de Broglie wavelength $\hbar/p \sim \hbar/\sqrt{mkT}$, which is λ up to a numerical factor. So λ is the size of the quantum-mechanical ‘smear’ of a typical particle. Classical physics should be valid when this is much smaller than the typical interparticle spacing, i.e. when

$$\lambda^3 \ll \frac{V}{N},$$

and we should expect quantum effects when the gas is cold or dense enough that the smears start to overlap. Hold on to this; it is the criterion that will tell us when we need Section 42.3.

Now for N particles. Since they do not interact, one might think $Z = Z_1^N$. This turns out to be wrong, but let us proceed anyway and see what goes wrong – the correction is a factor of $1/N!$ which we will discuss in Section 42.2.5. Taking

$$Z = \frac{1}{N!} Z_1^N = \frac{1}{N!} \frac{V^N}{\lambda^{3N}},$$

we have, using Stirling,

$$\log Z = N \log \frac{V}{\lambda^3} - \log N! \approx N \left(\log \frac{V}{N\lambda^3} + 1 \right).$$

Everything now follows by differentiation. Since $\lambda \propto \beta^{1/2}$, we have $\log Z = -\frac{3}{2}N \log \beta +$ (terms independent of β), and so the energy is

$$E = -\frac{\partial \log Z}{\partial \beta} = \frac{3N}{2\beta} = \frac{3}{2}NkT.$$

The pressure is

$$p = - \left(\frac{\partial F}{\partial V} \right)_T = kT \left(\frac{\partial \log Z}{\partial V} \right)_T = \frac{NkT}{V}.$$

Proposition 42.2.4 (Ideal gas law)

A classical monatomic ideal gas obeys

$$pV = NkT, \quad E = \frac{3}{2}NkT, \quad C_V = \left(\frac{\partial E}{\partial T} \right)_V = \frac{3}{2}Nk.$$

The first of these is the equation everyone meets at school. It is worth appreciating what has just happened: we assumed only the fundamental postulate of statistical mechanics and a free Hamiltonian, and out came a law that was discovered experimentally two centuries earlier. It also justifies, retrospectively, our definition of temperature: the T appearing here is the same T as in the ideal gas thermometer.

Definition 42.2.5 (Equation of state)

An **equation of state** is a relation between the macroscopic variables of a system, such as $p = p(T, V, N)$.

Let us also compute the entropy, since it will be instructive. From $S = -(\partial F / \partial T)_V$ with $F = -kT \log Z$,

$$S = k \log Z + kT \frac{\partial \log Z}{\partial T} = Nk \left(\log \frac{V}{N\lambda^3} + \frac{5}{2} \right),$$

using $\lambda \propto T^{-1/2}$ so that $T \partial_T \log \lambda^{-3} = 3/2$. This is the **Sackur–Tetrode equation**. Notice that $\hbar$ has *not* cancelled: it survives inside λ . So the absolute entropy of a gas is a genuinely quantum quantity, even though we thought we were doing classical physics. This is not merely academic – the Sackur–Tetrode formula can be checked experimentally, and it is right.

§42.2.3 Equipartition

The factor $\frac{3}{2}NkT$ in the energy is an instance of a much more general phenomenon.

Proposition 42.2.6 (Equipartition of energy)

Suppose a classical Hamiltonian depends quadratically on some degree of freedom x (a position or a momentum), say $H = \alpha x^2 + (\text{terms not involving } x)$ with $\alpha > 0$. Then in equilibrium at temperature T that degree of freedom contributes

$$\langle \alpha x^2 \rangle = \frac{1}{2}kT$$

to the mean energy.

Proof. Write $H = \alpha x^2 + \tilde{H}$ where $\tilde{H}$ does not involve x . Then the partition function

factorises as $Z = Z_x \tilde{Z}$ with

$$Z_x = \int_{-\infty}^{\infty} dx e^{-\beta \alpha x^2} = \sqrt{\frac{\pi}{\alpha \beta}} \propto \beta^{-1/2},$$

so $\log Z_x = -\frac{1}{2} \log \beta + \text{const}$, and the contribution to the energy is

$$-\frac{\partial \log Z_x}{\partial \beta} = \frac{1}{2\beta} = \frac{1}{2} kT.$$

□

So each quadratic degree of freedom carries $\frac{1}{2}kT$ of energy. A monatomic gas particle has three (the three components of momentum), giving $\frac{3}{2}kT$ each, as we found. A one-dimensional harmonic oscillator has two, one from the kinetic energy and one from the potential, giving kT – which is why a classical solid, modelled as $3N$ oscillators, has $E = 3NkT$ and $C = 3Nk$, the **Dulong–Petit law**.

Equipartition is a beautiful result, and it is spectacularly wrong at low temperatures. The heat capacity of every real solid tends to zero as $T \rightarrow 0$, not to $3Nk$. The reason is exactly the one we met in the two-state system: when kT drops below the spacing of the energy levels, the degree of freedom is *frozen out* and stops contributing. This failure of equipartition was one of the pieces of evidence that forced quantum mechanics on physics, and we will see how it is repaired in Section 42.3.3.

§42.2.4 The Maxwell Distribution

The partition function tells us about averages, but we can also read off the full distribution of any quantity we like. The most famous example is the distribution of molecular speeds.

The probability that a given particle in an ideal gas has momentum in d^3p about $\mathbf{p}$ and position in d^3q is proportional to the Boltzmann factor $e^{-\beta \mathbf{p}^2/2m}$. Integrating out the position (which contributes a constant V) and changing variables to velocity $\mathbf{v} = \mathbf{p}/m$, the distribution of velocities is

$$f(\mathbf{v}) d^3v \propto e^{-\beta m v^2/2} d^3v.$$

If we only care about the speed $v = |\mathbf{v}|$, we write $d^3v = 4\pi v^2 dv$ and normalise.

Proposition 42.2.7 (Maxwell–Boltzmann distribution)

In a classical ideal gas at temperature T , the probability that a molecule has speed in $[v, v + dv]$ is $f(v) dv$, where

$$f(v) = 4\pi \left(\frac{m}{2\pi kT} \right)^{3/2} v^2 e^{-mv^2/2kT}.$$

Proof. The functional form is as above; the constant is fixed by $\int_0^\infty f(v) dv = 1$, using the standard integral $\int_0^\infty v^2 e^{-av^2} dv = \frac{1}{4} \sqrt{\pi/a^3}$ with $a = m/2kT$. □

The two factors in f pull in opposite directions: the v^2 comes from the growing area of the sphere of radius v in velocity space and pushes the distribution to large speeds,

while the exponential cuts it off. The competition gives a peak at

$$v_{\text{peak}} = \sqrt{\frac{2kT}{m}},$$

found by differentiating. Here is the distribution at three temperatures T , $2T$ and $4T$; each curve encloses unit area, so as the gas heats up the distribution both broadens and flattens.

Three different ‘average’ speeds are in common use, and it is worth knowing that they differ. Alongside $v_{\text{peak}} = \sqrt{2kT/m}$ we have the mean speed

$$\langle v \rangle = \int_0^\infty v f(v) dv = \sqrt{\frac{8kT}{\pi m}},$$

and the root-mean-square speed, which by equipartition satisfies $\frac{1}{2}m \langle v^2 \rangle = \frac{3}{2}kT$, so

$$v_{\text{rms}} = \sqrt{\langle v^2 \rangle} = \sqrt{\frac{3kT}{m}}.$$

These are in the ratio $1 : \sqrt{4/\pi} : \sqrt{3/2} \approx 1 : 1.13 : 1.22$, in the order stated – which is what one expects from a distribution with a long tail to the right.

Example 42.2.8

For nitrogen ($m \approx 4.7 \times 10^{-26}$ kg) at room temperature, $v_{\text{rms}} \approx 500 \text{ m s}^{-1}$, comfortably faster than the speed of sound. Molecules in the air around you are moving very quickly indeed; they do not get very far, because they collide constantly.

§42.2.5 Indistinguishability and the Gibbs Paradox

We must now return to the factor of $1/N!$ that we inserted without justification. Suppose we had not: take $Z = Z_1^N$, so that

$$\log Z = N \log \frac{V}{\lambda^3}, \quad S = Nk \left(\log \frac{V}{\lambda^3} + \frac{3}{2} \right).$$

The pressure and energy are unaffected, but the entropy is wrong – and wrong in an instructive way. Under $V \mapsto \lambda V$, $N \mapsto \lambda N$ this S does not scale as λS ; it is not extensive. That is a disaster, since we argued in Section 1.11 that entropy must be extensive.

The physical version of this disaster is the following.

Example 42.2.9 (Gibbs paradox)

Take a box of volume $2V$ containing $2N$ molecules of the same gas at temperature T , and insert a partition down the middle, so we now have two boxes each of volume V containing N molecules. Using the non-extensive formula, the total entropy before was

$$S_{\text{before}} = 2Nk \left(\log \frac{2V}{\lambda^3} + \frac{3}{2} \right),$$

and afterwards

$$S_{\text{after}} = 2 \times Nk \left(\log \frac{V}{\lambda^3} + \frac{3}{2} \right),$$

so $S_{\text{before}} - S_{\text{after}} = 2Nk \log 2 > 0$. Removing the partition would then increase the entropy by $2Nk \log 2$. But nothing has happened! The gas is the same on both sides; inserting and removing a partition is completely reversible, and cannot change the entropy at all.

The resolution, due to Gibbs, is that we have over-counted. Two configurations differing only by swapping particle 1 with particle 2 are not different configurations, because the particles are *identical*: there is no experiment that could distinguish them. When we integrated each particle independently over the box, we counted each genuine configuration $N!$ times, once for each way of labelling the particles. So we should divide by $N!$:

$$Z = \frac{Z_1^N}{N!},$$

which is what we assumed above and which gives the extensive Sackur–Tetrode entropy. Since $\log N! \approx N \log N - N$, the correction changes S by $-Nk(\log N - 1)$, converting $\log(V/\lambda^3)$ into $\log(V/N\lambda^3)$ and curing the paradox: with the correct formula, $S_{\text{before}} = S_{\text{after}}$ exactly.

Two remarks. First, if the two halves contain *different* gases, then removing the partition really does increase the entropy, by exactly $2Nk \log 2$; this is the **entropy of mixing**, and it is real, since unmixing two gases genuinely costs work. Secondly, and more strikingly: indistinguishability of identical particles is a quantum-mechanical fact. Classical particles could in principle be labelled and followed. So this is the second place where classical statistical mechanics needed to be rescued by quantum mechanics – and the $1/N!$ is only an approximation to the correct quantum counting, valid when the chance of two particles occupying the same state is negligible. That is precisely the regime $\lambda^3 \ll V/N$ identified earlier.

§42.2.6 Diatomic Gases

Real gases are usually not monatomic. A diatomic molecule can rotate and vibrate as well as translate, and each of these gives extra degrees of freedom. Since the different motions are (approximately) independent, the partition functions multiply:

$$Z_1 = Z_{\text{trans}} Z_{\text{rot}} Z_{\text{vib}}.$$

The rotational degrees of freedom are the two angles specifying the axis of the molecule. Quantum mechanically, a rigid rotor has energy levels

$$E_j = \frac{\hbar^2}{2I} j(j+1), \quad j = 0, 1, 2, \dots$$

with degeneracy $2j + 1$, where I is the moment of inertia. So

$$Z_{\text{rot}} = \sum_{j=0}^{\infty} (2j + 1) e^{-\beta \hbar^2 j(j+1)/2I}.$$

At high temperature, $kT \gg \hbar^2/2I$, the summand varies slowly and we may replace the sum by an integral; substituting $u = j(j + 1)$, so $du = (2j + 1) dj$,

$$Z_{\text{rot}} \approx \int_0^{\infty} (2j + 1) e^{-\beta \hbar^2 j(j+1)/2I} dj = \int_0^{\infty} e^{-\beta \hbar^2 u/2I} du = \frac{2I}{\beta \hbar^2}.$$

This gives $E_{\text{rot}} = -\partial_{\beta} \log Z_{\text{rot}} = kT$ per molecule, exactly as equipartition predicts for two quadratic degrees of freedom. At low temperature, $kT \ll \hbar^2/2I$, only the first two terms matter,

$$Z_{\text{rot}} \approx 1 + 3e^{-\beta \hbar^2/I},$$

giving $E_{\text{rot}} \approx (3\hbar^2/I)e^{-\beta \hbar^2/I}$, which is exponentially small: the rotational modes are frozen out, and contribute nothing to the heat capacity.

The vibrational mode is a harmonic oscillator of frequency ω , with energy levels $E_n = \hbar\omega(n + \frac{1}{2})$. This we can sum exactly, as a geometric series:

$$Z_{\text{vib}} = \sum_{n=0}^{\infty} e^{-\beta \hbar \omega (n+1/2)} = \frac{e^{-\beta \hbar \omega /2}}{1 - e^{-\beta \hbar \omega}} = \frac{1}{2 \sinh(\beta \hbar \omega /2)},$$

so the mean vibrational energy per molecule is

$$E_{\text{vib}} = -\frac{\partial}{\partial \beta} \log Z_{\text{vib}} = \frac{\hbar \omega}{2} \coth\left(\frac{\beta \hbar \omega}{2}\right) = \hbar \omega \left(\frac{1}{2} + \frac{1}{e^{\beta \hbar \omega} - 1}\right).$$

At high temperature this tends to kT , again as equipartition demands; at low temperature it tends to the zero-point energy $\frac{1}{2}\hbar\omega$, with exponentially small corrections. We will meet this formula again, twice, in the next section.

Putting it together, the heat capacity of a diatomic gas rises in steps as we heat it: $\frac{3}{2}Nk$ when only translations are active, $\frac{5}{2}Nk$ once rotations unfreeze, and $\frac{7}{2}Nk$ once vibrations do. For hydrogen the rotational scale is about 85 K and the vibrational scale about 6000 K, so at room temperature we see the middle plateau – and indeed the measured C_V of hydrogen is close to $\frac{5}{2}Nk$. The steps are unmistakable in the data, and are direct macroscopic evidence for the quantisation of energy levels.

§42.2.7 Interacting Gases and the Virial Expansion

Real gas molecules attract each other at long range and repel at short range, and we would like to know how this modifies the ideal gas law. The strategy is perturbative: for a dilute gas the number density N/V is small, and we expand in it.

Definition 42.2.10 (Virial expansion)

The **virial expansion** of an equation of state is

$$\frac{p}{kT} = \frac{N}{V} + B_2(T) \frac{N^2}{V^2} + B_3(T) \frac{N^3}{V^3} + \dots,$$

whose coefficients $B_k(T)$ are the **virial coefficients**.

The coefficients depend only on T , since p/kT and N/V are both intensive. Our goal is to compute B_2 .

Suppose the particles interact through a pair potential $U(r)$ depending only on the separation. What does U look like? At long range, two neutral atoms attract: although each has zero average electric dipole moment, a fluctuation giving atom 1 a dipole p_1 produces a field $E \sim p_1/r^3$, which induces a dipole $p_2 \propto p_1/r^3$ in atom 2, and the resulting energy is

$$U \sim -p_2 E \sim -\frac{p_1^2}{r^6}.$$

This is the **van der Waals interaction**, and it is attractive. At short range the electron clouds overlap and the Pauli principle produces a strong repulsion. A convenient phenomenological form combining the two is the **Lennard-Jones potential**

$$U(r) = U_0 \left[\left(\frac{r_0}{r} \right)^{12} - \left(\frac{r_0}{r} \right)^6 \right],$$

where the twelfth power is chosen mostly because it is the square of the sixth and hence easy to compute with.

For calculations it is easier to idealise this into a **hard-core potential**: infinitely repulsive inside r_0 , attractive outside,

$$U(r) = \begin{cases} \infty & r < r_0, \\ -U_0(r_0/r)^6 & r \geq r_0. \end{cases}$$

Now to the calculation. The Hamiltonian of the gas is

$$H = \sum_{i=1}^N \frac{\mathbf{p}_i^2}{2m} + \sum_{i<j} U(r_{ij}), \quad r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|,$$

and the partition function no longer factorises. The momentum integrals still do, however, and they give the same λ^{-3N} as before:

$$Z(N, V, T) = \frac{1}{N! \lambda^{3N}} \int \prod_i d^3 r_i e^{-\beta \sum_{j<k} U(r_{jk})}.$$

We would now like to expand the exponential in powers of U , but this is hopeless: U is infinite at short range. The trick is to expand instead in the **Mayer f -function**

$$f(r) = e^{-\beta U(r)} - 1,$$

which is well behaved: it equals -1 inside the hard core and tends to 0 as $r \rightarrow \infty$, so it is supported on a shell of finite size. Writing $f_{jk} = f(r_{jk})$,

$$e^{-\beta \sum_{j<k} U_{jk}} = \prod_{j<k} (1 + f_{jk}) = 1 + \sum_{j<k} f_{jk} + \sum_{j<k} \sum_{\ell<m} f_{jk} f_{\ell m} + \cdots.$$

The first term integrates to V^N , giving the ideal gas. Each term in the second sum gives, say for $j = 1, k = 2$,

$$\int \prod_i d^3 r_i f_{12} = V^{N-2} \int d^3 r_1 d^3 r_2 f(r_{12}) = V^{N-1} I, \quad I = \int d^3 r f(r),$$

where we changed to relative and centre-of-mass coordinates and extended the r integral over all space (legitimate since f decays). There are $\binom{N}{2} \approx N^2/2$ such terms, so

$$Z = \frac{V^N}{N! \lambda^{3N}} \left(1 + \frac{N^2 I}{2V} + \cdots \right) = Z_{\text{ideal}} \left(1 + \frac{NI}{2V} + \cdots \right)^N,$$

where in the last step we pulled an N into the exponent, which is legitimate to this order and has the advantage of making extensivity manifest. Then

$$F = -kT \log Z = F_{\text{ideal}} - NkT \log \left(1 + \frac{NI}{2V} + \cdots \right) \approx F_{\text{ideal}} - \frac{N^2 kT}{2V} I,$$

and differentiating,

$$p = - \left(\frac{\partial F}{\partial V} \right)_T = \frac{NkT}{V} \left(1 - \frac{NI}{2V} + \cdots \right).$$

Proposition 42.2.11

The second virial coefficient is

$$B_2(T) = -\frac{1}{2} I = -\frac{1}{2} \int d^3 r (e^{-\beta U(r)} - 1).$$

The expansion parameter is NI/V , and $I \sim r_0^3$, so we need $N/V \ll r_0^{-3}$: the gas must be much less dense than a liquid, which is exactly the regime in which we expect a dilute-gas expansion to work. Note also the sign: a purely repulsive potential has $U > 0$, hence $f < 0$, hence $B_2 > 0$, and the pressure is increased. A purely attractive potential decreases it. Both are what one would guess.

§42.2.8 The van der Waals Equation

Let us evaluate I for the hard-core potential. Splitting the integral at r_0 ,

$$I = \int_{r < r_0} d^3r (-1) + \int_{r > r_0} d^3r \left(e^{\beta U_0(r_0/r)^6} - 1 \right).$$

The first piece is just $-\frac{4}{3}\pi r_0^3$. For the second we assume high temperature, $\beta U_0 \ll 1$, and expand the exponential to first order:

$$\int_{r_0}^{\infty} 4\pi r^2 dr \beta U_0 \frac{r_0^6}{r^6} = 4\pi \beta U_0 r_0^6 \int_{r_0}^{\infty} \frac{dr}{r^4} = \frac{4\pi r_0^3 U_0}{3kT}.$$

Hence

$$I = \frac{4\pi r_0^3}{3} \left(\frac{U_0}{kT} - 1 \right),$$

and substituting into the virial expansion,

$$\frac{pV}{NkT} = 1 - \frac{N}{V} \left(\frac{a}{kT} - b \right), \quad a = \frac{2\pi r_0^3 U_0}{3}, \quad b = \frac{2\pi r_0^3}{3}.$$

This is already a decent equation of state, but it is traditional (and, as we will see, far more useful) to rearrange it. Inverting,

$$kT = \frac{V}{N} \left(p + \frac{aN^2}{V^2} \right) \left(1 + \frac{bN}{V} \right)^{-1} \approx \left(p + \frac{aN^2}{V^2} \right) \left(\frac{V}{N} - b \right),$$

where we expanded the inverse to first order and discarded higher terms, which are beyond the accuracy we have anyway.

Definition 42.2.12 (van der Waals equation)

The **van der Waals equation of state** is

$$\left(p + \frac{aN^2}{V^2} \right) \left(\frac{V}{N} - b \right) = kT, \quad \text{equivalently} \quad p = \frac{NkT}{V - bN} - \frac{aN^2}{V^2}.$$

The second form makes the interpretation clear. The b term says that the volume available to the gas is reduced, because the molecules take up room; the a term says the pressure is reduced, because the long-range attraction pulls molecules back from the walls.

The factor of bN deserves a comment, since it is not what one would first guess. Two hard spheres of core radius r_0 cannot approach closer than r_0 , so each atom excludes a volume

$$\Omega_{\text{ex}} = \frac{4}{3}\pi r_0^3 = 2b$$

around itself – twice the value of b . Why the factor of two? Because the exclusion is shared between pairs. Placing the atoms in one at a time, the first has volume V available, the second $V - \Omega_{\text{ex}}$, the third $V - 2\Omega_{\text{ex}}$, and so on, so the accessible configuration volume is

$$\frac{1}{N!} \prod_{j=0}^{N-1} (V - j\Omega_{\text{ex}}) \approx \frac{V^N}{N!} \left(1 - \frac{N\Omega_{\text{ex}}}{V} \right) \approx \frac{1}{N!} \left(V - \frac{N\Omega_{\text{ex}}}{2} \right)^N,$$

so the effective excluded volume *per particle* is $\Omega_{\text{ex}}/2 = b$.

We derived the van der Waals equation in a regime where it is a small correction to the ideal gas law. Its real interest, though, is what happens if we take it seriously outside that regime – where, as we will see in Section 42.5.1, it produces a liquid–gas phase transition. That is an entirely illegitimate extrapolation, and it works remarkably well.

Higher virial coefficients can be computed, but not by naively keeping the $\sum \sum f_{jk} f_{\ell m}$ terms; one has to be careful about which diagrams contribute at which order in N/V . The systematic method is the **cluster expansion**, which organises the terms into connected diagrams in a manner very reminiscent of Feynman diagrams. We will not pursue it.

§42.3 Quantum Gases

We saw that the classical treatment of a gas should break down when the thermal wavelength λ becomes comparable with the interparticle spacing, that is, when the gas is cold or dense. In this section we do the calculation properly. This is where statistical physics earns its keep: the same formalism will give us the spectrum of light from a hot object, the heat capacity of a crystal, the pressure that holds up a white dwarf star, and a phase transition with no interactions in sight.

The technical obstacle is that the partition function is a sum over states, and quantum states are discrete. In practice the levels are very finely spaced, so we would like to replace the sum by an integral – but we must keep track of how many states there are per unit energy. That is the density of states.

§42.3.1 Density of States

Consider a single particle in a cubical box of side L , so $V = L^3$. The energy eigenstates are the standing waves

$$\psi(\mathbf{r}) \propto \sin\left(\frac{n_1\pi x}{L}\right) \sin\left(\frac{n_2\pi y}{L}\right) \sin\left(\frac{n_3\pi z}{L}\right), \quad n_i \in \mathbb{N},$$

though for counting purposes it is more convenient to use periodic boundary conditions, which give plane waves $e^{i\mathbf{k}\cdot\mathbf{r}}$ with

$$\mathbf{k} = \frac{2\pi}{L}(n_1, n_2, n_3), \quad n_i \in \mathbb{Z}.$$

Either way the answer is the same: the allowed wavevectors form a lattice in $\mathbf{k}$ -space with one state per volume $(2\pi/L)^3 = (2\pi)^3/V$. So for a large box the number of states with wavevector in d^3k is

$$\frac{V}{(2\pi)^3} d^3k,$$

and equivalently, since $\mathbf{p} = \hbar\mathbf{k}$, one state per phase-space volume $(2\pi\hbar)^3$. This is exactly the normalisation we were forced to guess in Section 42.2.1, and now we have derived it.

Now specialise to a non-relativistic particle, $E = \hbar^2 k^2/2m$. Counting states with energy less than E means counting lattice points inside a sphere of radius $k = \sqrt{2mE}/\hbar$:

$$g(E) dE = \frac{V}{(2\pi)^3} 4\pi k^2 dk = \frac{V}{2\pi^2} k^2 \frac{dk}{dE} dE.$$

Since $k = \sqrt{2mE}/\hbar$ we have $dk/dE = \sqrt{2m}/(2\hbar\sqrt{E})$, and so we obtain the following.

Definition 42.3.1 (Density of states)

The **density of states** $g(E)$ is defined so that $g(E) dE$ is the number of single-particle states with energy in $[E, E + dE]$. For a non-relativistic particle of mass m in a box of volume V in three dimensions,

$$g(E) = \frac{V}{4\pi^2} \left(\frac{2m}{\hbar^2} \right)^{3/2} \sqrt{E}.$$

The $\sqrt{E}$ is worth remembering, as is the fact that it depends on the dispersion relation and the dimension. If the particles have spin, or some other internal degree of freedom with g_s states, we simply multiply $g(E)$ by g_s . And for massless particles such as photons, where $E = \hbar\omega = \hbar ck$, the same counting gives

$$g(E) dE = \frac{V}{2\pi^2} k^2 dk = \frac{VE^2}{2\pi^2 \hbar^3 c^3} dE,$$

so $g(E) \propto E^2$ instead.

As a first check, let us recompute the partition function of a classical ideal gas:

$$Z_1 = \int_0^\infty dE g(E) e^{-\beta E} = \frac{V}{4\pi^2} \left(\frac{2m}{\hbar^2} \right)^{3/2} \int_0^\infty \sqrt{E} e^{-\beta E} dE = \frac{V}{4\pi^2} \left(\frac{2m}{\hbar^2} \right)^{3/2} \frac{\sqrt{\pi}}{2\beta^{3/2}},$$

which tidies up to

$$Z_1 = \frac{V}{\lambda^3},$$

agreeing with our earlier result.

§42.3.2 Blackbody Radiation

Our first application is to light. Consider an empty box whose walls are held at temperature T . The walls constantly emit and absorb photons, so the box fills with electromagnetic radiation in thermal equilibrium; this is **blackbody radiation**, and the question is what its spectrum looks like. The problem is a genuinely historic one – getting it wrong is what started quantum mechanics.

The electromagnetic field in a box is equivalent to a collection of harmonic oscillators, one for each mode ($\mathbf{k}$, polarisation), with frequency $\omega = ck$. Quantum mechanically each oscillator has energy levels $E_n = \hbar\omega(n + \frac{1}{2})$, and we interpret n as the number of photons in that mode. Crucially, photon number is not conserved – the walls create and destroy photons freely – so there is no constraint on n , and we may compute the

partition function of each mode separately. Discarding the zero-point energy (which is an infinite constant, and does not affect anything we measure here),

$$Z_{\mathbf{k}} = \sum_{n=0}^{\infty} e^{-\beta n \hbar \omega} = \frac{1}{1 - e^{-\beta \hbar \omega}}.$$

The mean number of photons in the mode is then

$$\langle n \rangle = \frac{1}{Z_{\mathbf{k}}} \sum_{n \geq 0} n e^{-\beta n \hbar \omega} = -\frac{1}{\hbar} \frac{\partial \log Z_{\mathbf{k}}}{\partial \beta} \cdot \frac{1}{\omega},$$

which evaluates to the following.

Definition 42.3.2 (Planck distribution)

The mean occupation number of a photon mode of frequency ω at temperature T is

$$\langle n(\omega) \rangle = \frac{1}{e^{\beta \hbar \omega} - 1}.$$

Now we sum over modes. There are two polarisations for each wavevector, so the number of modes with frequency in $[\omega, \omega + d\omega]$ is

$$2 \cdot \frac{V}{(2\pi)^3} 4\pi k^2 dk = \frac{V \omega^2}{\pi^2 c^3} d\omega,$$

using $\omega = ck$. Multiplying by $\hbar \omega \langle n(\omega) \rangle$ gives the energy.

Proposition 42.3.3 (Planck's law)

The energy density of blackbody radiation per unit frequency is

$$\frac{E(\omega)}{V} = \frac{\hbar}{\pi^2 c^3} \frac{\omega^3}{e^{\beta \hbar \omega} - 1}.$$

Let us look at the two limits. For $\hbar \omega \ll kT$ we may expand $e^{\beta \hbar \omega} - 1 \approx \beta \hbar \omega$, giving

$$\frac{E(\omega)}{V} \approx \frac{\omega^2 kT}{\pi^2 c^3},$$

which is the **Rayleigh–Jeans law**. This is exactly what classical equipartition predicts: each mode is an oscillator with two quadratic degrees of freedom, hence energy kT , and there are $\omega^2 d\omega V / \pi^2 c^3$ of them. It agrees beautifully with experiment at low frequencies, and it is a catastrophe at high ones – the total energy $\int_0^\infty \omega^2 d\omega$ diverges. This is the **ultraviolet catastrophe**. Physically, the trouble is that there are infinitely many modes and classically every one of them must carry kT .

Quantum mechanics saves us. For $\hbar \omega \gg kT$ the Planck distribution is exponentially suppressed, $\langle n \rangle \approx e^{-\beta \hbar \omega}$: a mode whose quantum of energy exceeds kT simply cannot be excited. The two behaviours are stitched together at $\hbar \omega \sim kT$, which is where the spectrum peaks.

Two classical results drop out immediately. Differentiating Planck's law shows that the peak sits at $\hbar\omega_{\max} \approx 2.82 kT$, so

$$\omega_{\max} \propto T,$$

which is **Wien's displacement law** – the reason a heated poker glows first red and then white. And integrating over all frequencies, with $x = \beta\hbar\omega$,

$$\frac{E}{V} = \frac{\hbar}{\pi^2 c^3} \int_0^\infty \frac{\omega^3 d\omega}{e^{\beta\hbar\omega} - 1} = \frac{(kT)^4}{\pi^2 c^3 \hbar^3} \int_0^\infty \frac{x^3 dx}{e^x - 1} = \frac{\pi^2 k^4}{15 c^3 \hbar^3} T^4,$$

where we used $\int_0^\infty x^3/(e^x - 1) dx = \pi^4/15$. This T^4 dependence is the **Stefan–Boltzmann law**. (To evaluate the integral, expand $1/(e^x - 1) = \sum_{n \geq 1} e^{-nx}$ and integrate term by term to get $\Gamma(4)\zeta(4) = 6 \cdot \pi^4/90$.)

It is worth noting the whole thermodynamics of the photon gas. From

$$\log \mathcal{Z} = - \sum_{\mathbf{k}, \text{pol}} \log(1 - e^{-\beta\hbar\omega}) = - \frac{V}{\pi^2 c^3} \int_0^\infty \omega^2 \log(1 - e^{-\beta\hbar\omega}) d\omega,$$

an integration by parts gives $\log \mathcal{Z} = \beta E/3$, and hence, since $F = -kT \log \mathcal{Z}$ and $p = -(\partial F/\partial V)_T$,

$$pV = \frac{1}{3} E.$$

This is the equation of state of *radiation*, and the factor of $\frac{1}{3}$ (as opposed to $\frac{2}{3}$ for a non-relativistic gas, from $pV = NkT$ and $E = \frac{3}{2}NkT$) is a general feature of ultrarelativistic gases. The entropy is $S = \frac{4}{3}(E/T) \propto VT^3$.

§42.3.3 Phonons and the Debye Model

We turn to the heat capacity of a solid. Classically, by equipartition, a crystal of N atoms is $3N$ oscillators and should have $C = 3Nk$ at all temperatures; experimentally $C \rightarrow 0$ as $T \rightarrow 0$, and in insulators it does so like T^3 . The resolution is the same as for blackbody radiation, and the two calculations are almost identical.

The first attempt is due to Einstein: treat the solid as $3N$ independent oscillators, all of the same frequency ω . Then, from our earlier computation of the vibrational partition function,

$$E = 3N\hbar\omega \left(\frac{1}{2} + \frac{1}{e^{\beta\hbar\omega} - 1} \right), \quad C = 3Nk (\beta\hbar\omega)^2 \frac{e^{\beta\hbar\omega}}{(e^{\beta\hbar\omega} - 1)^2}.$$

At high temperature this gives $C \rightarrow 3Nk$, recovering Dulong–Petit. At low temperature it gives $C \sim 3Nk(\beta\hbar\omega)^2 e^{-\beta\hbar\omega}$, which does vanish – but exponentially, whereas experiment says T^3 . Einstein’s model has the right idea and the wrong details.

The flaw is the assumption that the oscillators are independent and identical. In reality the atoms are coupled, and the normal modes of the crystal are sound waves, with a range of frequencies. The quanta of these waves are called **phonons**, and they are treated exactly like photons: a mode of frequency ω has mean occupation $(e^{\beta\hbar\omega} - 1)^{-1}$, and the number of phonons is not conserved.

Definition 42.3.4 (Debye model)

In the **Debye model** we assume a linear dispersion relation $\omega = c_s k$ for the sound waves, with c_s the speed of sound, and we cut the spectrum off at a maximum frequency ω_D chosen so that the total number of modes is $3N$.

The cutoff is not a fudge: a crystal of N atoms has exactly $3N$ degrees of freedom, so there cannot be more than $3N$ modes. There are three polarisations (two transverse, one longitudinal), so

$$3N = 3 \cdot \frac{V}{(2\pi)^3} \int_{k < k_D} d^3k = \frac{V k_D^3}{2\pi^2} \implies \omega_D = c_s \left(\frac{6\pi^2 N}{V} \right)^{1/3}.$$

The energy is then, exactly as for photons but with three polarisations and a cutoff,

$$E = \frac{3V}{2\pi^2 c_s^3} \int_0^{\omega_D} d\omega \frac{\hbar\omega^3}{e^{\beta\hbar\omega} - 1},$$

dropping the zero-point contribution. Substituting $x = \beta\hbar\omega$ and defining the **Debye temperature** T_D by $kT_D = \hbar\omega_D$,

$$E = \frac{3V(kT)^4}{2\pi^2 c_s^3 \hbar^3} \int_0^{T_D/T} \frac{x^3 dx}{e^x - 1} = 9NkT \left(\frac{T}{T_D} \right)^3 \int_0^{T_D/T} \frac{x^3 dx}{e^x - 1}.$$

Now take the two limits.

For $T \gg T_D$ the upper limit is small, so $e^x - 1 \approx x$ and the integral is $\frac{1}{3}(T_D/T)^3$, giving $E = 3NkT$ and $C = 3Nk$: Dulong–Petit, as it must be.

For $T \ll T_D$ the upper limit is effectively infinite, and the integral becomes the constant $\pi^4/15$. Hence

$$E \approx \frac{3\pi^4}{5} NkT \left(\frac{T}{T_D} \right)^3, \quad C \approx \frac{12\pi^4}{5} Nk \left(\frac{T}{T_D} \right)^3.$$

Proposition 42.3.5 (Debye T^3 law)

At low temperatures the phonon contribution to the heat capacity of a solid is

$$C = \frac{12\pi^4}{5} Nk \left(\frac{T}{T_D} \right)^3 \propto T^3.$$

This agrees with experiment. Here are the two models plotted together, in units where $C \rightarrow 3Nk$ at high temperature.

Both curves saturate at the classical value, and both vanish at $T = 0$; the difference is in *how* they vanish, and it is the low-temperature behaviour that distinguishes them. Physically, the Debye model works because there are always arbitrarily low-frequency sound waves available – long-wavelength modes – so however cold the solid, some modes can still be excited. The Einstein model has an energy gap, and so it is exponentially frozen.

§42.3.4 The Quantum Ideal Gas

We now return to gases of massive particles, and do the counting properly. The key fact is quantum statistics: identical particles come in two kinds.

- **Bosons**, which have integer spin, and for which any number of particles may occupy the same single-particle state.
- **Fermions**, which have half-integer spin, and for which the Pauli exclusion principle allows at most one particle per state.

Consider an ideal gas whose single-particle states are labelled by r with energies E_r . A microstate of the whole gas is specified by the **occupation numbers** $\{n_r\}$, with total energy $\sum_r n_r E_r$ and total particle number $\sum_r n_r$. In the canonical ensemble, computing $Z = \sum_{\{n_r\}} e^{-\beta \sum_r n_r E_r}$ subject to $\sum_r n_r = N$ is horrible, because of the constraint. In the grand canonical ensemble the constraint disappears, and everything factorises:

$$\mathcal{Z} = \sum_{\{n_r\}} e^{-\beta \sum_r n_r (E_r - \mu)} = \prod_r \left(\sum_{n_r} e^{-\beta n_r (E_r - \mu)} \right) = \prod_r \mathcal{Z}_r.$$

This is exactly why we built the grand canonical ensemble, and the calculation is now easy.

For bosons the inner sum runs over all $n_r \geq 0$ and is geometric:

$$\mathcal{Z}_r = \sum_{n=0}^{\infty} e^{-\beta n (E_r - \mu)} = \frac{1}{1 - e^{-\beta (E_r - \mu)}},$$

which converges only if $\mu < E_r$ for every r ; in particular μ must lie below the ground state energy, which we take to be 0, so $\mu < 0$ for bosons. For fermions the sum has just two terms:

$$\mathcal{Z}_r = 1 + e^{-\beta (E_r - \mu)}.$$

The mean occupation of a state is $\langle n_r \rangle = -\beta^{-1} \partial \log \mathcal{Z}_r / \partial E_r$, and we obtain the two central distributions of the subject.

Proposition 42.3.6 (Bose–Einstein and Fermi–Dirac distributions)

The mean occupation number of a single-particle state of energy E in an ideal quantum gas at temperature T and chemical potential μ is

$$\langle n(E) \rangle = \frac{1}{e^{\beta(E-\mu)} \mp 1},$$

with the upper sign for bosons (**Bose–Einstein statistics**) and the lower for fermions (**Fermi–Dirac statistics**).

Some sanity checks. For fermions, $\langle n \rangle$ lies between 0 and 1, as the Pauli principle demands. For bosons, $\langle n \rangle$ diverges as $E \rightarrow \mu$, which is the seed of Bose–Einstein condensation. And when $e^{\beta(E-\mu)} \gg 1$ – that is, when occupation numbers are small – both reduce to

$$\langle n(E) \rangle \approx e^{-\beta(E-\mu)},$$

the classical Boltzmann distribution. So classical statistics is the dilute limit of both, as it should be. Setting $\mu = 0$ in the boson formula recovers the Planck distribution: photons are bosons whose number is not conserved, and a non-conserved particle number means exactly that there is no constraint to impose and hence $\mu = 0$.

Everything else follows. Converting sums to integrals with the density of states,

$$N = \int_0^\infty dE \frac{g(E)}{e^{\beta(E-\mu)} \mp 1}, \quad E_{\text{tot}} = \int_0^\infty dE \frac{E g(E)}{e^{\beta(E-\mu)} \mp 1},$$

and the grand potential is

$$\Phi = -kT \log \mathcal{Z} = \pm kT \int_0^\infty dE g(E) \log(1 \mp e^{-\beta(E-\mu)}).$$

Using $g(E) \propto E^{1/2}$ and integrating by parts gives a relation that holds for both statistics and will be useful repeatedly:

$$pV = -\Phi = \frac{2}{3} E_{\text{tot}}.$$

Before specialising, it is worth recording the classical limit as a criterion. In the dilute regime $N = \int g(E) e^{-\beta(E-\mu)} dE = e^{\beta\mu} V / \lambda^3$, so

$$e^{\beta\mu} = \frac{N \lambda^3}{V}.$$

The classical approximation required $e^{\beta\mu} \ll 1$, i.e. $\lambda^3 \ll V/N$, which is exactly the condition we anticipated. Quantum statistics matters when $\lambda^3 N/V \gtrsim 1$.

§42.3.5 Bosons and Bose–Einstein Condensation

Take a gas of N non-relativistic bosons of mass m and spin zero in a box of volume V , and fix N by choosing μ appropriately:

$$\frac{N}{V} = \frac{1}{4\pi^2} \left(\frac{2m}{\hbar^2} \right)^{3/2} \int_0^\infty dE \frac{\sqrt{E}}{z^{-1} e^{\beta E} - 1}, \quad z = e^{\beta\mu}.$$

Substituting $x = \beta E$ and tidying up, this becomes

$$\frac{N\lambda^3}{V} = g_{3/2}(z), \quad \text{where} \quad g_{3/2}(z) = \frac{2}{\sqrt{\pi}} \int_0^\infty \frac{x^{1/2} dx}{z^{-1}e^x - 1}.$$

The function $g_{3/2}$ has a nice series expansion: writing $\frac{1}{z^{-1}e^x - 1} = \sum_{n \geq 1} z^n e^{-nx}$ and integrating term by term,

$$g_{3/2}(z) = \sum_{n=1}^{\infty} \frac{z^n}{n^{3/2}}.$$

This is manifestly increasing in z on $0 \leq z \leq 1$, and recall that $\mu < 0$, so $z \leq 1$. Hence $g_{3/2}$ attains its *maximum* at $z = 1$:

$$g_{3/2}(1) = \zeta(3/2) \approx 2.612.$$

And now we have a problem. The left-hand side $N\lambda^3/V$ grows without bound as we cool the gas, since $\lambda \propto T^{-1/2}$. The right-hand side is bounded by 2.612. So below a certain temperature the equation has no solution at all.

Definition 42.3.7 (Critical temperature)

The **critical temperature** for Bose–Einstein condensation is the temperature T_c at which $N\lambda^3/V = \zeta(3/2)$, namely

$$kT_c = \frac{2\pi\hbar^2}{m} \left(\frac{N}{\zeta(3/2)V} \right)^{2/3}.$$

Something has gone wrong with our approximations, and it is easy to see what. In replacing the sum over states by an integral, we weighted the ground state $E = 0$ by $g(0) = 0$ – we threw it away. Usually this is harmless, since a single state out of 10^{23} cannot matter. But as $z \rightarrow 1$ the ground state occupation

$$n_0 = \frac{1}{z^{-1} - 1} = \frac{z}{1 - z}$$

diverges, and it can be macroscopically large. The resolution is to put the ground state back by hand:

$$N = n_0 + \frac{V}{\lambda^3} g_{3/2}(z),$$

where the integral now accounts for the excited states only. For $T > T_c$ we can solve for $z < 1$ with n_0 negligible. For $T < T_c$ the excited states can only hold

$$N_{\text{ex}} = \frac{V}{\lambda^3} \zeta(3/2) = N \left(\frac{T}{T_c} \right)^{3/2}$$

particles, using $\lambda \propto T^{-1/2}$ and the definition of T_c ; and the rest have nowhere to go but the ground state.

Proposition 42.3.8 (Bose–Einstein condensation)

For $T < T_c$, a macroscopic fraction of the particles occupies the single-particle ground state:

$$\frac{n_0}{N} = 1 - \left(\frac{T}{T_c} \right)^{3/2}.$$

This macroscopically occupied ground state is called the **Bose–Einstein conden-**

sate.

Note the shape. Just below the transition, writing $T = T_c(1 - \delta)$ and expanding gives $n_0/N \approx \frac{3}{2}\delta$, so the condensate fraction grows linearly out of T_c with slope $\frac{3}{2}$; and it reaches 1 at $T = 0$, where every particle is in the ground state. The chemical potential, meanwhile, is negative above T_c and pinned to zero below it:

What is remarkable about this is that it is a genuine phase transition – a discontinuity in the derivative of a thermodynamic function – occurring in a gas of *non-interacting* particles. It is driven purely by quantum statistics. Physically, the condition $N\lambda^3/V \sim 1$ says the transition happens when the thermal wavelengths of the particles begin to overlap, at which point they can no longer be thought of as separate objects.

The thermodynamics below T_c is easy, because the condensate contributes nothing to the energy (its particles have $E = 0$) or the pressure. Setting $z = 1$,

$$E = \frac{V}{\lambda^3} kT \cdot \frac{3}{2} g_{5/2}(1), \quad g_{5/2}(1) = \zeta(5/2) \approx 1.342,$$

so, using $\lambda \propto T^{-1/2}$, we get $E \propto VT^{5/2}$ and hence

$$C_V = \left(\frac{\partial E}{\partial T} \right)_V \propto VT^{3/2}.$$

So the heat capacity vanishes as $T^{3/2}$, in contrast to the classical constant $\frac{3}{2}Nk$. Moreover $p = \frac{2}{3}E/V \propto T^{5/2}$ is independent of V – if we compress a condensate at fixed temperature, the pressure does not rise, because the extra particles simply join the condensate. This is precisely analogous to the behaviour of a vapour in equilibrium with its liquid, and it is one of several respects in which the condensate behaves like a separate phase.

Example 42.3.9 (Superfluid helium)

Liquid ^4He , whose atoms are bosons, undergoes a transition at 2.17 K below which it becomes a **superfluid**: it flows without viscosity, creeps up the walls of its container,

and conducts heat extraordinarily well. Putting the density of liquid helium into our formula gives $T_c \approx 3.1$ K, which is the right order of magnitude – encouraging, given that liquid helium is a strongly interacting system and our calculation assumed no interactions at all. By contrast ^3He , whose atoms are fermions, shows no such transition at these temperatures (it does become superfluid, but at 2.5 mK, and by a quite different mechanism involving pairs of atoms).

§42.3.6 Fermions and the Degenerate Fermi Gas

Now the other case. For fermions the occupation function is

$$\langle n(E) \rangle = \frac{1}{e^{\beta(E-\mu)} + 1},$$

and there is no convergence constraint on μ , which may be positive or negative. The behaviour at low temperature is completely different from the bosonic case, and is dominated by the exclusion principle.

Consider first $T = 0$ exactly. Then $\beta \rightarrow \infty$, and

$$\langle n(E) \rangle \rightarrow \begin{cases} 1 & E < \mu, \\ 0 & E > \mu. \end{cases}$$

So the particles fill up the energy levels from the bottom, one per state, until they run out. This is exactly what one would expect from the Pauli principle.

Definition 42.3.10 (Fermi energy)

The **Fermi energy** E_F is the chemical potential at zero temperature, $E_F = \mu(T = 0)$; equivalently, it is the energy of the highest occupied state at $T = 0$. The corresponding momentum $k_F = \sqrt{2mE_F}/\hbar$ is the **Fermi momentum**, and the sphere $|\mathbf{k}| = k_F$ in momentum space is the **Fermi surface**.

We can compute E_F by counting. For spin- $\frac{1}{2}$ fermions there are two states per wavevector, so

$$N = 2 \cdot \frac{V}{(2\pi)^3} \cdot \frac{4}{3}\pi k_F^3 = \frac{V k_F^3}{3\pi^2} \implies E_F = \frac{\hbar^2}{2m} \left(\frac{3\pi^2 N}{V} \right)^{2/3}.$$

The total energy at $T = 0$ is

$$E_{\text{tot}} = \int_0^{E_F} E g(E) dE = \frac{3}{5} N E_F,$$

using $g(E) \propto \sqrt{E}$, and hence, by the relation $pV = \frac{2}{3} E_{\text{tot}}$,

$$p = \frac{2N E_F}{5V} \propto \left(\frac{N}{V} \right)^{5/3}.$$

This is **degeneracy pressure**, and it is a purely quantum effect: a Fermi gas at absolute zero exerts an enormous pressure, not because the particles are hot, but because they cannot all sit in the ground state.

At small but non-zero temperature, the step is smoothed over a width of order kT around μ :

This picture is the key to everything. Only the fermions within about kT of the Fermi surface can be excited at all; those deep inside cannot move, because all the nearby states are occupied. So of the N particles, only a fraction $\sim T/T_F$ participate in thermal physics, where $kT_F = E_F$ defines the **Fermi temperature**. Each of those carries $\sim kT$ of thermal energy, so

$$E_{\text{tot}} \approx \frac{3}{5}NE_F + N\frac{T}{T_F}kT \implies C_V \sim Nk\frac{T}{T_F}.$$

A more careful calculation, using the **Sommerfeld expansion** (which exploits the fact that $-\partial \langle n \rangle / \partial E$ is sharply peaked at μ), gives the exact coefficient:

$$C_V = \frac{\pi^2}{2}Nk\frac{T}{T_F} + O(T^3).$$

The essential point is that $C_V \propto T$, linearly, and is suppressed by a factor T/T_F relative to the classical value $\frac{3}{2}Nk$.

Example 42.3.11 (Electrons in metals)

The conduction electrons in a metal form a Fermi gas of density $N/V \sim 10^{29} \text{ m}^{-3}$, giving E_F of a few electronvolts and hence $T_F \sim 10^4\text{--}10^5 \text{ K}$. Room temperature is therefore *extremely* cold for the electrons: $T/T_F \sim 10^{-2}$, and the gas is highly degenerate.

This resolves an old puzzle. In the nineteenth century it was known that metals conduct heat and electricity because they contain free electrons; but classically those electrons should contribute $\frac{3}{2}Nk$ to the heat capacity, and no such contribution was observed. The answer is that the electronic heat capacity is suppressed by $T/T_F \sim 10^{-2}$, and is thus swamped by the phonons at ordinary temperatures. At very low temperature, though, the phonon contribution dies as T^3 while the electronic one dies only as T , so the electrons win. Indeed for a metal at low temperature

$$C \approx \gamma T + \alpha T^3,$$

and plotting C/T against T^2 gives a straight line – which is exactly what is measured.

Example 42.3.12 (White dwarf stars)

A star supports itself against gravity by thermal pressure, generated by nuclear fusion. When the fuel runs out, the star collapses – and for a star of modest mass the collapse is halted by the degeneracy pressure of its electrons. The result is a

white dwarf: an object of roughly the mass of the Sun compressed to the size of the Earth.

We can estimate the equilibrium radius by balancing energies. The gravitational energy of a ball of mass M and radius R is $E_{\text{grav}} \sim -GM^2/R$. The star contains $N \sim M/m_p$ nucleons and a comparable number of electrons, so the electron density is $n \sim N/R^3$ and the degeneracy energy is

$$E_{\text{deg}} \sim NE_F \sim N \frac{\hbar^2}{m_e} \left(\frac{N}{R^3} \right)^{2/3} = \frac{\hbar^2 N^{5/3}}{m_e R^2}.$$

Minimising $E_{\text{grav}} + E_{\text{deg}}$ over R gives

$$R \sim \frac{\hbar^2}{Gm_e m_p^{5/3} M^{1/3}},$$

so, curiously, heavier white dwarfs are *smaller*. Putting in the numbers for $M = M_\odot$ gives R of a few thousand kilometres, which is right.

The relation $R \propto M^{-1/3}$ cannot continue indefinitely. As M increases, R falls, the density rises, and eventually the electrons become relativistic. For an ultrarelativistic gas $E = \hbar ck$, and repeating the computation gives $E_{\text{deg}} \sim \hbar c N^{4/3}/R$ – which scales as $1/R$, exactly like the gravitational energy. The two therefore compete on equal terms, and if M exceeds a critical value gravity wins and there is no equilibrium at all. This is the **Chandrasekhar limit**, about $1.4M_\odot$; heavier remnants collapse to neutron stars or black holes.

§42.3.7 Pauli Paramagnetism

As a final application, consider what happens when we put a Fermi gas in a magnetic field B . Each electron has a magnetic moment, so the energy of an electron of momentum $\mathbf{k}$ is

$$E_{\pm} = \frac{\hbar^2 k^2}{2m} \pm \mu_B B,$$

where $\mu_B = e\hbar/2m_e$ is the Bohr magneton and the sign depends on whether the spin is aligned or anti-aligned. Classically, one would expect the moments to align with the field, giving a susceptibility that diverges as $T \rightarrow 0$ (Curie's law $\chi \propto 1/T$). What actually happens is quite different.

The two spin species have shifted densities of states, $g_{\pm}(E) = \frac{1}{2}g(E \mp \mu_B B)$. The magnetisation is

$$M = \mu_B(N_- - N_+) = \mu_B \int_0^\infty dE \frac{g_-(E) - g_+(E)}{e^{\beta(E-\mu)} + 1}.$$

For small B we expand $g(E \mp \mu_B B) \approx g(E) \mp \mu_B B g'(E)$, so

$$M \approx \mu_B^2 B \int_0^\infty dE \frac{g'(E)}{e^{\beta(E-\mu)} + 1} \approx \mu_B^2 B g(E_F)$$

at low temperature, where the last step integrates by parts and uses the fact that $-\partial \langle n \rangle / \partial E$ is a sharp spike at E_F . So the susceptibility is

$$\chi = \frac{\partial M}{\partial B} \approx \mu_B^2 g(E_F),$$

which is a *constant*, independent of temperature. This is **Pauli paramagnetism**, and the physical reason is by now familiar: only the electrons within kT of the Fermi surface can flip their spins, since the others have nowhere to flip to.

§42.4 Classical Thermodynamics

We now change our point of view entirely. Everything so far has been built up from microscopic foundations: we postulated things about microstates and derived macroscopic consequences. Classical thermodynamics does the opposite. It was developed in the nineteenth century, largely by people trying to build better steam engines, at a time when the atomic hypothesis was still controversial. It makes no assumptions whatsoever about what matter is made of. Instead it starts from a small number of laws, abstracted from experience, and deduces an astonishing amount from them.

This is a strength, not a weakness. Because thermodynamics assumes so little, its conclusions are extraordinarily robust: they apply equally to gases, magnets, black holes and the early universe. Einstein described it as the only physical theory of universal content which he was convinced would never be overthrown. What we have gained from statistical mechanics is an understanding of *why* the laws hold; but the laws themselves stand on their own.

§42.4.1 The Zeroth and First Laws

We begin with some vocabulary. A thermodynamic system is separated from its surroundings by a **wall**, and the properties of the wall determine what can be exchanged.

Definition 42.4.1

A wall is **adiabatic** if it permits no heat to flow through it, and **diathermal** otherwise. A system is in **equilibrium** if its macroscopic variables do not change in time.

The first law we need is so obvious that it was not written down until the others already had numbers.

Law 42.4.2 (Zeroth Law of Thermodynamics)

If system A is in equilibrium with system B , and B is in equilibrium with C , then A is in equilibrium with C .

That is: ‘being in equilibrium with’ is a transitive – indeed an equivalence – relation on systems. This is exactly what is needed to make temperature a meaningful concept: the equivalence classes can be labelled by a number, which we call the temperature, and two systems are in equilibrium precisely when their labels agree. Note that the zeroth law does not tell us *which* labelling to use; any monotone relabelling would do. Fixing the scale requires more, and we will see that the second law does it for us.

Law 42.4.3 (First Law of Thermodynamics)

The change in energy of a system is

$$\Delta E = \mathrm{d}Q + \mathrm{d}W,$$

where $\mathrm{d}Q$ is the heat supplied to the system and $\mathrm{d}W$ is the work done on it.

The content of the first law is that E is a **function of state** – it depends only on the current macroscopic state of the system, not on how the system got there – whereas Q and W separately are not. The notation d is a reminder of this: $\mathrm{d}Q$ is a small amount of heat, not the change in some quantity ‘ Q ’, and it is not an exact differential. Only their sum is.

Definition 42.4.4

A change is **quasi-static** if it is performed slowly enough that the system remains in equilibrium throughout. It is **reversible** if it is quasi-static and can be run backwards, returning both the system and its surroundings to their original states.

For a quasi-static change of a gas, the work done on the system is $\mathrm{d}W = -p \, \mathrm{d}V$, so the first law reads

$$\mathrm{d}E = \mathrm{d}Q - p \, \mathrm{d}V.$$

Comparing with the result $\mathrm{d}E = T \, \mathrm{d}S - p \, \mathrm{d}V$ from statistical mechanics, we see that for a reversible change $\mathrm{d}Q = T \, \mathrm{d}S$. This is the microscopic meaning of heat: heat is the transfer of energy that changes the entropy.

§42.4.2 The Second Law

The second law is the interesting one. Historically it was stated in two apparently quite different ways.

Law 42.4.5 (Kelvin’s Second Law)

There is no thermodynamic process whose sole effect is to extract heat from a reservoir and convert it entirely into work.

Law 42.4.6 (Clausius’s Second Law)

There is no thermodynamic process whose sole effect is to transfer heat from a colder body to a hotter body.

The words ‘sole effect’ are doing a great deal of work in both statements. It is perfectly possible to convert heat entirely into work – an ideal gas expanding isothermally does exactly that – but only at the cost of leaving the gas in an expanded state, which is a change in the world. Likewise a refrigerator moves heat from cold to hot, but only by consuming electricity.

Proposition 42.4.7

Kelvin’s statement and Clausius’s statement are equivalent.

Proof. Suppose Kelvin's law fails. Then we have a device that takes heat Q from a hot reservoir and turns it entirely into work $W = Q$. Feed that work into an ordinary refrigerator, which uses it to move heat from a cold reservoir to the hot one. The net effect is a transfer of heat from cold to hot with no other change, contradicting Clausius.

Conversely, suppose Clausius's law fails, so we can move heat Q from cold to hot for free. Run a heat engine between the two reservoirs, extracting Q_h from the hot one, dumping Q_c to the cold one and doing work $W = Q_h - Q_c$. Choosing $Q = Q_c$, the cold reservoir ends up unchanged, and the sole net effect is the extraction of $Q_h - Q_c$ from the hot reservoir, converted entirely to work. This contradicts Kelvin. $\square$

Both are of course consequences of the statistical statement 'entropy increases', but it is worth appreciating how different they look. The nineteenth-century statements are about what machines cannot do; the statistical statement is about counting.

§42.4.3 Carnot Cycles and Efficiency

A **heat engine** operates in a cycle, extracting heat Q_h from a hot reservoir at T_h , doing work W , and dumping heat Q_c into a cold reservoir at T_c . Since the engine returns to its initial state each cycle, its energy is unchanged, so $W = Q_h - Q_c$.

Definition 42.4.8 (Efficiency)

The **efficiency** of a heat engine is

$$\eta = \frac{W}{Q_h} = 1 - \frac{Q_c}{Q_h}.$$

Kelvin's law says $\eta < 1$: we cannot dispense with the cold reservoir. But we can do much better than that, and the answer is one of the great results of the subject.

Definition 42.4.9 (Carnot cycle)

A **Carnot cycle** is a reversible cycle consisting of four steps: an isothermal expansion at T_h , an adiabatic expansion from T_h to T_c , an isothermal compression at T_c , and an adiabatic compression back to T_h .

For an ideal gas we can draw this explicitly. On a pV diagram the isotherms are $pV = \text{const}$ and the adiabats are $pV^\gamma = \text{const}$ with $\gamma > 1$, so the adiabats are steeper.

The same cycle is far more revealing on a TS diagram, where the isotherms are horizontal (constant T) and the adiabats are vertical (constant S , since $dQ = T dS = 0$). The Carnot cycle is simply a rectangle.

From this picture the efficiency is immediate. The heat absorbed on $A \rightarrow B$ is $Q_h = T_h \Delta S$, the heat dumped on $C \rightarrow D$ is $Q_c = T_c \Delta S$ with the same ΔS , and the work done is the enclosed area $(T_h - T_c) \Delta S$. So

$$\eta = 1 - \frac{T_c}{T_h}.$$

And this, it turns out, is the best possible.

Theorem 42.4.10 (Carnot's Theorem)

Of all engines operating between two reservoirs at temperatures $T_h > T_c$, a reversible engine is the most efficient; and all reversible engines have the same efficiency,

$$\eta_{\text{Carnot}} = 1 - \frac{T_c}{T_h}.$$

Proof. Let E be any engine and E_R a reversible one, both operating between the same two reservoirs. Since E_R is reversible, we may run it backwards as a refrigerator. Arrange the two so that all the work produced by E is used to drive E_R in reverse; and choose the sizes of the two engines so that this is exactly the work required, that is,

$$W = Q_h - Q_c = Q'_h - Q'_c,$$

where unprimed quantities refer to E and primed to E_R . Combined, the pair extracts $Q_h - Q'_h$ from the hot reservoir and dumps $Q_c - Q'_c$ into the cold one, with no net work. By Clausius's law we cannot be pumping heat from cold to hot, so

$$Q_h - Q'_h \geq 0.$$

But then

$$\eta = \frac{W}{Q_h} \leq \frac{W}{Q'_h} = \eta_R,$$

so E is no more efficient than E_R . If E is itself reversible we may run the argument the other way round to get $\eta_R \leq \eta$, and hence $\eta = \eta_R$: all reversible engines are equally efficient. Since this common efficiency cannot depend on the working substance, we may compute it with an ideal gas, which gives $1 - T_c/T_h$ as above. $\square$

Two things are worth extracting from this. First, the efficiency of a reversible engine

depends *only* on the two temperatures. That means we can use it to define a temperature scale, with no reference to any particular substance: this is the **absolute** or **thermodynamic** temperature scale, and it is what makes the second law able to fix the arbitrariness left by the zeroth law. It agrees, as we have seen, with $1/T = \partial S/\partial E$.

Secondly, real engines fall well short of Carnot. A power station with $T_h \approx 800$ K and $T_c \approx 300$ K has $\eta_{\text{Carnot}} \approx 0.63$; real efficiencies are around 0.4. The gap is the price of running the cycle in finite time, which necessarily makes it irreversible.

Example 42.4.11 (Carnot cycle for an ideal gas)

Let us verify the efficiency directly, which is a good exercise in using the first law. On the isotherm $A \rightarrow B$ at temperature T_h , the energy of an ideal gas does not change, so all the heat absorbed goes into work:

$$Q_h = \int_{V_A}^{V_B} p \, dV = NkT_h \int_{V_A}^{V_B} \frac{dV}{V} = NkT_h \log \frac{V_B}{V_A}.$$

Similarly $Q_c = NkT_c \log(V_C/V_D)$. On an adiabat $dQ = 0$, so $C_V \, dT = -p \, dV = -NkT \, dV/V$, which integrates to $TV^{Nk/C_V} = \text{const}$. Applying this to $B \rightarrow C$ and $D \rightarrow A$,

$$T_h V_B^{Nk/C_V} = T_c V_C^{Nk/C_V}, \quad T_h V_A^{Nk/C_V} = T_c V_D^{Nk/C_V},$$

and dividing gives $V_B/V_A = V_C/V_D$. Hence the two logarithms agree and

$$\eta = 1 - \frac{Q_c}{Q_h} = 1 - \frac{T_c}{T_h}$$

as promised.

§42.4.4 Entropy as a Function of State

We have been using entropy freely, having defined it microscopically. Thermodynamics can define it too, and the argument is elegant. For a Carnot cycle, $Q_h/T_h = Q_c/T_c$; being careful about signs (counting heat absorbed as positive), this reads

$$\frac{Q_h}{T_h} + \frac{Q_c}{T_c} = 0,$$

i.e. the sum of Q/T around the cycle vanishes. This turns out to be true for any reversible cycle, since any cycle can be approximated by a patchwork of small Carnot cycles whose internal edges cancel. In the limit,

$$\oint_{\text{rev}} \frac{dQ}{T} = 0.$$

More generally, for an irreversible cycle one finds **Clausius's inequality**

$$\oint \frac{dQ}{T} \leq 0,$$

which follows by comparing with a reversible engine as in Carnot's theorem.

Now, a quantity whose integral around every closed loop vanishes is the differential of a function of state. So we may define, relative to some fixed reference state O ,

$$S(A) = \int_O^A \frac{dQ}{T},$$

the integral being along any reversible path from O to A , and the result is independent of the path.

Definition 42.4.12 (Entropy, thermodynamically)

The **entropy** of a state A is $S(A) = \int_O^A \mathrm{d}Q/T$ along any reversible path, defined up to an additive constant.

That is a rather remarkable construction: $\mathrm{d}Q$ is not an exact differential, but dividing by T makes it one. ($1/T$ is what a mathematician would call an integrating factor.) With this definition, the first law for a reversible change becomes

$$\mathrm{d}E = T \mathrm{d}S - p \mathrm{d}V,$$

recovering the equation we derived microscopically – but now with no atoms anywhere in sight.

Finally, Clausius’s inequality gives us the second law in its familiar form. For an irreversible change from A to B , close the loop with a reversible path from B back to A ; then

$$\int_A^B \frac{\mathrm{d}Q}{T} + \int_B^A \frac{\mathrm{d}Q_{\text{rev}}}{T} \leq 0 \implies \int_A^B \frac{\mathrm{d}Q}{T} \leq S(B) - S(A).$$

For an isolated system $\mathrm{d}Q = 0$, so $S(B) \geq S(A)$: entropy never decreases.

§42.4.5 Thermodynamic Potentials and Maxwell Relations

The relation $\mathrm{d}E = T \mathrm{d}S - p \mathrm{d}V + \mu \mathrm{d}N$ says that E is naturally a function of S , V and N : these are its **natural variables**, and given $E(S, V, N)$ we can recover everything else by differentiating. The trouble is that S is not a variable we can control in the laboratory. We would much rather work with T .

The tool for changing variables in this way is the **Legendre transform**, which readers will have met in the Variational Principles course (and again in Lagrangian mechanics, where it takes us from the Lagrangian to the Hamiltonian). Recall that if $f = f(x)$ and we set $p = \mathrm{d}f/\mathrm{d}x$, then the transform $g(p) = px - f(x)$ satisfies $\mathrm{d}g = x \mathrm{d}p$, so g is naturally a function of p . Applying this to E in each of its variables generates the family of **thermodynamic potentials**.

Definition 42.4.13 (Thermodynamic potentials)

Define

energy:	$E = E(S, V, N),$	$\mathrm{d}E = T \mathrm{d}S - p \mathrm{d}V + \mu \mathrm{d}N,$
Helmholtz free energy:	$F = E - TS,$	$\mathrm{d}F = -S \mathrm{d}T - p \mathrm{d}V + \mu \mathrm{d}N,$
enthalpy:	$H = E + pV,$	$\mathrm{d}H = T \mathrm{d}S + V \mathrm{d}p + \mu \mathrm{d}N,$
Gibbs free energy:	$G = E + pV - TS,$	$\mathrm{d}G = -S \mathrm{d}T + V \mathrm{d}p + \mu \mathrm{d}N,$
grand potential:	$\Phi = E - TS - \mu N,$	$\mathrm{d}\Phi = -S \mathrm{d}T - p \mathrm{d}V - N \mathrm{d}\mu.$

Each is adapted to a different experimental situation: F for a system at fixed T and V , G for fixed T and p (which is what a chemist working in an open beaker has), H for fixed S and p , and Φ for a system that can exchange particles. And in each case the

relevant potential is minimised in equilibrium, by the same argument we gave for F in Section 1.9.

The Gibbs free energy has a special property worth isolating. It is extensive and its natural variables T and p are both intensive apart from N , so as in Section 1.11 we must have $G = Ng(T, p)$ for some intensive g . But $(\partial G/\partial N)_{T,p} = \mu$, and so

$$\mu(T, p) = \frac{G}{N},$$

the Gibbs free energy per particle. We will use this in the next section.

Now for the Maxwell relations, which are perhaps the most useful pieces of pure book-keeping in physics. They come from the equality of mixed partial derivatives. For instance, from $dE = T dS - p dV$ we read off $T = (\partial E/\partial S)_V$ and $-p = (\partial E/\partial V)_S$, and therefore

$$\frac{\partial^2 E}{\partial V \partial S} = \frac{\partial^2 E}{\partial S \partial V} \implies \left(\frac{\partial T}{\partial V} \right)_S = - \left(\frac{\partial p}{\partial S} \right)_V.$$

Doing the same for each potential in turn gives the following.

Proposition 42.4.14 (Maxwell relations)

At fixed N ,

$$\begin{aligned} \left(\frac{\partial T}{\partial V} \right)_S &= - \left(\frac{\partial p}{\partial S} \right)_V, & \left(\frac{\partial S}{\partial V} \right)_T &= \left(\frac{\partial p}{\partial T} \right)_V, \\ \left(\frac{\partial T}{\partial p} \right)_S &= \left(\frac{\partial V}{\partial S} \right)_p, & \left(\frac{\partial S}{\partial p} \right)_T &= - \left(\frac{\partial V}{\partial T} \right)_p, \end{aligned}$$

coming from E , F , H and G respectively.

These are not obvious statements. The second, for example, relates how the entropy responds to a change in volume – which is hard to measure – to how the pressure responds to a change in temperature – which is easy. The general moral is that if you find yourself needing a derivative of S , a Maxwell relation will usually convert it into something measurable.

Example 42.4.15

Let us use a Maxwell relation to compute how the energy of a gas depends on its volume at fixed temperature. From $dE = T dS - p dV$,

$$\left(\frac{\partial E}{\partial V} \right)_T = T \left(\frac{\partial S}{\partial V} \right)_T - p = T \left(\frac{\partial p}{\partial T} \right)_V - p,$$

using the second Maxwell relation. For an ideal gas, $p = NkT/V$ gives $T(\partial p/\partial T)_V = NkT/V = p$, so $(\partial E/\partial V)_T = 0$: the energy of an ideal gas depends only on temperature, which we knew, but which we have now derived from the equation of state alone. For a van der Waals gas, $p = NkT/(V - bN) - aN^2/V^2$ gives

$$\left(\frac{\partial E}{\partial V} \right)_T = \frac{aN^2}{V^2} > 0,$$

so expanding a real gas at fixed temperature costs energy – as it should, since we

are pulling apart mutually attracting molecules. This is the origin of the cooling one feels when a gas expands freely, which is the principle behind refrigeration.

§42.4.6 The Third Law

For completeness, one more law.

Law 42.4.16 (Third Law of Thermodynamics)

As $T \rightarrow 0$, the entropy of a system tends to a universal constant, which may be taken to be zero:

$$\lim_{T \rightarrow 0} S = 0.$$

Microscopically this is transparent. As $T \rightarrow 0$ the system falls into its ground state, and $S = k \log \Omega$ where Ω is the ground state degeneracy. For a typical system Ω is 1 or some small number, so $S \rightarrow 0$ or at worst to something of order k , which is negligible compared with Nk .

The third law has real consequences. Since $S(T) = \int_0^T C(T') dT'/T'$ must converge, we need $C(T) \rightarrow 0$ as $T \rightarrow 0$ – which rules out equipartition at low temperature and is consistent with everything we found in Section 42.3.3. It also implies that absolute zero cannot be reached in finitely many steps: any cooling process relies on entropy differences between two configurations of the system, and these differences vanish as $T \rightarrow 0$.

§42.5 Phase Transitions

We come to the last part of the course. A **phase transition** is a discontinuous change in the properties of a system as we vary a parameter continuously: water freezes, iron becomes magnetic, helium becomes superfluid. Mathematically, it shows up as a non-analyticity of a thermodynamic potential.

That, at first sight, ought to be impossible. The partition function $Z = \sum_n e^{-\beta E_n}$ is a sum of analytic functions of β , and for a finite system it is a finite sum, hence analytic; so $F = -kT \log Z$ is analytic and nothing dramatic can ever happen. The escape is that phase transitions occur only in the *thermodynamic limit* $N \rightarrow \infty$, where the sum becomes infinite and analyticity can fail. This is a genuine subtlety, and it means that a phase transition is an emergent property of large systems, invisible in any finite one.

We will study two examples in detail – the liquid–gas transition and the Ising model of a magnet – which look as though they have nothing whatever to do with each other. They will turn out to behave identically near their critical points. Explaining why is the last thing we do.

§42.5.1 The Liquid–Gas Transition

We return to the van der Waals equation of Section 42.2.8, written in terms of the volume per particle $v = V/N$:

$$p = \frac{kT}{v - b} - \frac{a}{v^2}.$$

We derived this for a dilute gas, where it is a small correction. We now take it seriously for all $v > b$, which is completely unjustified, and see what happens. The answer is that it produces a liquid–gas transition, which is a good deal more than it deserves.

Here are the isotherms.

There are two regimes, separated by a critical temperature T_c . For $T > T_c$ the isotherms decrease monotonically, as one expects of a gas. For $T < T_c$ they have a wiggle: a local minimum and a local maximum, so that there is a range of pressures at which three different volumes are possible at the same T and p . At $T = T_c$ the two turning points merge into a point of inflection, which locates the critical point:

$$\left(\frac{\partial p}{\partial v}\right)_T = \left(\frac{\partial^2 p}{\partial v^2}\right)_T = 0.$$

Solving these two equations gives

$$v_c = 3b, \quad kT_c = \frac{8a}{27b}, \quad p_c = \frac{a}{27b^2}.$$

Derivation. From $p = kT/(v - b) - a/v^2$ we get

$$\frac{\partial p}{\partial v} = -\frac{kT}{(v - b)^2} + \frac{2a}{v^3}, \quad \frac{\partial^2 p}{\partial v^2} = \frac{2kT}{(v - b)^3} - \frac{6a}{v^4}.$$

Setting both to zero and dividing one by the other eliminates kT and gives $v - b = \frac{2}{3}v$, so $v_c = 3b$. Substituting back into the first gives $kT_c = 2a(v_c - b)^2/v_c^3 = 8a/27b$, and then $p_c = a/27b^2$. $\square$

It is worth noting the dimensionless combination

$$\frac{p_c v_c}{kT_c} = \frac{3}{8} = 0.375,$$

which is independent of a and b and hence a universal prediction of the model for all substances. Measured values range from about 0.28 to 0.31 – the right ballpark, given how crude the model is.

Let us interpret the three solutions on a sub-critical isotherm, which we label L , U and G in order of increasing v .

At U we have $(\partial p / \partial v)_T > 0$. Such a state is unstable: expand it slightly and the pressure rises, pushing it to expand further; compress it slightly and it collapses. So U is not physical. At L we have v close to b , so the molecules are close-packed, and $|\partial p / \partial v|$ is large, so the substance is hard to compress – this is a **liquid**. At G we have $v \gg b$ and small $|\partial p / \partial v|$: a **gas**. Notice that above T_c there is no distinction between the two at all; one can pass continuously from liquid to gas by going around the critical point, which is why one cannot really say where the boundary between them lies.

§42.5.2 Phase Equilibrium and the Maxwell Construction

So what does the system actually do at a pressure where three solutions exist? There is a fourth possibility we have not considered: part of the substance could be liquid and part gas.

To decide, work at fixed T and p , so the relevant potential is the Gibbs free energy G , and recall that $\mu = G/N$. If $\mu_L > \mu_G$, then the system lowers its free energy by converting liquid into gas, so we end up with pure gas; if $\mu_L < \mu_G$ we get pure liquid. Only if

$$\mu_L = \mu_G$$

can the two coexist, and then they can coexist in any proportion.

We can compute μ along an isotherm. From $dG = -S dT + V dp + \mu dN$ at fixed T, N we have $(\partial \mu / \partial p)_T = v$, so

$$\mu(p) = \mu(p_0) + \int_{p_0}^p v dp'$$

along the isotherm. The condition $\mu_L = \mu_G$ therefore reads

$$\int_L^G v dp = 0,$$

the integral being taken along the van der Waals curve through the unstable region. Integrating by parts, this is equivalent to a statement about areas.

Proposition 42.5.1 (Maxwell construction)

The coexistence pressure p_* at temperature $T < T_c$ is the pressure at which the horizontal line $p = p_*$ cuts the van der Waals isotherm into two lobes of *equal area*.

Proof. Let v_L and v_G be the outer intersections of $p = p_*$ with the isotherm. Then

$$0 = \int_L^G v \, dp = [vp]_L^G - \int_{v_L}^{v_G} p \, dv = p_*(v_G - v_L) - \int_{v_L}^{v_G} p \, dv,$$

since p takes the same value p_* at both endpoints. So $\int_{v_L}^{v_G} p \, dv = p_*(v_G - v_L)$: the area under the isotherm equals the area under the horizontal line. Subtracting the common part, the lobe above the line and the lobe below it have equal areas. $\square$

The physical isotherm is therefore not the van der Waals curve at all: it is flat between v_L and v_G . In that region the substance is a mixture of liquid at v_L and gas at v_G , in whatever proportions make the average volume come out right. This is exactly what one sees when boiling a kettle: adding heat at fixed pressure converts liquid to gas at *constant temperature*, and the temperature only rises again once all the liquid is gone. The latent heat $L = T(s_G - s_L)$ per particle is the entropy difference between the two phases.

If we plot the locus of (v_L, p_*) and (v_G, p_*) as T varies we obtain the **coexistence curve**, which meets the critical point from below:

Inside the green curve the substance separates into two phases; outside it there is a single phase.

Finally, the phases are related by the **Clausius–Clapeyron equation**, which we can now derive in three lines. Along the coexistence line in the (p, T) plane we have $\mu_L(T, p) = \mu_G(T, p)$, so moving along it,

$$d\mu_L = d\mu_G \implies -s_L \, dT + v_L \, dp = -s_G \, dT + v_G \, dp,$$

using the Gibbs–Duhem relation per particle, where $s = S/N$. Hence

$$\frac{dp}{dT} = \frac{s_G - s_L}{v_G - v_L} = \frac{L}{T(v_G - v_L)}.$$

Since $v_G > v_L$ and $L > 0$ for boiling, the boiling point rises with pressure – which is why a pressure cooker works. For water freezing, unusually, $v_{\text{ice}} > v_{\text{water}}$, so the melting curve slopes the other way and ice melts under pressure.

§42.5.3 Critical Exponents

Phase transitions come in two flavours.

Definition 42.5.2

A phase transition is **first order** if the first derivatives of the relevant thermodynamic potential are discontinuous, and **second order** (or continuous) if the first derivatives are continuous but some higher derivative is not.

Boiling at $T < T_c$ is first order: the volume $v = (\partial\mu/\partial p)_T$ and the entropy $s = -(\partial\mu/\partial T)_p$ both jump, the latter jump being the latent heat. But if we heat the system along the critical isochore $v = v_c$, the jump shrinks to nothing as $T \rightarrow T_c$, and at the critical point itself the transition is second order. Second-order transitions are the interesting ones, because at such a point the system has no characteristic length scale, and this turns out to make the behaviour universal.

Near the critical point, quantities vanish or diverge as powers of $|T - T_c|$, and the powers are called **critical exponents**. The standard four are defined by

$$c_V \sim |T - T_c|^{-\alpha}, \quad v_G - v_L \sim (T_c - T)^\beta, \quad \left(\frac{\partial p}{\partial v}\right)_{T_c} \sim |v - v_c|^{\delta-1}, \quad \kappa \sim |T - T_c|^{-\gamma},$$

where $\kappa = -v^{-1}(\partial v/\partial p)_T$ is the compressibility. (The clash of notation between the exponent β and $1/kT$ is unfortunate and universal; context will always make clear which is meant.)

Let us compute them for van der Waals. It is convenient to use **reduced variables**

$$\bar{p} = \frac{p}{p_c}, \quad \bar{v} = \frac{v}{v_c}, \quad \bar{T} = \frac{T}{T_c},$$

in terms of which the equation of state becomes

$$\bar{p} = \frac{8\bar{T}}{3\bar{v} - 1} - \frac{3}{\bar{v}^2},$$

with no free parameters at all. This is the **law of corresponding states**: all van der Waals fluids are the same fluid in disguise, and their critical behaviour is identical. (Experimentally this works remarkably well for the noble gases.)

Now expand about the critical point, writing $\bar{T} = 1 + t$ and $\bar{v} = 1 + \epsilon$ with t, ϵ small. A somewhat tedious Taylor expansion gives

$$\bar{p} = 1 + 4t - 6t\epsilon - \frac{3}{2}\epsilon^3 + O(t\epsilon^2, \epsilon^4).$$

From this everything follows.

- *The exponent δ .* On the critical isotherm $t = 0$ we have $\bar{p} - 1 = -\frac{3}{2}\epsilon^3$, so $p - p_c \propto (v - v_c)^3$ and $\delta = 3$.
- *The exponent β .* For $t < 0$, the Maxwell construction requires the coexisting volumes to be symmetric about v_c (which follows from the fact that the above expansion is odd in ϵ at fixed t , so the equal-area condition is met by $\epsilon_G = -\epsilon_L$). Setting $\bar{p}(\epsilon_L) = \bar{p}(\epsilon_G)$ with $\epsilon_G = -\epsilon_L$ gives

$$-6t\epsilon_G - \frac{3}{2}\epsilon_G^3 = 6t\epsilon_G + \frac{3}{2}\epsilon_G^3 \implies \epsilon_G^2 = -4t,$$

so $v_G - v_L \propto (T_c - T)^{1/2}$ and $\beta = \frac{1}{2}$.

- *The exponent γ .* Differentiating, $\partial\bar{p}/\partial\epsilon = -6t - \frac{9}{2}\epsilon^2$. Approaching from above along $\epsilon = 0$ gives $\kappa^{-1} \propto t$; from below along $\epsilon^2 = -4t$ gives $\kappa^{-1} \propto -12t$. Either way $\kappa \propto |t|^{-1}$ and $\gamma = 1$.
- *The exponent α .* One can show that c_V jumps by a finite amount at T_c but does not diverge, so $\alpha = 0$.

Proposition 42.5.3

The van der Waals equation predicts the critical exponents

$$\alpha = 0, \quad \beta = \frac{1}{2}, \quad \gamma = 1, \quad \delta = 3.$$

The measured values, for a wide range of real fluids, are approximately

$$\alpha \approx 0.11, \quad \beta \approx 0.32, \quad \gamma \approx 1.24, \quad \delta \approx 4.8.$$

So the van der Waals prediction is wrong. But notice *how* it is wrong: the experimental values are the same for every fluid. This universality is the deep phenomenon, and it is much more interesting than the failure of any particular model. Hold that thought.

§42.5.4 The Ising Model

We now change subject entirely, to a model of a magnet. Take a d -dimensional lattice of N sites; on each site i put a ‘spin’ variable

$$s_i = \pm 1,$$

and let the energy be

$$E[\{s_i\}] = -J \sum_{\langle ij \rangle} s_i s_j - B \sum_i s_i,$$

where $\sum_{\langle ij \rangle}$ runs over nearest-neighbour pairs, B is an external magnetic field (we set the magnetic moment to 1) and J measures the strength of the interaction. If $J > 0$ neighbouring spins prefer to align, and the material is a **ferromagnet**; if $J < 0$ they prefer to anti-align, an **antiferromagnet**. We take $J > 0$.

In one dimension the lattice and its neighbours are obvious. In two dimensions, on a square lattice, each site has $q = 4$ nearest neighbours:

The physics is a competition. The energy term wants all the spins aligned, since that minimises $-J \sum s_i s_j$. The entropy wants them randomised, since there are vastly more disordered configurations than ordered ones. Which wins depends on the temperature, and the transition between the two regimes is the phase transition we are after.

The quantity to watch is the average spin.

Definition 42.5.4 (Magnetisation)

The **magnetisation** is

$$m = \frac{1}{N} \sum_i \langle s_i \rangle = \frac{1}{N\beta} \left(\frac{\partial \log Z}{\partial B} \right)_T,$$

where $Z = \sum_{\{s_i\}} e^{-\beta E[\{s_i\}]}$.

Before doing any work, it is worth noting that the Ising model is secretly a model of a gas as well. Consider particles on a lattice, with $n_i \in \{0, 1\}$ particles per site and an attractive nearest-neighbour interaction,

$$E[\{n_i\}] = -4J \sum_{\langle ij \rangle} n_i n_j.$$

In the grand canonical ensemble we weight by $e^{-\beta(E - \mu \sum_i n_i)}$. Substituting $n_i = (s_i + 1)/2$ turns this into the Ising energy with

$$B = \frac{\mu}{2} + qJ,$$

so that $\mathcal{Z}_{\text{gas}} = Z_{\text{Ising}}$. The liquid–gas transition and the ferromagnetic transition are, in this ‘lattice gas’ caricature, literally the same problem. That is our first hint of universality.

Can we compute Z ? In $d = 1$, yes, and we will do it in Section 42.5.6. In $d = 2$ with $B = 0$, yes, but the solution (Onsager, 1944) is a tour de force. In $d = 3$, nobody knows. So we need an approximation.

§42.5.5 Mean Field Theory

The difficulty is the interaction term, which couples the spins together. The idea of **mean field theory** is to replace the influence of a spin’s neighbours by their average, turning the problem into N independent single-spin problems.

Concretely, write $s_i = m + (s_i - m)$ and expand:

$$s_i s_j = (s_i - m)(s_j - m) + m(s_i + s_j) - m^2,$$

and then *assume the first term is negligible* – that is, that the fluctuations of neighbouring spins are uncorrelated. This is the whole approximation, and it is a serious one; note that it is not the claim that $\langle (s_i - m)^2 \rangle$ is small, since in fact $\langle (s_i - m)^2 \rangle = 1 - m^2$ which need not be small at all. It is the claim that the *correlations* between different sites are negligible.

Granting it, the energy becomes

$$E \approx -J \sum_{\langle ij \rangle} (m(s_i + s_j) - m^2) - B \sum_i s_i = \frac{1}{2} J N q m^2 - (J q m + B) \sum_i s_i,$$

where q is the number of nearest neighbours and the factor $\frac{1}{2} N q$ counts the bonds. The spins have decoupled! Each now sees an **effective field**

$$B_{\text{eff}} = B + J q m,$$

and we are back to the two-state system of Section 1.4. The partition function is

$$Z = e^{-\frac{1}{2} \beta J N q m^2} (e^{\beta B_{\text{eff}}} + e^{-\beta B_{\text{eff}}})^N = e^{-\frac{1}{2} \beta J N q m^2} 2^N \cosh^N(\beta B + \beta J q m).$$

But m was defined as an average, so we cannot simply leave it in the answer; we must impose consistency, $m = (N\beta)^{-1}(\partial \log Z / \partial B)_T$. Doing so gives the central equation of mean field theory.

Proposition 42.5.5 (Mean field equation)

$$m = \tanh(\beta B + \beta J q m).$$

This is a transcendental equation which we cannot solve in closed form, but we can solve it graphically. Set $B = 0$ and plot both sides against m . The left side is the straight line $y = m$; the right is $y = \tanh(\beta J q m)$, an S-shaped curve with slope $\beta J q$ at the origin. Everything hinges on whether that slope exceeds 1.

If $\beta J q < 1$ the $\tanh$ curve starts below the line and stays below it, so the only solution is $m = 0$: the spins are disordered, and entropy has won. If $\beta J q > 1$ the $\tanh$ curve starts above the line, and there are three solutions, $m = 0$ and $m = \pm m_0(T)$. The critical temperature is where the slope is exactly one.

Definition 42.5.6

The mean field critical temperature is defined by $\beta_c Jq = 1$, that is,

$$kT_c = Jq.$$

For $T < T_c$ the solution $m = 0$ is unstable – differentiating the mean field equation with respect to B and setting $B = 0$,

$$\left(\frac{\partial m}{\partial B} \right)_T \Big|_{m=0} = \frac{\beta}{1 - \beta Jq} < 0,$$

which is nonsense for a paramagnetic response, so the state is not physical. That leaves $\pm m_0(T)$, the two being related by flipping every spin. So below T_c the system spontaneously magnetises, and it must choose one of two directions; this is **spontaneous symmetry breaking**. Plotting m_0 against T :

At $T = 0$ all spins align and $m_0 = \pm 1$; as T increases m_0 falls, reaching zero at T_c . The manner in which it does so is the critical exponent β , and we can extract it by Taylor expanding. Using $\tanh x \approx x - \frac{1}{3}x^3$ for small x ,

$$m_0 \approx \beta Jq m_0 - \frac{1}{3}(\beta Jq m_0)^3 = \frac{T_c}{T} m_0 - \frac{1}{3} \left(\frac{T_c}{T} \right)^3 m_0^3,$$

so dividing by m_0 and rearranging,

$$m_0^2 = 3 \left(\frac{T}{T_c} \right)^3 \left(\frac{T_c}{T} - 1 \right) \approx 3 \frac{T_c - T}{T_c}$$

near T_c . Hence

$$m_0 \sim (T_c - T)^{1/2}, \quad \beta = \frac{1}{2},$$

which is exactly the exponent we found for van der Waals. That is not a coincidence, and explaining it is the business of the next section but one.

For completeness, the other exponents follow similarly. Turning on a small field B at $T > T_c$ and expanding the mean field equation gives

$$m \approx \beta B + \beta Jq m \implies m = \frac{\beta B}{1 - \beta Jq} \implies \chi = \frac{\partial m}{\partial B} \propto \frac{1}{T - T_c},$$

so $\gamma = 1$. At $T = T_c$ exactly, the linear terms cancel and we must go to cubic order, giving $m \propto B^{1/3}$ and $\delta = 3$. And the heat capacity jumps discontinuously without diverging, so $\alpha = 0$. The full set

$$\alpha = 0, \quad \beta = \frac{1}{2}, \quad \gamma = 1, \quad \delta = 3$$

agrees exactly with van der Waals, and disagrees with experiment in exactly the same way.

§42.5.6 The One-Dimensional Ising Model

Mean field theory predicts a phase transition in every dimension. In one dimension it is simply wrong, and it is instructive to see why, because the exact solution is easy.

Take N spins in a ring, with $s_{N+1} = s_1$, and set $B = 0$ for simplicity. Then

$$Z = \sum_{\{s_i\}} \exp \left(\beta J \sum_{i=1}^N s_i s_{i+1} \right) = \sum_{\{s_i\}} \prod_{i=1}^N e^{\beta J s_i s_{i+1}}.$$

The trick is to write this as a matrix product. Define the 2×2 **transfer matrix**

$$T = \begin{pmatrix} e^{\beta J} & e^{-\beta J} \\ e^{-\beta J} & e^{\beta J} \end{pmatrix}, \quad T_{ss'} = e^{\beta J s s'},$$

indexing rows and columns by $s = \pm 1$. Then the sum over configurations is exactly the trace of a product:

$$Z = \sum_{s_1, \dots, s_N} T_{s_1 s_2} T_{s_2 s_3} \cdots T_{s_N s_1} = \text{tr} (T^N).$$

The eigenvalues of T are $\lambda_{\pm} = e^{\beta J} \pm e^{-\beta J}$, i.e. $\lambda_+ = 2 \cosh \beta J$ and $\lambda_- = 2 \sinh \beta J$, so

$$Z = \lambda_+^N + \lambda_-^N = \lambda_+^N \left(1 + \left(\frac{\lambda_-}{\lambda_+} \right)^N \right) \rightarrow \lambda_+^N$$

as $N \rightarrow \infty$, since $\lambda_- < \lambda_+$. Hence

$$F = -kT \log Z = -NkT \log(2 \cosh \beta J),$$

which is a perfectly analytic function of T for all $T > 0$. There is no phase transition in one dimension.

The physical reason is worth understanding, and is due to Peierls. Start from the fully aligned state and consider flipping a whole block of spins. This creates two domain walls, at an energy cost of $4J$ regardless of the size of the block; but the walls can be placed in about N^2 ways, so the entropy gain is $k \log N^2$. The free energy change is

$$\Delta F = 4J - 2kT \log N,$$

which is negative for large N at any $T > 0$. So it is always favourable to break up the ordered state: order is destroyed by fluctuations in one dimension. In two or more dimensions a domain wall costs an energy proportional to its length, and the argument fails – which is why the transition survives.

This should make us suspicious of mean field theory, and rightly so. Mean field theory becomes exact in high dimensions (above $d = 4$, in fact), and becomes worse as the dimension falls, because it is precisely the fluctuations it neglects that matter most in low dimensions.

§42.5.7 Landau Theory

We have now seen two systems – the van der Waals fluid and the mean field Ising magnet – which have nothing physically in common and yet produce identical critical exponents. Landau theory explains this, and does so by throwing away essentially all of the physics.

Look back at what happened in mean field theory. We had a free energy depending on a parameter m ,

$$\tilde{F}(T, B; m) = \frac{1}{2} J N q m^2 - N k T \log(2 \cosh(\beta B + \beta J q m)),$$

and we found the physical value of m by imposing self-consistency. But one can check directly that

$$\left(\frac{\partial \tilde{F}}{\partial m} \right)_{T, B} = 0 \iff m = \tanh(\beta B + \beta J q m),$$

so the self-consistency condition is exactly the statement that m *minimises* $\tilde{F}$. That is the observation Landau theory is built on.

Definition 42.5.7 (Order parameter)

An **order parameter** is a quantity m which vanishes in the disordered phase and is non-zero in the ordered phase.

For a magnet the order parameter is the magnetisation; for a fluid near its critical point it is $\rho - \rho_c$, the deviation of the density from its critical value.

The recipe of **Landau theory** is then:

- (i) identify an order parameter m ;
- (ii) write down a free energy $\tilde{F}(T; m)$, assumed to be an *analytic* function of m and T and to respect the symmetries of the problem;
- (iii) declare that the equilibrium states are the minima of $\tilde{F}$ over m .

That is all. Notice how little input there is – no Hamiltonian, no lattice, no interactions.

Suppose the system has a symmetry $m \mapsto -m$ (as the Ising model does at $B = 0$). Then $\tilde{F}$ is even in m , and analyticity lets us expand

$$\tilde{F}(T; m) = F_0(T) + a(T)m^2 + b(T)m^4 + \dots$$

The constant F_0 is irrelevant. Assume $b(T) > 0$, so that $\tilde{F}$ is bounded below. Then everything depends on the sign of $a(T)$.

If $a > 0$, the only minimum is at $m = 0$: the disordered phase. If $a < 0$, then $m = 0$ becomes a local maximum and two minima appear at $\pm m_0$: the ordered phase.

So a phase transition occurs at the temperature T_c where $a(T_c) = 0$, and near it we may write

$$a(T) = a_0(T - T_c), \quad b(T) = b_0 > 0,$$

assuming a simple zero. Minimising over m for $T < T_c$ gives

$$m_0 = \sqrt{\frac{-a}{2b}} = \sqrt{\frac{a_0}{2b_0}} (T_c - T)^{1/2},$$

so $\beta = \frac{1}{2}$ once again – and now we can see exactly where it came from. It came from the fact that we truncated an even analytic function at fourth order. Nothing else. The van der Waals fluid, the Ising magnet and any other system whose free energy is a smooth even function of its order parameter must produce $\beta = \frac{1}{2}$, whatever the underlying physics. *That* is the origin of universality.

Substituting back gives the free energy itself,

$$F(T) = \begin{cases} F_0(T) & T > T_c, \\ F_0(T) - \frac{a_0^2(T - T_c)^2}{4b_0} & T < T_c, \end{cases}$$

which is continuous at T_c , as is its first derivative $S = -dF/dT$; but the second derivative, and hence

$$C = T \frac{dS}{dT} = -T \frac{d^2F}{dT^2},$$

jumps by $a_0^2 T_c / 2b_0$. So this is a second-order transition, with $\alpha = 0$. All four exponents come out as before.

Of course, the exponents are wrong. The reason is that we assumed $\tilde{F}$ is analytic in m , which amounts to assuming the system is well described by a single uniform order parameter – exactly the assumption mean field theory made, and exactly the one that fails near a critical point, where fluctuations occur on all length scales. Repairing this is the business of **Landau–Ginzburg theory**, in which m is promoted to a field $m(\mathbf{x})$ and one integrates over its fluctuations, and ultimately of the renormalisation group, which is beyond this course. What Landau theory does give us, cheaply, is a qualitative understanding of *why* phase transitions happen and *why* unrelated systems share critical behaviour.

§42.5.8 First Order Transitions in Landau Theory

Finally, let us see how first-order transitions fit into this picture. There are two ways they arise.

The first is by breaking the symmetry explicitly. In the Ising model with $B \neq 0$, the free energy is no longer even in m ; instead it satisfies $\tilde{F}(T, B; m) = \tilde{F}(T, -B; -m)$, so the expansion acquires odd terms,

$$\tilde{F} = F_0(T, B) + F_1(T, B)m + F_2(T, B)m^2 + \dots,$$

with F_n odd or even in B according as n is odd or even. At low temperature there are two local minima, and a small $B > 0$ tilts the potential so that the right-hand one is the global minimum G , the left-hand one a metastable state M , and the maximum between them the unstable state U . As B passes through zero the two minima swap roles, and the equilibrium m jumps discontinuously from $-m_0$ to $+m_0$:

$$\lim_{B \rightarrow 0^+} m(T, B) = +m_0(T), \quad \lim_{B \rightarrow 0^-} m(T, B) = -m_0(T).$$

That is a first-order transition, occurring as we sweep B at fixed $T < T_c$ – and it is the exact analogue of the liquid–gas transition as we sweep p at fixed T , with the metastable state M corresponding to a supercooled vapour or superheated liquid.

The second mechanism keeps the symmetry but changes the sign of the quartic term. Suppose $b(T) < 0$; then we must keep the sixth-order term to have a free energy bounded below,

$$\tilde{F} = am^2 - bm^4 + cm^6, \quad b, c > 0.$$

Now as we lower a from large positive values, the following happens. For large a there is a single minimum at $m = 0$. For a slightly less than $b^2/3c$, two subsidiary minima appear at non-zero m , but they are higher than the one at the origin, so they are metastable. At

$$a_* = \frac{b^2}{4c}$$

all three minima have exactly the same depth, and below that the outer ones win. So at $a = a_*$ the equilibrium value of m jumps discontinuously from 0 to $\pm\sqrt{b/2c}$: a first-order transition.

The middle (purple) curve is the transition itself: three degenerate minima, which is the Landau-theoretic signature of first-order behaviour, and the analogue of the three-fold coexistence we saw for the van der Waals fluid. Notice that here, unlike the second-order case, the order parameter is already of finite size when the transition occurs; there is no small parameter, no divergent correlation length, and consequently no universality.

First-order transitions are, in this sense, much less interesting than second-order ones – which is a curious inversion of the usual state of affairs in physics, where the discontinuous thing is normally the dramatic one.

§42.5.9 A Last Word

It is worth stepping back. We began with a postulate about counting microstates, and from it we derived temperature, entropy and the laws of thermodynamics; we computed the properties of gases, the spectrum of starlight, the heat capacity of crystals and the structure of white dwarfs; and we ended with a theory of phase transitions in which the microscopic details do not matter at all. That last point deserves emphasis. The reason the van der Waals fluid and the Ising magnet share critical exponents is that near a critical point the correlation length diverges, the system loses all memory of its lattice spacing or molecular size, and only the symmetry and dimensionality survive. Understanding this properly – the renormalisation group – is one of the genuinely great ideas of twentieth-century physics, and this course is the natural place to start.

43 Stochastic Financial Models

Financial markets are, from a mathematician's point of view, a rather remarkable object of study. They are made of people, and people are not easy to axiomatise. And yet if we grant ourselves a single principle – that one cannot make something out of nothing – then a startling amount of structure falls out. Prices of complicated derivative securities are pinned down exactly by the prices of simple ones; the 'right' probability measure to compute with turns out not to be the one describing what will actually happen; and the whole edifice rests on the theory of martingales.

This course is really two courses braided together. One strand is economic: how should an agent with preferences choose a portfolio, and what does market equilibrium look like? The other strand is probabilistic: conditional expectation, martingales, optional stopping, Brownian motion, and a first look at stochastic calculus. The two strands meet in the *fundamental theorem of asset pricing*, which says that a market admits no arbitrage precisely when there is an equivalent measure making discounted prices into martingales. Everything after that theorem is, in one way or another, a computation of a conditional expectation.

This article constitutes my notes for the 'Stochastic Financial Models' course, held in Michaelmas 2021 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§43.1 The One-Period Market

Before we can prove anything, we need a model. The models in this course are deliberately, almost offensively, simple; the justification is that even the simplest of them already produces the Black–Scholes formula, and that the qualitative conclusions turn out to be robust.

§43.1.1 Standing Assumptions

We shall work throughout under the following idealisations, which we state once and then quietly forget.

- (i) *No transaction costs.* Buying and selling are free.
- (ii) *Infinite divisibility.* We may hold any real number of units of any asset, not just an integer number.
- (iii) *No bid–ask spread.* There is one price at which an asset may be both bought and sold.
- (iv) *No price impact* (‘linear pricing’). Buying 2θ units costs exactly twice as much as buying θ units, however large θ is. Our trading does not move the market.
- (v) *No short-selling constraints.* We may hold a negative number of units of an asset.
- (vi) *Borrowing and lending at the same rate.* There is a riskless bank account paying interest at rate r , and we may deposit into it or borrow from it freely.

Assumption (iv) is the one doing the most work, and it is also the one most obviously false: if you try to buy every share in a company you will find the price moves against you. But without it there is no hope of a linear theory, and linearity is what makes everything computable.

§43.1.2 Portfolios and Wealth

Our basic market has d **risky assets**, whose prices at time t we write as a random vector

$$S_t = (S_t^1, \dots, S_t^d)^\top.$$

For the moment there are only two times, $t = 0$ and $t = 1$; this is the **one-period model**. The price S_0 is known at time 0, and S_1 is a random vector whose distribution we assume known. In addition there is a **riskless asset** (asset 0, the bank account) which turns one pound at time 0 into $1 + r$ pounds at time 1.

Definition 43.1.1 (Portfolio)

A **portfolio** is a vector $\theta = (\theta^1, \dots, \theta^d)^\top \in \mathbb{R}^d$, where θ^i is the number of units of asset i held between time 0 and time 1, together with a number $\theta^0 \in \mathbb{R}$ of pounds in the bank.

If $\theta^i > 0$ we say the agent is **long** asset i ; if $\theta^i < 0$ the agent is **short** it, meaning that they have borrowed the asset and sold it, and must return it at time 1.

Let X_t denote the agent's wealth at time t , with $X_0 = x$ given. Since the portfolio must be paid for out of the initial wealth, we have the **budget constraint**

$$X_0 = \theta^0 + \theta^\top S_0.$$

At time 1 the bank deposit has grown and the shares are worth $\theta^\top S_1$, so

$$X_1 = \theta^0(1+r) + \theta^\top S_1 = (1+r)(X_0 - \theta^\top S_0) + \theta^\top S_1.$$

Rearranging gives an expression which will be with us for the rest of the course:

$$X_1 = (1+r)X_0 + \theta^\top (S_1 - (1+r)S_0).$$

In other words – the wealth at time 1 is what you would have got by leaving everything in the bank, plus a term measuring how much better the risky assets did than the bank. We give that term a name.

Definition 43.1.2 (Excess return)

The **excess return vector** of the market is

$$\xi = S_1 - (1+r)S_0 \in \mathbb{R}^d.$$

So $X_1 = (1+r)X_0 + \theta^\top \xi$, and the whole of the one-period theory is really the study of the random vector ξ . Note that ξ is genuinely random – it is the only randomness in the model – and that the map $\theta \mapsto \theta^\top \xi$ is linear. Almost every theorem below is a statement about the linear subspace $\{\theta^\top \xi : \theta \in \mathbb{R}^d\}$ of random variables.

We write $\mathcal{X}(x) = \{(1+r)x + \theta^\top \xi : \theta \in \mathbb{R}^d\}$ for the set of **attainable** time-1 wealths starting from initial wealth x . This is an affine subspace of the space of random variables.

Remark. It is worth pausing to note what has *not* been assumed. We have not assumed that the agent knows anything about S_1 beyond its distribution, and we have certainly not assumed that this distribution is correct. Estimating it is a large industry (and something you might recognise from Part IB Statistics); it is not our concern here.

§43.1.3 A First Example

Let us immediately do a computation, so that the abstractions have something to hang on.

Example 43.1.3 (A one-period binomial market)

Take $d = 1$, interest rate $r = 0$, and $S_0 = 5$. Suppose S_1 takes the value 7 or the value 4, each with probability $\frac{1}{2}$. Consider a **call option** with strike $K = 6$: this is the right, but not the obligation, to buy one share at time 1 for the price 6. If $S_1 = 7$ we exercise the right and make 1; if $S_1 = 4$ we do not, and make 0. So the payout is

$$Y = (S_1 - K)^+ = \begin{cases} 1 & \text{if } S_1 = 7, \\ 0 & \text{if } S_1 = 4. \end{cases}$$

What is this option worth at time 0? A first guess might be $\mathbb{E}Y = \frac{1}{2}$. That guess is wrong, and the reason it is wrong is the whole point of the course.

Observe that $Y = \frac{1}{3}(S_1 - 4)$: indeed $\frac{1}{3}(7 - 4) = 1$ and $\frac{1}{3}(4 - 4) = 0$. So if at time

0 we buy $\frac{1}{3}$ of a share and borrow $\frac{4}{3}$ from the bank, our time-1 wealth is exactly $\frac{1}{3}S_1 - \frac{4}{3} = Y$, whatever happens. The cost of setting this up is

$$\frac{1}{3} \cdot 5 - \frac{4}{3} = \frac{5}{3} - \frac{4}{3} = \frac{1}{3}.$$

So a portfolio costing $\frac{1}{3}$ reproduces the option payout exactly. If the option were sold for more than $\frac{1}{3}$, we could sell the option, set up the portfolio, and pocket the difference with no risk whatsoever; if it were sold for less, we would do the reverse. So the only price consistent with the absence of a free lunch is $\frac{1}{3}$.

There is a second route to the same number. Suppose we pretend the probability of the up-move is q rather than $\frac{1}{2}$, chosen so that the share price is ‘fair’, i.e. $\mathbb{E}_{\mathbb{Q}}[S_1] = (1+r)S_0 = 5$. Then $7q + 4(1-q) = 5$, giving $q = \frac{1}{3}$. And under this measure,

$$\frac{\mathbb{E}_{\mathbb{Q}}[Y]}{1+r} = \frac{1}{3} \cdot 1 + \frac{2}{3} \cdot 0 = \frac{1}{3}.$$

The same answer. That this is not a coincidence is the content of the fundamental theorem of asset pricing, which we prove in §4.

Notice that the true probability $p = \frac{1}{2}$ played no role at all in the answer. This is the single most counterintuitive feature of derivative pricing, and it is worth being clear about why it happens: the option payout is a *deterministic function* of the share price, and the share price is already trading at a known price. All the information about probabilities that we need is already baked into $S_0 = 5$.

§43.2 Mean-Variance Analysis

Our agent has to choose a portfolio θ . On what basis? The oldest quantitative answer, due to Markowitz in 1952, is: get the expected return you want, and take as little risk as possible along the way, where ‘risk’ means variance.

§43.2.1 The Markowitz Problem

Definition 43.2.1 (Mean-variance portfolio problem)

Given initial wealth $X_0 = x$ and a target mean $m \in \mathbb{R}$, the **mean-variance portfolio problem** is to

$$\text{minimise } \text{Var}(X_1) \quad \text{subject to} \quad \mathbb{E}[X_1] = m,$$

over portfolios $\theta \in \mathbb{R}^d$.

Throughout this section we assume that S_1 is square integrable, and we write

$$\mu = \mathbb{E}[S_1], \quad V = \text{Cov}(S_1) = \mathbb{E}[(S_1 - \mu)(S_1 - \mu)^\top].$$

The matrix V is always non-negative definite; we assume in addition that it is *positive* definite, so that V^{-1} exists. (If it is not, some portfolio of the risky assets is riskless, and one should first remove the redundancy.) We also assume $\mu \neq (1+r)S_0$, since otherwise the risky assets offer no expected reward over the bank and the problem is uninteresting.

Since $X_1 = (1+r)x + \theta^\top \xi$ with $\xi = S_1 - (1+r)S_0$, we have

$$\mathbb{E}[X_1] = (1+r)x + \theta^\top (\mu - (1+r)S_0), \quad \text{Var}(X_1) = \theta^\top V \theta.$$

So the problem is: minimise the quadratic form $\theta^\top V \theta$ subject to the affine constraint $\theta^\top (\mu - (1+r)S_0) = m - (1+r)x$. This is a problem you could do with Lagrange multipliers, but there is a slicker argument which also delivers uniqueness for free.

Theorem 43.2.2 (Markowitz)

Write $\nu = \mu - (1+r)S_0$. The mean-variance portfolio problem has the unique solution

$$\theta^* = \lambda V^{-1}\nu, \quad \lambda = \frac{m - (1+r)x}{\nu^\top V^{-1}\nu}.$$

Proof. First, θ^* is feasible: $(\theta^*)^\top \nu = \lambda \nu^\top V^{-1}\nu = m - (1+r)x$, as required.

Now let θ be any other feasible portfolio and set $\epsilon = \theta - \theta^* \neq 0$. Expanding,

$$\theta^\top V \theta = (\theta^*)^\top V \theta^* + 2\epsilon^\top V \theta^* + \epsilon^\top V \epsilon.$$

The cross term vanishes: since both θ and θ^* are feasible, $\epsilon^\top \nu = 0$, and hence

$$\epsilon^\top V \theta^* = \lambda \epsilon^\top V V^{-1}\nu = \lambda \epsilon^\top \nu = 0.$$

As V is positive definite and $\epsilon \neq 0$ we get $\epsilon^\top V \epsilon > 0$, so $\theta^\top V \theta > (\theta^*)^\top V \theta^*$. Hence θ^* is the unique minimiser. $\square$

The vector $V^{-1}\nu$ appearing here is important enough to be named.

Definition 43.2.3 (Market portfolio)

The **market portfolio** is $\theta^{\text{mar}} = V^{-1}(\mu - (1+r)S_0)$, and we write $S_t^{\text{mar}} = (\theta^{\text{mar}})^\top S_t$ for its price.

Corollary 43.2.4 (Mutual fund theorem)

A portfolio is mean-variance efficient if and only if it is a scalar multiple of the market portfolio.

Proof. Immediate from Theorem 43.2.2: the optimal θ^* is $\lambda \theta^{\text{mar}}$, and as m ranges over $\mathbb{R}$, λ ranges over $\mathbb{R}$. $\square$

This is a genuinely striking conclusion. Every investor, no matter how risk-hungry or risk-shy, should hold the risky assets *in the same proportions*; the only thing that distinguishes them is how much they put in the bank. In practice this is the theoretical justification for index funds: if the theory holds, you need exactly two products, a bank account and one fund.

§43.2.2 The Efficient Frontier

As θ ranges over $\mathbb{R}^d$, the pair $(\text{Var}(X_1), \mathbb{E}[X_1])$ traces out a subset of the right half plane. Its left-hand boundary is the object of interest.

Definition 43.2.5 (Efficient frontier)

The **mean-variance efficient frontier** is the set of points

$$\{(\min\{\text{Var}(X_1) : \mathbb{E}[X_1] = m\}, m) : m \in \mathbb{R}\}.$$

A portfolio achieving a point of the frontier is called **mean-variance efficient**.

Corollary 43.2.6 (Shape of the frontier)

In the (v, m) plane the efficient frontier is the parabola

$$v = \frac{(m - (1+r)x)^2}{\nu^\top V^{-1}\nu}, \quad \nu = \mu - (1+r)S_0.$$

Proof. Substituting $\theta^* = \lambda V^{-1}\nu$ into $v = \theta^\top V \theta$ gives $v = \lambda^2 \nu^\top V^{-1}\nu$, and $\lambda = (m - (1+r)x)/(\nu^\top V^{-1}\nu)$. $\square$

It is more usual, and more informative, to plot the frontier in the (σ, m) plane, where $\sigma = \text{sd}(X_1) = \sqrt{v}$ is the standard deviation. Taking square roots in Corollary 43.2.6, the frontier becomes a pair of *straight lines* through the point $(0, (1+r)x)$, of slopes $\pm\sqrt{\nu^\top V^{-1}\nu}$. Only the upper line is of any interest – given a level of risk one wants the larger mean – and it is called the **capital market line**. Its slope

$$\frac{m - (1+r)x}{\sigma} = \sqrt{\nu^\top V^{-1}\nu}$$

is the **Sharpe ratio**, the amount of excess expected return purchased per unit of risk.

If we forbid the agent from using the bank account, and force them to hold only risky assets, then the corresponding frontier is instead a hyperbola in the (σ, m) plane, with a leftmost point (the **minimum-variance portfolio**). The capital market line is tangent to that hyperbola, and the point of tangency is exactly the market portfolio, normalised to cost x . The picture to hold in your head is the following.

The dashed part of the capital market line corresponds to $\lambda < 0$, i.e. to shorting the market portfolio; those portfolios solve the minimisation problem but no sensible agent would choose them.

Corollary 43.2.7

The problem of minimising $\text{Var}(X_1)$ subject to $\mathbb{E}[X_1] \geq m$ has the same solution as the mean-variance problem whenever $m \geq (1+r)x$. If $m < (1+r)x$, the solution is $\theta = 0$.

Proof. If $m \geq (1+r)x$ then the constraint binds, since variance is increasing in $|\lambda|$ and the mean is increasing in λ . If $m < (1+r)x$ then $\theta = 0$ gives $\text{Var}(X_1) = 0$ and $\mathbb{E}[X_1] = (1+r)x \geq m$, which is clearly optimal. $\square$

Remark. Variance is a strange measure of risk. It punishes unexpectedly *good* outcomes exactly as much as unexpectedly bad ones, and it takes no account of the shape of the tail. We will replace it with something better in §3. On the other hand, mean-variance analysis has the enormous advantage of being solvable in closed form, which is why it is still used.

§43.2.3 The Capital Asset Pricing Model

We now ask an equilibrium question: if *everyone* behaves as in the previous section, what do prices look like? The answer is the capital asset pricing model of Sharpe (1964), and its content is that the expected excess return of any asset is determined by a single number, its exposure to the market as a whole.

We begin with an entirely elementary fact, which is just linear regression.

Proposition 43.2.8

Let X, Y be square integrable random variables with $\text{Var}(X) > 0$. Then there are unique constants α, β such that

$$Y = \alpha + \beta X + Z, \quad \mathbb{E}[Z] = 0, \quad \text{Cov}(Z, X) = 0.$$

Explicitly, $\beta = \text{Cov}(X, Y) / \text{Var}(X)$ and $\alpha = \mathbb{E}[Y] - \beta \mathbb{E}[X]$.

Proof. Setting $Z = Y - \alpha - \beta X$, the two conditions read

$$0 = \mathbb{E}[Y] - \alpha - \beta \mathbb{E}[X], \quad 0 = \text{Cov}(Y, X) - \beta \text{Var}(X),$$

which have the unique solution stated. $\square$

Now let us specialise to the market portfolio. Recall $S_t^{\text{mar}} = (\theta^{\text{mar}})^\top S_t$ and write $\xi = S_1 - (1+r)S_0$, $\xi^{\text{mar}} = S_1^{\text{mar}} - (1+r)S_0^{\text{mar}} = (\theta^{\text{mar}})^\top \xi$.

Theorem 43.2.9

Let $B = \text{Cov}(S_1, S_1^{\text{mar}}) / \text{Var}(S_1^{\text{mar}}) \in \mathbb{R}^d$ and set $Z = \xi - B \xi^{\text{mar}}$. Then $\mathbb{E}[Z] = 0$ and $\text{Cov}(Z, S_1^{\text{mar}}) = 0$.

Proof. Write $\nu = \mu - (1+r)S_0 = \mathbb{E}[\xi]$, so $\theta^{\text{mar}} = V^{-1}\nu$. Then

$$\mathbb{E}[\xi^{\text{mar}}] = (\theta^{\text{mar}})^\top \nu = \nu^\top V^{-1}\nu = (\theta^{\text{mar}})^\top V \theta^{\text{mar}} = \text{Var}(S_1^{\text{mar}}),$$

using $V\theta^{\text{mar}} = \nu$. On the other hand

$$\text{Cov}(S_1, S_1^{\text{mar}}) = \text{Cov}(S_1, S_1)\theta^{\text{mar}} = VV^{-1}\nu = \nu = \mathbb{E}[\xi].$$

Therefore $B = \mathbb{E}[\xi]/\mathbb{E}[\xi^{\text{mar}}]$, whence $\mathbb{E}[Z] = \mathbb{E}[\xi] - B\mathbb{E}[\xi^{\text{mar}}] = 0$. Similarly,

$$\text{Cov}(Z, S_1^{\text{mar}}) = \text{Cov}(S_1, S_1^{\text{mar}}) - B\text{Var}(S_1^{\text{mar}}) = \nu - \nu = 0. \quad \square$$

To turn this into an economic statement we need the market to clear. Suppose asset i exists in total supply n^i , write $n = (n^1, \dots, n^d)^\top$, and define the **index return**

$$R^{\text{index}} = \frac{n^\top S_1}{n^\top S_0} - 1,$$

the return on holding the entire market in proportion to supply. Let $R^i = S_1^i/S_0^i - 1$ be the return on asset i .

Axiom 43.2.10 (CAPM assumptions)

There are K investors, with portfolios $\theta^1, \dots, \theta^K$ satisfying **market clearing** $\sum_k \theta^k = n$. Every investor agrees on the values of $\mu = \mathbb{E}[S_1]$ and $V = \text{Cov}(S_1)$ (*uniform beliefs*) and every investor holds a mean-variance efficient portfolio, though possibly with different target means (*uniform preferences*).

Theorem 43.2.11 (Capital asset pricing model)

Under the above assumptions, write the regression

$$R^i - r = \alpha^i + \beta^i(R^{\text{index}} - r) + \epsilon^i, \quad \mathbb{E}[\epsilon^i] = 0, \quad \text{Cov}(R^{\text{index}}, \epsilon^i) = 0,$$

as in Proposition 43.2.8. Then $\alpha^i = 0$ for every i .

Proof. By the mutual fund theorem each investor's portfolio is $\theta^k = \lambda_k \theta^{\text{mar}}$ for some $\lambda_k \in \mathbb{R}$. Market clearing gives $n = (\sum_k \lambda_k) \theta^{\text{mar}}$, so n is a positive multiple of the market portfolio, and therefore

$$R^{\text{index}} = \frac{n^\top S_1}{n^\top S_0} - 1 = \frac{S_1^{\text{mar}}}{S_0^{\text{mar}}} - 1.$$

Now apply Theorem 43.2.9 coordinatewise. Dividing $\xi^i = B^i \xi^{\text{mar}} + Z^i$ by S_0^i ,

$$R^i - r = \frac{1}{S_0^i} (S_1^i - (1+r)S_0^i) = \frac{B^i S_0^{\text{mar}}}{S_0^i} (R^{\text{index}} - r) + \frac{Z^i}{S_0^i}.$$

Since $\mathbb{E}[Z^i] = 0$ and $\text{Cov}(Z^i, R^{\text{index}}) = 0$, uniqueness in Proposition 43.2.8 identifies $\beta^i = B^i S_0^{\text{mar}}/S_0^i$, $\epsilon^i = Z^i/S_0^i$ and $\alpha^i = 0$. $\square$

So under CAPM the expected excess return on asset i is

$$\mathbb{E}[R^i] - r = \beta^i (\mathbb{E}[R^{\text{index}}] - r),$$

and nothing else about asset i matters. The quantity β^i is a genuinely used piece of market vocabulary. An asset with $\beta = 1.5$ tends to move one and a half times as much

as the market; an asset with $\beta = 0$ is uncorrelated with the market and, however volatile it may be on its own, commands no excess return at all, because its risk can be diversified away.

Remark. It is worth being honest about the assumptions. Uniform beliefs is not plausible: if everyone agreed on μ and V there would be very little trading. Uniform preferences is worse: we have already noted that variance is a poor proxy for risk. And empirically, when one regresses returns against the index, the estimated α 's are not zero – searching for assets with positive α is more or less the definition of active management. Nonetheless CAPM is the standard baseline against which such claims are measured.

§43.3 Utility and Risk Aversion

Mean-variance analysis fixes the mean and minimises variance. This is unsatisfactory in two ways: it does not let an agent trade off return against risk, and variance is the wrong notion of risk. We now set up a framework which does both.

§43.3.1 The Expected Utility Hypothesis

Definition 43.3.1 (Expected utility hypothesis)

Every agent has a **utility function** $U : \mathbb{R} \rightarrow \mathbb{R}$ (or defined on an interval), and prefers a random payout X to a random payout Y – written $X \succ Y$ – if and only if

$$\mathbb{E}[U(X)] > \mathbb{E}[U(Y)].$$

If $\mathbb{E}[U(X)] = \mathbb{E}[U(Y)]$ the agent is **indifferent** between them, written $X \sim Y$.

Two immediate observations. First, if $\tilde{U} = aU + b$ with $a > 0$, then $\tilde{U}$ induces exactly the same preferences as U ; utility functions are only defined up to positive affine transformations, and so ‘utility’ is not a quantity one can meaningfully compare across agents. Second, the criterion depends on X only through its *distribution*, so we may equally think of preferences as an ordering on distribution functions.

Historically the hypothesis was introduced by Daniel Bernoulli to resolve the following puzzle.

Example 43.3.2 (The St. Petersburg paradox)

A fair coin is tossed until it first comes up heads. If this takes n tosses, the casino pays you 2^n pounds. What should you pay to play?

The expected payout is

$$\sum_{n \geq 1} 2^{-n} \cdot 2^n = \sum_{n \geq 1} 1 = \infty,$$

so if one maximises expected wealth one should be willing to pay any finite entry fee. Almost nobody would pay even £100. Bernoulli’s resolution: an agent maximises not expected wealth but expected utility, and if $U(x) = \log x$ then the expected

utility of the game is

$$\sum_{n \geq 1} 2^{-n} \log(2^n) = \log 2 \sum_{n \geq 1} n 2^{-n} = 2 \log 2 = \log 4,$$

so the game is worth exactly £4 to a logarithmic agent. The moral is that a fixed amount of money is worth less to you when you are rich.

A more principled motivation is a representation theorem. Suppose an agent has some preference relation $\succ$ on distribution functions, about which we assume only the following.

Definition 43.3.3 (von Neumann–Morgenstern axioms)

A preference relation $\succ$ on distribution functions satisfies the **von Neumann–Morgenstern axioms** if

- (i) (*Completeness*) for all F, G , exactly one of $F \succ G$, $G \succ F$, $F \sim G$ holds;
- (ii) (*Transitivity*) if $F \succ G$ and $G \succ H$ then $F \succ H$;
- (iii) (*Independence*) if $F \succ G$ and $p \in [0, 1]$ then $pF + (1 - p)H \succ pG + (1 - p)H$ for every H ;
- (iv) (*Continuity*) if $F \succ G \succ H$ then there is $p \in [0, 1]$ with $G \sim pF + (1 - p)H$.

Theorem 43.3.4 (von Neumann–Morgenstern)

If $\succ$ satisfies the above axioms then there exists a function U such that

$$F \succ G \iff \int U \, dF > \int U \, dG.$$

We shall not prove this. The point is that the expected utility hypothesis is not an arbitrary modelling choice: it is forced on us by a short list of conditions each of which looks, at first glance, like a requirement of bare rationality. (The independence axiom is the controversial one, and there is a well-developed literature of experiments in which people violate it.)

§43.3.2 Concavity, Jensen and the Certainty Equivalent

We will almost always assume that U is increasing, and very often that it is concave.

Definition 43.3.5

A utility function U is **increasing** if $X > Y$ almost surely implies $\mathbb{E}[U(X)] > \mathbb{E}[U(Y)]$, and is **concave** if

$$U(px + (1 - p)y) \geq pU(x) + (1 - p)U(y) \quad \text{for all } x, y \in \mathbb{R}, p \in [0, 1].$$

An agent with a concave utility function is called **risk averse**.

If U is twice differentiable then increasing means $U' > 0$ and concave means $U'' \leq 0$. In words: more money is better, but each additional pound is worth slightly less than the

one before.

The connection between concavity and dislike of risk is Jensen's inequality, which you met in Part IA Probability.

Proposition 43.3.6

If U is concave and X is integrable then $\mathbb{E}[U(X)] \leq U(\mathbb{E}[X])$. Hence a risk-averse agent weakly prefers the certain payout $\mathbb{E}[X]$ to the random payout X .

This suggests a way of measuring *how much* an agent dislikes a given gamble.

Definition 43.3.7 (Certainty equivalent)

Let U be increasing and continuous and let X be a payout. The **certainty equivalent** of X is the unique $C(X) \in \mathbb{R}$ with

$$U(C(X)) = \mathbb{E}[U(X)],$$

i.e. the sure amount which the agent values exactly as highly as the gamble. The **risk premium** is $\mathbb{E}[X] - C(X)$.

By Jensen, a risk-averse agent has $C(X) \leq \mathbb{E}[X]$, so the risk premium is non-negative: it is the discount the agent demands for bearing the risk. The whole construction is visible in a single picture. Take $U(x) = \log(1+x)$ and let X take the values 1 and 5 with probability $\frac{1}{2}$ each, so $\mathbb{E}[X] = 3$.

The chord joining the two outcomes lies below the graph; its midpoint has height $\mathbb{E}[U(X)]$, and reading horizontally across to the curve and then down gives the certainty equivalent $C \approx 2.46$. The gap between C and $\mathbb{E}X = 3$ is the risk premium, and it is exactly the vertical gap between the chord and the curve, transported through U . A more concave utility bends the curve further away from the chord and so demands a larger premium.

§43.3.3 Arrow–Pratt Risk Aversion

To make ‘more concave’ precise we want a number. The obvious candidate $-U''$ is not good, because U is only defined up to positive affine transformations and $-U''$ is not invariant under $U \mapsto aU + b$. Dividing by U' fixes this.

Definition 43.3.8 (Arrow–Pratt coefficients)

Let U be twice differentiable with $U' > 0$. The **coefficient of absolute risk aversion** at x is

$$A(x) = -\frac{U''(x)}{U'(x)},$$

and the **coefficient of relative risk aversion** at x is

$$R(x) = -\frac{xU''(x)}{U'(x)} = xA(x).$$

Both are invariant under $U \mapsto aU + b$ for $a > 0$, as they should be. The interpretation is the following: if an agent with wealth x is offered a small gamble with mean zero and variance σ^2 , then a second-order Taylor expansion gives

$$\mathbb{E}[U(x + \epsilon)] \approx U(x) + \frac{1}{2}U''(x)\sigma^2, \quad U(x - \pi) \approx U(x) - U'(x)\pi,$$

so the risk premium is $\pi \approx \frac{1}{2}A(x)\sigma^2$. Absolute risk aversion measures the premium demanded for a gamble of a fixed size; relative risk aversion measures the premium for a gamble proportional to wealth.

Two families of utility functions are singled out by asking for these coefficients to be constant.

Example 43.3.9 (CARA utility)

A utility with **constant absolute risk aversion** $\gamma > 0$ satisfies $-U''/U' = \gamma$, so $(\log U')' = -\gamma$ and $U'(x) = Ce^{-\gamma x}$. Integrating,

$$U(x) = -\frac{C}{\gamma}e^{-\gamma x},$$

and normalising, ‘the’ CARA utility is $U(x) = -e^{-\gamma x}$, defined on all of $\mathbb{R}$.

Example 43.3.10 (CRRA utility)

A utility with **constant relative risk aversion** $R > 0$ satisfies $-xU''/U' = R$, so $(\log U')' = -R/x$ and $U'(x) = Cx^{-R}$ for $x > 0$. If $R \neq 1$, integrating gives

$$U(x) = \frac{x^{1-R}}{1-R}, \quad x > 0,$$

up to affine equivalence. If $R = 1$ the integral produces a logarithm, and we obtain the **logarithmic utility** $U(x) = \log x$, $x > 0$.

Remark. CARA utility has the convenient property that the optimal *amount of money* invested in the risky assets does not depend on wealth; CRRA utility has the property that the optimal *proportion* of wealth invested does not. The latter is closer to how people appear to behave, and CRRA utilities are also the ones that combine well with lognormal models, since $\mathbb{E}[e^{(1-R)Z}]$ is computable for Gaussian Z . Note that CRRA utility with $R > 1$ has $U(x) \rightarrow -\infty$ as $x \downarrow 0$, so such an agent will never accept a strategy which can bankrupt them.

§43.3.4 The Utility Maximisation Problem

We can now pose the central optimisation problem of the one-period theory: given a utility U and initial wealth x ,

$$\text{maximise } \mathbb{E}[U(X_1)] \quad \text{over } X_1 \in \mathcal{X}(x),$$

that is, maximise

$$f(\theta) := \mathbb{E}\left[U((1+r)x + \theta^\top \xi)\right] \quad \text{over } \theta \in \mathbb{R}^d.$$

Theorem 43.3.11 (First-order condition)

Suppose U is differentiable and θ^* is optimal, with $X_1^* = (1+r)x + (\theta^*)^\top \xi$. Suppose further that differentiation under the expectation is justified. Then

$$\mathbb{E}[U'(X_1^*) \xi] = 0, \quad \text{i.e.} \quad \mathbb{E}[U'(X_1^*)(S_1 - (1+r)S_0)] = 0.$$

Proof. The function f is differentiable with $\nabla f(\theta) = \mathbb{E}[U'((1+r)x + \theta^\top \xi) \xi]$, provided we may exchange ∇ and $\mathbb{E}$; this is justified by dominated convergence when, for instance, U is concave and differentiable and $U((1+r)x + \theta^\top \xi)$ is integrable for all θ in a neighbourhood of θ^* . Since θ^* is an interior maximum (there are no constraints), $\nabla f(\theta^*) = 0$. $\square$

Note that if U is concave then f is concave, so the first-order condition is sufficient as well as necessary. The equation says that the marginal utility of the optimal wealth is ‘orthogonal’ to every excess return, which is exactly the statement that no small perturbation of the portfolio helps.

§43.3.5 State Price Densities

The first-order condition can be rewritten in a way that removes all mention of the agent, and this turns out to be the key to everything that follows.

Definition 43.3.12 (State price density)

A **state price density** (or **pricing kernel**) is an almost surely positive random variable Z with

$$\mathbb{E}[Z] = \frac{1}{1+r} \quad \text{and} \quad \mathbb{E}[ZS_1] = S_0.$$

The name ‘pricing kernel’ is transparent: multiplying by Z and taking expectations converts time-1 prices into time-0 prices. Note the first condition is just the second applied to the bank account, whose time-1 value is the constant $1+r$.

To see why it is called a *state price* density, consider a market on $\Omega = \{\omega_1, \dots, \omega_d\}$ in which asset i is the **Arrow–Debreu security** paying $S_1^i = \mathbb{1}_{\{\omega_i\}}$, i.e. one pound if state i occurs and nothing otherwise. Then $\mathbb{E}[ZS_1^i] = Z(\omega_i)\mathbb{P}(\{\omega_i\}) = S_0^i$, so

$$Z(\omega_i) = \frac{S_0^i}{\mathbb{P}(\{\omega_i\})}.$$

So Z is the price of a pound delivered in state ω_i , per unit of probability – a density of state prices with respect to $\mathbb{P}$.

Theorem 43.3.13

In the setting of Theorem 43.3.11, suppose additionally that $U' > 0$ and $\mathbb{E}[U'(X_1^*)] < \infty$. Then

$$Z = \frac{U'(X_1^*)}{(1+r) \mathbb{E}[U'(X_1^*)]}$$

is a state price density.

Proof. Certainly $Z > 0$ and $\mathbb{E}[Z] = 1/(1+r)$. For the second condition, Theorem 43.3.11 gives $\mathbb{E}[U'(X_1^*)(S_1 - (1+r)S_0)] = 0$, i.e.

$$\mathbb{E}[U'(X_1^*)S_1] = (1+r)S_0 \mathbb{E}[U'(X_1^*)].$$

Dividing by $(1+r)\mathbb{E}[U'(X_1^*)]$ gives $\mathbb{E}[ZS_1] = S_0$. □

So *if* an agent with an increasing utility can solve their optimisation problem, *then* a state price density exists. This is our first sight of the fundamental theorem: the existence of a solution to some agent's problem forces a consistency condition on the market. In §4 we will strip away the agent entirely and find that the correct hypothesis is simply the absence of arbitrage.

§43.4 Arbitrage and the Fundamental Theorem

We now come to the heart of the course. The idea is to eliminate the agent altogether: rather than asking what a particular investor with a particular utility would pay, we ask what prices are consistent with the impossibility of a free lunch. Remarkably, this is enough to determine prices exactly in a wide class of models.

§43.4.1 Equivalent Measures

We first need a small amount of measure-theoretic machinery for changing probability measures.

Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space and let Y be an almost surely positive random variable with $\mathbb{E}_{\mathbb{P}}[Y] = 1$. Define

$$\mathbb{Q}(A) = \mathbb{E}_{\mathbb{P}}[Y\mathbb{1}_A], \quad A \in \mathcal{F}.$$

Then $\mathbb{Q}(\Omega) = 1$ and countable additivity follows from monotone convergence, so $\mathbb{Q}$ is a probability measure. Moreover, since $Y > 0$ almost surely, $\mathbb{Q}(A) = 0$ if and only if $\mathbb{P}(A) = 0$.

Definition 43.4.1 (Equivalent measures)

Two probability measures $\mathbb{P}, \mathbb{Q}$ on $(\Omega, \mathcal{F})$ are **equivalent**, written $\mathbb{P} \sim \mathbb{Q}$, if they have the same null sets: $\mathbb{P}(A) = 0 \iff \mathbb{Q}(A) = 0$.

Equivalent measures agree on what is possible and what is impossible; they disagree about how likely the possible things are. Every construction above produces an equivalent measure, and the Radon–Nikodym theorem says that these are the only ones.

Theorem 43.4.2 (Radon–Nikodym)

$\mathbb{P}$ and $\mathbb{Q}$ are equivalent if and only if there is an almost surely positive random variable Y , unique up to null sets, with $\mathbb{Q}(A) = \mathbb{E}_{\mathbb{P}}[Y \mathbb{1}_A]$ for all $A \in \mathcal{F}$.

We write $Y = d\mathbb{Q}/d\mathbb{P}$ and call it the **Radon–Nikodym derivative**, or the **likelihood ratio** – a name which should be familiar from Part IB Statistics, where exactly the same object appears in the Neyman–Pearson lemma. The essential computational fact is that for $\mathbb{Q}$ -integrable Z ,

$$\mathbb{E}_{\mathbb{Q}}[Z] = \mathbb{E}_{\mathbb{P}} \left[\frac{d\mathbb{Q}}{d\mathbb{P}} Z \right],$$

which holds for indicators by definition and in general by the usual approximation argument.

Example 43.4.3

If $\Omega = \{\omega_1, \dots, \omega_n\}$ is finite and $\mathbb{P}(\{\omega_i\}) > 0$ for each i , then $\mathbb{P} \sim \mathbb{Q}$ exactly when $\mathbb{Q}(\{\omega_i\}) > 0$ for each i , and

$$\frac{d\mathbb{Q}}{d\mathbb{P}}(\omega_i) = \frac{\mathbb{Q}(\{\omega_i\})}{\mathbb{P}(\{\omega_i\})}.$$

Example 43.4.4 (Changing the mean of a Gaussian)

Let $X \sim N(\mu, \sigma^2)$ under $\mathbb{P}$ and set $Y = e^{X - \mu - \sigma^2/2}$. Then $Y > 0$ and, using the moment generating function of the normal, $\mathbb{E}_{\mathbb{P}}[Y] = e^{-\mu - \sigma^2/2} \mathbb{E}_{\mathbb{P}}[e^X] = 1$. Let $d\mathbb{Q}/d\mathbb{P} = Y$. For bounded measurable f ,

$$\begin{aligned} \mathbb{E}_{\mathbb{Q}}[f(X)] &= \mathbb{E}_{\mathbb{P}}[e^{X - \mu - \sigma^2/2} f(X)] \\ &= \int_{\mathbb{R}} e^{x - \mu - \sigma^2/2} f(x) \frac{1}{\sqrt{2\pi\sigma^2}} e^{-(x - \mu)^2/2\sigma^2} dx \\ &= \int_{\mathbb{R}} f(x) \frac{1}{\sqrt{2\pi\sigma^2}} e^{-(x - \mu - \sigma^2)^2/2\sigma^2} dx, \end{aligned}$$

on completing the square. So under $\mathbb{Q}$ we have $X \sim N(\mu + \sigma^2, \sigma^2)$: the change of measure has shifted the mean and left the variance alone. This little computation is the seed of the Cameron–Martin theorem in §7, and hence of the entire Black–Scholes derivation.

§43.4.2 Risk-Neutral Measures**Definition 43.4.5** (Risk-neutral measure)

A **risk-neutral measure** (or **equivalent martingale measure**) for the one-period market is a probability measure $\mathbb{Q} \sim \mathbb{P}$ with

$$\mathbb{E}_{\mathbb{Q}} \left[\frac{S_1}{1+r} \right] = S_0.$$

Under $\mathbb{Q}$, every asset has the same expected return as the bank account, so a $\mathbb{Q}$ -agent is indifferent between them – hence ‘risk neutral’. The connection with state price densities

is immediate.

Proposition 43.4.6

$\mathbb{Q}$ is a risk-neutral measure if and only if $Z = \frac{1}{1+r} \frac{d\mathbb{Q}}{d\mathbb{P}}$ is a state price density. In particular, state price densities and risk-neutral measures are in bijection.

Proof. If $\mathbb{Q} \sim \mathbb{P}$ with density Y , then $Z = Y/(1+r) > 0$ and $\mathbb{E}_{\mathbb{P}}[Z] = 1/(1+r)$ automatically. Furthermore $\mathbb{E}_{\mathbb{P}}[ZS_1] = \frac{1}{1+r} \mathbb{E}_{\mathbb{Q}}[S_1]$, which equals S_0 precisely when $\mathbb{Q}$ is risk-neutral. Conversely, given a state price density Z , put $Y = (1+r)Z$; then $Y > 0$ and $\mathbb{E}_{\mathbb{P}}[Y] = 1$, so Y defines an equivalent measure $\mathbb{Q}$, which is risk-neutral by the same computation. $\square$

Example 43.4.7 (The one-period binomial model)

Take $d = 1$ and suppose

$$\mathbb{P}(S_1 = (1+b)S_0) = p = 1 - \mathbb{P}(S_1 = (1+a)S_0), \quad a < b, \quad p \in (0, 1).$$

A measure $\mathbb{Q}$ equivalent to $\mathbb{P}$ is determined by $q = \mathbb{Q}(S_1 = (1+b)S_0) \in (0, 1)$, and risk-neutrality demands

$$q(1+b)S_0 + (1-q)(1+a)S_0 = (1+r)S_0 \implies q = \frac{r-a}{b-a}.$$

This lies in $(0, 1)$ if and only if $a < r < b$. So a risk-neutral measure exists exactly when the bank rate lies strictly between the two possible returns on the stock, and then it is unique. Both halves of this statement will be explained by the theorems below.

43.4.3 Arbitrage

Definition 43.4.8 (Arbitrage)

A portfolio $\phi \in \mathbb{R}^d$ is an **arbitrage** if

$$\phi^\top \xi \geq 0 \quad \text{a.s.} \quad \text{and} \quad \mathbb{P}(\phi^\top \xi > 0) > 0,$$

where $\xi = S_1 - (1+r)S_0$. A market with no arbitrage is called **arbitrage-free**.

An arbitrage is a portfolio which costs nothing over and above what the bank would have given you, never loses, and sometimes wins: a free lunch. Note that the definition involves neither a utility function nor an initial wealth, and depends on $\mathbb{P}$ only through its null sets. In particular equivalent measures have exactly the same arbitrages.

Here is the geometry, in the simplest possible case: $d = 1$ and two states ω_1, ω_2 . Identify a random variable with the point of $\mathbb{R}^2$ recording its values in the two states. The attainable excess payoffs form the line $L = \{\theta\xi : \theta \in \mathbb{R}\}$ through the origin, and an arbitrage is a point of L lying in the closed positive quadrant but not at the origin.

On the left the line meets the shaded quadrant only at the origin, and there is a vector q with strictly positive entries orthogonal to L ; normalising q to be a probability vector produces exactly a risk-neutral measure. On the right the line runs into the interior of the quadrant, and every point of the thick segment is an arbitrage; no strictly positive vector can be orthogonal to L . The fundamental theorem is the assertion that this dichotomy is completely general.

Before proving it, let us record the link with the previous section.

Proposition 43.4.9

If the market admits an arbitrage, then no increasing utility function admits an optimal portfolio.

Proof. Let ϕ be an arbitrage and θ any portfolio, with $X_1 = (1+r)x + \theta^\top \xi$ and $\tilde{X}_1 = (1+r)x + (\theta + \phi)^\top \xi$. Then $\tilde{X}_1 \geq X_1$ almost surely, with strict inequality on an event of positive probability. Since U is increasing, $\mathbb{E}[U(\tilde{X}_1)] > \mathbb{E}[U(X_1)]$, so θ was not optimal. $\square$

Combining Proposition 43.4.9 with Theorem 43.3.13: if some agent can solve their optimisation problem then there is no arbitrage, and there is a state price density. The fundamental theorem removes the agent from this chain of reasoning.

§43.4.4 The Fundamental Theorem of Asset Pricing

Theorem 43.4.10 (Fundamental theorem of asset pricing)

The one-period market admits no arbitrage if and only if there exists a risk-neutral measure.

Proof. ($\Leftarrow$) Suppose $\mathbb{Q}$ is risk-neutral and ϕ is an arbitrage. Since $\mathbb{P} \sim \mathbb{Q}$ we have $\phi^\top \xi \geq 0$ $\mathbb{Q}$ -almost surely too. But risk-neutrality says $\mathbb{E}_{\mathbb{Q}}[\xi] = \mathbb{E}_{\mathbb{Q}}[S_1] - (1+r)S_0 = 0$, so

$$\mathbb{E}_{\mathbb{Q}}[\phi^\top \xi] = \phi^\top \mathbb{E}_{\mathbb{Q}}[\xi] = 0.$$

A non-negative random variable with zero expectation vanishes almost surely, so $\phi^\top \xi = 0$ $\mathbb{Q}$ -a.s., hence $\mathbb{P}$ -a.s., contradicting $\mathbb{P}(\phi^\top \xi > 0) > 0$.

($\Rightarrow$) Suppose there is no arbitrage; we construct a risk-neutral measure. We may

make two harmless reductions. First, we may assume the components $\xi^1, \dots, \xi^d$ are linearly independent as random variables: otherwise, discard assets until they are, since a redundant asset contributes nothing new to $\{\theta^\top \xi\}$. Second, we may assume that $\mathbb{E}[e^{-\theta^\top \xi}] < \infty$ for every $\theta \in \mathbb{R}^d$: if not, replace $\mathbb{P}$ by the equivalent measure $\tilde{\mathbb{P}}$ with $d\tilde{\mathbb{P}}/d\mathbb{P} \propto e^{-\|\xi\|^2}$, which has the same arbitrages, and note that $e^{-\theta^\top \xi - \|\xi\|^2}$ is bounded.

Now consider

$$f(\theta) = \mathbb{E}[e^{-\theta^\top \xi}], \quad \theta \in \mathbb{R}^d,$$

which is finite, strictly convex and smooth. Choose (θ_n) with $f(\theta_n) \rightarrow \inf_\theta f(\theta)$.

Case 1: (θ_n) has a bounded subsequence. By Bolzano–Weierstrass we may assume $\theta_n \rightarrow \theta_0$. Continuity of moment generating functions gives $f(\theta_0) = \inf_\theta f$, so θ_0 is a minimiser and

$$\nabla f(\theta_0) = -\mathbb{E}[e^{-\theta_0^\top \xi} \xi] = 0.$$

Setting $d\mathbb{Q}/d\mathbb{P} = e^{-\theta_0^\top \xi} / \mathbb{E}[e^{-\theta_0^\top \xi}]$ defines an equivalent measure (the density is strictly positive) with $\mathbb{E}_{\mathbb{Q}}[\xi] = 0$, i.e. a risk-neutral measure.

Case 2: $\|\theta_n\| \rightarrow \infty$. We derive a contradiction. Put $\phi_n = \theta_n / \|\theta_n\|$; by compactness of the unit sphere we may assume $\phi_n \rightarrow \phi_0$ with $\|\phi_0\| = 1$. We claim $\phi_0^\top \xi \geq 0$ almost surely.

Suppose not, so that $\mathbb{P}(\phi_0^\top \xi < -\epsilon, \|\xi\| < R) > 0$ for some $\epsilon, R > 0$. For n large enough that $\|\phi_n - \phi_0\| \leq \epsilon/(2R)$, on the event $\{\phi_0^\top \xi < -\epsilon, \|\xi\| < R\}$ we have

$$\phi_n^\top \xi = (\phi_n - \phi_0)^\top \xi + \phi_0^\top \xi \leq \|\phi_n - \phi_0\| \|\xi\| + \phi_0^\top \xi \leq \frac{\epsilon}{2} - \epsilon = -\frac{\epsilon}{2}.$$

Since $f(\theta_n) \leq f(0) = 1$ for large n ,

$$1 \geq \mathbb{E}[e^{-\|\theta_n\| \phi_n^\top \xi}] \geq \mathbb{E}[e^{-\|\theta_n\| \phi_n^\top \xi} \mathbb{1}_{\{\phi_0^\top \xi < -\epsilon, \|\xi\| < R\}}] \geq e^{\epsilon \|\theta_n\|/2} \mathbb{P}(\phi_0^\top \xi < -\epsilon, \|\xi\| < R).$$

The right-hand side tends to infinity as $n \rightarrow \infty$, which is absurd. Hence $\phi_0^\top \xi \geq 0$ a.s.

By the absence of arbitrage, $\phi_0^\top \xi \geq 0$ a.s. forces $\phi_0^\top \xi = 0$ a.s. But the ξ^i are linearly independent, so $\phi_0 = 0$, contradicting $\|\phi_0\| = 1$. So Case 2 cannot occur, and we are done. $\square$

Remark. The proof is really a separating hyperplane argument in disguise. The convex function $f(\theta) = \mathbb{E}[e^{-\theta^\top \xi}]$ is a smooth surrogate for the indicator of the ‘no free lunch’ condition, and Case 2 is exactly the statement that if f has no minimiser then the recession direction ϕ_0 is an arbitrage. In finite sample spaces one can give a purely finite-dimensional proof using the separating hyperplane theorem, and the picture above is that proof.

§43.4.5 Contingent Claims and Payoff Diagrams

We now enlarge the market by an extra asset.

Definition 43.4.11 (Contingent claim)

A **contingent claim** with maturity 1 is a random variable Y , interpreted as a

payout at time 1. It is **vanilla** if $Y = g(S_1)$ for some function g .

The two basic examples are the following.

Definition 43.4.12 (Call and put)

A **European call option** with **strike** K is the right, but not the obligation, to buy one unit of the asset at time 1 for the price K ; its payout is $(S_1 - K)^+$. A **European put option** with strike K is the right to sell at price K , with payout $(K - S_1)^+$.

It is customary and extremely useful to draw the payout as a function of S_1 .

Because the space of claims is a vector space and pricing will turn out to be linear, one can build more elaborate payoffs by adding these together. Two standard combinations:

A **straddle** is a call plus a put with the same strike, and pays off when the price moves a long way in either direction: it is a bet on volatility rather than on direction. A **bull spread** is a long call at strike K_1 and a short call at strike $K_2 > K_1$; it is a bet that the price will rise, but with the upside capped in exchange for a lower initial cost. Notice that the bull spread payoff is bounded, which is often what a regulator wants to see.

§43.4.6 No-Arbitrage Pricing

Suppose the fundamental market (the d assets and the bank) is arbitrage-free, and we add a claim with payout Y and initial price π . When is the enlarged market still arbitrage-free?

Theorem 43.4.13 (No-arbitrage pricing)

Let the fundamental market be arbitrage-free. The augmented market containing the claim (Y, π) is arbitrage-free if and only if

$$\pi = \frac{1}{1+r} \mathbb{E}_{\mathbb{Q}}[Y]$$

for some risk-neutral measure $\mathbb{Q}$ of the fundamental market.

Proof. Apply Theorem 43.4.10 to the augmented market, whose price vectors are $(S_0, \pi)^\top$ and $(S_1, Y)^\top$. The augmented market is arbitrage-free if and only if there is $\mathbb{Q} \sim \mathbb{P}$ with

$$\frac{1}{1+r} \mathbb{E}_{\mathbb{Q}}[(S_1, Y)^\top] = (S_0, \pi)^\top.$$

The first d coordinates say exactly that $\mathbb{Q}$ is risk-neutral for the fundamental market, and the last says $\pi = \mathbb{E}_{\mathbb{Q}}[Y]/(1+r)$. $\square$

Proposition 43.4.14

The set of no-arbitrage prices of a claim Y is an interval.

Proof. If $\mathbb{Q}_0, \mathbb{Q}_1$ are risk-neutral, so is $\mathbb{Q}_t = t\mathbb{Q}_1 + (1-t)\mathbb{Q}_0$ for $t \in [0, 1]$: it is a probability measure, it is equivalent to $\mathbb{P}$ (its null sets are the common null sets), and $\mathbb{E}_{\mathbb{Q}_t}[S_1] = t\mathbb{E}_{\mathbb{Q}_1}[S_1] + (1-t)\mathbb{E}_{\mathbb{Q}_0}[S_1] = (1+r)S_0$. The corresponding price is $\pi_t = t\pi_1 + (1-t)\pi_0$, so the set of prices is convex. $\square$

So a claim either has a unique no-arbitrage price, or a whole interval of them, in which case the model simply does not determine the price. The good case has a name.

Definition 43.4.15 (Attainable claim)

A claim Y is **attainable** (or **replicable**) if $Y = a + b^\top S_1$ for some $a \in \mathbb{R}$, $b \in \mathbb{R}^d$; equivalently, if $Y \in \mathcal{X}(y)$ for some y . The portfolio achieving this is called a **replicating portfolio** or a **hedge**.

Theorem 43.4.16

If $Y \in \mathcal{X}(y)$ is attainable, then its unique no-arbitrage price is y , the initial cost of the replicating portfolio.

Proof. Write $Y = a + b^\top S_1$, so $y = a/(1+r) + b^\top S_0$. For any risk-neutral $\mathbb{Q}$,

$$\frac{1}{1+r} \mathbb{E}_{\mathbb{Q}}[Y] = \frac{a}{1+r} + \frac{1}{1+r} b^\top \mathbb{E}_{\mathbb{Q}}[S_1] = \frac{a}{1+r} + b^\top S_0 = y,$$

independently of $\mathbb{Q}$. By Theorem 43.4.13 this is the unique no-arbitrage price. $\square$

This is the **law of one price**: two portfolios with the same payout must have the same price. Our very first example was an instance – there the call was attainable, $Y = \frac{1}{3}(S_1 - 4)$, and the price $\frac{1}{3}$ was the cost of the hedge.

The converse of Theorem 43.4.16 is also true, though we shall not prove it here (it is on the example sheet): a claim with a unique no-arbitrage price is attainable.

§43.4.7 Complete Markets

Definition 43.4.17 (Complete market)

A market model is **complete** if every contingent claim is attainable.

Proposition 43.4.18

In a complete market model, S_1 takes at most $d + 1$ values.

Proof. Let $A_1, \dots, A_n$ be disjoint events of positive probability. The indicators $\mathbb{1}_{A_1}, \dots, \mathbb{1}_{A_n}$ are linearly independent random variables. By completeness each $\mathbb{1}_{A_i} = a_i + b_i^\top S_1$, so

$$\text{span}\{\mathbb{1}_{A_1}, \dots, \mathbb{1}_{A_n}\} \subseteq \text{span}\{1, S_1^1, \dots, S_1^d\},$$

a space of dimension at most $d + 1$. Hence $n \leq d + 1$. As S_1 taking n distinct values would give n such disjoint events, the result follows. $\square$

So completeness is a strong requirement: with one stock ($d = 1$) it forces a binomial model. This is precisely why the binomial model is the workhorse of discrete-time finance.

Theorem 43.4.19 (Second fundamental theorem of asset pricing)

An arbitrage-free market model is complete if and only if the risk-neutral measure is unique.

Proof. ($\Rightarrow$) Suppose the market is complete and $\mathbb{Q}_0, \mathbb{Q}_1$ are both risk-neutral. Set

$$Y = \frac{d\mathbb{Q}_1}{d\mathbb{P}} - \frac{d\mathbb{Q}_0}{d\mathbb{P}},$$

which is a bounded-below claim (in a complete market S_1 takes finitely many values, so Y is a genuine random variable and everything is integrable). Since Y is attainable, write $Y = a + b^\top S_1$; then for $i = 0, 1$,

$$\mathbb{E}_{\mathbb{Q}_i}[Y] = a + b^\top \mathbb{E}_{\mathbb{Q}_i}[S_1] = a + (1 + r)b^\top S_0,$$

the same value for both. But

$$\mathbb{E}_{\mathbb{Q}_1}[Y] - \mathbb{E}_{\mathbb{Q}_0}[Y] = \mathbb{E}_{\mathbb{P}} \left[\left(\frac{d\mathbb{Q}_1}{d\mathbb{P}} - \frac{d\mathbb{Q}_0}{d\mathbb{P}} \right) Y \right] = \mathbb{E}_{\mathbb{P}}[Y^2],$$

so $\mathbb{E}_{\mathbb{P}}[Y^2] = 0$ and hence $Y = 0$ a.s., i.e. $\mathbb{Q}_0 = \mathbb{Q}_1$.

($\Leftarrow$) If the risk-neutral measure is unique then by Theorem 43.4.13 every claim has exactly one no-arbitrage price, and hence (by the converse to Theorem 43.4.16) is attainable. $\square$

Example 43.4.20

Return to Example 43.4.7. If $a < r < b$ the model is arbitrage-free with a unique risk-neutral measure $q = (r - a)/(b - a)$, hence complete: every claim $Y = g(S_1)$ is

replicable, and

$$\pi = \frac{1}{1+r} \left(q g((1+b)S_0) + (1-q) g((1+a)S_0) \right).$$

The replicating portfolio is obtained by solving two linear equations in two unknowns; the number of shares held is

$$\theta = \frac{g((1+b)S_0) - g((1+a)S_0)}{(b-a)S_0},$$

the ratio of the change in payout to the change in stock price. This quantity will reappear as the *delta* of the claim, and it is the single most important number in practical derivative trading.

§43.4.8 Utility Indifference Pricing

Theorem 43.4.13 pins down the price of a claim only when the claim is attainable. When it is not, we must go back to preferences. This subsection is a little more technical and may be skipped on a first reading, but it explains *why* the risk-neutral price is the right answer even in incomplete markets, at least for small trades.

Definition 43.4.21 (Indifference price)

Fix a utility U and initial wealth x . The **utility indifference price** (or **reservation bid price**) of a claim Y is the largest π with

$$\sup\{\mathbb{E}[U(X+Y)] : X \in \mathcal{X}(x-\pi)\} \geq \sup\{\mathbb{E}[U(X)] : X \in \mathcal{X}(x)\}.$$

In words – the most the agent would pay for Y while remaining at least as happy as if they had not bought it. We write $F_Y(\pi)$ for the left-hand side; note that $X \in \mathcal{X}(x-\pi)$ if and only if $X + (1+r)\pi \in \mathcal{X}(x)$, so

$$F_Y(\pi) = \sup\{\mathbb{E}[U(X - (1+r)\pi + Y)] : X \in \mathcal{X}(x)\},$$

which is decreasing and (given mild regularity) continuous in π , with $F_Y(\mp\infty) = U(\pm\infty)$. Thus $\pi(Y)$ is the unique solution of $F_Y(\pi) = F_0(0)$.

Theorem 43.4.22

The map $Y \mapsto \pi(Y)$ is concave.

Proof. Fix claims Y_0, Y_1 and $t \in [0, 1]$, and set $Y_t = tY_1 + (1-t)Y_0$. Let X_i attain the supremum defining $F_{Y_i}(\pi(Y_i))$ for $i = 0, 1$. Then $tX_1 + (1-t)X_0 \in \mathcal{X}(x - t\pi(Y_1) - (1-t)\pi(Y_0))$ by linearity, and so, using concavity of U ,

$$\begin{aligned} F_{Y_t}(\pi(Y_t)) &= F_0(0) = tF_{Y_1}(\pi(Y_1)) + (1-t)F_{Y_0}(\pi(Y_0)) \\ &= t\mathbb{E}[U(X_1 + Y_1)] + (1-t)\mathbb{E}[U(X_0 + Y_0)] \\ &\leq \mathbb{E}[U(tX_1 + (1-t)X_0 + Y_t)] \\ &\leq F_{Y_t}(t\pi(Y_1) + (1-t)\pi(Y_0)). \end{aligned}$$

Since F_{Y_t} is decreasing, $\pi(Y_t) \geq t\pi(Y_1) + (1-t)\pi(Y_0)$. $\square$

Concavity says that an investor values diversification: half of one claim plus half of another is worth at least the average of the two. It also implies that $t \mapsto \pi(tY)/t$ is decreasing, so the limit

$$\pi_0 := \lim_{t \downarrow 0} \frac{\pi(tY)}{t}$$

exists. This is the **marginal** price of the claim – the price per unit for an infinitesimally small trade.

Lemma 43.4.23 (Supporting hyperplane)

If U is concave and differentiable then $U(y) - U(x) \leq U'(x)(y - x)$ for all x, y .

Proof. For $x < x + \epsilon < y$, concavity of U gives that the chord slopes decrease, so

$$\frac{U(y) - U(x)}{y - x} \leq \frac{U(x + \epsilon) - U(x)}{\epsilon}.$$

Letting $\epsilon \downarrow 0$ gives the claim, and the case $y < x$ is symmetric. $\square$

Lemma 43.4.24

If X^* maximises $\mathbb{E}[U(X+Y)]$ over $X \in \mathcal{X}(x)$, then $\mathbb{E}[U'(X^*+Y)\xi] = 0$; consequently $\mathbb{E}[U'(X^*+Y)(X^* - X)] = 0$ for all $X \in \mathcal{X}(x)$.

Proof. Identical to Theorem 43.3.11, differentiating in θ . The second claim follows since $X^* - X$ is of the form $\eta^\top \xi$. $\square$

Theorem 43.4.25 (Marginal pricing)

Let X_0 maximise $\mathbb{E}[U(X)]$ over $X \in \mathcal{X}(x)$. Then

$$\pi_0 = \frac{\mathbb{E}[U'(X_0)Y]}{(1+r)\mathbb{E}[U'(X_0)]} = \mathbb{E}[ZY],$$

where Z is the state price density of Theorem 43.3.13.

Proof. Write $\pi_t = \pi(tY)/t$ and let X_t maximise $\mathbb{E}[U(X+tY)]$ over $X \in \mathcal{X}(x - t\pi_t)$. By definition of the indifference price, $\mathbb{E}[U(X_t + tY)] = \mathbb{E}[U(X_0)]$.

For the upper bound, note that $X_0 - t\pi_t(1+r) \in \mathcal{X}(x - t\pi_t)$, so it is a candidate in the supremum defining X_t , whence

$$\begin{aligned} 0 = \frac{\mathbb{E}[U(X_t + tY) - U(X_0)]}{t} &\geq \frac{\mathbb{E}[U(X_0 - t\pi_t(1+r) + tY) - U(X_0)]}{t} \\ &\xrightarrow{t \downarrow 0} \mathbb{E}[U'(X_0)(Y - (1+r)\pi_0)] \end{aligned}$$

using $\pi_t \downarrow \pi_0$ and dominated convergence. So $\mathbb{E}[U'(X_0)(Y - (1+r)\pi_0)] \leq 0$.

For the lower bound, apply Lemma 43.4.23 and then Lemma 43.4.24:

$$\begin{aligned}
 0 &= \frac{\mathbb{E}[U(X_t + tY) - U(X_0)]}{t} \leq \frac{\mathbb{E}[U'(X_0)(X_t + tY - X_0)]}{t} \\
 &= \mathbb{E}[U'(X_0)(Y - (1+r)\pi_t)] \\
 &\quad + \frac{1}{t}\mathbb{E}[U'(X_0)(X_t + t\pi_t(1+r) - X_0)] \\
 &= \mathbb{E}[U'(X_0)(Y - (1+r)\pi_t)],
 \end{aligned}$$

since $X_t + t\pi_t(1+r) \in \mathcal{X}(x)$ and Lemma 43.4.24 (with $Y = 0$) makes the last expectation vanish. Letting $t \downarrow 0$ gives $\mathbb{E}[U'(X_0)(Y - (1+r)\pi_0)] \geq 0$.

Combining the two bounds gives equality, which rearranges to the stated formula. $\square$

So for small trades the indifference price is linear, and the linear functional is given by a state price density – equivalently, by a risk-neutral expectation. This is the sense in which risk-neutral pricing is the right answer even when replication is impossible: it is the first-order approximation to what an optimising agent would pay.

§43.5 Martingales in Discrete Time

To do finance in more than one period we must be able to say what an agent knows at each time. The mathematical device for this is the σ -algebra, and the resulting theory – conditional expectation and martingales – is the technical backbone of everything that follows.

§43.5.1 Information and σ -Algebras

Suppose we toss a coin twice, so $\Omega = \{HH, HT, TH, TT\}$. After the first toss we know whether the outcome lies in $\{HH, HT\}$ or in $\{TH, TT\}$, but nothing more. So the events we can resolve are

$$\mathcal{G} = \{\emptyset, \{HH, HT\}, \{TH, TT\}, \Omega\}.$$

The general shape of such a collection is clear: if we can resolve A we can resolve A^c ; if we can resolve each of $A_1, A_2, \dots$ we can resolve $\bigcup_n A_n$; and we can always resolve $\emptyset$. That is exactly the definition of a σ -algebra.

Definition 43.5.1 (σ -algebra)

A σ -algebra on a set Ω is a collection $\mathcal{G}$ of subsets of Ω with $\emptyset \in \mathcal{G}$, closed under complements and under countable unions. A random variable X is $\mathcal{G}$ -measurable if $X^{-1}(B) \in \mathcal{G}$ for every Borel set $B \subseteq \mathbb{R}$; equivalently, if $\{X \leq x\} \in \mathcal{G}$ for every $x \in \mathbb{R}$.

The intuition is: $\mathcal{G}$ is ‘the information available’, and X is $\mathcal{G}$ -measurable if X is known once that information is revealed. The two extreme cases are the **trivial σ -algebra** $\{\emptyset, \Omega\}$ (no information – the only measurable random variables are constants) and the power set 2^Ω (everything is known).

Definition 43.5.2

The σ -algebra **generated** by a random variable X is $\sigma(X) = \{X^{-1}(B) : B \text{ Borel}\}$, the smallest σ -algebra making X measurable. More generally $\sigma(X_1, \dots, X_n)$ is the smallest σ -algebra making all of $X_1, \dots, X_n$ measurable.

Fact 43.5.3

A random variable Y is $\sigma(X)$ -measurable if and only if $Y = g(X)$ for some Borel measurable g .

This is the precise sense in which ‘knowing X ’ means ‘knowing every function of X , and nothing else’. We shall use it without further comment.

§43.5.2 Conditional Expectation

In Part IA Probability you defined $\mathbb{E}[X | A] = \mathbb{E}[X \mathbb{1}_A] / \mathbb{P}(A)$ for an event A of positive probability, and $\mathbb{E}[X | Y]$ for a discrete random variable Y as the random variable taking value $\mathbb{E}[X | Y = y]$ on $\{Y = y\}$. We now want to condition on a whole σ -algebra, including ones generated by continuous random variables where every individual event has probability zero. The trick is to characterise the answer rather than construct it.

Note first the key property of the discrete construction: if $f(y) = \mathbb{E}[X | Y = y]$ then for every bounded $\sigma(Y)$ -measurable Z ,

$$\mathbb{E}[XZ] = \mathbb{E}[f(Y)Z],$$

as one checks by decomposing over the values of Y . We turn this into a definition.

Definition 43.5.4 (Conditional expectation)

Let X be an integrable random variable on $(\Omega, \mathcal{F}, \mathbb{P})$ and $\mathcal{G} \subseteq \mathcal{F}$ a σ -algebra. A random variable $\tilde{X}$ is a **conditional expectation** of X given $\mathcal{G}$ if

- (i) $\tilde{X}$ is $\mathcal{G}$ -measurable and integrable;
- (ii) $\mathbb{E}[XZ] = \mathbb{E}[\tilde{X}Z]$ for every bounded $\mathcal{G}$ -measurable Z .

Proposition 43.5.5

A conditional expectation exists and is almost surely unique. We write it $\mathbb{E}[X | \mathcal{G}]$, and $\mathbb{E}[X | Y] := \mathbb{E}[X | \sigma(Y)]$.

Proof. We prove uniqueness, existence being a genuinely measure-theoretic matter (it follows from the Radon–Nikodym theorem, or from the L^2 projection argument below). Suppose $\tilde{X}_0$ and $\tilde{X}_1$ both work. Take $Z = \mathbb{1}_{\{\tilde{X}_0 < \tilde{X}_1\}}$, which is bounded and $\mathcal{G}$ -measurable. Then

$$\mathbb{E}[(\tilde{X}_1 - \tilde{X}_0) \mathbb{1}_{\{\tilde{X}_0 < \tilde{X}_1\}}] = \mathbb{E}[XZ] - \mathbb{E}[XZ] = 0.$$

The integrand is non-negative and strictly positive on $\{\tilde{X}_0 < \tilde{X}_1\}$, so $\mathbb{P}(\tilde{X}_0 < \tilde{X}_1) = 0$. By symmetry $\mathbb{P}(\tilde{X}_0 > \tilde{X}_1) = 0$. $\square$

The following interpretation is worth recording, since it explains why conditional expectation is ‘the best guess’.

Proposition 43.5.6 (L^2 projection)

Let X be square integrable and $\tilde{X} = \mathbb{E}[X \mid \mathcal{G}]$. Then for every square-integrable $\mathcal{G}$ -measurable Z ,

$$\mathbb{E}[(X - \tilde{X})^2] \leq \mathbb{E}[(X - Z)^2].$$

Proof. Expand:

$$\mathbb{E}[(X - Z)^2] = \mathbb{E}[(X - \tilde{X})^2] + 2\mathbb{E}[(X - \tilde{X})(\tilde{X} - Z)] + \mathbb{E}[(\tilde{X} - Z)^2].$$

The middle term vanishes: $\tilde{X} - Z$ is $\mathcal{G}$ -measurable, so the defining property gives $\mathbb{E}[X(\tilde{X} - Z)] = \mathbb{E}[\tilde{X}(\tilde{X} - Z)]$ (first for bounded $\tilde{X} - Z$, then in general by truncation).

The last term is non-negative. $\square$

So $\mathbb{E}[X \mid \mathcal{G}]$ is the orthogonal projection of X onto the closed subspace of $\mathcal{G}$ -measurable square-integrable random variables. All the familiar properties now follow.

Proposition 43.5.7 (Properties of conditional expectation)

Assume all the conditional expectations below are well defined. Then, almost surely:

- (i) (*Linearity*) $\mathbb{E}[aX + bY \mid \mathcal{G}] = a\mathbb{E}[X \mid \mathcal{G}] + b\mathbb{E}[Y \mid \mathcal{G}]$;
- (ii) (*Taking out what is known*) if Y is $\mathcal{G}$ -measurable then $\mathbb{E}[XY \mid \mathcal{G}] = Y \mathbb{E}[X \mid \mathcal{G}]$;
- (iii) (*Positivity*) if $X \geq 0$ a.s. then $\mathbb{E}[X \mid \mathcal{G}] \geq 0$ a.s.;
- (iv) (*Independence*) if $\sigma(X)$ is independent of $\mathcal{G}$ then $\mathbb{E}[X \mid \mathcal{G}] = \mathbb{E}[X]$;
- (v) (*Jensen*) if f is convex then $\mathbb{E}[f(X) \mid \mathcal{G}] \geq f(\mathbb{E}[X \mid \mathcal{G}])$;
- (vi) (*Tower property*) if $\mathcal{G} \subseteq \mathcal{H} \subseteq \mathcal{F}$ then $\mathbb{E}[\mathbb{E}[X \mid \mathcal{H}] \mid \mathcal{G}] = \mathbb{E}[X \mid \mathcal{G}]$.

Proof. (i) Both sides are $\mathcal{G}$ -measurable and satisfy the defining identity, so uniqueness applies. (ii) For bounded $\mathcal{G}$ -measurable Z we have $\mathbb{E}[(XY)Z] = \mathbb{E}[X(YZ)] = \mathbb{E}[\mathbb{E}[X \mid \mathcal{G}]YZ]$, since YZ is $\mathcal{G}$ -measurable (first for bounded Y , then by truncation). (iii) Take $Z = \mathbb{1}_{\{\mathbb{E}[X \mid \mathcal{G}] < 0\}}$; then $\mathbb{E}[\mathbb{E}[X \mid \mathcal{G}]Z] = \mathbb{E}[XZ] \geq 0$, whereas the left-hand side is ≤ 0 and is < 0 unless $\mathbb{P}(\mathbb{E}[X \mid \mathcal{G}] < 0) = 0$. (iv) Immediate from the definition, since $\mathbb{E}[XZ] = \mathbb{E}[X]\mathbb{E}[Z]$ for $\mathcal{G}$ -measurable Z . (v) A convex f satisfies $f(y) \geq f(x) + \lambda(x)(y - x)$ for a suitable $\lambda(x)$; put $x = \mathbb{E}[X \mid \mathcal{G}]$, $y = X$ and condition. (vi) $\mathbb{E}[X \mid \mathcal{G}]$ is $\mathcal{H}$ -measurable so equals its own conditional expectation given $\mathcal{H}$; for the other order, any bounded $\mathcal{G}$ -measurable Z is $\mathcal{H}$ -measurable, so $\mathbb{E}[\mathbb{E}[X \mid \mathcal{H}]Z] = \mathbb{E}[XZ]$. $\square$

Example 43.5.8

Let $(A_n)_{n \geq 1}$ partition Ω with $\mathbb{P}(A_n) > 0$ and let $\mathcal{G} = \sigma(A_1, A_2, \dots)$. A random variable is $\mathcal{G}$ -measurable exactly when it is constant on each A_n , and

$$\mathbb{E}[X \mid \mathcal{G}] = \sum_n \mathbb{E}[X \mid A_n] \mathbb{1}_{A_n},$$

which recovers the Part IA definition.

§43.5.3 Filtrations and Martingales

Definition 43.5.9 (Filtration)

A **filtration** on $(\Omega, \mathcal{F})$ is an increasing sequence $(\mathcal{F}_n)_{n \geq 0}$ of σ -algebras, $\mathcal{F}_0 \subseteq \mathcal{F}_1 \subseteq \dots \subseteq \mathcal{F}$. A stochastic process $(X_n)_{n \geq 0}$ is **adapted** to $(\mathcal{F}_n)$ if X_n is $\mathcal{F}_n$ -measurable for every n . The filtration **generated** by a process (X_n) is $\mathcal{F}_n = \sigma(X_0, \dots, X_n)$.

We adopt the convention that $\mathcal{F}_0 = \{\emptyset, \Omega\}$ is trivial, so X_0 is a constant and $\mathbb{E}[Z \mid \mathcal{F}_0] = \mathbb{E}[Z]$ for every integrable Z .

Definition 43.5.10 (Martingale)

An adapted, integrable process $(X_n)_{n \geq 0}$ is a **martingale** with respect to $(\mathcal{F}_n)$ if

$$\mathbb{E}[X_n \mid \mathcal{F}_{n-1}] = X_{n-1} \quad \text{for all } n \geq 1.$$

It is a **supermartingale** if $\mathbb{E}[X_n \mid \mathcal{F}_{n-1}] \leq X_{n-1}$ and a **submartingale** if $\mathbb{E}[X_n \mid \mathcal{F}_{n-1}] \geq X_{n-1}$.

A martingale is a fair game: given everything you know today, your expected fortune tomorrow is exactly your fortune today. A supermartingale is a game which is unfavourable to you (it goes *down* on average – the terminology is unfortunate but universal), and a submartingale is a favourable one.

Proposition 43.5.11

For an adapted integrable process (X_n) the following are equivalent:

- (i) (X_n) is a martingale;
- (ii) $\mathbb{E}[X_n - X_{n-1} \mid \mathcal{F}_{n-1}] = 0$ for all $n \geq 1$;
- (iii) $\mathbb{E}[X_n \mid \mathcal{F}_m] = X_m$ for all $0 \leq m \leq n$.

Proof. (i) $\iff$ (ii) is immediate from linearity, and (iii) $\implies$ (i) is the case $m = n - 1$. For (i) $\implies$ (iii), induct on $n - m$ using the tower property:

$$\mathbb{E}[X_n \mid \mathcal{F}_m] = \mathbb{E}[\mathbb{E}[X_n \mid \mathcal{F}_{n-1}] \mid \mathcal{F}_m] = \mathbb{E}[X_{n-1} \mid \mathcal{F}_m] = X_m. \quad \square$$

Condition (iii) makes no reference to ‘the previous time step’, and so is the definition that generalises to continuous time.

Example 43.5.12 (Martingales built backwards)

Let Z be integrable and $(\mathcal{F}_n)$ a filtration. Then $X_n = \mathbb{E}[Z \mid \mathcal{F}_n]$ is a martingale. Integrability follows from conditional Jensen, $\mathbb{E}|X_n| \leq \mathbb{E}[\mathbb{E}[|Z| \mid \mathcal{F}_n]] = \mathbb{E}|Z| < \infty$, and the martingale property is the tower property. Every martingale on a finite horizon arises this way, with $Z = X_N$.

Example 43.5.13 (Martingales built forwards) (i) Let (Y_n) be independent integrable random variables with $\mathbb{E}[Y_n] = 0$, and let $\mathcal{F}_n = \sigma(Y_1, \dots, Y_n)$. Then $S_0 = 0$, $S_n = Y_1 + \dots + Y_n$ defines a martingale, since

$$\mathbb{E}[S_n - S_{n-1} \mid \mathcal{F}_{n-1}] = \mathbb{E}[Y_n \mid \mathcal{F}_{n-1}] = \mathbb{E}[Y_n] = 0$$

by independence. In particular the simple symmetric random walk is a martingale.

(ii) If instead (Y_n) are independent, positive, with $\mathbb{E}[Y_n] = 1$, then $M_0 = 1$, $M_n = Y_1 \cdots Y_n$ is a martingale by the same computation.

(iii) If (S_n) is a simple symmetric random walk then $Q_n = S_n^2 - n$ is a martingale: indeed $\mathbb{E}[S_n^2 \mid \mathcal{F}_{n-1}] = S_{n-1}^2 + 2S_{n-1}\mathbb{E}[Y_n] + \mathbb{E}[Y_n^2] = S_{n-1}^2 + 1$.

The definition immediately relevant to us is the following, which we shall justify in §6.

Definition 43.5.14 (Risk-neutral measure, multi-period)

For a multi-period market with prices $(S_n)_{n \geq 0}$ adapted to $(\mathcal{F}_n)$ and interest rate r , a probability measure $\mathbb{Q} \sim \mathbb{P}$ is **risk-neutral** if the discounted price process $(S_n/(1+r)^n)_{n \geq 0}$ is a $\mathbb{Q}$ -martingale, i.e. if

$$\mathbb{E}_{\mathbb{Q}}[S_n \mid \mathcal{F}_{n-1}] = (1+r)S_{n-1} \quad \text{for all } n \geq 1.$$

§43.5.4 Stopping Times and Optional Stopping

Definition 43.5.15 (Stopping time)

A random variable T taking values in $\{0, 1, 2, \dots\} \cup \{\infty\}$ is a **stopping time** for the filtration $(\mathcal{F}_n)$ if $\{T \leq n\} \in \mathcal{F}_n$ for every n .

The condition says that we can decide whether to stop at time n using only information available at time n – no peeking into the future.

Example 43.5.16 (i) If (X_n) is adapted then the first hitting time $T = \inf\{n \geq 0 : X_n > 0\}$ (with $\inf \emptyset = \infty$) is a stopping time, since $\{T \leq n\} = \bigcup_{k \leq n} \{X_k > 0\} \in \mathcal{F}_n$.

(ii) The last time $T = \sup\{n \geq 0 : X_n > 0\}$ is generally *not* a stopping time: $\{T \leq n\} = \bigcap_{k > n} \{X_k \leq 0\}$ requires knowledge of the whole future. ‘Sell at the top’ is not an implementable strategy.

Definition 43.5.17 (Stopped process)

Given a process X and a random time T , the **stopped process** X^T is defined by

$$X_n^T = X_{n \wedge T} = X_0 + \sum_{k=1}^n \mathbb{1}_{\{k \leq T\}} (X_k - X_{k-1}).$$

Proposition 43.5.18

If X is integrable and adapted and T is a stopping time, then X^T is integrable and adapted.

Proof. Integrability follows from the triangle inequality applied to the sum. For adaptedness, note $\{k \leq T\} = \{T \leq k-1\}^c \in \mathcal{F}_{k-1} \subseteq \mathcal{F}_n$ for $k \leq n$, and $X_k - X_{k-1}$ is $\mathcal{F}_n$ -measurable. $\square$

Theorem 43.5.19 (Optional sampling)

Let X be a martingale and T a stopping time. Then X^T is a martingale. In particular, if $T \leq N$ almost surely for some constant N , then $\mathbb{E}[X_T] = X_0$.

Proof. We know X^T is adapted and integrable, so it remains to compute, for $n \geq 1$,

$$\begin{aligned} \mathbb{E}[X_n^T - X_{n-1}^T \mid \mathcal{F}_{n-1}] &= \mathbb{E}[\mathbb{1}_{\{n \leq T\}} (X_n - X_{n-1}) \mid \mathcal{F}_{n-1}] \\ &= \mathbb{1}_{\{n \leq T\}} \mathbb{E}[X_n - X_{n-1} \mid \mathcal{F}_{n-1}] = 0, \end{aligned}$$

where we took out the $\mathcal{F}_{n-1}$ -measurable factor $\mathbb{1}_{\{n \leq T\}}$. If $T \leq N$ a.s. then $X_T = X_{T \wedge N} = X_N^T$, and $\mathbb{E}[X_N^T] = X_0^T = X_0$. $\square$

The boundedness hypothesis is essential.

Example 43.5.20 (Why boundedness matters)

Let (S_n) be a simple symmetric random walk from 0 and let $T = \inf\{n \geq 0 : S_n = b\}$ for $b > 0$. From Part IB Markov Chains we know the walk is recurrent, so $T < \infty$ a.s. and $S_T = b$. Then $\mathbb{E}[S_T] = b \neq 0 = S_0$. Optional sampling fails, because T is unbounded and unboundedly large excursions occur before T .

This is not a mere technicality: it is the martingale-theoretic reason why the ‘double your bet until you win’ strategy does not actually work. It requires an unbounded amount of credit, and $\mathbb{E}[\min_{n \leq T} S_n] = -\infty$.

To handle unbounded stopping times we need an integrability condition.

Theorem 43.5.21 (Optional stopping)

Let X be a martingale and T a stopping time with $T < \infty$ a.s. Suppose there is an integrable random variable Y with $|X_n^T| \leq Y$ for all n . Then $X_n^T \rightarrow X_T$ a.s. and $\mathbb{E}[X_T] = X_0$.

Proof. Since $T < \infty$ a.s., $X_n^T = X_T$ for all $n \geq T$, giving almost sure convergence. By Theorem 43.5.19, $\mathbb{E}[X_n^T] = X_0$ for every n ; the dominated convergence theorem lets us pass to the limit. $\square$

In particular the conclusion holds if T is bounded, or if T is integrable and the increments of X are bounded, or if X^T is bounded. Let us see the last of these in action.

Example 43.5.22 (Gambler's ruin, again)

Let (S_n) be a simple symmetric random walk from 0 and $T = \inf\{n \geq 0 : S_n \in \{-a, b\}\}$ for integers $a, b > 0$. Then $|S_n^T| \leq \max(a, b)$, and $T < \infty$ a.s. (again by recurrence), so Theorem 43.5.21 gives

$$0 = \mathbb{E}[S_T] = -a\mathbb{P}(S_T = -a) + b\mathbb{P}(S_T = b).$$

With $\mathbb{P}(S_T = -a) + \mathbb{P}(S_T = b) = 1$ this yields

$$\mathbb{P}(S_T = -a) = \frac{b}{a+b}, \quad \mathbb{P}(S_T = b) = \frac{a}{a+b},$$

which is the gambler's ruin formula from Part IA. Applying the same argument to the martingale $Q_n = S_n^2 - n$ and the bounded stopping time $T \wedge n$,

$$\mathbb{E}[S_{T \wedge n}^2] = \mathbb{E}[T \wedge n].$$

The right-hand side increases to $\mathbb{E}[T]$ by monotone convergence and the left-hand side converges to $\mathbb{E}[S_T^2]$ by dominated convergence, so

$$\mathbb{E}[T] = \mathbb{E}[S_T^2] = a^2 \frac{a}{a+b} \cdot \frac{b}{a} + b^2 \frac{a}{a+b} = ab,$$

after simplification: the expected duration is ab .

§43.5.5 Martingale Transforms

Definition 43.5.23 (Previsible process)

A process $(H_n)_{n \geq 1}$ is **previsible** (or **predictable**) for $(\mathcal{F}_n)$ if H_n is $\mathcal{F}_{n-1}$ -measurable for every $n \geq 1$.

Definition 43.5.24 (Martingale transform)

The **martingale transform** of X by H is the process

$$(H \cdot X)_n = \sum_{k=1}^n H_k (X_k - X_{k-1}), \quad (H \cdot X)_0 = 0.$$

Think of $X_k - X_{k-1}$ as the winnings per unit stake in game k and H_k as the stake, chosen before the game is played. Then $(H \cdot X)_n$ is the total winnings. The martingale transform is the discrete-time ancestor of the stochastic integral $\int H \, dX$.

Theorem 43.5.25 (You cannot beat the system)

Let H be previsible and bounded.

- (i) If X is a martingale then so is $H \cdot X$.
- (ii) If X is a supermartingale and $H \geq 0$, then $H \cdot X$ is a supermartingale.

Proof. In both cases $H \cdot X$ is adapted (since H_k is $\mathcal{F}_{k-1}$ -measurable and X adapted) and integrable (since H is bounded). Then

$$\mathbb{E}[(H \cdot X)_n - (H \cdot X)_{n-1} \mid \mathcal{F}_{n-1}] = \mathbb{E}[H_n(X_n - X_{n-1}) \mid \mathcal{F}_{n-1}] = H_n \mathbb{E}[X_n - X_{n-1} \mid \mathcal{F}_{n-1}],$$

which is 0 in case (i) and ≤ 0 in case (ii) as $H_n \geq 0$. $\square$

The name is apt: no gambling strategy, however clever, can turn a fair game into a favourable one, provided your stakes are chosen without knowledge of the future and you are not allowed to bet unboundedly.

Notice that the stopped process is a special case: $X^T - X_0 = H \cdot X$ with $H_k = \mathbb{1}_{\{k \leq T\}}$, which is previsible precisely because T is a stopping time.

§43.5.6 Supermartingales and the Snell Envelope

For optimal stopping problems we need the supermartingale analogue of optional sampling.

Theorem 43.5.26 (Optional sampling for supermartingales)

Let X be a supermartingale and let $S \leq T$ be bounded stopping times. Then $\mathbb{E}[X_S] \geq \mathbb{E}[X_T]$.

Proof. Suppose $T \leq N$. Writing the difference as a sum,

$$X_{N \wedge T} - X_{N \wedge S} = \sum_{k=1}^N \mathbb{1}_{\{S < k \leq T\}} (X_k - X_{k-1}).$$

Now $\{S < k\} = \{S \leq k-1\} \in \mathcal{F}_{k-1}$ and $\{k \leq T\} = \{T \leq k-1\}^c \in \mathcal{F}_{k-1}$, so $\mathbb{1}_{\{S < k \leq T\}}$ is $\mathcal{F}_{k-1}$ -measurable. Hence

$$\mathbb{E}[X_T - X_S] = \sum_{k=1}^N \mathbb{E} \left[\mathbb{1}_{\{S < k \leq T\}} \mathbb{E}[X_k - X_{k-1} \mid \mathcal{F}_{k-1}] \right] \leq 0,$$

since each conditional expectation is ≤ 0 and the indicator is non-negative. $\square$

Now consider the following optimal stopping problem. Fix a horizon N , an adapted process $(Y_n)_{0 \leq n \leq N}$ of payouts, and ask for

$$\sup \{ \mathbb{E}[Y_T] : T \text{ a stopping time with } T \leq N \}.$$

Definition 43.5.27 (Snell envelope)

The **Snell envelope** of $(Y_n)_{n \leq N}$ is the process defined by backward recursion

$$Z_N = Y_N, \quad Z_{n-1} = \max \{Y_{n-1}, \mathbb{E}[Z_n | \mathcal{F}_{n-1}]\}.$$

At each time we compare the payout from stopping now with the expected value of carrying on optimally; the Snell envelope is the value of the problem.

Theorem 43.5.28 (Optimal stopping)

The Snell envelope (Z_n) is the smallest supermartingale dominating (Y_n) . Moreover

$$T^* = \min\{n \geq 0 : Z_n = Y_n\}$$

is an optimal stopping time, and $Z_0 = \mathbb{E}[Y_{T^*}] = \sup_{T \leq N} \mathbb{E}[Y_T]$.

Proof. By construction $Z_n \geq Y_n$ and $Z_{n-1} \geq \mathbb{E}[Z_n | \mathcal{F}_{n-1}]$, so Z is a supermartingale dominating Y . If W is any other such supermartingale then $W_N \geq Y_N = Z_N$, and inductively

$$W_{n-1} \geq \max\{Y_{n-1}, \mathbb{E}[W_n | \mathcal{F}_{n-1}]\} \geq \max\{Y_{n-1}, \mathbb{E}[Z_n | \mathcal{F}_{n-1}]\} = Z_{n-1},$$

so Z is the smallest.

For any stopping time $T \leq N$, Theorem 43.5.26 applied with $S = 0$ gives $\mathbb{E}[Y_T] \leq \mathbb{E}[Z_T] \leq Z_0$.

It remains to show equality for T^* . The definition of T^* gives $Z_n > Y_n$ for $n < T^*$, so on $\{n \leq T^*\}$ we have $Z_{n-1} = \mathbb{E}[Z_n | \mathcal{F}_{n-1}]$ for $n \leq T^*$; hence the stopped process Z^{T^*} satisfies

$$\mathbb{E}[Z_n^{T^*} - Z_{n-1}^{T^*} | \mathcal{F}_{n-1}] = \mathbb{1}_{\{n \leq T^*\}} (\mathbb{E}[Z_n | \mathcal{F}_{n-1}] - Z_{n-1}) = 0,$$

so Z^{T^*} is a martingale. Therefore $Z_0 = \mathbb{E}[Z_N^{T^*}] = \mathbb{E}[Z_{T^*}] = \mathbb{E}[Y_{T^*}]$, using $Z_{T^*} = Y_{T^*}$. $\square$

This is the engine that will price American options. Note the structure of the answer: one solves a backward recursion, and the optimal rule is ‘stop as soon as the payout from stopping equals the value of the problem’.

§43.5.7 Convergence

We record, without proof, the two convergence results that we shall occasionally need. The first is the martingale convergence theorem; you will meet it properly in Part II Probability and Measure.

Theorem 43.5.29 (Martingale convergence)

Let (X_n) be a martingale bounded in L^1 , i.e. $\sup_n \mathbb{E}|X_n| < \infty$. Then $X_n \rightarrow X_\infty$ almost surely for some integrable X_∞ .

In general $\mathbb{E}[X_\infty] \neq X_0$: Example 43.5.20 is a counterexample if one truncates suitably.

What is needed for the limit to be ‘honest’ is uniform integrability, and then $X_n = \mathbb{E}[X_\infty | \mathcal{F}_n]$ for all n .

Theorem 43.5.30 (Monotone and dominated convergence)

If $0 \leq X_n \leq X_{n+1}$ a.s. then $\mathbb{E}[X_n] \rightarrow \mathbb{E}[\lim_n X_n]$. If $X_n \rightarrow X$ a.s. and $|X_n| \leq Y$ for an integrable Y , then $\mathbb{E}[X_n] \rightarrow \mathbb{E}[X]$.

§43.6 Multi-Period Models

We now let the market run for N periods. The state space carries a filtration $(\mathcal{F}_n)_{0 \leq n \leq N}$, prices (S_n) are adapted, and the bank account grows by a factor $1 + r$ each period. Everything from §4 will survive, with ‘random variable’ replaced by ‘adapted process’ and ‘expectation’ by ‘conditional expectation’.

§43.6.1 Self-Financing Portfolios

Let $\theta_n \in \mathbb{R}^d$ be the portfolio of risky assets held over the interval $(n-1, n]$, and θ_n^0 the amount in the bank over the same interval. These must be chosen at time $n-1$, so we require $(\theta_n)_{n \geq 1}$ to be *previsible*. Let X_n be the agent’s wealth at time n .

Definition 43.6.1 (Self-financing)

A previsible portfolio process (θ_n) is **self-financing** if no money is added to or removed from the portfolio after time 0; that is, if

$$X_{n-1} = \theta_n^0 + \theta_n^\top S_{n-1} \quad \text{and} \quad X_n = \theta_n^0(1+r) + \theta_n^\top S_n$$

for all $n \geq 1$.

Eliminating θ_n^0 exactly as in the one-period case gives the wealth recursion

$$X_n = (1+r)X_{n-1} + \theta_n^\top (S_n - (1+r)S_{n-1}).$$

It is neater in discounted terms. Write $\tilde{X}_n = X_n/(1+r)^n$ and $\tilde{S}_n = S_n/(1+r)^n$ for the discounted wealth and prices, i.e. prices measured in units of the bank account rather than in pounds. Dividing the recursion by $(1+r)^n$,

$$\tilde{X}_n - \tilde{X}_{n-1} = \theta_n^\top (\tilde{S}_n - \tilde{S}_{n-1}),$$

and summing,

$$\tilde{X}_n = X_0 + \sum_{k=1}^n \theta_k^\top (\tilde{S}_k - \tilde{S}_{k-1}) = X_0 + (\theta \cdot \tilde{S})_n.$$

In other words – the discounted wealth of a self-financing strategy is the initial wealth plus the martingale transform of the strategy against the discounted prices. Theorem 43.5.25 now does an enormous amount of work for us.

Remark. The change from pounds to units of the bank account is our first **change of numeraire**. A **numeraire** is any asset with strictly positive price which we use as the unit of account; discounting is the statement that in the numeraire of the bank account the riskless asset has constant price 1. Other choices are possible and sometimes much more convenient; we take this up in §6.3.

§43.6.2 Arbitrage in Multi-Period Models

Definition 43.6.2 (Arbitrage)

A previsible process $(\theta_n)_{1 \leq n \leq N}$ is an **arbitrage** if the terminal discounted gain $G = \sum_{k=1}^N \theta_k^\top (\tilde{S}_k - \tilde{S}_{k-1})$ satisfies

$$\mathbb{P}(G \geq 0) = 1 \quad \text{and} \quad \mathbb{P}(G > 0) > 0.$$

Theorem 43.6.3 (Fundamental theorem of asset pricing)

A finite-horizon market model admits no arbitrage if and only if there exists a risk-neutral measure, that is, a $\mathbb{Q} \sim \mathbb{P}$ under which $(\tilde{S}_n)_{0 \leq n \leq N}$ is a martingale.

Proof. ($\Leftarrow$) Let $\mathbb{Q}$ be risk-neutral and let θ be previsible and bounded. By Theorem 43.5.25 the discounted wealth $\tilde{X}_n = X_0 + (\theta \cdot \tilde{S})_n$ is a $\mathbb{Q}$ -martingale, so

$$\mathbb{E}_{\mathbb{Q}}[G] = \mathbb{E}_{\mathbb{Q}}[\tilde{X}_N] - X_0 = 0.$$

If θ were an arbitrage then $G \geq 0$ $\mathbb{P}$ -a.s., hence $\mathbb{Q}$ -a.s. since $\mathbb{P} \sim \mathbb{Q}$; a non-negative random variable of zero mean vanishes a.s., so $G = 0$ $\mathbb{Q}$ -a.s. and therefore $\mathbb{P}$ -a.s., contradicting $\mathbb{P}(G > 0) > 0$. (For unbounded θ one first localises using the stopping times $T_m = \inf\{n : \|\theta_{n+1}\| > m\}$ and then lets $m \rightarrow \infty$.)

($\Rightarrow$) Conversely, suppose there is no arbitrage. Then in particular, for each n there is no one-period arbitrage conditional on $\mathcal{F}_{n-1}$: if η were an $\mathcal{F}_{n-1}$ -measurable random vector with $\eta^\top (\tilde{S}_n - \tilde{S}_{n-1}) \geq 0$ a.s. and positive with positive probability, then the strategy which is η at time n and zero otherwise would be an arbitrage. Applying the one-period Theorem 43.4.10 conditionally on $\mathcal{F}_{n-1}$ produces, for each n , a strictly positive $\mathcal{F}_n$ -measurable Y_n with $\mathbb{E}[Y_n \mid \mathcal{F}_{n-1}] = 1$ and $\mathbb{E}[Y_n \tilde{S}_n \mid \mathcal{F}_{n-1}] = \tilde{S}_{n-1}$. Setting $d\mathbb{Q}/d\mathbb{P} = \prod_{n=1}^N Y_n$ defines an equivalent measure, and a short computation with the tower property shows $\tilde{S}$ is a $\mathbb{Q}$ -martingale. $\square$

Theorem 43.6.4 (Second fundamental theorem)

An arbitrage-free model is complete – every $\mathcal{F}_N$ -measurable claim Y is replicable by a self-financing strategy – if and only if the risk-neutral measure is unique. In that case the unique time- n no-arbitrage price of a claim Y payable at time N is

$$\pi_n = \frac{1}{(1+r)^{N-n}} \mathbb{E}_{\mathbb{Q}}[Y \mid \mathcal{F}_n].$$

Proof sketch. The equivalence is proved exactly as in Theorem 43.4.19. For the formula, note that $(\pi_n/(1+r)^n)$ must be a $\mathbb{Q}$ -martingale (else the augmented market has an arbitrage, by the argument of Theorem 43.4.13 applied at each time), with terminal value $Y/(1+r)^N$; and a martingale is determined by its terminal value via Proposition 43.5.11(iii). $\square$

§43.6.3 Change of Numeraire

We took it for granted above that the natural thing to divide by is the bank account. It is not the only choice, and being flexible about it is a genuinely useful technique.

Definition 43.6.5 (Numeraire)

A **numeraire** is an adapted process $(M_n)_{0 \leq n \leq N}$ with $M_n > 0$ for all n , which is the price process of a self-financing portfolio. Prices measured in units of the numeraire are S_n/M_n .

The bank account $M_n = (1+r)^n$ is the numeraire we have used so far; another asset, or the price of a bond maturing at a fixed date, will do just as well. The point is that arbitrage is a numeraire-independent notion – multiplying every price by a strictly positive process changes neither the sign of a gain nor its vanishing – so the fundamental theorem must hold for each choice, and we may pick whichever makes a given computation easiest.

Theorem 43.6.6 (Change of numeraire)

Let the market be arbitrage-free with risk-neutral measure $\mathbb{Q}$ (for the bank-account numeraire), and let M be a numeraire with $M_0 = 1$. Define $\mathbb{Q}^M \sim \mathbb{Q}$ by

$$\frac{d\mathbb{Q}^M}{d\mathbb{Q}} = \frac{M_N}{(1+r)^N}.$$

Then $\mathbb{Q}^M$ is a probability measure, and (S_n/M_n) is a $\mathbb{Q}^M$ -martingale. Moreover the time- n price of a claim Y payable at time N is

$$\pi_n = M_n \mathbb{E}_{\mathbb{Q}^M} \left[\frac{Y}{M_N} \mid \mathcal{F}_n \right].$$

Proof. Since M is the value of a self-financing portfolio, $\tilde{M}_n = M_n/(1+r)^n$ is a $\mathbb{Q}$ -martingale with $\tilde{M}_0 = 1$, so the proposed density is positive with $\mathbb{Q}$ -expectation 1 and $\mathbb{Q}^M$ is an equivalent probability measure. For a positive $\mathcal{F}_m$ -measurable random variable Z the density relation together with the tower property gives the conditional Bayes formula

$$\mathbb{E}_{\mathbb{Q}^M} [Z \mid \mathcal{F}_n] = \frac{\mathbb{E}_{\mathbb{Q}} [Z \tilde{M}_m \mid \mathcal{F}_n]}{\tilde{M}_n}, \quad n \leq m,$$

because $\mathbb{E}_{\mathbb{Q}} [d\mathbb{Q}^M / d\mathbb{Q} \mid \mathcal{F}_m] = \tilde{M}_m$. Taking $Z = S_m/M_m$ and $m = N$,

$$\mathbb{E}_{\mathbb{Q}^M} \left[\frac{S_m}{M_m} \mid \mathcal{F}_n \right] = \frac{\mathbb{E}_{\mathbb{Q}} [\tilde{S}_m \mid \mathcal{F}_n]}{\tilde{M}_n} = \frac{\tilde{S}_n}{\tilde{M}_n} = \frac{S_n}{M_n},$$

using that $\tilde{S}$ is a $\mathbb{Q}$ -martingale. The pricing formula is the same computation applied to π_m/M_m , whose $\mathbb{Q}$ -discounted version is a martingale by the second fundamental theorem. $\square$

The formula is worth reading aloud: *the price of anything, measured in units of the numeraire, is a martingale under the measure associated with that numeraire.* We shall

use it in §9.2, where the numeraire is a foreign bank account and the change of measure resolves what looks like a paradox about exchange rates.

§43.6.4 The Binomial Model

We now specialise to the model in which every computation can be carried out explicitly.

Definition 43.6.7 (Cox–Ross–Rubinstein model)

Take $d = 1$ and let $(\xi_n)_{n \geq 1}$ be i.i.d. with

$$\mathbb{P}(\xi = 1 + b) = p = 1 - \mathbb{P}(\xi = 1 + a), \quad a < b, \quad p \in (0, 1),$$

and set $S_n = S_{n-1}\xi_n = S_0\xi_1 \cdots \xi_n$, with $(\mathcal{F}_n)$ the filtration generated by (S_n) . This is the **binomial** or **Cox–Ross–Rubinstein** model.

Proposition 43.6.8

The binomial model is arbitrage-free if and only if $a < r < b$, and in that case the risk-neutral measure is unique: under $\mathbb{Q}$ the ξ_n are i.i.d. with

$$\mathbb{Q}(\xi = 1 + b) = q = \frac{r - a}{b - a}.$$

Consequently the model is complete.

Proof. If $r \leq a$ then $\theta_1 = 1$ (buy a share, hold it one period, do nothing thereafter) is an arbitrage, since $S_1 - (1+r)S_0 \geq (1+a-1-r)S_0 \geq 0$ with strict inequality when $\xi_1 = 1 + b$. If $r \geq b$ then $\theta_1 = -1$ is an arbitrage. Conversely, suppose $a < r < b$. A measure $\mathbb{Q}$ under which $\tilde{S}$ is a martingale must satisfy $\mathbb{E}_{\mathbb{Q}}[\xi_n | \mathcal{F}_{n-1}] = 1 + r$; since ξ_n takes two values this determines the conditional law of ξ_n given $\mathcal{F}_{n-1}$ to be the two-point law with mass $q = (r - a)/(b - a)$ at $1 + b$, and $q \in (0, 1)$ exactly when $a < r < b$. This makes the ξ_n i.i.d. under $\mathbb{Q}$, and conversely that choice visibly works. Uniqueness plus the second fundamental theorem gives completeness. $\square$

The price process is **recombining**: an up-move followed by a down-move gives the same price as a down followed by an up, so after n steps there are only $n + 1$ possible prices rather than 2^n . Here is the tree we shall use as a running example, with

$$S_0 = 100, \quad 1 + b = 1.2, \quad 1 + a = 0.9, \quad r = 0.05, \quad N = 3,$$

so that $q = (0.05 + 0.1)/(0.2 + 0.1) = \frac{1}{2}$.

§43.6.5 European Claims: Pricing and Replication

Definition 43.6.9

A **European contingent claim** with expiry N is an $\mathcal{F}_N$ -measurable payout Y , payable at time N . It is **vanilla** if $Y = g(S_N)$.

In the binomial model (S_n) is a Markov chain under $\mathbb{Q}$, so the conditional expectation defining the price depends on $\mathcal{F}_n$ only through S_n . This gives the following.

Theorem 43.6.10

In an arbitrage-free binomial model, the unique time- n price of the vanilla claim $Y = g(S_N)$ is $\pi_n = V(n, S_n)$, where

$$\begin{aligned}
 V(n, s) &= \frac{1}{(1+r)^{N-n}} \mathbb{E}_{\mathbb{Q}}[g(S_N) \mid S_n = s] \\
 &= \frac{1}{(1+r)^{N-n}} \sum_{j=0}^{N-n} \binom{N-n}{j} q^j (1-q)^{N-n-j} g(s(1+b)^j (1+a)^{N-n-j}).
 \end{aligned}$$

Equivalently, V satisfies the backward recursion

$$(1+r)V(n-1, s) = qV(n, s(1+b)) + (1-q)V(n, s(1+a)), \quad V(N, s) = g(s).$$

Proof. Under $\mathbb{Q}$ we have $S_N = S_n \xi_{n+1} \cdots \xi_N$ with the ξ 's i.i.d. and independent of $\mathcal{F}_n$, so $\mathbb{E}_{\mathbb{Q}}[g(S_N) \mid \mathcal{F}_n]$ is the stated function of S_n , and the number of up-moves in $N-n$ steps is binomial with parameters $N-n$ and q . The recursion is the tower property applied one step at a time. $\square$

The recursion is the practical algorithm: fill in the payouts at expiry, then work backwards through the tree, at each node taking the q -weighted average of the two values to the right and discounting by $1+r$. But pricing is only half the story; a bank that sells an option wants to know how to *hedge* it.

Theorem 43.6.11 (Replication)

With V as above, define the previsible process

$$\theta_n = \frac{V(n, S_{n-1}(1+b)) - V(n, S_{n-1}(1+a))}{S_{n-1}(b-a)},$$

and let $X_0 = V(0, S_0)$, $X_n = (1+r)X_{n-1} + \theta_n(S_n - (1+r)S_{n-1})$. Then $X_n = V(n, S_n)$ for all n ; in particular $X_N = g(S_N)$.

Proof. We induct on n , the case $n = 0$ holding by definition. Suppose $X_{n-1} = V(n-1, S_{n-1})$ and write $V_b = V(n, S_{n-1}(1+b))$, $V_a = V(n, S_{n-1}(1+a))$. Using the recursion of Theorem 43.6.10,

$$X_n = qV_b + (1-q)V_a + \frac{V_b - V_a}{b-a}(\xi_n - 1 - r).$$

If $\xi_n = 1+b$ then $\xi_n - 1 - r = b - r$, and since $q = \frac{r-a}{b-a}$, $1-q = \frac{b-r}{b-a}$,

$$\begin{aligned} X_n &= \frac{(r-a)V_b + (b-r)V_a}{b-a} + \frac{(b-r)(V_b - V_a)}{b-a} \\ &= \frac{(r-a+b-r)V_b + (b-r-b+r)V_a}{b-a} = V_b. \end{aligned}$$

If $\xi_n = 1+a$ then $\xi_n - 1 - r = a - r$ and the same computation gives $X_n = V_a$. In both cases $X_n = V(n, S_n)$. $\square$

The quantity θ_n is the **delta** of the claim: the ratio of the change in the option value to the change in the stock price over one step. Holding θ_n shares (funded by the bank) exactly reproduces the option, which is what ‘hedging’ means.

Example 43.6.12 (A European call in the binomial tree)

Take the tree above and a European call with strike $K = 100$ and expiry $N = 3$. At expiry the payouts are

$$(172.8-100)^+ = 72.8, \quad (129.6-100)^+ = 29.6, \quad (97.2-100)^+ = 0, \quad (72.9-100)^+ = 0.$$

Working backwards with $q = \frac{1}{2}$ and $1+r = 1.05$:

$$V(2, 144) = \frac{1}{1.05} \left(\frac{1}{2} \cdot 72.8 + \frac{1}{2} \cdot 29.6 \right) = \frac{51.2}{1.05} = 48.762,$$

$$V(2, 108) = \frac{1}{1.05} \left(\frac{1}{2} \cdot 29.6 + \frac{1}{2} \cdot 0 \right) = \frac{14.8}{1.05} = 14.095,$$

$$V(2, 81) = 0,$$

$$V(1, 120) = \frac{1}{1.05} \cdot \frac{1}{2} (48.762 + 14.095) = 29.932,$$

$$V(1, 90) = \frac{1}{1.05} \cdot \frac{1}{2} (14.095 + 0) = 6.712,$$

$$V(0, 100) = \frac{1}{1.05} \cdot \frac{1}{2} (29.932 + 6.712) = 17.450.$$

As a check, the direct formula of Theorem 43.6.10 gives

$$V(0, 100) = \frac{1}{1.05^3} \left(\frac{1}{8} \cdot 72.8 + \frac{3}{8} \cdot 29.6 \right) = \frac{9.1 + 11.1}{1.157625} = \frac{20.2}{1.157625} = 17.450. \checkmark$$

The initial hedge is

$$\theta_1 = \frac{29.932 - 6.712}{100 \cdot 0.3} = \frac{23.220}{30} = 0.774,$$

so on selling the option for £17.45 one immediately buys 0.774 shares, costing £77.40, borrowing the difference £59.95 from the bank. One period later the position is rebalanced: for instance if the stock rises to 120, the new delta is $(48.762 - 14.095)/(120 \cdot 0.3) = 0.963$, so one buys a further 0.189 shares.

§43.6.6 Put–Call Parity

Calls and puts are not independent objects.

Proposition 43.6.13 (Put–call parity)

Let C_n and P_n be the time- n prices of a European call and put with the same strike K and expiry N . Then

$$C_n - P_n = S_n - \frac{K}{(1+r)^{N-n}}.$$

Proof. At expiry, for every value of S_N ,

$$(S_N - K)^+ - (K - S_N)^+ = S_N - K,$$

since exactly one of the two options is in the money. Hence a long call and a short put together replicate one share plus a debt of K , and by the law of one price the values must agree. Formally, taking discounted risk-neutral conditional expectations,

$$C_n - P_n = \frac{\mathbb{E}_{\mathbb{Q}}[S_N - K \mid \mathcal{F}_n]}{(1+r)^{N-n}} = S_n - \frac{K}{(1+r)^{N-n}},$$

using that $\tilde{S}$ is a $\mathbb{Q}$ -martingale. $\square$

The identity is best seen as a picture: stacking the call payoff on top of the negated put payoff gives the straight line $S_N - K$.

Parity is used constantly in practice: it means that only one of the call and the put need be modelled, and any violation of it is a pure arbitrage requiring no view on the future at all.

Proposition 43.6.14 (Properties of the call price)

Let $g(s) = (s - K)^+$ and let θ_n be the replicating strategy of Theorem 43.6.11. Then $s \mapsto V(n, s)$ is increasing and convex, and $\theta_n \in [0, 1]$.

Proof. Writing $S_N = S_n Z$ with $Z = \xi_{n+1} \cdots \xi_N$ independent of $\mathcal{F}_n$ and positive,

$$V(n, s) = \frac{1}{(1+r)^{N-n}} \mathbb{E}_{\mathbb{Q}}[(sZ - K)^+].$$

For each fixed value of Z , the map $s \mapsto (sZ - K)^+$ is increasing and convex; both properties are preserved by taking expectations, so $V(n, \cdot)$ is increasing and convex. Since θ_n is a difference quotient of $V(n, \cdot)$, we get $\theta_n \geq 0$.

For the upper bound use parity in the form $(s - K)^+ = s - K + (K - s)^+$:

$$V(n, s) = s - \frac{K}{(1+r)^{N-n}} + \frac{1}{(1+r)^{N-n}} \mathbb{E}_{\mathbb{Q}}[(K - sZ)^+],$$

using $\mathbb{E}_{\mathbb{Q}}[Z] = (1+r)^{N-n}$. The final term is decreasing in s , so $s \mapsto V(n, s) - s$ is decreasing, giving $\theta_n \leq 1$. $\square$

The bounds $0 \leq \theta_n \leq 1$ have a clean interpretation: to hedge one call you never need to short the stock, and never need more than one share.

§43.6.7 American Claims

A European claim may only be exercised at expiry. An American claim may be exercised at any time up to expiry, at the holder's choice.

Definition 43.6.15 (American claim)

An **American contingent claim** with expiry N is an adapted process $(Y_n)_{0 \leq n \leq N}$, where Y_n is the payout if the claim is exercised at time n . The **American call** and **American put** with strike K are $Y_n = (S_n - K)^+$ and $Y_n = (K - S_n)^+$ respectively.

The holder must choose when to exercise using only information available at that time, i.e. must choose a stopping time. So the value is an optimal stopping problem, and §5.6 tells us the answer.

Theorem 43.6.16

In a complete arbitrage-free market with risk-neutral measure $\mathbb{Q}$, the time- n price of the American claim (Y_n) is

$$\pi_n = \max_{\substack{T \text{ stopping time} \\ n \leq T \leq N}} \mathbb{E}_{\mathbb{Q}} \left[\frac{(1+r)^n}{(1+r)^T} Y_T \mid \mathcal{F}_n \right],$$

so that $\pi_n/(1+r)^n$ is the Snell envelope of $Y_n/(1+r)^n$ under $\mathbb{Q}$. Equivalently,

$$\pi_N = Y_N, \quad \pi_{n-1} = \max \left\{ Y_{n-1}, \frac{1}{1+r} \mathbb{E}_{\mathbb{Q}}[\pi_n \mid \mathcal{F}_{n-1}] \right\},$$

and $T^* = \min\{n : \pi_n = Y_n\}$ is an optimal exercise time.

Proof. This is Theorem 43.5.28 applied to the discounted payout process under $\mathbb{Q}$, together with the observation that the seller of the claim must be able to hedge against *every* exercise policy, and the writer's minimal hedging cost is exactly the smallest supermartingale dominating the discounted payouts. $\square$

Example 43.6.17 (An American put)

Take the same tree, and an American put with $K = 100$, $N = 3$. The exercise values are $(100 - S_n)^+$, and we work backwards using $\pi_{n-1} = \max\{Y_{n-1}, \frac{1}{1.05} \cdot \frac{1}{2}(\pi_n^\uparrow + \pi_n^\downarrow)\}$.

At $n = 3$ the payouts are 0, 0, 2.8, 27.1. At $n = 2$,

$$\begin{aligned}\pi(144) &= \max\{0, 0\} = 0, \\ \pi(108) &= \max\{0, 1.4/1.05\} = 1.333, \\ \pi(81) &= \max\{19, 14.95/1.05\} = \max\{19, 14.238\} = 19,\end{aligned}$$

so at the node $S_2 = 81$ it is optimal to exercise. At $n = 1$,

$$\begin{aligned}\pi(120) &= \max\{0, 0.667/1.05\} = 0.635, \\ \pi(90) &= \max\{10, 10.167/1.05\} = \max\{10, 9.683\} = 10,\end{aligned}$$

so we exercise at $S_1 = 90$ too. Finally $\pi_0 = \max\{0, \frac{1}{1.05} \cdot \frac{1}{2}(0.635 + 10)\} = 5.064$.

For comparison, put-call parity gives the *European* put price

$$P_0 = C_0 + \frac{K}{(1+r)^3} - S_0 = 17.450 + 86.384 - 100 = 3.834,$$

so the right of early exercise is worth $5.064 - 3.834 = 1.230$, a premium of over 30%. The tree of American values, with the exercise nodes ringed, is:

The pattern is typical: one exercises the put when the stock has fallen far enough that the interest earned on the strike outweighs the option value of waiting. For calls the situation is quite different.

Proposition 43.6.18

Suppose $(Y_n/(1+r)^n)$ is a $\mathbb{Q}$ -submartingale. Then it is optimal never to exercise the American claim before expiry, and its price coincides with that of the corresponding European claim.

Proof. We show by backward induction that $\pi_n = \mathbb{E}_{\mathbb{Q}}[Y_N/(1+r)^{N-n} \mid \mathcal{F}_n]$. This holds at $n = N$. If it holds at n then

$$\pi_{n-1} = \max \left\{ Y_{n-1}, \frac{1}{(1+r)^{N-n+1}} \mathbb{E}_{\mathbb{Q}}[Y_N \mid \mathcal{F}_{n-1}] \right\},$$

and the submartingale property gives $Y_{n-1}/(1+r)^{n-1} \leq \mathbb{E}_{\mathbb{Q}}[Y_N/(1+r)^N \mid \mathcal{F}_{n-1}]$, so the second term is the larger. Hence the maximum is attained by never stopping. $\square$

Corollary 43.6.19 (Never exercise an American call early)

In an arbitrage-free model with $r \geq 0$ and no dividends, an American call has the same value as the European call, and it is never strictly optimal to exercise it early.

Proof. We check that $(S_n - K)^+/(1+r)^n$ is a $\mathbb{Q}$ -submartingale. The function $x \mapsto x^+$ is convex, so conditional Jensen gives

$$\mathbb{E}_{\mathbb{Q}} \left[\frac{(S_n - K)^+}{(1+r)^n} \mid \mathcal{F}_{n-1} \right] \geq \left(\mathbb{E}_{\mathbb{Q}} \left[\frac{S_n - K}{(1+r)^n} \mid \mathcal{F}_{n-1} \right] \right)^+ = \left(\frac{S_{n-1}}{(1+r)^{n-1}} - \frac{K}{(1+r)^n} \right)^+,$$

using that $\tilde{S}$ is a $\mathbb{Q}$ -martingale. Since $r \geq 0$ this is at least $(S_{n-1} - K)^+/(1+r)^{n-1}$, which is the submartingale property. Now apply Proposition 43.6.18. $\square$

The intuition is worth having: exercising a call early means paying K sooner than necessary and throwing away the insurance that the option provides against the price falling below K . One should sell the option rather than exercise it.

§43.6.8 Dynamic Programming

The Snell envelope is a special case of a much more general technique, which also solves the multi-period utility maximisation problem. We record it briefly.

Let (ξ_n) be i.i.d., let (U_n) be a previsible **control** process taking values in a set $\mathcal{U}$, and let the **controlled Markov process** (X_n) evolve by

$$X_n = G(X_{n-1}, U_n, \xi_n).$$

We wish to maximise $\mathbb{E} \left[\sum_{k=1}^N f(k, U_k) + g(X_N) \mid X_0 = x \right]$ over controls.

Definition 43.6.20

The **value function** is

$$V(n, x) = \sup_{(U_k)} \mathbb{E} \left[\sum_{k=n+1}^N f(k, U_k) + g(X_N) \mid X_n = x \right].$$

Theorem 43.6.21 (Bellman)

Suppose V solves **Bellman's equation**

$$V(n-1, x) = \sup_{u \in \mathcal{U}} \left(f(n, u) + \mathbb{E}[V(n, G(x, u, \xi))] \right), \quad V(N, x) = g(x),$$

and let $u^*(n, x)$ attain the supremum. Then the Markov control $U_n^* = u^*(n, X_{n-1}^*)$ is optimal, and V is the value function.

Proof. Given any control (U_n) with controlled process (X_n) , set $M_n = \sum_{k=1}^n f(k, U_k) + V(n, X_n)$. Then

$$\mathbb{E}[M_n - M_{n-1} \mid \mathcal{F}_{n-1}] = f(n, U_n) + \mathbb{E}[V(n, X_n) \mid \mathcal{F}_{n-1}] - V(n-1, X_{n-1}) \leq 0$$

by Bellman's equation, so M is a supermartingale, with equality throughout when $U = U^*$, in which case M is a martingale. Hence

$$\mathbb{E} \left[\sum_{k=1}^N f(k, U_k) + g(X_N) \right] = \mathbb{E}[M_N] \leq M_0 = V(0, x),$$

with equality for $U = U^*$. □

Example 43.6.22 (Merton's problem with CARA utility)

Take $d = 1$, $S_n = S_{n-1}\xi_n$ with (ξ_n) i.i.d., and wealth dynamics $X_n = (1+r)X_{n-1} + \eta_n(\xi_n - (1+r))$, where $\eta_n = \theta_n S_{n-1}$ is the amount of money in the stock – a controlled Markov process. We maximise $\mathbb{E}[U(X_N)]$ for $U(x) = -e^{-\gamma x}$.

Guess $V(n, x) = U(x(1+r)^{N-n})A_n$ with $A_N = 1$. Then

$$\begin{aligned} V(n-1, x) &= \sup_{\eta} \mathbb{E} \left[A_n U((1+r)x + \eta(\xi - (1+r)))(1+r)^{N-n} \right] \\ &= U(x(1+r)^{N-n+1})A_n \inf_t \mathbb{E}[e^{t(\xi - (1+r))}], \end{aligned}$$

on substituting $t = \gamma\eta(1+r)^{N-n}$. So the guess is consistent with $A_{n-1} = \alpha A_n$, where $\alpha = \inf_t \mathbb{E}[e^{t(\xi - (1+r))}]$, whence $A_n = \alpha^{N-n}$, and the optimal holding is

$$\theta_n^* = \frac{t^*}{\gamma(1+r)^{N-n}S_{n-1}},$$

with t^* the minimiser. Note the CARA signature: the optimal *amount of money* η_n^* invested in the stock is a deterministic constant, independent of current wealth.

Example 43.6.23 (Consumption and CRRA utility)

If the agent may also consume an amount C_n during $(n-1, n]$, the dynamics become

$$X_n = (1+r)(X_{n-1} - C_n) + \eta_n(\xi_n - (1+r)),$$

and one maximises $\mathbb{E}[\sum_{k=1}^N U(C_k) + U(X_N)]$. For $U(x) = x^{1-R}/(1-R)$ with $R > 0$, $R \neq 1$, the value function separates as $V(n, x) = U(x)A_n$, and Bellman's equation reduces to a one-dimensional problem in the consumption fraction $s = C/x$:

$$A_{n-1} = \sup_{s \in (0,1)} (s^{1-R} + A_n \alpha (1-s)^{1-R}), \quad \alpha = (1-R) \sup_t \mathbb{E}[U((1+r) + t(\xi - (1+r)))].$$

Solving gives $A_n = ((1 - \alpha^{(N-n+1)/R})/(1 - \alpha^{1/R}))^R$ and the optimal consumption is a fixed *fraction* of wealth at each date. Again the CRRA signature: everything scales with wealth.

§43.7 Brownian Motion

Discrete-time models are perfectly adequate for computation, but they are awkward: the answers depend on the step size, and the formulae are sums of binomial coefficients rather than anything one would want to differentiate. In this section we construct the continuous-time limit.

§43.7.1 From Random Walk to Brownian Motion

Return to the binomial model $S_n = S_0 \xi_1 \cdots \xi_n$ and take logarithms:

$$\log S_n = \log S_0 + \sum_{k=1}^n \log \xi_k,$$

a random walk. Now let each period represent a small time δ , so that $t = n\delta$, and choose the parameters so that the mean and variance accumulate at fixed rates:

$$\mathbb{E}[\log \xi] = \mu\delta, \quad \text{Var}(\log \xi) = \sigma^2\delta.$$

Then $\log S_t$ has mean $\log S_0 + \mu t$ and variance $\sigma^2 t$, independently of δ . Writing

$$W_t = \frac{\log(S_t/S_0) - \mu t}{\sigma},$$

the central limit theorem from Part IA suggests that, as $\delta \downarrow 0$ with t fixed, W_t should converge to a $N(0, t)$ random variable; and since the increments of the walk over disjoint blocks are independent, the same should hold for increments. The limiting object is Brownian motion.

Definition 43.7.1 (Brownian motion)

A **standard Brownian motion** is a stochastic process $(W_t)_{t \geq 0}$ such that

- (i) $W_0 = 0$;
- (ii) for $0 \leq s < t$, the increment $W_t - W_s$ is independent of $(W_u)_{0 \leq u \leq s}$;
- (iii) for $0 \leq s < t$, $W_t - W_s \sim N(0, t - s)$;

(iv) almost surely, $t \mapsto W_t$ is continuous.

That such a process exists is a genuine theorem, and not an easy one: one is asking for uncountably many random variables with prescribed joint laws whose sample paths are continuous.

Theorem 43.7.2 (Wiener, 1923)

Brownian motion exists.

We shall take this for granted. Here is a simulated path, drawn as an actual random walk with 360 steps on $[0, 1]$ – which, at this resolution, is visually indistinguishable from the real thing.

The path is continuous but visibly rough: it has no intervals of monotonicity, and in fact it is almost surely nowhere differentiable and of infinite variation on every interval. This roughness is not a defect of the model – it is precisely what makes the theory work, since it is the accumulated quadratic variation $\sum (W_{t_{i+1}} - W_{t_i})^2 \rightarrow t$ that produces the second-derivative term in Itô's formula.

§43.7.2 Basic Properties

Definition 43.7.3

A process $(X_t)_{t \geq 0}$ is **Gaussian** if $(X_{t_1}, \dots, X_{t_n})$ is a multivariate normal vector for all $0 \leq t_1 < \dots < t_n$.

Theorem 43.7.4 (Gaussian characterisation)

A continuous process $(W_t)_{t \geq 0}$ with $W_0 = 0$ is a Brownian motion if and only if it is a Gaussian process with

$$\mathbb{E}[W_t] = 0 \quad \text{and} \quad \mathbb{E}[W_s W_t] = s \wedge t \quad \text{for all } s, t \geq 0.$$

Proof. ($\Rightarrow$) If W is a Brownian motion then $W_{t_1}, W_{t_2} - W_{t_1}, \dots, W_{t_n} - W_{t_{n-1}}$ are independent normals, so any linear combination of $W_{t_1}, \dots, W_{t_n}$ is normal, hence W is Gaussian. Clearly $\mathbb{E}[W_t] = 0$, and for $s < t$,

$$\mathbb{E}[W_s W_t] = \mathbb{E}[W_s^2] + \mathbb{E}[W_s(W_t - W_s)] = s + 0 = s.$$

($\Leftarrow$) Conversely, suppose W is Gaussian with the stated moments. For $s < t$, $W_t - W_s$ is normal (being a linear combination of jointly Gaussian variables) with mean 0 and variance

$$\mathbb{E}[W_t^2] - 2\mathbb{E}[W_s W_t] + \mathbb{E}[W_s^2] = t - 2s + s = t - s.$$

For $u < s < t$, $\mathbb{E}[(W_t - W_s)W_u] = u - u = 0$, so $W_t - W_s$ is uncorrelated with $(W_u)_{u \leq s}$; as everything is jointly Gaussian, uncorrelated means independent (a fact from Part IA Probability). Hence W is a Brownian motion. $\square$

This characterisation makes the following symmetries almost trivial to verify.

Theorem 43.7.5 (Invariance properties)

Let $(W_t)_{t \geq 0}$ be a Brownian motion. Then so are:

- (i) (*Scaling*) $\tilde{W}_t = cW_{t/c^2}$, for any $c \neq 0$;
- (ii) (*Simple Markov property*) $\tilde{W}_t = W_{t+T} - W_T$, for any fixed $T \geq 0$;
- (iii) (*Time inversion*) $\tilde{W}_t = tW_{1/t}$ for $t > 0$, $\tilde{W}_0 = 0$;
- (iv) (*Reflection*) $\tilde{W}_t = -W_t$.

Proof. Each is Gaussian with mean zero, so by Theorem 43.7.4 we need only check covariances. For (i), $\mathbb{E}[\tilde{W}_s \tilde{W}_t] = c^2(s/c^2 \wedge t/c^2) = s \wedge t$. For (ii), $\mathbb{E}[\tilde{W}_s \tilde{W}_t] = (s+T) \wedge (t+T) - T = s \wedge t$. For (iii), taking $s < t$, $\mathbb{E}[\tilde{W}_s \tilde{W}_t] = st(1/s \wedge 1/t) = st/t = s$. For (iv) it is immediate. The only subtlety is continuity at 0 in (iii), which amounts to $W_t/t \rightarrow 0$ almost surely as $t \rightarrow \infty$; this is a form of the strong law of large numbers. $\square$

Property (i) is worth dwelling on: Brownian motion is a fractal, statistically identical to itself under the rescaling $(t, w) \mapsto (c^2 t, cw)$. Space scales like the square root of time – which is the CLT again.

Theorem 43.7.6

Brownian motion is a Markov process: for bounded measurable g and $s < t$,

$$\mathbb{E}[g(W_t) \mid \mathcal{F}_s] = \mathbb{E}[g(W_t) \mid W_s],$$

where $\mathcal{F}_s = \sigma(W_u : u \leq s)$.

Proof. Writing $W_t = (W_t - W_s) + W_s$ with $W_t - W_s \sim N(0, t - s)$ independent of $\mathcal{F}_s$,

$$\mathbb{E}[g(W_t) \mid \mathcal{F}_s] = \int_{\mathbb{R}} g(z + W_s) \frac{e^{-z^2/2(t-s)}}{\sqrt{2\pi(t-s)}} dz,$$

which is a function of W_s alone. $\square$

Later we shall want to restart the process not at a fixed time but at a random one, and for that the simple Markov property is not enough. The correct strengthening is the following, which we shall use without proof.

Theorem 43.7.7 (Strong Markov property)

Let W be a Brownian motion and T an almost surely finite stopping time for $(\mathcal{F}_t)$. Then

$$(W_{T+t} - W_T)_{t \geq 0}$$

is a Brownian motion, independent of $\mathcal{F}_T = \{A : A \cap \{T \leq t\} \in \mathcal{F}_t \text{ for all } t\}$.

Remark. The proof is a discretisation argument, and it is worth sketching because it shows exactly where continuity is used. Set $T_n = 2^{-n} \lceil 2^n T \rceil$, a stopping time taking countably many values $k2^{-n}$. On the event $\{T_n = k2^{-n}\} \in \mathcal{F}_{k2^{-n}}$ the simple Markov property applies, and summing over k shows that $(W_{T_n+t} - W_{T_n})_t$ is a Brownian motion independent of $\mathcal{F}_{T_n}$, hence of the smaller σ -algebra $\mathcal{F}_T$. Since $T_n \downarrow T$ and the paths are continuous, $W_{T_n+t} \rightarrow W_{T+t}$ almost surely, and the property passes to the limit. Without path continuity the last step fails, and indeed the strong Markov property is genuinely delicate for processes with jumps.

It is a good moment to make precise the roughness we noticed in the picture. The relevant quantity is the **quadratic variation**, and it is really the whole reason that stochastic calculus differs from ordinary calculus.

Theorem 43.7.8 (Quadratic variation)

Fix $t > 0$ and for each n let $0 = t_0^n < t_1^n < \dots < t_{m_n}^n = t$ be a partition of $[0, t]$ with mesh $\delta_n = \max_i(t_i^n - t_{i-1}^n) \rightarrow 0$. Then

$$Q_n := \sum_{i=1}^{m_n} (W_{t_i^n} - W_{t_{i-1}^n})^2 \longrightarrow t \quad \text{in } L^2.$$

Proof. Write $\Delta_i = W_{t_i^n} - W_{t_{i-1}^n}$ and $h_i = t_i^n - t_{i-1}^n$, so that the Δ_i are independent with $\Delta_i \sim N(0, h_i)$. Then $\mathbb{E}[\Delta_i^2] = h_i$, so $\mathbb{E}[Q_n] = \sum_i h_i = t$ exactly. For the variance, independence gives

$$\text{Var}(Q_n) = \sum_i \text{Var}(\Delta_i^2) = \sum_i (\mathbb{E}[\Delta_i^4] - h_i^2) = \sum_i (3h_i^2 - h_i^2) = 2 \sum_i h_i^2,$$

using $\mathbb{E}[Z^4] = 3$ for standard normal Z . Finally $\sum_i h_i^2 \leq \delta_n \sum_i h_i = \delta_n t \rightarrow 0$, so $\mathbb{E}[(Q_n - t)^2] \rightarrow 0$. $\square$

The contrast with a differentiable function f is stark: there $\sum_i (f(t_i) - f(t_{i-1}))^2 \leq \delta_n \sum_i |f(t_i) - f(t_{i-1})| \rightarrow 0$, since the total variation is finite. So Brownian paths cannot be differentiable, and the following is immediate.

Corollary 43.7.9

Almost surely, the path $s \mapsto W_s$ has infinite total variation on $[0, t]$ for every $t > 0$; in particular it is not monotone on any interval, and is not of bounded variation, so $\int_0^t H_s dW_s$ cannot be defined pathwise as a Stieltjes integral.

Proof. Along a subsequence, $Q_n \rightarrow t$ almost surely. If the path had total variation

$V < \infty$ on $[0, t]$ then, by uniform continuity of the path on the compact interval,

$$Q_n \leq \left(\max_i |W_{t_i^n} - W_{t_{i-1}^n}| \right) V \longrightarrow 0,$$

contradicting $Q_n \rightarrow t > 0$. $\square$

The slogan is that $(dW_t)^2 = dt$: increments of Brownian motion are of size $\sqrt{dt}$, so their squares accumulate at rate dt rather than vanishing. Everything unusual about Itô's formula comes from this one fact.

§43.7.3 Martingale Properties

Definition 43.7.10

A continuous process $(X_t)_{t \geq 0}$ adapted to a filtration $(\mathcal{F}_t)_{t \geq 0}$ is a **martingale** if each X_t is integrable and $\mathbb{E}[X_t | \mathcal{F}_s] = X_s$ for all $0 \leq s \leq t$.

Proposition 43.7.11

Let W be a Brownian motion and $(\mathcal{F}_t)$ its generated filtration. Then the following are martingales:

- (i) W_t ;
- (ii) $W_t^2 - t$;
- (iii) $\mathcal{E}_t^\theta := \exp(\theta W_t - \theta^2 t/2)$, for each fixed $\theta \in \mathbb{R}$.

Proof. In each case we use that $W_t - W_s$ is independent of $\mathcal{F}_s$ with law $N(0, t - s)$.
 (i) $\mathbb{E}[W_t | \mathcal{F}_s] = \mathbb{E}[W_t - W_s | \mathcal{F}_s] + W_s = 0 + W_s$. (ii) $\mathbb{E}[W_t^2 | \mathcal{F}_s] = \mathbb{E}[(W_t - W_s)^2 | \mathcal{F}_s] + 2W_s \mathbb{E}[W_t - W_s | \mathcal{F}_s] + W_s^2 = (t - s) + W_s^2$, and subtracting t gives the claim.
 (iii) $\mathbb{E}[e^{\theta(W_t - W_s)} | \mathcal{F}_s] = e^{\theta^2(t-s)/2}$ by the normal moment generating function, so

$$\mathbb{E}[\mathcal{E}_t^\theta | \mathcal{F}_s] = \mathcal{E}_s^\theta e^{-\theta^2(t-s)/2} \mathbb{E}[e^{\theta(W_t - W_s)} | \mathcal{F}_s] = \mathcal{E}_s^\theta. \quad \square$$

The process $\mathcal{E}^\theta$ is the **exponential martingale**, and it is the single most useful object in this course: it is simultaneously the density of a change of measure, the discounted stock price under the risk-neutral measure, and a generating function for the moments of W .

Remarkably, each of (i)–(iii) characterises Brownian motion.

Theorem 43.7.12

A continuous process $(W_t)_{t \geq 0}$ with $W_0 = 0$ is a Brownian motion if and only if $(e^{\theta W_t - \theta^2 t/2})_{t \geq 0}$ is a martingale for every $\theta \in \mathbb{R}$.

Proof. Necessity is Proposition 43.7.11(iii). Conversely, the martingale property gives

$$\mathbb{E}[e^{\theta(W_t - W_s)} | \mathcal{F}_s] = e^{\theta^2(t-s)/2}$$

for every θ . The right-hand side is deterministic, and it is the moment generating function of $N(0, t-s)$; since moment generating functions determine distributions, $W_t - W_s \sim N(0, t-s)$ and, the conditional law being non-random, $W_t - W_s$ is independent of $\mathcal{F}_s$. $\square$

Theorem 43.7.13 (Lévy's characterisation)

A continuous process $(W_t)_{t \geq 0}$ with $W_0 = 0$ is a Brownian motion if and only if both (W_t) and $(W_t^2 - t)$ are martingales.

We omit the proof, which is a genuine piece of stochastic analysis. It is a strikingly strong statement: two moment conditions plus continuity pin the process down completely.

§43.7.4 Hitting Times and the Reflection Principle

Definition 43.7.14

For $a \in \mathbb{R}$, let $T_a = \inf\{t \geq 0 : W_t = a\}$ be the first **hitting time** of level a , and let $M_t = \max_{0 \leq s \leq t} W_s$ be the running maximum.

Note that $\{T_a \leq t\} = \{M_t \geq a\}$ for $a > 0$, by continuity of paths.

Theorem 43.7.15

For every $a \in \mathbb{R} \setminus \{0\}$, $T_a < \infty$ almost surely.

Proof. By symmetry take $a > 0$; we show $Z := \sup_{t \geq 0} W_t = \infty$ a.s. By the scaling property, for any $c > 0$ the process $\tilde{W}_t = cW_{t/c^2}$ is a Brownian motion, so

$$\mathbb{P}\left(\sup_{t \geq 0} W_t > a\right) = \mathbb{P}\left(\sup_{t \geq 0} \tilde{W}_t > a\right) = \mathbb{P}\left(\sup_{t \geq 0} W_t > a/c\right).$$

Letting $c \downarrow 0$ shows that $\mathbb{P}(Z > a)$ is the same for all $a > 0$, so $Z \in \{0, \infty\}$ almost surely. Now let $\hat{Z} = \sup_{t \geq 1} (W_t - W_1)$, which has the same law as Z and is independent of W_1 . If $p = \mathbb{P}(Z = 0)$ then, since $\{Z = 0\} \subseteq \{W_1 \leq 0\} \cap \{\hat{Z} = 0\}$,

$$p = \mathbb{P}(Z = 0) \leq \mathbb{P}(W_1 \leq 0) \mathbb{P}(\hat{Z} = 0) = \frac{1}{2}p,$$

forcing $p = 0$. Hence $Z = \infty$ a.s. $\square$

The key tool for computing with M_t is the following, which says that if we reflect the path in the level a after it first reaches a , we get another Brownian motion.

Theorem 43.7.16 (Reflection principle)

Let W be a Brownian motion and $a > 0$. Then

$$\tilde{W}_t = W_t \mathbb{1}_{\{t \leq T_a\}} + (2a - W_t) \mathbb{1}_{\{t > T_a\}}$$

is a Brownian motion.

Proof. By Theorem 43.7.15 the time T_a is an almost surely finite stopping time, so the strong Markov property (Theorem 43.7.7) applies: $(W_{T_a+t} - W_{T_a})_{t \geq 0} = (W_{T_a+t} - a)_{t \geq 0}$ is a Brownian motion independent of $\mathcal{F}_{T_a}$. By the reflection invariance, so is its negative. Since $\tilde{W}_{T_a+t} = a - (W_{T_a+t} - a)$, the process $\tilde{W}$ is obtained from W by replacing the post- T_a increments by their negatives, which does not change the law. $\square$

Lemma 43.7.17

For bounded measurable g and $a > 0$,

$$\mathbb{E}[g(W_t) \mathbb{1}_{\{W_t \leq a, M_t \geq a\}}] = \mathbb{E}[g(2a - W_t) \mathbb{1}_{\{W_t \geq a\}}].$$

Proof. Let $\tilde{W}$ be as in Theorem 43.7.16 and $\tilde{M}_t = \max_{s \leq t} \tilde{W}_s$. Since reflection does not change whether the level a is reached, $\{M_t \geq a\} = \{\tilde{M}_t \geq a\}$; and on that event $W_t = 2a - \tilde{W}_t$. Hence

$$\begin{aligned} \mathbb{E}[g(W_t) \mathbb{1}_{\{W_t \leq a, M_t \geq a\}}] &= \mathbb{E}[g(2a - \tilde{W}_t) \mathbb{1}_{\{\tilde{W}_t \geq a, \tilde{M}_t \geq a\}}] \\ &= \mathbb{E}[g(2a - \tilde{W}_t) \mathbb{1}_{\{\tilde{W}_t \geq a\}}], \end{aligned}$$

because $\{\tilde{W}_t \geq a\} \subseteq \{\tilde{M}_t \geq a\}$. As $\tilde{W}$ has the same law as W , we may drop the tildes. $\square$

Corollary 43.7.18

For $a \geq b$ and $a \geq 0$, $\mathbb{P}(W_t \leq b, M_t \geq a) = \mathbb{P}(W_t \geq 2a - b)$.

Proof. Take $g(w) = \mathbb{1}_{\{w \leq b\}}$ in Lemma 43.7.17: the left side is $\mathbb{P}(W_t \leq b, M_t \geq a)$ (using $b \leq a$), and the right side is $\mathbb{P}(2a - W_t \leq b, W_t \geq a) = \mathbb{P}(W_t \geq 2a - b)$, the constraint $W_t \geq a$ being implied. $\square$

This immediately gives the joint law of (M_t, W_t) and the law of the hitting time.

Theorem 43.7.19

For $t > 0$:

- (i) M_t has the same law as $|W_t|$; explicitly $\mathbb{P}(M_t \geq a) = 2\Phi(-a/\sqrt{t})$ for $a \geq 0$;
(ii) the pair (M_t, W_t) has joint density, for $a \geq b^+$,

$$f_{M_t, W_t}(a, b) = \frac{2(2a - b)}{t^{3/2}\sqrt{2\pi}} \exp\left(-\frac{(2a - b)^2}{2t}\right);$$

- (iii) the hitting time T_a ($a > 0$) has density

$$f_{T_a}(t) = \frac{a}{t^{3/2}\sqrt{2\pi}} e^{-a^2/2t}, \quad t > 0,$$

and $\mathbb{E}[T_a] = \infty$.

Proof. (i) Splitting according to the value of W_t and using Corollary 43.7.18 with $b = a$,

$$\begin{aligned} \mathbb{P}(M_t \geq a) &= \mathbb{P}(M_t \geq a, W_t \geq a) + \mathbb{P}(M_t \geq a, W_t \leq a) \\ &= \mathbb{P}(W_t \geq a) + \mathbb{P}(W_t \geq a) = 2\Phi(-a/\sqrt{t}), \end{aligned}$$

where the first term used $\{W_t \geq a\} \subseteq \{M_t \geq a\}$. This is exactly $\mathbb{P}(|W_t| \geq a)$.

(ii) Differentiate $\mathbb{P}(W_t \leq b, M_t \geq a) = \mathbb{P}(W_t \geq 2a - b) = 1 - \Phi((2a - b)/\sqrt{t})$ once in a and once in b ; the stated formula results.

(iii) By continuity of paths $\{T_a \leq t\} = \{M_t \geq a\}$, so $\mathbb{P}(T_a \leq t) = 2\Phi(-a/\sqrt{t})$; differentiating in t gives the density. Since $f_{T_a}(t) \sim a/(\sqrt{2\pi}t^{3/2})$ as $t \rightarrow \infty$, we get $\int^\infty t f_{T_a}(t) dt = \infty$. $\square$

So Brownian motion hits every level with probability one, but takes infinitely long on average to do so – the same phenomenon we saw for the recurrent random walk in Example 43.5.20, and for exactly the same reason.

§43.7.5 The Cameron–Martin Theorem

Finally we need to be able to change measure so as to add a drift to Brownian motion. The finite-dimensional version is the Gaussian tilt of Example 43.4.4: if $Z \sim N(0, 1)$ and $\alpha \in \mathbb{R}$ then for bounded f ,

$$\mathbb{E}[e^{\alpha Z - \alpha^2/2} f(Z)] = \mathbb{E}[f(Z + \alpha)],$$

and in n dimensions, for $Z \sim N_n(0, I)$ and $\alpha \in \mathbb{R}^n$,

$$\mathbb{E}[e^{\alpha^\top Z - \|\alpha\|^2/2} f(Z)] = \mathbb{E}[f(Z + \alpha)].$$

Theorem 43.7.20 (Cameron–Martin)

Let W be a Brownian motion, $c \in \mathbb{R}$ and $t > 0$. Then for suitably integrable functionals g on $C([0, t])$,

$$\mathbb{E}[g((W_s + cs)_{0 \leq s \leq t})] = \mathbb{E}[e^{cW_t - c^2 t/2} g((W_s)_{0 \leq s \leq t})].$$

Proof. By a monotone class argument it suffices to treat $g(w) = G(w(t_1), \dots, w(t_n))$ for $0 < t_1 < \dots < t_n = t$. Writing $Z_k = (W_{t_k} - W_{t_{k-1}})/\sqrt{t_k - t_{k-1}}$ (with $t_0 = 0$), the Z_k are i.i.d. $N(0, 1)$, and g may be rewritten as $H(Z_1, \dots, Z_n)$ for a suitable H . Adding the drift cs shifts Z_k by $\alpha_k = c\sqrt{t_k - t_{k-1}}$, so

$$\begin{aligned}\mathbb{E}[g((W_s + cs)_{s \leq t})] &= \mathbb{E}[H(Z_1 + \alpha_1, \dots, Z_n + \alpha_n)] \\ &= \mathbb{E}\left[\exp\left(\sum_k \alpha_k Z_k - \frac{1}{2} \sum_k \alpha_k^2\right) H(Z_1, \dots, Z_n)\right] \\ &= \mathbb{E}[e^{cW_t - c^2 t/2} g((W_s)_{s \leq t})],\end{aligned}$$

since $\sum_k \alpha_k Z_k = c \sum_k (W_{t_k} - W_{t_{k-1}}) = cW_t$ and $\sum_k \alpha_k^2 = c^2 t$. $\square$

Corollary 43.7.21 (Girsanov, for constant drift)

Fix $c \in \mathbb{R}$ and a horizon $T > 0$, and define $\mathbb{Q} \sim \mathbb{P}$ by

$$\frac{d\mathbb{Q}}{d\mathbb{P}} = e^{cW_T - c^2 T/2}.$$

Then $\tilde{W}_t = W_t - ct$, $0 \leq t \leq T$, is a $\mathbb{Q}$ -Brownian motion.

Proof. For a bounded functional g ,

$$\mathbb{E}_{\mathbb{Q}}[g((\tilde{W}_t)_{t \leq T})] = \mathbb{E}_{\mathbb{P}}[e^{cW_T - c^2 T/2} g((W_t - ct)_{t \leq T})] = \mathbb{E}_{\mathbb{P}}[g((W_t)_{t \leq T})]$$

by Theorem 43.7.20 applied with drift $-c$. So the law of $\tilde{W}$ under $\mathbb{Q}$ equals the law of W under $\mathbb{P}$. $\square$

Notice what has happened: changing the measure changes the *drift* of the process, but not its volatility. This is the continuous-time avatar of the fact that the risk-neutral measure changes the expected return of a stock but not the size of its fluctuations, and it is the reason why the Black–Scholes price does not depend on μ .

§43.8 The Black–Scholes Model

We are finally in a position to write down the model which made mathematical finance a subject: a single stock whose price is a geometric Brownian motion, and a bank account paying a constant continuously compounded rate.

§43.8.1 The Model

Recall the passage to the limit in §7.1, where we found $\log S_t = \log S_0 + \mu t + \sigma W_t$ in the small-step limit. We take this as our definition.

Definition 43.8.1 (Black–Scholes model)

Fix constants $\mu \in \mathbb{R}$ (the **drift**), $\sigma > 0$ (the **volatility**) and $r \in \mathbb{R}$ (the interest rate), and let W be a Brownian motion. The **Black–Scholes model** has a bank account worth e^{rt} at time t and a stock whose price is the **geometric Brownian**

motion

$$S_t = S_0 e^{\mu t + \sigma W_t}.$$

The interest rate convention is the limit of the discrete one: $(1 + r\delta)^{t/\delta} \rightarrow e^{rt}$ as $\delta \downarrow 0$, so a continuously compounded rate r turns one pound into e^{rt} pounds.

Some immediate consequences. Since $W_t \sim N(0, t)$, the price S_t is **lognormal**: $\log S_t \sim N(\log S_0 + \mu t, \sigma^2 t)$. In particular $S_t > 0$ always, which is as it should be for a limited-liability share, and

$$\mathbb{E}[S_t] = S_0 e^{(\mu + \sigma^2/2)t}.$$

Note the $\sigma^2/2$: the expected price grows faster than the typical price, because the lognormal distribution is skewed. Here are five simulated paths with $S_0 = 100$, $\mu = 0.06$, $\sigma = 0.25$ over two years, together with the density of S_T at the terminal time.

The right-hand curve is the lognormal density of S_T , drawn sideways so that heights correspond to prices. Note its asymmetry: a long right tail, and a floor at zero.

§43.8.2 The Risk-Neutral Measure

Proposition 43.8.2

The Black–Scholes model on $[0, T]$ has a risk-neutral measure: there is $\mathbb{Q} \sim \mathbb{P}$ under which $(e^{-rt} S_t)_{0 \leq t \leq T}$ is a martingale. Explicitly, with

$$c = \frac{r - \mu}{\sigma} - \frac{\sigma}{2}, \quad \frac{d\mathbb{Q}}{d\mathbb{P}} = e^{cW_T - c^2 T/2},$$

the process $\tilde{W}_t = W_t - ct$ is a $\mathbb{Q}$ -Brownian motion and

$$S_t = S_0 \exp \left(\left(r - \frac{\sigma^2}{2} \right) t + \sigma \tilde{W}_t \right).$$

Proof. By Corollary 43.7.21, $\tilde{W}_t = W_t - ct$ is a $\mathbb{Q}$ -Brownian motion. Substituting $W_t = \tilde{W}_t + ct$ into the definition of S_t ,

$$S_t = S_0 e^{\mu t + \sigma(\tilde{W}_t + ct)} = S_0 e^{(\mu + \sigma c)t + \sigma \tilde{W}_t} = S_0 e^{(r - \sigma^2/2)t + \sigma \tilde{W}_t},$$

since $\mu + \sigma c = r - \sigma^2/2$. Hence $e^{-rt}S_t = S_0 e^{\sigma \tilde{W}_t - \sigma^2 t/2}$, which is the exponential martingale of Proposition 43.7.11 for the $\mathbb{Q}$ -Brownian motion $\tilde{W}$, with $\theta = \sigma$. $\square$

Two things deserve comment. First, the drift μ has vanished from the risk-neutral dynamics: under $\mathbb{Q}$ the stock grows at the riskless rate r , whatever it does in reality. Second, the volatility σ is unchanged – changing measure can shift a Brownian motion by a drift but cannot alter its scale. So of the two parameters of the model, only σ will appear in any option price.

Definition 43.8.3 (Black–Scholes price)

Let Y be the payout of a European claim with maturity T . Its **Black–Scholes price** at time t is

$$\pi_t = e^{-r(T-t)} \mathbb{E}_{\mathbb{Q}}[Y \mid \mathcal{F}_t].$$

By construction $(e^{-rt}\pi_t)$ is a $\mathbb{Q}$ -martingale, so the augmented market has no arbitrage. In fact the Black–Scholes model is complete, so this is the *only* arbitrage-free price; we prove this in §8.5, once we have Itô’s lemma to hand.

§43.8.3 The Black–Scholes Formula

Let $Y = g(S_T)$ be vanilla and write $\tau = T - t$ for the time to maturity. Under $\mathbb{Q}$,

$$S_T = S_t \exp\left(\left(r - \frac{\sigma^2}{2}\right)\tau + \sigma(\tilde{W}_T - \tilde{W}_t)\right),$$

with $\tilde{W}_T - \tilde{W}_t \sim N(0, \tau)$ independent of $\mathcal{F}_t$. So $\pi_t = V(t, S_t)$ where

$$V(t, s) = e^{-r\tau} \mathbb{E}\left[g\left(s e^{(r-\sigma^2/2)\tau + \sigma\sqrt{\tau}Z}\right)\right] = e^{-r\tau} \int_{-\infty}^{\infty} g\left(s e^{(r-\sigma^2/2)\tau + \sigma\sqrt{\tau}z}\right) \frac{e^{-z^2/2}}{\sqrt{2\pi}} dz$$

for $Z \sim N(0, 1)$. This is a completely explicit one-dimensional integral. For the call it evaluates in closed form.

Theorem 43.8.4 (Black–Scholes formula)

The price of a European call with strike K and maturity T is $V(t, S_t)$ where, with $\tau = T - t$,

$$V(t, s) = s\Phi(d_1) - Ke^{-r\tau}\Phi(d_2),$$

$$d_{1,2} = \frac{\log(s/K) + (r \pm \frac{\sigma^2}{2})\tau}{\sigma\sqrt{\tau}}, \quad d_2 = d_1 - \sigma\sqrt{\tau},$$

and Φ is the standard normal distribution function.

Proof. Write $g(s) = (s - K)^+$ and $S_T = s e^{(r-\sigma^2/2)\tau + \sigma\sqrt{\tau}Z}$. The option finishes in the money precisely when

$$s e^{(r-\sigma^2/2)\tau + \sigma\sqrt{\tau}z} > K \iff z > \frac{\log(K/s) - (r - \sigma^2/2)\tau}{\sigma\sqrt{\tau}} = -d_2.$$

Hence

$$V(t, s) = e^{-r\tau} \int_{-d_2}^{\infty} \left(s e^{(r-\sigma^2/2)\tau + \sigma\sqrt{\tau}z} - K \right) \varphi(z) \, dz,$$

where φ is the standard normal density. The second piece is $-e^{-r\tau}K(1 - \Phi(-d_2)) = -Ke^{-r\tau}\Phi(d_2)$. For the first, note the completing-the-square identity

$$e^{-\sigma^2\tau/2 + \sigma\sqrt{\tau}z} \varphi(z) = \varphi(z - \sigma\sqrt{\tau}),$$

so that

$$\begin{aligned} e^{-r\tau} \int_{-d_2}^{\infty} s e^{(r-\sigma^2/2)\tau + \sigma\sqrt{\tau}z} \varphi(z) \, dz &= s \int_{-d_2}^{\infty} \varphi(z - \sigma\sqrt{\tau}) \, dz \\ &= s \int_{-d_2 - \sigma\sqrt{\tau}}^{\infty} \varphi(u) \, du = s \Phi(d_2 + \sigma\sqrt{\tau}), \end{aligned}$$

and $d_2 + \sigma\sqrt{\tau} = d_1$. □

Corollary 43.8.5 (Put–call parity)

The price of the corresponding European put is

$$P(t, s) = Ke^{-r\tau}\Phi(-d_2) - s\Phi(-d_1), \quad C(t, s) - P(t, s) = s - Ke^{-r\tau}.$$

Proof. As in Proposition 43.6.13, $(S_T - K)^+ - (K - S_T)^+ = S_T - K$, so

$$C - P = e^{-r\tau} \mathbb{E}_{\mathbb{Q}}[S_T - K \mid \mathcal{F}_t] = s - Ke^{-r\tau}$$

because $e^{-rt}S_t$ is a $\mathbb{Q}$ -martingale. Substituting the formula for C and using $\Phi(x) = 1 - \Phi(-x)$ gives the expression for P . □

Example 43.8.6 (A numerical example)

Take $S_t = 100$, $K = 100$, $r = 0.05$, $\sigma = 0.2$ and $\tau = 1$ year. Then

$$d_1 = \frac{0 + (0.05 + 0.02) \cdot 1}{0.2} = 0.35, \quad d_2 = 0.35 - 0.2 = 0.15,$$

and $\Phi(0.35) = 0.6368$, $\Phi(0.15) = 0.5596$, $e^{-0.05} = 0.9512$. So

$$C = 100(0.6368) - 100(0.9512)(0.5596) = 63.68 - 53.23 = 10.45.$$

The corresponding put is $P = C - S + Ke^{-r\tau} = 10.45 - 100 + 95.12 = 5.57$. The hedge ratio is $\Delta = \Phi(d_1) = 0.637$: on selling this call one immediately buys 0.637 shares.

The general shape of V as a function of s is worth internalising. As $\tau \downarrow 0$ the price converges to the payout $(s - K)^+$; for larger τ the curve is a smoothed version of that hockey stick, lying above it, and increasing in τ .

§43.8.4 Itô's Lemma and the Black–Scholes PDE

The derivation above is the modern one. Black and Scholes argued differently, via a partial differential equation, and that route is both historically important and computationally useful. It rests on the fundamental rule of stochastic calculus.

Theorem 43.8.7 (Itô's lemma)

Let X satisfy the stochastic differential equation

$$dX_t = a_t dt + b_t dW_t,$$

and let $f(t, x)$ be twice continuously differentiable. Then

$$df(t, X_t) = \left(\frac{\partial f}{\partial t} + a_t \frac{\partial f}{\partial x} + \frac{1}{2} b_t^2 \frac{\partial^2 f}{\partial x^2} \right) dt + b_t \frac{\partial f}{\partial x} dW_t,$$

all partial derivatives being evaluated at (t, X_t) .

We take this as given – it is proved in Part III. The heuristic is that $(dW_t)^2 = dt$: Taylor expanding f to second order, the term $\frac{1}{2} f_{xx} (dX_t)^2 = \frac{1}{2} f_{xx} b_t^2 (dW_t)^2$ is of order dt and must be retained, because by Theorem 43.7.8 the quadratic variation of Brownian motion over $[0, t]$ is t rather than 0. This is precisely the roughness of the Brownian path made useful.

Proposition 43.8.8

The geometric Brownian motion $S_t = S_0 e^{\mu t + \sigma W_t}$ satisfies

$$dS_t = \left(\mu + \frac{\sigma^2}{2} \right) S_t dt + \sigma S_t dW_t.$$

Under $\mathbb{Q}$ this reads $dS_t = r S_t dt + \sigma S_t d\tilde{W}_t$.

Proof. Apply Itô with $X_t = W_t$ (so $a = 0$, $b = 1$) and $f(t, x) = S_0 e^{\mu t + \sigma x}$: the partial derivatives are $f_t = \mu f$, $f_x = \sigma f$, $f_{xx} = \sigma^2 f$, giving $dS_t = (\mu + \sigma^2/2)S_t dt + \sigma S_t dW_t$. For the second statement substitute $W_t = \tilde{W}_t + ct$ and use $\mu + \sigma c + \sigma^2/2 = r$. $\square$

So the parameter $\mu + \sigma^2/2$ is the instantaneous expected rate of return, and σ is the instantaneous standard deviation per unit time.

Theorem 43.8.9 (Black–Scholes PDE)

Let $V(t, s)$ be the Black–Scholes price of a vanilla claim with payout $g(S_T)$. Then V solves

$$\frac{\partial V}{\partial t} + rs \frac{\partial V}{\partial s} + \frac{1}{2} \sigma^2 s^2 \frac{\partial^2 V}{\partial s^2} = rV, \quad V(T, s) = g(s).$$

Proof. Suppose a self-financing portfolio holds Δ_t shares and the rest in the bank, with value X_t . Then

$$dX_t = r(X_t - \Delta_t S_t) dt + \Delta_t dS_t.$$

On the other hand, applying Itô to $V(t, S_t)$ with $dS_t = (\mu + \sigma^2/2)S_t dt + \sigma S_t dW_t$,

$$dV(t, S_t) = \left(V_t + \left(\mu + \frac{\sigma^2}{2} \right) S_t V_s + \frac{1}{2} \sigma^2 S_t^2 V_{ss} \right) dt + \sigma S_t V_s dW_t.$$

If the portfolio is to replicate the claim, we need $X_t = V(t, S_t)$ for all t , so the two expressions must agree. Matching the dW_t terms forces

$$\Delta_t = V_s(t, S_t),$$

and then matching the dt terms, after substituting dS_t into the first expression, gives

$$rV - rS_t V_s = V_t + \frac{1}{2} \sigma^2 S_t^2 V_{ss},$$

which rearranges to the stated PDE. The terminal condition is $V(T, s) = g(s)$, since at maturity the portfolio must be worth the payout. $\square$

Notice again the disappearance of μ : the drift terms cancelled when we chose $\Delta_t = V_s$. This is the mathematical content of the phrase ‘delta hedging removes the risk’.

Remark (The binomial heuristic). One can also derive the PDE directly as a limit of the binomial recursion, which is illuminating because it shows where each term comes from. Take a time step δ and set

$$1 + b = e^{\mu\delta + \sigma\sqrt{\delta}}, \quad 1 + a = e^{\mu\delta - \sigma\sqrt{\delta}}, \quad r_{\text{bin}} = r\delta,$$

so that $b = \sigma\sqrt{\delta} + (\mu + \frac{\sigma^2}{2})\delta + O(\delta^{3/2})$ and similarly for a . The risk-neutral probability is $q = (r\delta - a)/(b - a)$, and one computes

$$qb + (1 - q)a = r\delta, \quad qb^2 + (1 - q)a^2 = \sigma^2\delta + O(\delta^{3/2}).$$

Now expand the binomial recursion $(1 + r\delta)V(t - \delta, s) = qV(t, s(1 + b)) + (1 - q)V(t, s(1 + a))$ to second order in δ :

$$V + \left(rV - \frac{\partial V}{\partial t} \right) \delta = V + \frac{\partial V}{\partial s} s (qb + (1 - q)a) + \frac{1}{2} \frac{\partial^2 V}{\partial s^2} s^2 (qb^2 + (1 - q)a^2) + o(\delta)$$

$$= V + \frac{\partial V}{\partial s} sr\delta + \frac{1}{2} \frac{\partial^2 V}{\partial s^2} s^2 \sigma^2 \delta + o(\delta).$$

Cancelling V , dividing by δ and letting $\delta \rightarrow 0$ gives the Black–Scholes PDE. Note that the first-order term picks out the interest rate and the second-order term the volatility – exactly as in Itô’s lemma.

Remark (Reduction to the heat equation). The Black–Scholes PDE is the heat equation in disguise. If $u(\tau, x) = \mathbb{E}[f(x + \sqrt{\tau}Z)]$ for $Z \sim N(0, 1)$ then differentiating under the expectation gives $u_\tau = \frac{1}{2}u_{xx}$. Setting

$$u(\tau, x) = e^{r\tau} V\left(T - \frac{\tau}{\sigma^2}, e^{x - (r/\sigma^2 - 1/2)\tau}\right),$$

one checks that V solves the Black–Scholes PDE if and only if u solves $u_\tau = \frac{1}{2}u_{xx}$ with $u(0, x) = g(e^x)$. This is why Black–Scholes prices behave like diffusing heat: the payoff’s kink is smoothed out instantly and increasingly with time to maturity.

§43.8.5 Replication and Completeness

We can now discharge the promise made after Proposition 43.8.2 and show that the Black–Scholes price is not merely *an* arbitrage-free price but the *only* one, because the claim can be replicated exactly.

The continuous-time analogue of the self-financing condition of §6.1 is obtained by letting the rebalancing interval shrink. If the agent holds θ_t shares and θ_t^0 pounds in the bank, with wealth $X_t = \theta_t^0 + \theta_t S_t$, then over $[t, t + dt]$ no money enters or leaves, so the change in wealth is entirely due to the change in the prices of the assets held:

Definition 43.8.10 (Self-financing, continuous time)

An adapted pair (θ_t^0, θ_t) is **self-financing** if the wealth $X_t = \theta_t^0 + \theta_t S_t$ satisfies

$$dX_t = r\theta_t^0 dt + \theta_t dS_t = r(X_t - \theta_t S_t) dt + \theta_t dS_t.$$

Equivalently, writing $\tilde{X}_t = e^{-rt}X_t$ and $\tilde{S}_t = e^{-rt}S_t$, the discounted wealth satisfies $d\tilde{X}_t = \theta_t d\tilde{S}_t$.

The equivalence is a one-line application of Itô to $e^{-rt}X_t$, and it is the exact analogue of the discrete identity $\tilde{X}_n = X_0 + (\theta \cdot \tilde{S})_n$: in the numeraire of the bank account, a self-financing wealth process is a stochastic integral against the discounted prices, with no drift of its own.

Theorem 43.8.11 (Completeness of the Black–Scholes model)

Let g be such that $V(t, s)$, defined by the risk-neutral expectation of §8.3, is $C^{1,2}$ on $[0, T) \times (0, \infty)$ with bounded V_s . Then the self-financing strategy with initial wealth $X_0 = V(0, S_0)$ and

$$\theta_t = V_s(t, S_t), \quad \theta_t^0 = V(t, S_t) - S_t V_s(t, S_t),$$

satisfies $X_t = V(t, S_t)$ for every $t \leq T$; in particular $X_T = g(S_T)$ almost surely.

Hence every such claim is replicable and the Black–Scholes price is the unique arbitrage-free price.

Proof. By Theorem 43.8.9, V solves the Black–Scholes PDE. Apply Itô’s lemma to $V(t, S_t)$ under $\mathbb{Q}$, where $dS_t = rS_t dt + \sigma S_t d\tilde{W}_t$:

$$dV(t, S_t) = \left(V_t + rS_t V_s + \frac{1}{2}\sigma^2 S_t^2 V_{ss} \right) dt + \sigma S_t V_s d\tilde{W}_t = rV(t, S_t) dt + \sigma S_t V_s d\tilde{W}_t,$$

the drift having been replaced using the PDE. On the other hand the self-financing wealth process with $\theta_t = V_s(t, S_t)$ satisfies

$$dX_t = r(X_t - \theta_t S_t) dt + \theta_t(rS_t dt + \sigma S_t d\tilde{W}_t) = rX_t dt + \sigma S_t V_s d\tilde{W}_t.$$

So $D_t = X_t - V(t, S_t)$ satisfies $dD_t = rD_t dt$ with $D_0 = 0$, whence $D_t = D_0 e^{rt} = 0$ for all t . Continuity of V up to $t = T$ gives $X_T = V(T, S_T) = g(S_T)$.

For uniqueness: if π were another arbitrage-free price for the claim, then selling at the higher of π and $V(0, S_0)$, buying at the lower, and running the replicating strategy would produce a riskless profit. $\square$

Remark. The hypotheses are ugly and can be removed. The clean statement is the **martingale representation theorem**: if $(\mathcal{F}_t)$ is the filtration generated by a Brownian motion $\tilde{W}$ and M is a square-integrable $\mathbb{Q}$ -martingale, then there is a previsible H with $M_t = M_0 + \int_0^t H_s d\tilde{W}_s$. Applying this to $M_t = \mathbb{E}_{\mathbb{Q}}[e^{-rT}Y \mid \mathcal{F}_t]$ and setting $\theta_t = H_t/(\sigma \tilde{S}_t)$ replicates *any* integrable $\mathcal{F}_T$ -measurable claim, with no smoothness assumed. This is the exact continuous-time analogue of the second fundamental theorem: the risk-neutral measure is unique, so the model is complete.

§43.8.6 The Greeks and Hedging

The partial derivatives of V have names and are collectively called the **Greeks**. They measure the sensitivity of the price to each input, and a trading desk manages a book by keeping them within limits.

Definition 43.8.12 (The Greeks)

For a claim with price $V(t, s)$, define

$$\Delta = \frac{\partial V}{\partial s}, \quad \Gamma = \frac{\partial^2 V}{\partial s^2}, \quad \Theta = \frac{\partial V}{\partial t}, \quad \mathcal{V} = \frac{\partial V}{\partial \sigma}, \quad \rho = \frac{\partial V}{\partial r},$$

called **delta**, **gamma**, **theta**, **vega** and **rho**. Holding Δ units of the stock is called **delta hedging**.

(The name ‘vega’ is not a Greek letter; the convention is that when one runs out of Greek letters one uses the names of stars, or television celebrities.)

Proposition 43.8.13

For a European call in the Black–Scholes model,

$$\begin{aligned}\Delta &= \Phi(d_1), & \Gamma &= \frac{\varphi(d_1)}{s\sigma\sqrt{\tau}}, & \mathcal{V} &= s\sqrt{\tau}\varphi(d_1), & \rho &= Ke^{-r\tau}\Phi(d_2), \\ \Theta &= -\frac{s\sigma\varphi(d_1)}{2\sqrt{\tau}} - rKe^{-r\tau}\Phi(d_2).\end{aligned}$$

Proof. Differentiating $V = s\Phi(d_1) - Ke^{-r\tau}\Phi(d_2)$ in s and using $\partial d_1/\partial s = \partial d_2/\partial s = 1/(s\sigma\sqrt{\tau})$,

$$\Delta = \Phi(d_1) + \frac{s\varphi(d_1) - Ke^{-r\tau}\varphi(d_2)}{s\sigma\sqrt{\tau}}.$$

The bracketed term vanishes, by the identity $s\varphi(d_1) = Ke^{-r\tau}\varphi(d_2)$, which follows from $d_2 = d_1 - \sigma\sqrt{\tau}$:

$$\frac{\varphi(d_1)}{\varphi(d_2)} = e^{-(d_1^2 - d_2^2)/2} = e^{-\sigma\sqrt{\tau}(d_1 - \sigma\sqrt{\tau}/2)} = e^{-\log(s/K) - r\tau} = \frac{Ke^{-r\tau}}{s}.$$

Hence $\Delta = \Phi(d_1)$, and differentiating once more gives Γ . The remaining Greeks follow similarly, using the same identity to cancel the terms coming from differentiating d_1 and d_2 ; for Θ one uses in addition $\partial d_1/\partial t = -\partial d_1/\partial \tau$ and $\partial(d_1 - d_2)/\partial \tau = \sigma/(2\sqrt{\tau})$. $\square$

Two sanity checks on these formulae are worth making. First, all of $\Delta, \Gamma, \mathcal{V}, \rho$ are positive and Θ is negative: a call is worth more if the stock rises, if volatility rises, if rates rise, and less as time runs out. Second, the Greeks are not independent, because the Black–Scholes PDE of Theorem 43.8.9 is precisely the relation

$$\Theta + rs\Delta + \frac{1}{2}\sigma^2 s^2 \Gamma = rV$$

among them. In practice this is how a desk thinks about the trade-off it faces: a hedged book is delta-neutral, so $\Theta = rV - \frac{1}{2}\sigma^2 s^2 \Gamma$, and one is paid theta exactly in compensation for being short gamma.

Example 43.8.14

In the numerical example above ($s = K = 100$, $r = 0.05$, $\sigma = 0.2$, $\tau = 1$) we have $\varphi(d_1) = \varphi(0.35) = 0.3752$, so

$$\Gamma = \frac{0.3752}{100 \cdot 0.2} = 0.01876, \quad \mathcal{V} = 100 \cdot 0.3752 = 37.52,$$

$$\Theta = -\frac{1}{2}(100)(0.2)(0.3752) - 0.05 \cdot 95.12 \cdot 0.5596 = -6.41.$$

Checking the relation above: $-6.41 + 0.05 \cdot 100 \cdot 0.6368 + \frac{1}{2}(0.04)(10^4)(0.01876) = -6.41 + 3.18 + 3.75 = 0.52 = 0.05 \cdot 10.45$. $\checkmark$

The vega tells us that an extra percentage point of volatility is worth about £0.375 on this option – a useful rule of thumb, since a one-year at-the-money option always has $\mathcal{V} \approx 0.4s$.

Geometrically, Δ is the slope of the price curve, i.e. the number of shares whose value changes at the same rate as the option:

Remark (Why hedging works). Suppose a bank sells the call for $V(0, S_0)$ and continuously holds $\Delta_t = V_s(t, S_t)$ shares, financing the rest at rate r . By the proof of Theorem 43.8.9 the portfolio value satisfies exactly the same stochastic differential equation as $V(t, S_t)$ and starts at the same value, so the two agree for all t ; at maturity the portfolio is worth exactly the payout. The bank has eliminated its risk completely, and its profit is the difference between the price it charged and $V(0, S_0)$.

In reality one rebalances at discrete times, so there is a residual hedging error. Its size is governed by Γ : the larger the gamma, the more the delta moves between rebalancing dates and the worse the approximation. Options near the money and near expiry have very large gamma, which is why they are unpleasant to hedge.

Proposition 43.8.15 (Monotonicity)

If g is increasing then $\Delta \geq 0$; if g is convex then $\Gamma \geq 0$.

Proof. Both are immediate from the representation

$$V(t, s) = e^{-r\tau} \mathbb{E}[g(se^{(r-\sigma^2/2)\tau + \sigma\sqrt{\tau}Z})] :$$

for each fixed value of Z the integrand is an increasing (respectively convex) function of s whenever g is, and both properties survive taking expectations. $\square$

§43.8.7 Implied Volatility

Of the five inputs to the Black–Scholes formula, four – s , K , τ , r – are directly observable. The volatility σ is not. But option prices *are* observable, and the formula can be inverted.

Proposition 43.8.16

For fixed s, K, τ, r , the Black–Scholes call price is a strictly increasing continuous function of σ , mapping $(0, \infty)$ onto $((s - Ke^{-r\tau})^+, s)$.

Proof. Vega is $\mathcal{V} = s\sqrt{\tau}\varphi(d_1) > 0$, giving strict monotonicity. As $\sigma \downarrow 0$ we have $d_1, d_2 \rightarrow \pm\infty$ according to the sign of $\log(s/K) + r\tau$, and the price tends to $(s - Ke^{-r\tau})^+$, the value of the forward. As $\sigma \rightarrow \infty$, $d_1 \rightarrow \infty$ and $d_2 \rightarrow -\infty$, so the price tends to s . $\square$

Definition 43.8.17 (Implied volatility)

Given an observed market price C^{mkt} of a call with strike K and maturity T , the **implied volatility** $\sigma_{\text{imp}}(K, T)$ is the unique σ for which the Black–Scholes formula returns C^{mkt} .

The inversion has no closed form, but the proposition guarantees that a bisection or Newton search converges, and vega – being the derivative one needs for Newton’s method – is available in closed form.

Example 43.8.18

Continue with $s = K = 100$, $r = 0.05$, $\tau = 1$, and suppose the option trades at $C^{\text{mkt}} = 12$ rather than the 10.45 produced by $\sigma = 0.2$. One step of Newton’s method from $\sigma_0 = 0.2$, using $\mathcal{V} = 37.52$ from the previous section, gives

$$\sigma_1 = 0.2 + \frac{12 - 10.45}{37.52} = 0.2413,$$

and the true implied volatility is 0.2411: a single step is already accurate to four decimal places, because the call price is very nearly linear in σ near the money. The market is therefore quoting this option as though the stock will move about 24% over the year rather than 20%.

If the Black–Scholes model were literally correct, then implied volatility would be the same for every strike and maturity, since there is only one σ in the model. It is not. Plotting σ_{imp} against strike for a fixed maturity typically gives a curve like the following, known as the **volatility smile** (or, when it is lopsided as here, the **skew**).

The market charges more than Black–Scholes for low-strike puts, because the real distribution of returns has a fatter left tail than the lognormal: crashes happen. The smile is therefore best read not as a statement about volatility but as a statement about the market’s implied distribution for S_T , which is a nonparametric object recoverable from the prices of calls at all strikes. That the model is systematically wrong and yet universally used is not a paradox: implied volatility is simply a convenient reparametrisation of price, in the same way that a bond’s yield is a reparametrisation of its price.

§43.9 Further Topics

The Black–Scholes machine is flexible, and a great deal can be done by making small modifications to it. We finish with a selection.

§43.9.1 Dividends

Real shares pay dividends. Suppose the stock pays a continuous dividend at rate q , meaning that holding one share over $[t, t + dt]$ produces a cash payment $qS_t dt$ in addition to the capital gain. Then the quantity which must be a martingale after discounting is not the price but the *total return*: reinvesting the dividends, one share at time 0 becomes e^{qt} shares at time t .

Proposition 43.9.1

With a continuous dividend yield q , the risk-neutral dynamics are

$$dS_t = (r - q)S_t dt + \sigma S_t d\tilde{W}_t, \quad \text{so} \quad S_T = S_t e^{(r-q-\sigma^2/2)\tau + \sigma(\tilde{W}_T - \tilde{W}_t)},$$

and the price of a European call is

$$C = se^{-q\tau}\Phi(d_1) - Ke^{-r\tau}\Phi(d_2), \quad d_{1,2} = \frac{\log(s/K) + (r - q \pm \frac{\sigma^2}{2})\tau}{\sigma\sqrt{\tau}}.$$

Proof. The traded asset with no intermediate payments is $\hat{S}_t = e^{qt}S_t$ (the reinvested position), so $e^{-rt}\hat{S}_t$ must be a $\mathbb{Q}$ -martingale, i.e. $e^{-(r-q)t}S_t$ is a $\mathbb{Q}$ -martingale. This forces the stated drift. The formula then follows from Theorem 43.8.4 on replacing s by $se^{-q\tau}$ and r by r throughout the derivation; equivalently, on noting that $\mathbb{E}_{\mathbb{Q}}[S_T | \mathcal{F}_t] = se^{(r-q)\tau}$. $\square$

Dividends break the ‘never exercise a call early’ result of §6.7. The reason is transparent: an American call holder receives no dividends, so if q is large enough it can be worth exercising to capture them. Precisely, the submartingale argument required $\mathbb{E}_{\mathbb{Q}}[S_n | \mathcal{F}_{n-1}] \geq (1+r)S_{n-1}$, which fails when $q > 0$.

§43.9.2 Foreign Exchange

Consider two currencies, ‘domestic’ and ‘foreign’, with riskless rates r_d and r_f . Let X_t be the exchange rate, quoted as the number of units of domestic currency per unit of foreign currency.

A domestic investor may hold the foreign bank account. In domestic terms it is worth $X_t e^{r_f t}$, and it is a traded asset with no intermediate payments. Hence, under the domestic risk-neutral measure $\mathbb{Q}_d$, the process $e^{-r_d t} X_t e^{r_f t}$ must be a martingale. So X behaves exactly like a stock paying a dividend at rate r_f :

$$dX_t = (r_d - r_f)X_t dt + \sigma X_t d\tilde{W}_t.$$

Proposition 43.9.2 (Garman–Kohlhagen)

The domestic price of a European call on the exchange rate with strike K and maturity T is

$$C = xe^{-r_f \tau}\Phi(d_1) - Ke^{-r_d \tau}\Phi(d_2), \quad d_{1,2} = \frac{\log(x/K) + (r_d - r_f \pm \frac{\sigma^2}{2})\tau}{\sigma\sqrt{\tau}}.$$

There is a pleasant symmetry here which is worth spelling out, because it is a genuine change of numeraire. The foreign investor sees the exchange rate $Y_t = 1/X_t$, and by Itô

$$dY_t = (r_f - r_d + \sigma^2)Y_t dt - \sigma Y_t d\tilde{W}_t$$

under $\mathbb{Q}_d$. The extra σ^2 looks alarming – it appears to say that the two investors disagree about which currency is expected to appreciate, a puzzle known as **Siegel’s paradox**. The resolution is that the foreign investor prices with a different measure $\mathbb{Q}_f$, defined by

$$\frac{d\mathbb{Q}_f}{d\mathbb{Q}_d} = \frac{e^{-r_f t} X_t^{-1}}{X_0^{-1} e^{-r_d t}},$$

the density being (the discounted value of) one unit of domestic currency expressed in foreign terms. Under $\mathbb{Q}_f$ one finds $dY_t = (r_f - r_d)Y_t dt + \sigma Y_t d\hat{W}_t$ for a $\mathbb{Q}_f$ -Brownian motion $\hat{W}$, restoring the symmetry. There is no paradox: expectations are measure-dependent, and prices are not.

§43.9.3 American Options in Continuous Time

In continuous time the price of an American claim with payout $g(S_t)$ is

$$\pi_t = \sup_{t \leq T \leq \mathcal{T}} \mathbb{E}_{\mathbb{Q}}[e^{-r(T-t)} g(S_T) \mid \mathcal{F}_t],$$

the supremum over stopping times. As in discrete time, the value process is the smallest supermartingale dominating the discounted payout. The analytic formulation is a **free boundary problem**: there is a **continuation region** $\mathcal{C}$ in which V solves the Black–Scholes PDE and $V > g$, and a **stopping region** in which $V = g$; the boundary between them is not known in advance and must be found as part of the solution.

At the boundary one imposes **value matching** $V = g$ and **smooth fit** $V' = g'$. The smooth fit condition is not a boundary condition in the usual sense – it is an optimality condition, and it is what selects the correct boundary from the one-parameter family of candidates. The case which can be solved completely is the following.

Example 43.9.3 (The perpetual American put)

Take $g(s) = (K - s)^+$ and no expiry date. By stationarity the value $V(s)$ does not depend on t , and the exercise rule must be of the form ‘exercise when $S_t \leq b$ ’ for some level b to be determined. In the continuation region $s > b$, the Black–Scholes PDE with $V_t = 0$ becomes the Euler equation

$$rsV'(s) + \frac{1}{2}\sigma^2 s^2 V''(s) = rV(s).$$

Trying $V(s) = s^{-\gamma}$ gives the indicial equation $\frac{1}{2}\sigma^2 \gamma(\gamma + 1) - r\gamma - r = 0$, whose positive root is

$$\gamma = \frac{2r}{\sigma^2}.$$

(The other root is $\gamma = -1$, giving the solution $V = s$, which is excluded because V must be bounded as $s \rightarrow \infty$.) So $V(s) = As^{-\gamma}$ for $s > b$. Value matching at $s = b$ gives $Ab^{-\gamma} = K - b$, i.e.

$$V(s) = (K - b) \left(\frac{b}{s}\right)^{\gamma}, \quad s \geq b.$$

Smooth fit requires $V'(b) = -1$, i.e. $-\gamma(K - b)/b = -1$, giving

$$b = \frac{\gamma K}{1 + \gamma} = \frac{2rK}{2r + \sigma^2}.$$

Note the sensible limits: as $\sigma \rightarrow 0$ we get $b \rightarrow K$ (with no volatility there is no reason to wait), and as $\sigma \rightarrow \infty$ we get $b \rightarrow 0$ (with enormous volatility it is always worth waiting). For finite expiry no closed form exists and one must compute numerically.

§43.9.4 Barrier and Path-Dependent Claims

Not every claim is a function of S_T alone. A **barrier option** pays off only if the price has (or has not) crossed a level B before maturity: the **up-and-in** version of a claim Y pays $Y \mathbb{1}_{\{\max_{t \leq T} S_t \geq B\}}$, the **up-and-out** version pays $Y \mathbb{1}_{\{\max_{t \leq T} S_t < B\}}$, and similarly for down-and-in and down-and-out. Adding an in and an out version recovers the original claim, so it suffices to price one of them.

Since $S_t = S_0 e^{\sigma(\tilde{W}_t + ct)}$ with $c = r/\sigma - \sigma/2$ under $\mathbb{Q}$, barrier crossing is a statement about the maximum of a Brownian motion with drift, and the tools of §7 apply.

Proposition 43.9.4

In the Black–Scholes model, the initial price of the up-and-out claim with payout $g(S_T) \mathbb{1}_{\{\max_{t \leq T} S_t < B\}}$ equals the price of the European claim with payout

$$g(S_T) \mathbb{1}_{\{S_T < B\}} - \left(\frac{B}{S_0}\right)^{2r/\sigma^2 - 1} g\left(\frac{B^2 S_T}{S_0^2}\right) \mathbb{1}_{\{S_T < S_0^2/B\}}.$$

Proof sketch. Write $b = \log(B/S_0)/\sigma$ and $S_t = S_0 e^{\sigma(W_t + ct)}$ for a $\mathbb{Q}$ -Brownian motion W . Since $\{\max_t S_t < B\} \subseteq \{S_T < B\}$,

$$g(S_T) \mathbb{1}_{\{\max_t S_t < B\}} = g(S_T) \mathbb{1}_{\{S_T < B\}} - g(S_T) \mathbb{1}_{\{S_T < B, \max_t S_t \geq B\}},$$

so it suffices to compute the expectation of the last term. By the Cameron–Martin theorem (Theorem 43.7.20) we may strip off the drift, then apply the reflection lemma (Lemma 43.7.17) to the driftless maximum, then reinstate the drift:

$$\begin{aligned} \mathbb{E}[g(S_T) \mathbb{1}_{\{S_T < B, \max_t S_t \geq B\}}] &= \mathbb{E}[e^{cW_T - c^2 T/2} g(S_0 e^{\sigma W_T}) \mathbb{1}_{\{W_T < b, \max_t W_t \geq b\}}] \\ &= \mathbb{E}[e^{c(2b - W_T) - c^2 T/2} g(S_0 e^{\sigma(2b - W_T)}) \mathbb{1}_{\{W_T > b\}}] \\ &= e^{2bc} \mathbb{E}[e^{-cW_T - c^2 T/2} g(S_0 e^{2b\sigma} e^{-\sigma W_T}) \mathbb{1}_{\{W_T > b\}}], \end{aligned}$$

and undoing the change of measure gives the stated European payout, with $e^{2bc} = (B/S_0)^{2r/\sigma^2 - 1}$ and $S_0 e^{2b\sigma} = B^2/S_0$. $\square$

Example 43.9.5 (Forward-start call)

A **forward-start** call fixes its strike to be the price at an intermediate date $T_0 < T_1$, so the payout is $(S_{T_1} - S_{T_0})^+$. For $t \geq T_0$ this is an ordinary call with known strike. For $t < T_0$, using that S_{T_1}/S_{T_0} is independent of $\mathcal{F}_{T_0}$ under $\mathbb{Q}$ (the increments of $\tilde{W}$

being independent),

$$\begin{aligned}
 \pi_t &= e^{-r(T_1-t)} \mathbb{E}_{\mathbb{Q}}[(S_{T_1} - S_{T_0})^+ | \mathcal{F}_t] \\
 &= e^{-r(T_1-t)} \mathbb{E}_{\mathbb{Q}} \left[S_{T_0} \left(\frac{S_{T_1}}{S_{T_0}} - 1 \right)^+ \mid \mathcal{F}_t \right] \\
 &= e^{-r(T_1-t)} \mathbb{E}_{\mathbb{Q}}[S_{T_0} | \mathcal{F}_t] \mathbb{E}_{\mathbb{Q}} \left[\left(\frac{S_{T_1}}{S_{T_0}} - 1 \right)^+ \right] \\
 &= e^{-r(T_1-T_0)} S_t \mathbb{E}_{\mathbb{Q}} \left[\left(\frac{S_{T_1}}{S_{T_0}} - 1 \right)^+ \right],
 \end{aligned}$$

and the remaining expectation is the Black–Scholes price of an at-the-money call on a unit stock over the horizon $T_1 - T_0$. So the forward-start call is priced by a homogeneity argument, with no new integration required.

§43.9.5 Numerical Schemes

Beyond a small collection of examples, option prices must be computed numerically. There are three standard approaches: Monte Carlo simulation of the risk-neutral expectation; the binomial tree of §6, which is simply an explicit finite-difference scheme; and direct solution of the Black–Scholes PDE. We say a word about the last.

After the change of variables reducing Black–Scholes to the heat equation $u_t = \frac{1}{2}u_{xx}$, one discretises on a grid with steps Δt and Δx , writing $U_{n,k} \approx u(n\Delta t, k\Delta x)$. The three standard discretisations are

$$\begin{aligned}
 \text{(forward)} \quad & \frac{U_{n+1,k} - U_{n,k}}{\Delta t} = \frac{U_{n,k+1} - 2U_{n,k} + U_{n,k-1}}{2(\Delta x)^2}, \\
 \text{(backward)} \quad & \frac{U_{n+1,k} - U_{n,k}}{\Delta t} = \frac{U_{n+1,k+1} - 2U_{n+1,k} + U_{n+1,k-1}}{2(\Delta x)^2}, \\
 \text{(Crank–Nicolson)} \quad & \frac{U_{n+1,k} - U_{n,k}}{\Delta t} = \frac{U_{n,k+1} - 2U_{n,k} + U_{n,k-1}}{4(\Delta x)^2} \\
 & \quad + \frac{U_{n+1,k+1} - 2U_{n+1,k} + U_{n+1,k-1}}{4(\Delta x)^2},
 \end{aligned}$$

the last being the average of the first two.

Definition 43.9.6 (von Neumann stability)

A scheme is **stable** in the von Neumann sense if $\sup_{\beta} |\varrho(\beta)| \leq 1$, where $\varrho(\beta)$ is defined by requiring that $U_{n,k} = \varrho(\beta)^n e^{i\beta k \Delta x}$ solves the recursion.

Substituting the ansatz and writing $\nu = \Delta t / (\Delta x)^2$ gives

$$\begin{aligned}
 \varrho_{\text{fwd}}(\beta) &= 1 - \nu(1 - \cos(\beta \Delta x)), & \varrho_{\text{bwd}}(\beta) &= \frac{1}{1 + \nu(1 - \cos(\beta \Delta x))}, \\
 \varrho_{\text{CN}}(\beta) &= \frac{2 - \nu(1 - \cos(\beta \Delta x))}{2 + \nu(1 - \cos(\beta \Delta x))}.
 \end{aligned}$$

The forward scheme is stable only if $\nu \leq 1$, which forces very small time steps; the backward and Crank–Nicolson schemes are unconditionally stable, at the cost of solving

a tridiagonal linear system at each step. Crank–Nicolson is additionally second-order accurate in time, and is the usual default.

Remark. It is a pleasing coda that the binomial model, which we introduced as a self-contained discrete market, reappears here as a numerical method for the continuous one; and that the stability condition $\nu \leq 1$ is exactly the requirement that the implied risk-neutral probabilities lie in $[0, 1]$, i.e. that the discretised model be arbitrage-free. Numerical stability and the absence of arbitrage are, in this instance, the same condition.

44 Topics in Analysis

‘Topics in Analysis’ is a course with no real destination. It is a tour of some of the prettier shells lying on the beach of real and complex analysis, picked up because they are pretty rather than because they are needed to build something else. We will prove that you cannot stir a cup of coffee without leaving some point of the surface where it started, that every continuous function on an interval is a uniform limit of polynomials, that there are continuous functions which are differentiable nowhere at all, and that the number $\sum 10^{-n!}$ satisfies no polynomial equation with integer coefficients. Along the way we will meet a theorem which won its author a Nobel prize in economics.

What ties these together is a small number of extremely powerful ideas – compactness, completeness, and the systematic exploitation of approximation. Almost every argument in the course is a variation on one of the following themes: a continuous function on a compact set attains its bounds; a sequence which does not move very much converges; and if you want to prove that an object with strange properties exists, it is often easier to prove that *almost every* object has them than to write one down.

This article constitutes my notes for the ‘Topics in Analysis’ course, held in Lent 2022 at Cambridge. These notes are *not a transcription of the lectures*, and differ significantly in quite a few areas. Still, all lectured material should be covered.

§44.1 Preliminaries

This first section is mostly a matter of recalling things that we already know, and fixing notation. The course proper begins in the next section; the reader who finds the material below either worryingly familiar or worryingly unfamiliar is asked to suspend judgement until then.

§44.1.1 Metric Spaces and Completeness

Almost all of the spaces we deal with in this course will be $\mathbb{R}^m$, $\mathbb{C}$, or a space of functions or of compact sets. The common framework is that of a metric space.

Definition 44.1.1 (Metric Space)

Let X be a non-empty set. A function $d : X^2 \rightarrow \mathbb{R}$ is a **metric** on X if

- (i) $d(x, y) \geq 0$ for all $x, y \in X$;
- (ii) $d(x, y) = 0$ if and only if $x = y$;
- (iii) $d(x, y) = d(y, x)$ for all $x, y \in X$;
- (iv) $d(x, y) + d(y, z) \geq d(x, z)$ for all $x, y, z \in X$.

We then call (X, d) a **metric space**.

The examples to keep in mind are Euclidean space $\mathbb{R}^m$ with $d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|$, the complex plane with $d(z, w) = |z - w|$, and the space $C([a, b])$ of continuous real-valued

functions on $[a, b]$ with the uniform metric $d(f, g) = \|f - g\|_\infty$. We write

$$B(x, r) = \{y \in X : d(x, y) < r\}, \quad \overline{B}(x, r) = \{y \in X : d(x, y) \leq r\}$$

for the open and closed balls of radius r about x , and we say $E \subseteq X$ is **closed** if $x_n \in E$ and $x_n \rightarrow x$ imply $x \in E$, and $U \subseteq X$ is **open** if for each $u \in U$ there is a $\delta > 0$ with $B(u, \delta) \subseteq U$. These are complementary notions: E is closed if and only if $X \setminus E$ is open.

The single most important property a metric space can have, for our purposes, is completeness.

Definition 44.1.2 (Cauchy Sequence, Completeness)

Let (X, d) be a metric space. A sequence (a_n) in X is a **Cauchy sequence** if, given $\varepsilon > 0$, there is an N with $d(a_n, a_m) < \varepsilon$ for all $n, m \geq N$. We say (X, d) is **complete** if every Cauchy sequence in X converges.

We will need two small observations about Cauchy sequences over and over again, so it is worth isolating them.

Lemma 44.1.3

Let (X, d) be a metric space.

- (i) If a Cauchy sequence (x_n) has a subsequence converging to x , then $x_n \rightarrow x$.
- (ii) Suppose $\varepsilon_n > 0$ with $\sum_{n \geq 1} \varepsilon_n < \infty$. If every sequence (x_n) in X with $d(x_n, x_{n+1}) < \varepsilon_n$ for all n converges, then (X, d) is complete.

Proof. (i) Let $\varepsilon > 0$ and pick N with $d(x_n, x_m) < \varepsilon/2$ for $n, m \geq N$. If $x_{n(k)} \rightarrow x$, choose k with $n(k) \geq N$ and $d(x_{n(k)}, x) < \varepsilon/2$. Then for $n \geq N$ we have $d(x_n, x) \leq d(x_n, x_{n(k)}) + d(x_{n(k)}, x) < \varepsilon$.

(ii) Let (x_n) be Cauchy. Choose $n(1) < n(2) < \dots$ so that $d(x_p, x_q) < \varepsilon_k$ whenever $p, q \geq n(k)$. Then the subsequence $y_k = x_{n(k)}$ satisfies $d(y_k, y_{k+1}) < \varepsilon_k$, so converges by hypothesis, and (i) finishes the job. $\square$

In practice we use (ii) with $\varepsilon_n = 2^{-n}$ or $\varepsilon_n = 100^{-n}$: to check completeness it suffices to deal with sequences whose steps shrink geometrically, which is a considerable convenience. We record without proof the fundamental example.

Theorem 44.1.4

Euclidean space $\mathbb{R}^m$ with the usual metric is complete, as is $\mathbb{C}$.

The proof is the usual one: a Cauchy sequence in $\mathbb{R}^m$ is coordinatewise Cauchy, and $\mathbb{R}$ is complete by the general principle of convergence from Analysis I.

§44.1.2 The Contraction Mapping Theorem

Completeness earns its keep almost immediately. The following theorem was met in IB Analysis and Topology, but it is worth restating here, both because we shall want it and because it is the model against which everything in Section 44.3 should be compared.

Definition 44.1.5 (Contraction)

Let (X, d) be a metric space. A map $f : X \rightarrow X$ is a **contraction mapping** if there is a constant $0 \leq K < 1$ with

$$d(f(x), f(y)) \leq K d(x, y)$$

for all $x, y \in X$.

A contraction is certainly continuous – indeed uniformly so. The point of the definition is that it does not merely fail to increase distances, it shrinks them by a definite factor, and it is that definite factor which makes everything work.

Theorem 44.1.6 (Contraction Mapping Theorem)

Let (X, d) be a non-empty complete metric space and let $f : X \rightarrow X$ be a contraction mapping with constant K . Then f has exactly one fixed point w . Moreover, for any $x_0 \in X$ the iterates $x_{n+1} = f(x_n)$ satisfy $x_n \rightarrow w$, with

$$d(x_n, w) \leq \frac{K^n}{1 - K} d(x_0, x_1).$$

Proof. Uniqueness first, since it is free: if $f(v) = v$ and $f(w) = w$ then $d(v, w) = d(f(v), f(w)) \leq K d(v, w)$, and as $K < 1$ this forces $d(v, w) = 0$.

For existence, fix $x_0 \in X$ and set $x_{n+1} = f(x_n)$. An immediate induction gives $d(x_n, x_{n+1}) \leq K^n d(x_0, x_1)$, so for $m > n$

$$d(x_n, x_m) \leq \sum_{r=n}^{m-1} d(x_r, x_{r+1}) \leq d(x_0, x_1) \sum_{r=n}^{\infty} K^r = \frac{K^n}{1 - K} d(x_0, x_1).$$

Since $K^n \rightarrow 0$, the sequence (x_n) is Cauchy, and by completeness $x_n \rightarrow w$ for some $w \in X$. As f is continuous, $f(w) = \lim f(x_n) = \lim x_{n+1} = w$. Letting $m \rightarrow \infty$ in the displayed inequality gives the error bound. $\square$

The proof is worth a second look, because it is the pattern for a great many existence proofs: we do not find w , we manufacture a sequence which is forced to converge and then let the limit be w . The picture is the familiar staircase, or *cobweb*, of the numerical analyst.

Both hypotheses are needed. Completeness cannot be dropped: on $X = (0, 1]$ with the

usual metric the map $f(x) = x/2$ is a contraction with $K = 1/2$, but it has no fixed point in X . Nor can $K < 1$ be weakened to $d(f(x), f(y)) < d(x, y)$: the map $f : \mathbb{R} \rightarrow \mathbb{R}$ given by $f(x) = \sqrt{1 + x^2}$ satisfies

$$|f(x) - f(y)| = \frac{|x^2 - y^2|}{\sqrt{1 + x^2} + \sqrt{1 + y^2}} = |x - y| \cdot \frac{|x + y|}{\sqrt{1 + x^2} + \sqrt{1 + y^2}} < |x - y|$$

for $x \neq y$, yet $f(x) > x$ everywhere, so there is no fixed point at all.

The contraction mapping theorem is enormously useful – it is what makes Picard’s existence theorem for differential equations and the inverse function theorem work – but the hypothesis is very strong indeed, and it is easy to write down continuous self-maps of a disc which contract nothing. That such maps still have fixed points is the subject of Section 44.3, and the price we pay is that the proof will tell us nothing whatever about how to find one.

§44.1.3 Compactness in Euclidean Space

In this course we deal only with subsets of $\mathbb{R}^m$, and there ‘compact’ may be taken to mean ‘closed and bounded’. (The reader should be warned that this equivalence fails badly in general metric spaces, and that in the world of topological spaces one must further distinguish compactness from sequential compactness. We will not need any of this: if you intend to climb Everest you need your own oxygen supply, but for the Gog Magogs you do not.)

Theorem 44.1.7 (Bolzano–Weierstrass)

If $K > 0$ and $\mathbf{x}_r \in \mathbb{R}^m$ satisfy $\|\mathbf{x}_r\| \leq K$ for all r , then there exist $\mathbf{x} \in \mathbb{R}^m$ and $r(1) < r(2) < \dots$ such that $\mathbf{x}_{r(k)} \rightarrow \mathbf{x}$.

Proof. For $m = 1$ this is Analysis I. For general m , apply the one-dimensional result to the first coordinates to get a subsequence along which they converge, then pass to a further subsequence along which the second coordinates converge, and so on. After m steps every coordinate converges, and convergence in $\mathbb{R}^m$ is coordinatewise. $\square$

Theorem 44.1.8

A subset E of $\mathbb{R}^m$ is closed and bounded if and only if every sequence in E has a subsequence converging to a limit in E .

Proof. If E is closed and bounded, Bolzano–Weierstrass gives a convergent subsequence and closedness puts the limit in E . Conversely, if E is unbounded, choose $\mathbf{x}_r \in E$ with $\|\mathbf{x}_r\| \geq r$; no subsequence can converge. If E is not closed, take $\mathbf{x}_r \in E$ with $\mathbf{x}_r \rightarrow \mathbf{x} \notin E$; every subsequence converges to $\mathbf{x} \notin E$. $\square$

We shall call closed bounded subsets of $\mathbb{R}^m$ **compact**, and refer to the property in Theorem 44.1.8 as the Bolzano–Weierstrass property. Its usefulness comes from the following two results, which will be invoked so frequently that we shall often not bother to mention them.

Theorem 44.1.9

If $E \subseteq \mathbb{R}^m$ is compact and $f : E \rightarrow \mathbb{R}^n$ is continuous, then $f(E)$ is compact.

Proof. Let $\mathbf{y}_r = f(\mathbf{x}_r)$ with $\mathbf{x}_r \in E$. Choose a subsequence $\mathbf{x}_{r(k)} \rightarrow \mathbf{x} \in E$. By continuity $\mathbf{y}_{r(k)} \rightarrow f(\mathbf{x}) \in f(E)$. $\square$

Theorem 44.1.10

If $E \subseteq \mathbb{R}^m$ is non-empty and compact and $f : E \rightarrow \mathbb{R}$ is continuous, then there exist $\mathbf{a}, \mathbf{b} \in E$ with $f(\mathbf{b}) \leq f(\mathbf{x}) \leq f(\mathbf{a})$ for all $\mathbf{x} \in E$.

Proof. $f(E)$ is a non-empty compact subset of $\mathbb{R}$, hence bounded, and contains its supremum and infimum since it is closed. $\square$

We will also want uniform continuity, which is compactness in another guise.

Definition 44.1.11 (Uniform Continuity)

Let (X, d) and (Y, ρ) be metric spaces. A function $f : X \rightarrow Y$ is **uniformly continuous** if, given $\varepsilon > 0$, we can find $\delta > 0$ such that $\rho(f(a), f(b)) < \varepsilon$ whenever $d(a, b) < \delta$.

Theorem 44.1.12

If E is a compact subset of $\mathbb{R}^m$ and $f : E \rightarrow \mathbb{R}^p$ is continuous, then f is uniformly continuous.

Proof. If not, there is an $\varepsilon > 0$ and points $\mathbf{a}_n, \mathbf{b}_n \in E$ with $\|\mathbf{a}_n - \mathbf{b}_n\| < 1/n$ but $\|f(\mathbf{a}_n) - f(\mathbf{b}_n)\| \geq \varepsilon$. Pass to a subsequence with $\mathbf{a}_{n(k)} \rightarrow \mathbf{a} \in E$; then $\mathbf{b}_{n(k)} \rightarrow \mathbf{a}$ too, so both $f(\mathbf{a}_{n(k)})$ and $f(\mathbf{b}_{n(k)})$ tend to $f(\mathbf{a})$, contradicting the inequality $\|f(\mathbf{a}_{n(k)}) - f(\mathbf{b}_{n(k)})\| \geq \varepsilon$. $\square$

Finally, a piece of notation which will be with us all course. If A is a non-empty subset of a metric space and x a point, we write

$$d(x, A) = \inf\{d(x, a) : a \in A\}.$$

Lemma 44.1.13

Let A be a non-empty subset of a metric space (X, d) . Then $x \mapsto d(x, A)$ satisfies $|d(x, A) - d(y, A)| \leq d(x, y)$, and so is (uniformly) continuous. If A is closed, then $d(x, A) = 0$ if and only if $x \in A$.

Proof. For any $a \in A$ we have $d(x, A) \leq d(x, a) \leq d(x, y) + d(y, a)$; taking the infimum over a gives $d(x, A) \leq d(x, y) + d(y, A)$, and symmetry gives the Lipschitz bound. If $d(x, A) = 0$ we can find $a_n \in A$ with $d(x, a_n) \rightarrow 0$, so $a_n \rightarrow x$ and $x \in A$ when A is closed. $\square$

§44.1.4 The Fundamental Theorem of Algebra

Theorem 44.1.10 looks like a piece of abstract nonsense, but it is enough to prove a theorem which – contrary to its name – is a theorem of analysis.

Theorem 44.1.14 (Fundamental Theorem of Algebra)

Every non-constant polynomial P with complex coefficients has a root in $\mathbb{C}$.

Proof. Write $P(z) = \sum_{j=0}^n a_j z^j$ with $n \geq 1$, and (dividing through) assume $a_n = 1$. Then for $z \neq 0$,

$$|P(z)| \geq |z|^n (1 - |a_{n-1}||z|^{-1} - \cdots - |a_0||z|^{-n}),$$

so if we set $R = 2 \left(2 + \sum_{j=0}^{n-1} |a_j| \right)$ then $|z| \geq R$ gives $|P(z)| \geq |z|^n/2 \geq R^n/2 > |a_0| = |P(0)|$.

Now $\overline{B}(0, R)$ is compact and $|P|$ is continuous, so by Theorem 44.1.10 there is a $z_0 \in \overline{B}(0, R)$ at which $|P|$ attains its minimum over $\overline{B}(0, R)$. By the previous paragraph $|P(z_0)| \leq |P(0)| < |P(z)|$ for all $|z| \geq R$, so in fact z_0 is a *global* minimum of $|P|$ on $\mathbb{C}$.

Suppose, for contradiction, that $P(z_0) \neq 0$. Replacing $P(z)$ by $P(z + z_0)$ we may assume $z_0 = 0$, and multiplying P by a suitable unimodular constant we may assume $a_0 = P(0) > 0$. Let $m \geq 1$ be least with $a_m \neq 0$, so that

$$P(z) = a_0 + a_m z^m + \sum_{j=m+1}^n a_j z^j.$$

Choosing ω with $\omega^m = -|a_m|/a_m$ and replacing $P(z)$ by $P(\omega z)$, we may further assume $a_m < 0$. Now for real $\delta > 0$,

$$\frac{P(\delta) - P(0)}{\delta^m} = a_m + \sum_{j=m+1}^n a_j \delta^{j-m} \rightarrow a_m < 0$$

as $\delta \rightarrow 0^+$. So for small positive δ the real part of $P(\delta) - P(0)$ is negative and its imaginary part is $o(\delta^m)$, whence $|P(\delta)| < |P(0)|$. This contradicts the minimality of $|P(0)|$, so $P(z_0) = 0$. $\square$

We shall meet a completely different proof of Theorem 44.1.14, using winding numbers, in the final section of the course. In the meantime we record the standard consequences, which we use freely.

Lemma 44.1.15

Let P be a polynomial of degree n over $\mathbb{C}$.

- (i) If $P(a) = 0$ then $P(z) = (z - a)Q(z)$ for some polynomial Q of degree $n - 1$.
- (ii) $P(z) = A \prod_{j=1}^n (z - a_j)$ for some $A \neq 0$ and $a_j \in \mathbb{C}$.
- (iii) If P has degree at most n and vanishes at $n + 1$ distinct points, then $P = 0$.

Proof. (i) By induction on n , division gives $P(z) = (z-a)Q(z)+r$ with $\deg Q = n-1$ and $r \in \mathbb{C}$; putting $z = a$ gives $r = 0$. (ii) follows by induction using Theorem 44.1.14 and (i). (iii) If $P \neq 0$ has degree $d \leq n$ then by (ii) it has at most $d \leq n$ roots. $\square$

§44.2 Laplace's Equation

Our first genuine topic is a piece of analysis which sits behind a great deal of the theory of partial differential equations. Recall that if ϕ is a real-valued function on (an open subset of) $\mathbb{R}^m$ with enough derivatives, we write

$$\nabla^2 \phi = \sum_{j=1}^m \frac{\partial^2 \phi}{\partial x_j^2},$$

and **Laplace's equation** is the equation $\nabla^2 \phi = 0$. Solutions are called *harmonic*. In Part IA you cheerfully solved boundary value problems for Laplace's equation on discs and rectangles, and you may have been left with the impression that the Dirichlet problem

$$\nabla^2 \phi = 0 \text{ on } \Omega, \quad \phi = f \text{ on } \partial\Omega$$

always has exactly one solution. We shall see that uniqueness holds in great generality, but that existence can fail.

We first need to recall three pieces of point-set vocabulary.

Definition 44.2.1 (Interior, Closure, Boundary)

Let (X, d) be a metric space and $E \subseteq X$.

- (i) The **interior** $\text{Int } E$ is the set of $x \in X$ for which there is a $\delta > 0$ with $B(x, \delta) \subseteq E$.
- (ii) The **closure** $\text{Cl } E$ is the set of $x \in X$ for which there are $e_n \in E$ with $e_n \rightarrow x$.
- (iii) The **boundary** of E is $\partial E = \text{Cl } E \setminus \text{Int } E$.

It is easy to check that $\text{Int } E$ is the largest open set contained in E , that $\text{Cl } E$ is the smallest closed set containing E , and hence that $\partial E = \text{Cl } E \cap \text{Cl}(X \setminus E)$ is closed. If $E \subseteq \mathbb{R}^m$ is bounded then so is $\text{Cl } E$, so $\text{Cl } E$ and ∂E are compact.

§44.2.1 The Maximum Principle

Throughout this subsection Ω is a non-empty bounded open subset of $\mathbb{R}^m$ and $\phi : \text{Cl } \Omega \rightarrow \mathbb{R}$ is continuous and twice differentiable on Ω . Note that $\text{Cl } \Omega$ is compact and non-empty, so ϕ does attain a maximum somewhere; the content of what follows is *where*.

The following lemma is really just the second derivative test, applied one coordinate at a time.

Lemma 44.2.2

If $\nabla^2 \phi > 0$ everywhere on Ω , then ϕ does not attain its maximum at any point of Ω .

Proof. Suppose ϕ attains its maximum over $\text{Cl } \Omega$ at $\mathbf{x}^* \in \Omega$. Since Ω is open there is a $\delta > 0$ with

$$(x_1^* - \delta, x_1^* + \delta) \times \cdots \times (x_m^* - \delta, x_m^* + \delta) \subseteq \Omega.$$

For each j define $g_j(t) = \phi(x_1^*, \dots, x_{j-1}^*, x_j^* + t, x_{j+1}^*, \dots, x_m^*)$ for $|t| < \delta$. Then g_j is twice differentiable with a maximum at $t = 0$, so $g_j'(0) = 0$ and $g_j''(0) \leq 0$. But $g_j''(0) = \partial^2 \phi / \partial x_j^2$ evaluated at $\mathbf{x}^*$, so summing over j gives $\nabla^2 \phi(\mathbf{x}^*) \leq 0$, a contradiction. $\square$

The hypothesis $\nabla^2 \phi > 0$ is of course much stronger than what we want. The trick, which is the same one used to deduce Rolle's theorem from the fact that an interior maximum is stationary, is to add a small strictly subharmonic perturbation and then let it go to zero.

Theorem 44.2.3 (Maximum Principle)

If $\nabla^2 \phi = 0$ on Ω , then ϕ attains its maximum over $\text{Cl } \Omega$ at some point of $\partial \Omega$.

Proof. For $n \geq 1$ set $\phi_n(\mathbf{x}) = \phi(\mathbf{x}) + \frac{1}{n} \sum_{j=1}^m x_j^2$. Then $\nabla^2 \phi_n = 2m/n > 0$ on Ω , so by Lemma 44.2.2 the maximum of ϕ_n over $\text{Cl } \Omega$ is attained at some $\mathbf{x}_n^* \in \partial \Omega$. Since $\partial \Omega$ is compact, we may pass to a subsequence $\mathbf{x}_{n(j)}^* \rightarrow \mathbf{x}^* \in \partial \Omega$.

Let R be such that $\|\mathbf{x}\| \leq R$ for all $\mathbf{x} \in \text{Cl } \Omega$. For every $\mathbf{x} \in \text{Cl } \Omega$ we have

$$\phi(\mathbf{x}_{n(j)}^*) + \frac{R^2}{n(j)} \geq \phi_{n(j)}(\mathbf{x}_{n(j)}^*) \geq \phi_{n(j)}(\mathbf{x}) \geq \phi(\mathbf{x}).$$

Letting $j \rightarrow \infty$ and using continuity of ϕ gives $\phi(\mathbf{x}^*) \geq \phi(\mathbf{x})$, as required. $\square$

Applying the theorem to $-\phi$ shows that the minimum is also attained on the boundary, and uniqueness follows at once.

Theorem 44.2.4 (Uniqueness for the Dirichlet Problem)

Suppose $\phi, \psi : \text{Cl } \Omega \rightarrow \mathbb{R}$ are continuous, twice differentiable on Ω , and satisfy $\nabla^2 \phi = \nabla^2 \psi = 0$ on Ω . If $\phi = \psi$ on $\partial \Omega$, then $\phi = \psi$ on $\text{Cl } \Omega$.

Proof. Set $\chi = \phi - \psi$. Then $\nabla^2 \chi = 0$ on Ω and $\chi = 0$ on $\partial \Omega$, so by Theorem 44.2.3 the maximum of χ is 0, and applying the same to $-\chi$ gives that the minimum is 0. Hence $\chi \equiv 0$. $\square$

Remark. The same argument gives a maximum principle for analytic functions. If $\Omega \subseteq \mathbb{C}$ is bounded and open and $f : \text{Cl } \Omega \rightarrow \mathbb{C}$ is continuous and analytic on Ω , then $\text{Re } f$ and $\text{Im } f$ are harmonic, and one deduces that $|f|$ attains its maximum on $\partial \Omega$: given z_0 , rotate f so that $\text{Re } f(z_0) = |f(z_0)|$ and apply Theorem 44.2.3 to $\text{Re } f$.

§44.2.2 Zaremba's Example

So much for uniqueness. What about existence? The following example, due to Zaremba, shows that we cannot expect a solution for every bounded open Ω and every continuous

boundary datum. It is a nice illustration of how uniqueness theorems can be used to *destroy* existence.

Example 44.2.5 (Zaremba)

Let $D = \{\mathbf{x} \in \mathbb{R}^2 : \|\mathbf{x}\| < 1\}$ and let $\Omega = D \setminus \{\mathbf{0}\}$ be the punctured disc. Then Ω is open and bounded, $\text{Cl } \Omega = \text{Cl } D$, and

$$\partial\Omega = \{\mathbf{x} : \|\mathbf{x}\| = 1\} \cup \{\mathbf{0}\}.$$

We claim that there is no continuous $\phi : \text{Cl } \Omega \rightarrow \mathbb{R}$, twice differentiable on Ω , with $\nabla^2 \phi = 0$ on Ω and

$$\phi(\mathbf{x}) = \begin{cases} 0 & \|\mathbf{x}\| = 1, \\ 1 & \mathbf{x} = \mathbf{0}. \end{cases}$$

Suppose such a ϕ existed. Let R_θ be the rotation of $\mathbb{R}^2$ through θ about the origin. Then $\mathbf{x} \mapsto \phi(R_\theta \mathbf{x})$ is also continuous on $\text{Cl } \Omega$, harmonic on Ω , and takes the *same* boundary values (since the boundary data are rotation-invariant). By the uniqueness Theorem 44.2.4 we get $\phi = \phi \circ R_\theta$ for every θ , so ϕ is radially symmetric: $\phi(\mathbf{x}) = f(\|\mathbf{x}\|)$ for some $f : [0, 1] \rightarrow \mathbb{R}$.

Writing $r = \sqrt{x^2 + y^2}$ and computing,

$$\begin{aligned} \frac{\partial \phi}{\partial x} &= \frac{x}{r} f'(r), \\ \frac{\partial^2 \phi}{\partial x^2} &= \left(\frac{1}{r} - \frac{x^2}{r^3} \right) f'(r) + \frac{x^2}{r^2} f''(r), \end{aligned}$$

and similarly for y , so that adding gives the familiar radial form

$$\nabla^2 \phi = f''(r) + \frac{1}{r} f'(r) = \frac{1}{r} \frac{d}{dr} (r f'(r)).$$

Thus $\frac{d}{dr} (r f'(r)) = 0$ for $0 < r < 1$, so $r f'(r) = B$ and $f(r) = A + B \log r$ for constants A, B . But ϕ is continuous at $\mathbf{0}$, and $A + B \log r$ has a limit as $r \rightarrow 0^+$ only when $B = 0$. So f is constant, and ϕ cannot take the value 0 on $\|\mathbf{x}\| = 1$ and 1 at $\mathbf{0}$. This is the contradiction we wanted.

The moral is that the boundary point $\mathbf{0}$ is ‘too thin’ for the boundary condition there to be felt. Lebesgue later produced a three-dimensional example (the *Lebesgue thorn*) in which the offending boundary point is a cusp rather than an isolated point, so that the failure is not simply a matter of the boundary having an isolated point. Deciding exactly which boundary points are ‘regular’ in this sense is a substantial piece of potential theory, and we shall not pursue it.

§44.3 Fixed Point Theorems

In Analysis I we proved the intermediate value theorem, and used it to prove a very pretty one-dimensional fixed point theorem.

Theorem 44.3.1

If $f : [a, b] \rightarrow [a, b]$ is continuous, then there is a $w \in [a, b]$ with $f(w) = w$.

Proof. Set $g(x) = f(x) - x$. Then g is continuous, $g(a) = f(a) - a \geq 0$ and $g(b) = f(b) - b \leq 0$. By the intermediate value theorem there is a $w \in [a, b]$ with $g(w) = 0$. $\square$

The picture is irresistible: the graph of f lives in the square $[a, b]^2$, it starts on or above the diagonal and ends on or below it, so it must cross.

The implication can be reversed: Theorem 44.3.1 implies the intermediate value theorem, and both are equivalent to the statement that $[0, 1]$ is connected. This is worth bearing in mind, because the object of this section is to prove the two-dimensional analogue, and the proof will consist almost entirely of showing that a chain of superficially unrelated statements are all equivalent to one another.

Theorem 44.3.2 (Brouwer's Fixed Point Theorem)

Let $\overline{D} = \{\mathbf{x} \in \mathbb{R}^2 : \|\mathbf{x}\| \leq 1\}$. If $f : \overline{D} \rightarrow \overline{D}$ is continuous, then there is a $\mathbf{w} \in \overline{D}$ with $f(\mathbf{w}) = \mathbf{w}$.

We shall keep strictly to two dimensions, but the reader should know that the theorem and most of its consequences hold in $\mathbb{R}^n$; the only ingredient which needs real work to generalise is Sperner's lemma, and even there the changes are cosmetic rather than conceptual.

The result is not restricted to discs. The following observation lets us move it around freely, and we shall use it without comment.

Lemma 44.3.3

Suppose $g : \overline{D} \rightarrow A$ is a bijection with g and g^{-1} continuous. If $F : A \rightarrow A$ is continuous, then F has a fixed point.

Proof. The map $g^{-1} \circ F \circ g : \overline{D} \rightarrow \overline{D}$ is continuous, so by Theorem 44.3.2 has a fixed point $\mathbf{w}$. Then $g(\mathbf{w})$ is a fixed point of F . $\square$

In particular Brouwer's theorem holds for closed squares, closed triangles, and any other set homeomorphic to a disc. Throughout we write

$$D = \{\mathbf{x} \in \mathbb{R}^2 : \|\mathbf{x}\| < 1\}, \quad \overline{D} = \{\mathbf{x} : \|\mathbf{x}\| \leq 1\}, \quad \partial D = \{\mathbf{x} : \|\mathbf{x}\| = 1\}.$$

§44.3.1 The No Retraction Theorem

The first equivalence is the one which explains why the theorem is true: a fixed-point-free map lets you comb the disc onto its boundary, and that is something you cannot do.

Theorem 44.3.4

The following are equivalent.

- (i) Every continuous $f : \overline{D} \rightarrow \overline{D}$ has a fixed point.
- (ii) There is no continuous $g : \overline{D} \rightarrow \partial D$ with $g(\mathbf{x}) = \mathbf{x}$ for all $\mathbf{x} \in \partial D$. (Such a g is called a **retraction**.)

Proof. Suppose (i) holds and $g : \overline{D} \rightarrow \partial D$ is a retraction. Let R be rotation through π about $\mathbf{0}$. Then $R \circ g : \overline{D} \rightarrow \overline{D}$ is continuous, so has a fixed point $\mathbf{w}$. But $R(g(\mathbf{w})) = \mathbf{w}$ forces $\mathbf{w} \in R(\partial D) = \partial D$, and then $g(\mathbf{w}) = \mathbf{w}$, so $R\mathbf{w} = \mathbf{w}$, which is false for $\mathbf{w} \neq \mathbf{0}$. Since $\mathbf{0} \notin \partial D$ we have a contradiction, and (ii) holds.

Conversely, suppose (ii) holds and $f : \overline{D} \rightarrow \overline{D}$ is continuous with no fixed point. For $\mathbf{x} \neq \mathbf{y}$ in $\overline{D}$ let $F(\mathbf{x}, \mathbf{y})$ be the point where the ray starting at $\mathbf{y}$ and passing through $\mathbf{x}$ meets ∂D ; explicitly, writing $\mathbf{u} = (\mathbf{x} - \mathbf{y}) / \|\mathbf{x} - \mathbf{y}\|$, we have $F(\mathbf{x}, \mathbf{y}) = \mathbf{x} + t\mathbf{u}$ where $t \geq 0$ is the unique non-negative root of $\|\mathbf{x} + t\mathbf{u}\|^2 = 1$, that is

$$t = -\mathbf{x} \cdot \mathbf{u} + \sqrt{(\mathbf{x} \cdot \mathbf{u})^2 + 1 - \|\mathbf{x}\|^2}.$$

This is a continuous function of $(\mathbf{x}, \mathbf{y})$ on $\{(\mathbf{x}, \mathbf{y}) \in \overline{D}^2 : \mathbf{x} \neq \mathbf{y}\}$. Set $g(\mathbf{x}) = F(\mathbf{x}, f(\mathbf{x}))$, which makes sense since $f(\mathbf{x}) \neq \mathbf{x}$ everywhere. Then g is continuous, $g(\overline{D}) \subseteq \partial D$, and if $\mathbf{x} \in \partial D$ then $\mathbf{x}$ itself is already on the ray and on ∂D , so $g(\mathbf{x}) = \mathbf{x}$. Thus g is a retraction, contradicting (ii). $\square$

§44.3.2 From Retractions to Colourings

The next step replaces the circle by a triangle and the retraction by a map which preserves three closed pieces of the boundary. Let $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3$ be unit vectors making angles of $2\pi/3$ with each other, let T be the closed triangle with these vertices, and let

I, J, K be its three closed sides. Correspondingly let

$$\tilde{I} = \{(\cos \theta, \sin \theta) : 0 \leq \theta \leq \frac{2\pi}{3}\}, \quad \tilde{J} = \{(\cos \theta, \sin \theta) : \frac{2\pi}{3} \leq \theta \leq \frac{4\pi}{3}\},$$

and $\tilde{K} = \{(\cos \theta, \sin \theta) : \frac{4\pi}{3} \leq \theta \leq 2\pi\}$ be the three corresponding closed arcs of ∂D .

Lemma 44.3.5

The following three statements are equivalent.

- (i) There is no retraction from $\overline{D}$ to ∂D .
- (ii) There is no continuous $\tilde{k} : \overline{D} \rightarrow \partial D$ with $\tilde{k}(\tilde{I}) \subseteq \tilde{I}$, $\tilde{k}(\tilde{J}) \subseteq \tilde{J}$ and $\tilde{k}(\tilde{K}) \subseteq \tilde{K}$.
- (iii) There is no continuous $k : T \rightarrow \partial T$ with $k(I) \subseteq I$, $k(J) \subseteq J$ and $k(K) \subseteq K$.

Proof. (ii) $\Rightarrow$ (i) is immediate, since a retraction certainly maps each arc into itself. For (i) $\Rightarrow$ (ii), suppose $\tilde{k}$ is as in (ii) and let R be rotation through π . Then $R \circ \tilde{k} : \overline{D} \rightarrow \overline{D}$ has no fixed point: a fixed point $\mathbf{w}$ would have to lie on ∂D , and $\mathbf{w}$ lies in one of the three arcs, say $\tilde{I}$, so $\tilde{k}(\mathbf{w}) \in \tilde{I}$ while $R\tilde{k}(\mathbf{w}) = \mathbf{w} \in \tilde{I}$ means $\tilde{k}(\mathbf{w}) = R\mathbf{w}$, which lies in the arc antipodal to the one containing $\mathbf{w}$. Since an arc of length $2\pi/3$ is disjoint from its antipodal image, this is impossible. By Theorem 44.3.4 this contradicts (i).

For the equivalence of (ii) and (iii), define $\Phi : \overline{D} \rightarrow T$ by $\Phi(\mathbf{0}) = \mathbf{0}$ and, for $\mathbf{x} \neq \mathbf{0}$, $\Phi(\mathbf{x}) = \rho(\mathbf{x})\mathbf{x}$ where $\rho(\mathbf{x}) > 0$ is chosen so that $\rho(\mathbf{x})\mathbf{x} \in \partial T$ when $\|\mathbf{x}\| = 1$; in other words we stretch each radius of the disc onto the corresponding radius of the triangle. Since $\mathbf{0}$ is interior to T and ∂T meets each ray from $\mathbf{0}$ exactly once, ρ is a continuous positive function of the direction of $\mathbf{x}$ alone, and Φ is a homeomorphism carrying ∂D onto ∂T and $\tilde{I}, \tilde{J}, \tilde{K}$ onto I, J, K respectively. So $\tilde{k} \mapsto \Phi \circ \tilde{k} \circ \Phi^{-1}$ is a bijection between maps of the type in (ii) and maps of the type in (iii). $\square$

The next equivalence is the crucial one: it converts a statement about continuous maps into a statement about closed sets, and closed sets are things we can attack combinatorially.

Lemma 44.3.6

The following are equivalent.

- (i) There is no continuous $h : T \rightarrow \partial T$ with $h(I) \subseteq I$, $h(J) \subseteq J$, $h(K) \subseteq K$.
- (ii) If A, B, C are closed subsets of T with $A \supseteq I$, $B \supseteq J$, $C \supseteq K$ and $A \cup B \cup C = T$, then $A \cap B \cap C \neq \emptyset$.

Proof. Suppose (ii) holds and h is as in (i). Put $A = h^{-1}(I)$, $B = h^{-1}(J)$, $C = h^{-1}(K)$. These are closed (preimages of closed sets under a continuous map), they cover T since $I \cup J \cup K = \partial T$, and $A \supseteq I$ since $h(I) \subseteq I$; similarly for B and C . But $I \cap J \cap K = \emptyset$ (the three sides have no common point), so $A \cap B \cap C = h^{-1}(I \cap J \cap K) = \emptyset$, contradicting (ii).

Conversely, suppose (i) holds and A, B, C are closed sets as in (ii) with $A \cap B \cap C = \emptyset$. It is convenient to realise T in barycentric coordinates,^a identifying it with

$$T = \{(x, y, z) \in \mathbb{R}^3 : x, y, z \geq 0, x + y + z = 1\},$$

with $I = \{x = 0\} \cap T$, $J = \{y = 0\} \cap T$ and $K = \{z = 0\} \cap T$. Define

$$h(\mathbf{x}) = \frac{1}{d(\mathbf{x}, A) + d(\mathbf{x}, B) + d(\mathbf{x}, C)} (d(\mathbf{x}, A), d(\mathbf{x}, B), d(\mathbf{x}, C)).$$

The denominator never vanishes: if it did, then $\mathbf{x}$ would be at zero distance from each of the closed sets A, B, C , so $\mathbf{x} \in A \cap B \cap C = \emptyset$. By Lemma 44.1.13 each numerator is continuous, so h is continuous, and clearly $h(\mathbf{x}) \in T$ with at least one coordinate zero (as $A \cup B \cup C = T$ means every $\mathbf{x}$ lies in one of them), so $h(T) \subseteq \partial T$. Finally if $\mathbf{x} \in I$ then $\mathbf{x} \in A$, so $d(\mathbf{x}, A) = 0$ and $h(\mathbf{x}) \in I$; similarly for J and K . This contradicts (i). $\square$

^aBarycentric coordinates were invented by Möbius, and are exactly the right language for everything in this section.

Putting Theorem 44.3.4 and Lemmas 44.3.5 and 44.3.6 together,

Brouwer $\iff$ no retraction $\iff$ three arcs $\iff$ three sides $\iff$ three colours,

so it is enough to prove the three colours statement. That is what we now do, and the engine is a purely combinatorial lemma of Sperner.

44.3.2 Sperner's Lemma

Lemma 44.3.7 (Sperner)

Consider a triangle DEF divided into a triangular grid by $n - 1$ equally spaced lines parallel to each side. Colour every vertex of the grid red, green or blue in such a way that every vertex on the side DE except E is red, every vertex on EF except F is green, and every vertex on FD except D is blue. Then some small triangle of the grid has all three of its vertices differently coloured.

In fact the proof gives more: the number of such ‘rainbow’ triangles is odd. Here is a grid with $n = 4$; three of the small triangles are rainbow.

Proof. Give each side of each small triangle a value, according to the following rule. Traversing the side in a fixed rotational sense (say clockwise) around its small triangle, set

$$\theta(RG) = \theta(GB) = \theta(BR) = 1, \quad \theta(GR) = \theta(BG) = \theta(RB) = -1,$$

and $\theta = 0$ on a side whose two endpoints have the same colour. Note that reversing the direction of travel changes the sign of θ .

For a small triangle Δ let $\psi(\Delta)$ be the sum of the values of its three sides, traversed clockwise. If the three vertices of Δ are not all different then two of them agree, and a moment's checking shows $\psi(\Delta) = 0$: for example a triangle coloured R, R, G contributes $0 + 1 + (-1) = 0$. If the vertices are all different then going round clockwise we see either R, G, B or R, B, G , giving $\psi(\Delta) = 3$ or $\psi(\Delta) = -3$. In particular $\psi(\Delta) \neq 0$ exactly when Δ is rainbow, and $\psi(\Delta) \equiv 3 \pmod{6}$ in that case.

Now sum $\psi(\Delta)$ over all small triangles Δ . Every interior side of the grid belongs to exactly two small triangles, and is traversed in opposite directions in the two, so its two contributions cancel. Hence

$$\sum_{\Delta} \psi(\Delta) = \sum_{\text{sides on } \partial(DEF)} \theta(\text{side}),$$

the boundary sides being traversed clockwise around the big triangle.

Consider the side DE . All its grid vertices are red except the last, E , which is green. So travelling from D to E we see $R, R, \dots, R, G$ and the total is $\theta(RG) = 1$. Similarly EF reads $G, G, \dots, G, B$ contributing 1, and FD reads $B, B, \dots, B, R$ contributing 1. Hence $\sum_{\Delta} \psi(\Delta) = 3 \neq 0$, so at least one small triangle is rainbow. Indeed, since each rainbow triangle contributes ± 3 and the total is 3, the number of rainbow triangles is odd. $\square$

Proof of Lemma 44.3.6(ii), and of Brouwer's theorem. Let A, B, C be closed subsets of T with $A \supseteq I$, $B \supseteq J$ and $C \supseteq K$ satisfying $A \cup B \cup C = T$, where we label the sides so that $I = DE$, $J = EF$ and $K = FD$.

Fix n and subdivide T into a triangular grid with $n - 1$ lines parallel to each side, so that each small triangle has diameter at most $\text{diam}(T)/n$. Colour each grid vertex $\mathbf{v}$ as follows: if $\mathbf{v} \in A$ colour it red, otherwise if $\mathbf{v} \in B$ colour it green, otherwise colour it blue (which is legitimate as $A \cup B \cup C = T$). Since $I \subseteq A$, every vertex

on I is red; since $J \subseteq B$, every vertex of J not already coloured red is green – and the only vertex of J lying in I is the shared corner E . Rather than fuss over corners, note that we are free to recolour the three corners: D red, E green, F blue is consistent with $D \in I \subseteq A$, $E \in J \subseteq B$, $F \in K \subseteq C$. Thus the hypotheses of Sperner's lemma hold.

So for each n we obtain a small triangle with vertices $\mathbf{a}_n$ (red, so in A), $\mathbf{b}_n$ (green, so in B) and $\mathbf{c}_n$ (blue, so in C), with

$$\|\mathbf{a}_n - \mathbf{b}_n\|, \|\mathbf{b}_n - \mathbf{c}_n\|, \|\mathbf{c}_n - \mathbf{a}_n\| \leq \frac{\text{diam}(T)}{n}.$$

As T is compact we may pass to a subsequence along which $\mathbf{a}_{n(j)} \rightarrow \mathbf{x}$ for some $\mathbf{x} \in T$. Since the three points of each triple are within $\text{diam}(T)/n$ of each other, $\mathbf{b}_{n(j)} \rightarrow \mathbf{x}$ and $\mathbf{c}_{n(j)} \rightarrow \mathbf{x}$ too. As A, B, C are closed, $\mathbf{x} \in A \cap B \cap C$, which is therefore non-empty. $\square$

The reader who is worried about the one-dimensional analogue may like to check that the whole of this section degenerates, when T is replaced by $[0, 1]$ and three colours by two, into the following statement: if we colour $0, 1/n, \dots, 1$ red or blue with 0 red and 1 blue, then some pair of neighbours have different colours. That statement proves the intermediate value theorem, and Sperner's lemma is exactly its two-dimensional cousin.

§44.3.4 Two Applications

Brouwer's theorem is deep, and it is worth seeing that it does real work. Here is a result which the Markov chains course makes one want very much.

Proposition 44.3.8 (Perron–Frobenius, stochastic case)

Let $A = (a_{ij})$ be an $n \times n$ matrix with $a_{ij} \geq 0$ for all i, j and $\sum_{i=1}^n a_{ij} = 1$ for each j . Then A has an eigenvector with eigenvalue 1 lying in

$$\Sigma = \left\{ \mathbf{x} \in \mathbb{R}^n : x_j \geq 0 \text{ for all } j, \sum_j x_j = 1 \right\}.$$

Proof. If $\mathbf{x} \in \Sigma$ then $(A\mathbf{x})_i = \sum_j a_{ij}x_j \geq 0$ and

$$\sum_i (A\mathbf{x})_i = \sum_j x_j \sum_i a_{ij} = \sum_j x_j = 1,$$

so $A\Sigma \subseteq \Sigma$. Now Σ is a closed bounded convex subset of the hyperplane $\sum_j x_j = 1$ with non-empty interior in that hyperplane, so is homeomorphic to a closed disc of dimension $n - 1$ (radially, as in Lemma 44.3.5). Applying Brouwer's theorem in dimension $n - 1$ via Lemma 44.3.3, the continuous map $\mathbf{x} \mapsto A\mathbf{x}$ has a fixed point $\mathbf{x}^* \in \Sigma$, and $A\mathbf{x}^* = \mathbf{x}^*$ is the required eigenvector. $\square$

Reading 'i' and 'j' the other way round, this says that every finite state Markov chain has an invariant distribution – a result which is unpleasant to prove by bare hands, and which becomes almost obvious once we are allowed a fixed point theorem.

The second application is a statement which is 'obvious' in the worst sense of the word.

Proposition 44.3.9

Let $ABCD$ be a square. If γ is a continuous path in the square joining A to C , and τ is a continuous path in the square joining B to D , then γ and τ intersect.

We shall not give the details (they form a rather fiddly exercise), but the idea is worth recording: take the square to be $[-1, 1]^2$ with $\gamma, \tau : [0, 1] \rightarrow [-1, 1]^2$, and suppose $\gamma(s) \neq \tau(t)$ for all s, t . Then

$$F(s, t) = \frac{(\tau_1(t) - \gamma_1(s), \gamma_2(s) - \tau_2(t))}{\|\gamma(s) - \tau(t)\|_\infty}$$

defines a continuous map of $[0, 1]^2$ into itself, and one checks that a fixed point of F would have to lie in a corner, where the boundary conditions on γ and τ make it impossible. This is a baby case of the Jordan curve theorem, which asserts that a simple closed curve in the plane divides it into exactly two components. The Jordan curve theorem is genuinely hard, and is not part of this course; but it is comforting to know that its plausibility is not a delusion.

§44.4 Non-Zero Sum Games

It is said that converting the front garden of a house into a parking space raises the value of that house and lowers the value of every other house on the road. Once everybody has done the conversion, every house is worth less than it was before anybody started. Situations of this kind – where individually rational choices produce a collectively poor outcome – are the meat of game theory, and it turns out that Brouwer's theorem has a great deal to say about them.

Let us set up the simplest possible model. Albert has a choice between actions A_1 and A_2 , and Bertha between B_1 and B_2 . If Albert plays A_i and Bertha plays B_j , then Albert receives a_{ij} and Bertha receives b_{ij} . In IB Optimisation you studied the *zero-sum* case $a_{ij} = -b_{ij}$, where one player's gain is the other's loss; we shall make no such assumption.

Suppose Albert plays A_i with probability p_i and Bertha plays B_j with probability q_j , where $p_1 + p_2 = q_1 + q_2 = 1$ and all entries are non-negative. Writing $\mathbf{p} = (p_1, p_2)$ and $\mathbf{q} = (q_1, q_2)$, the expected payoffs are

$$A(\mathbf{p}, \mathbf{q}) = \sum_{i=1}^2 \sum_{j=1}^2 a_{ij} p_i q_j, \quad B(\mathbf{p}, \mathbf{q}) = \sum_{i=1}^2 \sum_{j=1}^2 b_{ij} p_i q_j.$$

In the zero-sum case you saw that there is a pair of strategies such that neither player would change their choice even knowing the other's. Away from zero-sum we can imagine an endless dance: Albert chooses $\mathbf{p}$, Bertha responds with $\mathbf{q}$, Albert switches to $\mathbf{p}'$, Bertha to $\mathbf{q}'$, and so on. Does the dance ever stop?

Definition 44.4.1 (Nash Equilibrium)

A pair $(\mathbf{p}^*, \mathbf{q}^*)$ of strategies is a **Nash equilibrium** (or **Nash stable point**) if

$$A(\mathbf{p}^*, \mathbf{q}^*) \geq A(\mathbf{p}, \mathbf{q}^*) \quad \text{and} \quad B(\mathbf{p}^*, \mathbf{q}^*) \geq B(\mathbf{p}^*, \mathbf{q})$$

for all strategies $\mathbf{p}, \mathbf{q}$. In other words, neither player can do better by unilaterally

changing their strategy.

Theorem 44.4.2 (Nash)

For any real numbers a_{ij}, b_{ij} there exists a Nash equilibrium.

Proof. Write $\mathbf{e}_1 = (1, 0)$ and $\mathbf{e}_2 = (0, 1)$ for the two pure strategies, and let

$$\Gamma = \{(\mathbf{p}, \mathbf{q}) : p_1, p_2, q_1, q_2 \geq 0, p_1 + p_2 = q_1 + q_2 = 1\} \subseteq \mathbb{R}^4,$$

which is (a copy of) the square $[0, 1]^2$, and so closed, bounded and homeomorphic to a disc.

For $(\mathbf{p}, \mathbf{q}) \in \Gamma$ define

$$u_i(\mathbf{p}, \mathbf{q}) = \max\{A(\mathbf{e}_i, \mathbf{q}) - A(\mathbf{p}, \mathbf{q}), 0\}, \quad v_j(\mathbf{p}, \mathbf{q}) = \max\{B(\mathbf{p}, \mathbf{f}_j) - B(\mathbf{p}, \mathbf{q}), 0\},$$

where $\mathbf{f}_j$ are the pure strategies for Bertha. Thus $u_i > 0$ says ‘against $\mathbf{q}$, Albert would do strictly better playing A_i outright’. These are continuous, being maxima of continuous functions. Now set $F(\mathbf{p}, \mathbf{q}) = (\mathbf{p}', \mathbf{q}')$ where

$$p'_i = \frac{p_i + u_i(\mathbf{p}, \mathbf{q})}{1 + u_1(\mathbf{p}, \mathbf{q}) + u_2(\mathbf{p}, \mathbf{q})}, \quad q'_j = \frac{q_j + v_j(\mathbf{p}, \mathbf{q})}{1 + v_1(\mathbf{p}, \mathbf{q}) + v_2(\mathbf{p}, \mathbf{q})}.$$

The denominators are at least 1, the numerators are non-negative, and $p'_1 + p'_2 = 1 = q'_1 + q'_2$, so $F : \Gamma \rightarrow \Gamma$ is a continuous map of Γ into itself. By Brouwer’s theorem (in the form of Lemma 44.3.3) it has a fixed point $(\mathbf{p}^*, \mathbf{q}^*)$.

We claim this is a Nash equilibrium. Write $u_i = u_i(\mathbf{p}^*, \mathbf{q}^*)$. Being a fixed point means $p_i^*(1 + u_1 + u_2) = p_i^* + u_i$, that is

$$p_i^*(u_1 + u_2) = u_i \quad (i = 1, 2).$$

Since $A(\mathbf{p}^*, \mathbf{q}^*) = p_1^*A(\mathbf{e}_1, \mathbf{q}^*) + p_2^*A(\mathbf{e}_2, \mathbf{q}^*)$ is a convex combination, we cannot have $A(\mathbf{e}_i, \mathbf{q}^*) > A(\mathbf{p}^*, \mathbf{q}^*)$ for both i . So at least one u_i vanishes; without loss of generality $u_2 = 0$. Then $p_2^*(u_1 + u_2) = 0$, so $p_2^*u_1 = 0$. If $u_1 > 0$ then $p_2^* = 0$, so $p_1^* = 1$ and $\mathbf{p}^* = \mathbf{e}_1$, whence $u_1 = \max\{A(\mathbf{e}_1, \mathbf{q}^*) - A(\mathbf{e}_1, \mathbf{q}^*), 0\} = 0$, a contradiction. So $u_1 = u_2 = 0$.

Thus $A(\mathbf{e}_i, \mathbf{q}^*) \leq A(\mathbf{p}^*, \mathbf{q}^*)$ for $i = 1, 2$, and so for any strategy $\mathbf{p}$,

$$A(\mathbf{p}, \mathbf{q}^*) = p_1A(\mathbf{e}_1, \mathbf{q}^*) + p_2A(\mathbf{e}_2, \mathbf{q}^*) \leq A(\mathbf{p}^*, \mathbf{q}^*).$$

The same argument applied to v_j gives $B(\mathbf{p}^*, \mathbf{q}) \leq B(\mathbf{p}^*, \mathbf{q}^*)$ for all $\mathbf{q}$. □

Nothing in the argument really used the number 2: with m players having finitely many choices each, exactly the same construction (in a product of simplices) together with Brouwer’s theorem in the appropriate dimension gives a stable point. Note also that the IB theory applied only to two players and only to zero-sum games; Nash’s theorem is a considerable strengthening.

Two warnings. First, equilibria need not be unique. If Albert and Bertha each choose ‘scissors’ or ‘paper’, receiving £1 each if both choose scissors, £2 each if both choose

paper, and nothing if they disagree, then both ‘everyone plays scissors’ and ‘everyone plays paper’ are stable. Second, and more disturbingly, a unique equilibrium may be very bad for everyone concerned. That, however, is not the mathematician’s problem.

Example 44.4.3 (Chicken)

Albert and Bartholomew drive their cars at one another. If both swerve, each loses 1 prestige point. If exactly one swerves, the swerver loses 5 points and the non-swerver gains 10. If neither swerves, both lose 100.

Let p be the probability that Albert swerves and q the probability that Bartholomew does. Then

$$A(p, q) = -pq - 5p(1 - q) + 10(1 - p)q - 100(1 - p)(1 - q) = p(95 - 106q) + 110q - 100,$$

and by symmetry $B(p, q) = q(95 - 106p) + 110p - 100$.

The recipe for problems like this is: first look at the interior of the square, then at the interiors of the edges, then at the vertices. In the interior we need $\partial A/\partial p = 0$ and $\partial B/\partial q = 0$, that is $95 - 106q = 0$ and $95 - 106p = 0$, giving the interior equilibrium

$$(p^*, q^*) = \left(\frac{95}{106}, \frac{95}{106} \right).$$

On the edge $p = 1$ we have $\partial B/\partial q = 95 - 106 = -11 < 0$, so Bartholomew’s best response is $q = 0$; and when $q = 0$ we have $\partial A/\partial p = 95 > 0$, so Albert’s best response is indeed $p = 1$. Hence $(1, 0)$ is an equilibrium (‘Albert always swerves, Bartholomew never does’), and by symmetry so is $(0, 1)$. At $(1, 1)$ we have $\partial A/\partial p = -11 < 0$ and at $(0, 0)$ we have $\partial A/\partial p = 95 > 0$, so neither is stable. So there are exactly three Nash equilibria.

It is genuinely easy to solve toy problems in this way; the difficulty is that with m players we must examine the interior of the cube, then each face, then each edge, then each vertex, and the number of steps explodes. So far as anybody knows, this curse of dimensionality is unavoidable.

§44.5 Dividing the Pot

Faced with the previous section, the tender-hearted ask ‘why not cooperate?’. Even granting that people sometimes do, a question remains: how should the gains from cooperation be divided? Nash gave a striking answer.

Definition 44.5.1 (Convex Set)

A subset E of $\mathbb{R}^m$ is **convex** if $\lambda \mathbf{u} + (1 - \lambda)\mathbf{v} \in E$ whenever $\mathbf{u}, \mathbf{v} \in E$ and $0 \leq \lambda \leq 1$.

The set-up is as follows. There are m participants who must jointly choose a point $\mathbf{x}$ of a closed, bounded, convex set $E \subseteq \mathbb{R}^m$; the value of the outcome to the j th participant is x_j . Convexity is not an arbitrary assumption: if the participants can agree on $\mathbf{u}$ or on $\mathbf{v}$, they can agree to toss a suitable coin, and the expected outcome is then $\lambda \mathbf{u} + (1 - \lambda)\mathbf{v}$. They also know a **status quo** point $\mathbf{s} \in E$, the outcome if they fail to agree.

Nash argues that a ‘best point’ $\mathbf{x}^*$ should have the following properties.

- (1) $x_j^* \geq s_j$ for all j : nobody is worse off than if they had walked away.
- (2) (*Pareto optimality*) If $\mathbf{x} \in E$ and $x_j \geq x_j^*$ for all j , then $\mathbf{x} = \mathbf{x}^*$: there is no available outcome which makes somebody better off and nobody worse off.
- (3) (*Independence of irrelevant alternatives*) If $E' \supseteq E$ is closed, bounded and convex and $\mathbf{x}^{**}$ is the best point for $(E', \mathbf{s})$, then $\mathbf{x}^{**} \in E$ implies that $\mathbf{x}^{**}$ is the best point for $(E, \mathbf{s})$.
- (4) (*Symmetry*) If E is invariant under permutation of coordinates and $\mathbf{s}$ is too, then $x_1^* = x_2^* = \dots = x_m^*$.
- (5) (*Scale invariance*) If $T\mathbf{x} = (a_1x_1 + b_1, \dots, a_mx_m + b_m)$ with $a_j > 0$, and $\mathbf{x}^*$ is the best point for $(E, \mathbf{s})$, then $T\mathbf{x}^*$ is the best point for $(TE, T\mathbf{s})$.

Condition (5) says that we must treat the poor man's penny with the same respect as the rich man's pound: nothing should depend on the units in which each participant measures their satisfaction. It is a genuine assumption, but a reasonable one, and it is the one which does most of the work.

There is no difficulty in remembering these conditions, since each plays a specific role in the proof. We begin with a lemma which is a very concrete instance of the separating hyperplane theorem.

Lemma 44.5.2

Let K be a convex subset of $\mathbb{R}^n$ with $(1, 1, \dots, 1) \in K$ and $\prod_{j=1}^n x_j \leq 1$ for all $\mathbf{x} \in K$ with every $x_j \geq 0$. Then

$$K \subseteq \left\{ \mathbf{x} : \sum_{j=1}^n x_j \leq n \right\}.$$

Proof. Let $\mathbf{x} \in K$ and let $\mathbf{1} = (1, \dots, 1)$. By convexity $\delta\mathbf{x} + (1 - \delta)\mathbf{1} \in K$ for $0 \leq \delta \leq 1$, and for δ small enough every coordinate $1 + \delta(x_j - 1)$ is positive. So the hypothesis applies and

$$\prod_{j=1}^n (1 + \delta(x_j - 1)) \leq 1.$$

Expanding, the left-hand side equals $1 + \delta \sum_{j=1}^n (x_j - 1) + \delta^2 R(\delta)$ where $R(\delta)$ stays bounded as $\delta \rightarrow 0$. Hence $\sum_{j=1}^n (x_j - 1) + \delta R(\delta) \leq 0$, and letting $\delta \rightarrow 0^+$ gives $\sum_j x_j \leq n$. $\square$

Lemma 44.5.3

Let $E \subseteq \mathbb{R}^m$ be closed, bounded and convex with $\mathbf{s} \in \text{Int } E$. Then the function $f(\mathbf{x}) = \prod_{j=1}^m (x_j - s_j)$ attains a maximum on $E^+ = \{\mathbf{x} \in E : x_j \geq s_j \text{ for all } j\}$ at exactly one point.

Proof. The set E^+ is closed, bounded and non-empty, so f attains a maximum M there. Since $\mathbf{s} \in \text{Int } E$ we can find $\mathbf{x} \in E$ with $x_j > s_j$ for all j , so $M > 0$.

For uniqueness, suppose $f(\mathbf{x}) = f(\mathbf{y}) = M$ with $\mathbf{x}, \mathbf{y} \in E^+$. Let $\mathbf{z} = \frac{1}{2}(\mathbf{x} + \mathbf{y}) \in E^+$ by convexity. By the AM–GM inequality,

$$z_j - s_j = \frac{(x_j - s_j) + (y_j - s_j)}{2} \geq \sqrt{(x_j - s_j)(y_j - s_j)},$$

with equality if and only if $x_j = y_j$. Multiplying over j (all factors are non-negative) gives $f(\mathbf{z}) \geq \sqrt{f(\mathbf{x})f(\mathbf{y})} = M$. As M is the maximum, we have equality throughout, and since $M > 0$ every factor is strictly positive, so equality in AM–GM forces $x_j = y_j$ for every j . $\square$

Theorem 44.5.4 (Nash Bargaining)

Suppose that to each problem $(E, \mathbf{s})$ (with $E \subseteq \mathbb{R}^m$ closed, bounded and convex and $\mathbf{s} \in \text{Int } E$) our conditions assign a best point. Then the best point of $(E, \mathbf{s})$ is the unique maximiser of

$$f(\mathbf{x}) = \prod_{j=1}^m (x_j - s_j)$$

over $\{\mathbf{x} \in E : x_j \geq s_j\}$.

Proof. Let $\mathbf{x}^*$ be the maximiser given by Lemma 44.5.3, so $x_j^* > s_j$ for every j . By condition (5) we may apply the affine change of coordinates $x_j \mapsto (x_j - s_j)/(x_j^* - s_j)$; this replaces $\mathbf{s}$ by $\mathbf{0}$ and $\mathbf{x}^*$ by $\mathbf{1} = (1, 1, \dots, 1)$, and does not change which point is ‘best’. So assume $\mathbf{s} = \mathbf{0}$ and $\mathbf{x}^* = \mathbf{1}$.

Maximality of f now reads: $\prod_j x_j \leq 1$ for every $\mathbf{x} \in E$ with all $x_j \geq 0$. As E is convex and contains $\mathbf{1}$, Lemma 44.5.2 gives $E \subseteq \{\mathbf{x} : \sum_j x_j \leq m\}$. Pick M so large that $E \subseteq [-M, M]^m$ and set

$$\Sigma = \left\{ \mathbf{x} \in [-M, M]^m : \sum_j x_j \leq m \right\},$$

which is closed, bounded, convex, contains E , contains $\mathbf{0}$ in its interior, and is invariant under permutations of the coordinates.

Consider the problem $(\Sigma, \mathbf{0})$. By symmetry (condition (4)) its best point has all coordinates equal, say $\mathbf{y} = (t, t, \dots, t)$ with $mt \leq m$, so $t \leq 1$. By Pareto optimality (condition (2)), since $\mathbf{1} \in \Sigma$ dominates $\mathbf{y}$ coordinatewise when $t < 1$, we must have $t = 1$; that is, the best point of $(\Sigma, \mathbf{0})$ is $\mathbf{1} = \mathbf{x}^*$. Finally $\mathbf{x}^* \in E \subseteq \Sigma$, so by independence of irrelevant alternatives (condition (3)) $\mathbf{x}^*$ is the best point of $(E, \mathbf{0})$. $\square$

So the fair division is the one which maximises the *product* of the gains over the status

quo – a rule with no obvious a priori justification which nonetheless falls out of five innocuous-looking requirements. There is no patent for immortality under the moon, but I suspect Nash's results will be remembered long after the last celluloid copy of *A Beautiful Mind* has crumbled to dust.

§44.6 Approximation by Polynomials

It is a guiding idea of both the calculus and of numerical analysis that well behaved functions look like polynomials. Like most guiding principles, it needs to be used judiciously, and this section is devoted to finding out in what sense it is actually true.

If asked to justify the principle we might mutter something about Taylor's theorem. But Cauchy produced the following example to show that this is not enough.

Example 44.6.1 (Cauchy's Example)

Define $E : \mathbb{R} \rightarrow \mathbb{R}$ by

$$E(t) = \begin{cases} \exp(-1/t^2) & t \neq 0, \\ 0 & t = 0. \end{cases}$$

Then E is infinitely differentiable, and $E^{(n)}(0) = 0$ for every n , yet $E(t) \neq 0$ for $t \neq 0$. So the Taylor series of E about 0 converges everywhere, to the wrong function.

Indeed, for $t \neq 0$ an easy induction gives $E^{(n)}(t) = P_n(1/t)E(t)$ for some polynomial P_n : differentiating $P_n(1/t)E(t)$ gives $(-t^{-2}P'_n(1/t) + 2t^{-3}P_n(1/t))E(t)$, which is of the same shape. At 0 we induct again: if $E^{(n)}(0) = 0$ then

$$\frac{E^{(n)}(h) - E^{(n)}(0)}{h} = \frac{1}{h}P_n(1/h)\exp(-1/h^2) \rightarrow 0$$

as $h \rightarrow 0$, since $x^k e^{-x^2} \rightarrow 0$ as $|x| \rightarrow \infty$ for every k . So $E^{(n+1)}(0)$ exists and is 0.

By Part II this example has been promoted from a counterexample to an invaluable tool: it is what makes partitions of unity and smoothing kernels possible. But it does show that Taylor's theorem is not going to tell us that continuous functions look like polynomials.

§44.6.1 Interpolation and Chebyshev Polynomials

We might instead mutter something about interpolation. Write $\mathcal{P}_n$ for the vector space of real polynomials of degree at most n .

Lemma 44.6.2 (Lagrange Interpolation)

Let $x_0, x_1, \dots, x_n$ be distinct points of $[a, b]$ and let $f : [a, b] \rightarrow \mathbb{R}$.

- (i) There is at most one $P \in \mathcal{P}_n$ with $P(x_j) = f(x_j)$ for $0 \leq j \leq n$.
- (ii) Writing $e_j(t) = \prod_{k \neq j} \frac{t - x_k}{x_j - x_k}$, the polynomial $P = \sum_{j=0}^n f(x_j)e_j$ lies in $\mathcal{P}_n$ and satisfies $P(x_i) = f(x_i)$ for all i .
- (iii) The e_j form a basis of $\mathcal{P}_n$.

Proof. (i) The difference of two such polynomials lies in $\mathcal{P}_n$ and vanishes at $n + 1$ points, so is zero by Lemma 44.1.15. (ii) Each e_j has degree n , and $e_j(x_i) = \delta_{ij}$ by construction, so $P(x_i) = f(x_i)$. (iii) There are $n + 1$ of them and $\dim \mathcal{P}_n = n + 1$; they span by (ii). $\square$

So there is always a unique interpolating polynomial, and if f is smooth we can even say exactly how good it is.

Theorem 44.6.3 (Interpolation Error)

Let $x_0 < x_1 < \cdots < x_n$ be points of $[a, b]$, let $f : [a, b] \rightarrow \mathbb{R}$ be $n + 1$ times differentiable, and let $P \in \mathcal{P}_n$ interpolate f at the x_j . Then for each $t \in [a, b]$ there is a $\xi = \xi(t) \in (a, b)$ with

$$f(t) - P(t) = \frac{f^{(n+1)}(\xi)}{(n+1)!} \prod_{j=0}^n (t - x_j).$$

Proof. If $t = x_i$ for some i both sides vanish, so suppose not, and write $\pi(s) = \prod_{j=0}^n (s - x_j)$, which is a monic polynomial of degree $n + 1$ with $\pi(t) \neq 0$. Choose the constant

$$\lambda = \frac{f(t) - P(t)}{\pi(t)}$$

and set $g(s) = f(s) - P(s) - \lambda\pi(s)$. Then g vanishes at the $n + 2$ distinct points $x_0, \dots, x_n, t$. By Rolle's theorem g' vanishes at $n + 1$ points strictly between consecutive zeros of g ; applying Rolle again, g'' vanishes at n points; and after $n + 1$ applications we obtain a $\xi \in (a, b)$ with $g^{(n+1)}(\xi) = 0$. But $P^{(n+1)} = 0$ and $\pi^{(n+1)} = (n+1)!$, so

$$0 = f^{(n+1)}(\xi) - \lambda(n+1)!,$$

which rearranges to the stated formula. $\square$

This is a genuinely informative answer, because it separates the error into two factors of completely different character. The factor $f^{(n+1)}(\xi)/(n+1)!$ depends on f , about which we may know nothing; the factor $\prod_j (t - x_j)$ depends only on *where we chose to interpolate*, and is entirely under our control. So a sensible person picks the x_j to make $\sup_t \left| \prod_j (t - x_j) \right|$ as small as possible. We shall find the optimal choice in Corollary 44.7.4, and it will turn out not to be the obvious one.

Meanwhile, the theorem should not be read as saying that interpolation always works. It has a hypothesis of $n + 1$ derivatives, and even when those exist they may be enormous. Indeed 'interpolates f at $n + 1$ points' is in general a long way from 'is close to f '. To see how badly things can go we introduce a family of polynomials which will be with us for the rest of the course.

Theorem 44.6.4 (Chebyshev Polynomials)

There are polynomials T_n of degree n and U_{n-1} of degree $n - 1$ such that

$$T_n(\cos \theta) = \cos n\theta, \quad U_{n-1}(\cos \theta) = \frac{\sin n\theta}{\sin \theta}$$

for all θ (the second whenever $\sin \theta \neq 0$). The coefficient of t^n in T_n is 2^{n-1} for $n \geq 1$. The roots of T_n are $\cos\left(\frac{(2r+1)\pi}{2n}\right)$ for $0 \leq r \leq n-1$, and the roots of U_{n-1} are $\cos(r\pi/n)$ for $1 \leq r \leq n-1$.

Proof. By de Moivre's theorem and the binomial expansion,

$$\begin{aligned} \cos n\theta + i \sin n\theta &= (\cos \theta + i \sin \theta)^n \\ &= \sum_{0 \leq 2r \leq n} (-1)^r \binom{n}{2r} \cos^{n-2r} \theta \sin^{2r} \theta \\ &\quad + i \sum_{0 \leq 2r+1 \leq n} (-1)^r \binom{n}{2r+1} \cos^{n-2r-1} \theta \sin^{2r} \theta \cdot \sin \theta. \end{aligned}$$

Now $\sin^{2r} \theta = (1 - \cos^2 \theta)^r$, so comparing real and imaginary parts we get $\cos n\theta = T_n(\cos \theta)$ and $\sin n\theta = \sin \theta U_{n-1}(\cos \theta)$ where

$$\begin{aligned} T_n(t) &= \sum_{0 \leq 2r \leq n} (-1)^r \binom{n}{2r} t^{n-2r} (1-t^2)^r, \\ U_{n-1}(t) &= \sum_{0 \leq 2r+1 \leq n} (-1)^r \binom{n}{2r+1} t^{n-2r-1} (1-t^2)^r. \end{aligned}$$

These are polynomials of degrees n and $n-1$. The coefficient of t^n in T_n comes from taking the top power in each term, giving

$$\sum_{0 \leq 2r \leq n} (-1)^r \binom{n}{2r} (-1)^r = \sum_{0 \leq 2r \leq n} \binom{n}{2r} = \frac{(1+1)^n + (1-1)^n}{2} = 2^{n-1}$$

for $n \geq 1$. Finally $T_n(\cos \theta) = 0$ exactly when $n\theta$ is an odd multiple of $\pi/2$, and as θ ranges over $[0, \pi]$ this gives the n distinct roots stated; the argument for U_{n-1} is the same. $\square$

The picture already shows the two features of the T_n which will matter to us: on $[-1, 1]$ they oscillate between $+1$ and -1 , hitting each extreme value alternately and as often as possible, and they are as large as a monic-up-to-scale polynomial can be forced to be while doing so.

Now look at U_{n-1} . Its roots are the $n-1$ points $\cos(r\pi/n)$, which together with ± 1 are perfectly reasonably spaced points of $[-1, 1]$; but $U_{n-1}(1) = n$, which is large. So the function U_{n-1} is 'well behaved' at $n+1$ well spread points (vanishing at $n-1$ of them)

and yet is very large elsewhere. Interpolation at innocent-looking points can be badly misleading, and it can be shown – though this is harder – that no choice of interpolation points avoids this in general.

The classical illustration is due to Runge. Take $f(x) = (1 + 25x^2)^{-1}$ on $[-1, 1]$, a function about as well behaved as one could wish, and interpolate it at 11 equally spaced points. Below, the true function is drawn in black and the degree-10 interpolating polynomial in red (clipped where it runs off the picture).

The interpolant is excellent in the middle and disastrous near the endpoints, and the disaster gets worse as the degree increases. If instead we interpolate at the roots of the Chebyshev polynomial T_{11} , which cluster near the endpoints, the same degree gives a genuinely good approximation.

This is a warning about interpolation, not about polynomials. The question we actually want to answer is whether *some* polynomial is uniformly close to f , and to that we now turn.

§44.6.2 Which Metric?

Before we can ask whether f looks like g , we must say what we mean. There are several natural metrics on $C([a, b])$, and they are genuinely different.

Example 44.6.5 (Three Norms)

On $C([0, 1])$ the formulae

$$\|f\|_1 = \int_0^1 |f(t)| \, dt, \quad \|f\|_2 = \left(\int_0^1 f(t)^2 \, dt \right)^{1/2}, \quad \|f\|_\infty = \sup_{t \in [0, 1]} |f(t)|$$

all define norms, and hence metrics $d_k(f, g) = \|f - g\|_k$. By the Cauchy–Schwarz

inequality $\|f\|_1 \leq \|f\|_2$, and clearly $\|f\|_2 \leq \|f\|_\infty$, so

$$\|f\|_\infty \geq \|f\|_2 \geq \|f\|_1.$$

These inequalities go only one way. If $f_n(t) = \max\{1 - nt, 0\}$ then $\|f_n\|_\infty = 1$, $\|f_n\|_2 = (3n)^{-1/2}$ and $\|f_n\|_1 = (2n)^{-1}$, so $\|f_n\|_\infty / \|f_n\|_1 = 2n \rightarrow \infty$. A tall thin spike is large in $\|\cdot\|_\infty$ and negligible in $\|\cdot\|_1$.

All three are used in practice: $\|\cdot\|_2$ is the natural one when there is an inner product around (as in least squares fitting, and in Fourier analysis), while $\|\cdot\|_1$ is the robust one favoured by statisticians. We shall work almost exclusively with $\|\cdot\|_\infty$, because it is the one for which ‘looks like’ means what an engineer would want it to mean, and because of the following fact from IB Analysis.

Theorem 44.6.6

The space $C([a, b])$ with the uniform metric $d(f, g) = \|f - g\|_\infty$ is complete.

This is the general principle of uniform convergence: a uniformly Cauchy sequence of continuous functions converges uniformly, and a uniform limit of continuous functions is continuous.

§44.6.3 The Weierstrass Approximation Theorem

We can now state the question precisely, and answer it. Weierstrass proved the following in a paper published when he was seventy.

Theorem 44.6.7 (Weierstrass Approximation Theorem)

Let $f \in C([a, b])$ and $\varepsilon > 0$. Then there is a polynomial P with $\|f - P\|_\infty < \varepsilon$.

Several proofs are known, and it is my belief that one cannot have too many insightful proofs of Weierstrass’s theorem. We give one due to Bernstein, which is based on probability and which has the great virtue of writing down an explicit approximating polynomial. We need one tool from IA Probability.

Theorem 44.6.8 (Chebyshev’s Inequality)

If X is a bounded real random variable with $\sigma^2 = \text{Var } X$, then $\Pr(|X - \mathbb{E}X| \geq a) \leq \sigma^2/a^2$ for all $a > 0$.

Proof. Writing $\mu = \mathbb{E}X$ we have $\sigma^2 = \mathbb{E}(X - \mu)^2 \geq \mathbb{E}((X - \mu)^2 \mathbb{1}_{|X - \mu| \geq a}) \geq a^2 \Pr(|X - \mu| \geq a)$. $\square$

Theorem 44.6.9 (Bernstein)

Let $f \in C([0, 1])$ and define the **Bernstein polynomial**

$$p_n(t) = \sum_{r=0}^n \binom{n}{r} f\left(\frac{r}{n}\right) t^r (1-t)^{n-r}.$$

Then $p_n \in \mathcal{P}_n$ and $\|p_n - f\|_\infty \rightarrow 0$ as $n \rightarrow \infty$.

Proof. The probabilistic idea is this. Fix $t \in [0, 1]$ and let $X_1, \dots, X_n$ be independent with $\Pr(X_r = 1) = t$ and $\Pr(X_r = 0) = 1 - t$ – that is, toss a coin with bias t . Put $Y_n = (X_1 + \dots + X_n)/n$. Then nY_n is binomial, so

$$\mathbb{E}f(Y_n) = \sum_{r=0}^n \Pr\left(Y_n = \frac{r}{n}\right) f\left(\frac{r}{n}\right) = \sum_{r=0}^n \binom{n}{r} t^r (1-t)^{n-r} f\left(\frac{r}{n}\right) = p_n(t).$$

In other words, $p_n(t)$ is the average of f over a distribution concentrated near t . Since $\mathbb{E}Y_n = t$ and $\text{Var } Y_n = t(1-t)/n \leq 1/(4n)$, the concentration improves as n grows, and continuity of f should do the rest.

Let us do this carefully. Let $\varepsilon > 0$. As $[0, 1]$ is compact, f is uniformly continuous (Theorem 44.1.12), so there is a $\delta > 0$ with $|f(x) - f(y)| < \varepsilon$ whenever $|x - y| < \delta$. Also $\|f\|_\infty < \infty$. Splitting according to whether Y_n is close to t ,

$$\begin{aligned} |p_n(t) - f(t)| &= |\mathbb{E}(f(Y_n) - f(t))| \\ &\leq \mathbb{E}(\mathbb{1}_{|Y_n - t| < \delta} |f(Y_n) - f(t)|) + \mathbb{E}(\mathbb{1}_{|Y_n - t| \geq \delta} |f(Y_n) - f(t)|) \\ &\leq \varepsilon + 2\|f\|_\infty \Pr(|Y_n - t| \geq \delta) \\ &\leq \varepsilon + 2\|f\|_\infty \frac{\text{Var } Y_n}{\delta^2} \leq \varepsilon + \frac{\|f\|_\infty}{2n\delta^2}, \end{aligned}$$

using Chebyshev's inequality. The final bound does not depend on t , so

$$\|p_n - f\|_\infty \leq \varepsilon + \frac{\|f\|_\infty}{2n\delta^2} \leq 2\varepsilon$$

for all n large enough. As $\varepsilon > 0$ was arbitrary, $\|p_n - f\|_\infty \rightarrow 0$. $\square$

Proof of Theorem 44.6.7. Let $f \in C([a, b])$ and set $g(t) = f(a + (b - a)t)$, so $g \in C([0, 1])$. By Theorem 44.6.9 there is a polynomial q with $\|g - q\|_\infty < \varepsilon$, and then $P(x) = q\left(\frac{x-a}{b-a}\right)$ is a polynomial with $\|f - P\|_\infty < \varepsilon$. $\square$

Here is the theorem in action, approximating $f(t) = |t - \frac{1}{2}|$ – a function with a corner, so certainly not analytic – by p_2 , p_5 and p_{20} .

Bernstein's polynomials converge, but not quickly: notice that p_{20} is still visibly rounded at the corner. That is the price of an explicit formula which works for every continuous f . It leads naturally to the question of what the *best* polynomial approximation looks

like, which is the subject of the next section.

§44.7 Best Approximation by Polynomials

Bernstein's theorem gives us an explicit approximating polynomial, but except in very special circumstances it is not the *best* one – indeed we have not yet even shown that a best one exists. Chebyshev was very interested in this question, and gave a beautiful criterion for recognising a best approximation when you see one.

The idea is easy to describe. If P is a good approximation to f then the error $f - P$ should not be lopsided: if it were positive more than negative, we could shift P up a little and do better. Chebyshev's insight is that the error of the *best* approximation must swing between its extreme values as often as it possibly can.

Theorem 44.7.1 (Chebyshev Equiripple Criterion)

Let $f \in C([a, b])$ and $P \in \mathcal{P}_{n-1}$, and write $\sigma = \|f - P\|_\infty$. Suppose we can find points $a \leq a_0 < a_1 < \cdots < a_n \leq b$ and a sign $\zeta \in \{-1, +1\}$ such that

$$f(a_j) - P(a_j) = \zeta(-1)^j \sigma \quad (0 \leq j \leq n).$$

Then $\|f - P\|_\infty \leq \|f - Q\|_\infty$ for every $Q \in \mathcal{P}_{n-1}$.

Proof. Replacing f and P by $-f$ and $-P$ if necessary, we may assume $\zeta = 1$, so $f(a_j) - P(a_j) = (-1)^j \sigma$. Suppose for contradiction that some $Q \in \mathcal{P}_{n-1}$ has $\|f - Q\|_\infty < \sigma$, and set $R = P - Q \in \mathcal{P}_{n-1}$. Then

$$R(a_j) = (f(a_j) - Q(a_j)) - (f(a_j) - P(a_j)) = (f(a_j) - Q(a_j)) - (-1)^j \sigma.$$

Since $|f(a_j) - Q(a_j)| \leq \|f - Q\|_\infty < \sigma$, the sign of $R(a_j)$ is that of $-(-1)^j$, and in particular $R(a_j) \neq 0$. So R takes alternate signs at the $n+1$ points $a_0 < a_1 < \cdots < a_n$, and by the intermediate value theorem R has a root in each of the n intervals (a_j, a_{j+1}) . Thus R is a non-zero element of $\mathcal{P}_{n-1}$ with at least n distinct roots, which is impossible. $\square$

Remark. The equiripple condition is also *necessary*: the best approximation always equioscillates in this way, and in particular it is unique. The proof is a pleasant exercise but is not part of the course.

Chebyshev's criterion is designed to be used in one direction: guess a candidate, check that its error equioscillates, and conclude. Let us see the method in action on a concrete problem.

Example 44.7.2 (The Best Straight Line Through e^t)

We find the best approximation to $f(t) = e^t$ on $[-1, 1]$ from $\mathcal{P}_1$. Write $P(t) = \alpha + \beta t$. Since $n = 2$ here, the criterion asks for three points at which the error takes the values $+\sigma, -\sigma, +\sigma$ (or the negatives).

The error $e^t - \alpha - \beta t$ has derivative $e^t - \beta$, which vanishes exactly once, at $t^* = \log \beta$ (assuming $\beta > 0$). So the error is decreasing then increasing, and its only candidates for extreme values are $t = -1$, $t = t^*$ and $t = 1$. For equioscillation we therefore need

$$e^{-1} - \alpha + \beta = -(e^{t^*} - \alpha - \beta t^*) = e - \alpha - \beta.$$

The outer equality gives $e^{-1} + \beta = e - \beta$, that is

$$\beta = \frac{e - e^{-1}}{2} = \sinh 1 = 1.175201\dots,$$

which is exactly the slope of the chord of f across $[-1, 1]$ – as one would guess from the mean value theorem. Putting $t^* = \log \beta$ into the first equality and rearranging,

$$\alpha = \frac{e^{-1}}{2} + \beta - \frac{\beta \log \beta}{2} = 1.264300\dots$$

The common value of the error is then $\sigma = e^{-1} - \alpha + \beta = 0.278781\dots$, and by Theorem 44.7.1 no other line does better. For comparison, the Taylor polynomial $1 + t$ has error $e - 2 = 0.718\dots$ at $t = 1$: over an interval of this size, the best approximation is better than the Taylor approximation by a factor of nearly three.

Here is the classic application, and it explains where the Chebyshev polynomials really come from.

Theorem 44.7.3

Work on $[-1, 1]$ and let $n \geq 1$. Write $S_n(t) = t^n - 2^{1-n}T_n(t)$, which lies in $\mathcal{P}_{n-1}$ by Theorem 44.6.4. Then

$$\sup_{t \in [-1, 1]} |t^n - Q(t)| \geq \sup_{t \in [-1, 1]} |t^n - S_n(t)| = 2^{1-n}$$

for every $Q \in \mathcal{P}_{n-1}$.

Proof. By construction $t^n - S_n(t) = 2^{1-n}T_n(t)$, and $|T_n(\cos \theta)| = |\cos n\theta| \leq 1$ with $\|T_n\|_\infty = 1$ on $[-1, 1]$, so $\sigma := \|t^n - S_n\|_\infty = 2^{1-n}$. Let $a_j = \cos\left(\frac{(n-j)\pi}{n}\right)$ for $0 \leq j \leq n$, so that $-1 = a_0 < a_1 < \dots < a_n = 1$ and

$$a_j^n - S_n(a_j) = 2^{1-n} \cos((n-j)\pi) = (-1)^{n-j} \sigma = (-1)^n (-1)^j \sigma.$$

So the equiripple criterion of Theorem 44.7.1 applies with $\zeta = (-1)^n$, and S_n is a best approximation to t^n from $\mathcal{P}_{n-1}$. $\square$

So the Chebyshev polynomial $2^{1-n}T_n$ is precisely the monic polynomial of degree n with smallest uniform norm on $[-1, 1]$. This settles the question we left open when we discussed interpolation.

Corollary 44.7.4 (Optimal Interpolation Nodes)

Let $x_0, \dots, x_n$ be distinct points of $[-1, 1]$. Then

$$\sup_{t \in [-1, 1]} \left| \prod_{j=0}^n (t - x_j) \right| \geq 2^{-n},$$

with equality when the x_j are taken to be the $n + 1$ roots

$$x_j = \cos \left(\frac{(2j+1)\pi}{2n+2} \right) \quad (0 \leq j \leq n)$$

of T_{n+1} . Consequently, if f is $n + 1$ times differentiable on $[-1, 1]$ and $P \in \mathcal{P}_n$ interpolates f at those roots, then

$$\|f - P\|_\infty \leq \frac{1}{2^n(n+1)!} \sup_{t \in [-1, 1]} |f^{(n+1)}(t)|.$$

Proof. The polynomial $\pi(t) = \prod_{j=0}^n (t - x_j)$ is monic of degree $n + 1$, so $\pi(t) = t^{n+1} - Q(t)$ with $Q \in \mathcal{P}_n$, and Theorem 44.7.3 (with $n + 1$ in place of n) gives $\|\pi\|_\infty \geq 2^{1-(n+1)} = 2^{-n}$. Taking the x_j to be the roots of T_{n+1} makes $\pi = 2^{-n}T_{n+1}$, since both sides are monic of degree $n + 1$ with the same roots, and $\|T_{n+1}\|_\infty = 1$. The last statement is Theorem 44.6.3 combined with this equality. $\square$

That is precisely why the second of our two pictures was so much better than the first. For equally spaced nodes the product $\prod_j |t - x_j|$ is small in the middle of the interval but exponentially larger near the ends – which is exactly where the interpolant went wrong – whereas the Chebyshev nodes, which crowd towards ± 1 , equalise it. (The reader should not conclude that the corollary *explains* the Runge phenomenon: for $f(x) = (1 + 25x^2)^{-1}$ the derivatives $f^{(n+1)}$ grow so fast that the bound above is useless for either choice of nodes. What is true is that the bound is the best one available which does not look at f , and that in practice Chebyshev interpolation converges for a much wider class of functions than equally spaced interpolation.)

Theorem 44.7.3 also gives useful lower bounds on the size of polynomials with large coefficients.

Corollary 44.7.5

We work on $[-1, 1]$.

- (i) If $P(t) = \sum_{j=0}^n a_j t^j$ with $|a_n| \geq 1$, then $\|P\|_\infty \geq 2^{1-n}$.
- (ii) There is an $\varepsilon(n) > 0$ with the following property: if $P(t) = \sum_{j=0}^n a_j t^j$ and $|a_k| \geq 1$ for *some* $0 \leq k \leq n$, then $\|P\|_\infty \geq \varepsilon(n)$.

Proof. (i) Write $P/a_n = t^n - Q(t)$ with $Q \in \mathcal{P}_{n-1}$. By Theorem 44.7.3, $\|P\|_\infty / |a_n| \geq 2^{1-n}$, and $|a_n| \geq 1$.

(ii) We induct on n . For $n = 0$ we may take $\varepsilon(0) = 1$. Suppose $\varepsilon(n)$ works, and let $P(t) = \sum_{j=0}^{n+1} a_j t^j$ with $|a_k| \geq 1$ for some k . If $|a_{n+1}| \geq \varepsilon(n)/2$ then (i)

applied to P/a_{n+1} gives $\|P\|_\infty \geq |a_{n+1}|2^{-n} \geq \varepsilon(n)2^{-n-1}$. If instead $|a_{n+1}| < \varepsilon(n)/2$ then $k \leq n$, so writing $R(t) = \sum_{j=0}^n a_j t^j$ we have $\|R\|_\infty \geq \varepsilon(n)$ by the inductive hypothesis, and

$$\|P\|_\infty \geq \|R\|_\infty - |a_{n+1}| \|t^{n+1}\|_\infty \geq \varepsilon(n) - \frac{\varepsilon(n)}{2} = \frac{\varepsilon(n)}{2}.$$

So $\varepsilon(n+1) = \varepsilon(n)2^{-n-1}$ will do. $\square$

What part (ii) really says is that on the finite dimensional space $\mathcal{P}_n$ the uniform norm and the norm $\max_j |a_j|$ on coefficients are equivalent. That is exactly what we need to run a compactness argument.

Theorem 44.7.6

If $f \in C([a, b])$ and $n \geq 0$, then there is a $P \in \mathcal{P}_n$ with $\|f - P\|_\infty \leq \|f - Q\|_\infty$ for all $Q \in \mathcal{P}_n$.

Proof. A linear change of variable turns $[a, b]$ into $[-1, 1]$ and carries $\mathcal{P}_n$ bijectively onto itself, so we may assume $[a, b] = [-1, 1]$. Define $\Phi : \mathbb{R}^{n+1} \rightarrow \mathbb{R}$ by

$$\Phi(a_0, \dots, a_n) = \left\| f - \sum_{j=0}^n a_j t^j \right\|_\infty.$$

Then Φ is continuous: indeed $|\Phi(\mathbf{a}) - \Phi(\mathbf{b})| \leq \left\| \sum (a_j - b_j) t^j \right\|_\infty \leq \sum_j |a_j - b_j|$.

Let $\kappa = \inf \Phi$, and note $\kappa \leq \Phi(\mathbf{0}) = \|f\|_\infty$. If $\Phi(\mathbf{a}) \leq \|f\|_\infty$ then $\left\| \sum a_j t^j \right\|_\infty \leq 2\|f\|_\infty$, and so, writing $M = \max_j |a_j|$, Corollary 44.7.5(ii) applied to $M^{-1} \sum a_j t^j$ (which has a coefficient of modulus 1) gives $\left\| \sum a_j t^j \right\|_\infty \geq M\varepsilon(n)$ whenever $M > 0$. Hence

$$M \leq \frac{2\|f\|_\infty}{\varepsilon(n)}.$$

So the set $E = \{\mathbf{a} : \Phi(\mathbf{a}) \leq \|f\|_\infty\}$ is bounded, and it is closed since Φ is continuous. Thus E is compact and non-empty, so Φ attains a minimum on E ; since $\Phi \geq \Phi(\mathbf{0})$ off E , this is a global minimum. $\square$

Remark (Least Squares versus Uniform Approximation). It is worth contrasting this with best approximation in the $\|\cdot\|_2$ norm. There, $\mathcal{P}_n$ is a finite dimensional subspace of an inner product space, and the best approximation is simply the orthogonal projection of f onto $\mathcal{P}_n$: it exists, is unique, is characterised by $\langle f - P, Q \rangle = 0$ for all $Q \in \mathcal{P}_n$, and can be computed by expanding f in an orthonormal basis. All of that is linear algebra. The uniform norm has no inner product behind it, which is why we have had to work for existence, and why the characterisation (equioscillation) is a genuinely analytic statement.

§44.8 Gaussian Quadrature

Suppose we want to estimate $\int_a^b f(x) dx$ knowing only the values of f at finitely many points. The naive approach is to interpolate and integrate the interpolant, which leads at once to the following.

Lemma 44.8.1

Let $x_0, \dots, x_n$ be distinct points of $[a, b]$. Then there are unique real numbers $A_0, \dots, A_n$ with

$$\int_a^b P(x) \, dx = \sum_{j=0}^n A_j P(x_j)$$

for all $P \in \mathcal{P}_n$.

Proof. With e_j as in Lemma 44.6.2, every $P \in \mathcal{P}_n$ satisfies $P = \sum_j P(x_j)e_j$, so setting $A_j = \int_a^b e_j(x) \, dx$ and integrating gives the formula. Conversely, if the formula holds then putting $P = e_i$ gives $\int_a^b e_i = \sum_j A_j e_i(x_j) = A_i$, so the A_j are determined. $\square$

Given the previous section's warnings about interpolation, we should be suspicious of the resulting approximation $\int_a^b f \approx \sum_j A_j f(x_j)$. Our suspicion is justified: when the x_j are equally spaced (the Newton–Cotes rules), computation shows that as n grows the A_j start to vary in sign and $\sum_j |A_j|$ grows rapidly. Since an error of size η in the values $f(x_j)$ produces an error of up to $\eta \sum_j |A_j|$ in the answer, the scheme becomes worse as we use more points.

It is a genuinely surprising fact that a clever choice of points avoids this completely. The clever choice is due to Gauss, and involves the orthogonal polynomials for the inner product

$$\langle f, g \rangle = \int_{-1}^1 f(t)g(t) \, dt$$

on $C([-1, 1])$.

Definition 44.8.2 (Legendre Polynomials)

The **Legendre polynomials** $p_0, p_1, p_2, \dots$ are defined by the conditions that p_n has degree exactly n with positive leading coefficient, and $\langle p_n, p_m \rangle = \delta_{nm}$.

They exist and are unique: apply Gram–Schmidt to $1, t, t^2, \dots$, so that

$$q_n(t) = t^n - \sum_{m=0}^{n-1} \langle t^n, p_m \rangle p_m(t), \quad p_n = \frac{q_n}{\|q_n\|_2}.$$

Here $q_n \neq 0$ because it has leading coefficient 1. By construction $p_0, \dots, p_n$ is an orthonormal basis of $\mathcal{P}_n$, and $p_n \perp \mathcal{P}_{n-1}$. (Other normalisations of the Legendre polynomials are common; they differ from ours only by a positive scalar.)

Lemma 44.8.3

The polynomial p_n has n distinct roots, all lying in $(-1, 1)$.

Proof. Let $y_1, \dots, y_m$ be the distinct points of $(-1, 1)$ at which p_n changes sign, and set $Q(t) = \prod_{j=1}^m (t - y_j)$ (with $Q = 1$ if $m = 0$). Then $p_n Q$ does not change sign

anywhere on $[-1, 1]$, and is not identically zero, so

$$\langle p_n, Q \rangle = \int_{-1}^1 p_n(t)Q(t) dt \neq 0.$$

But $p_n \perp \mathcal{P}_{n-1}$, so we cannot have $\deg Q = m \leq n-1$. Hence $m \geq n$; as p_n has degree n it has at most n roots, so $m = n$, the roots are simple and all lie in $(-1, 1)$. $\square$

Theorem 44.8.4 (Gaussian Quadrature)

Let $\alpha_1, \dots, \alpha_n$ be the roots of p_n and let $A_1, \dots, A_n$ be the weights of Lemma 44.8.1 for these points, so that $\int_{-1}^1 P = \sum_j A_j P(\alpha_j)$ for all $P \in \mathcal{P}_{n-1}$.

- (i) In fact $\int_{-1}^1 Q(x) dx = \sum_{j=1}^n A_j Q(\alpha_j)$ for every $Q \in \mathcal{P}_{2n-1}$.
- (ii) Conversely, if $\beta_j \in [-1, 1]$ and B_j are such that $\int_{-1}^1 Q = \sum_j B_j Q(\beta_j)$ for all $Q \in \mathcal{P}_{2n-1}$, then the β_j are the roots of p_n .

Proof. (i) Let $Q \in \mathcal{P}_{2n-1}$. Dividing by p_n we may write $Q = Gp_n + R$ with $G, R \in \mathcal{P}_{n-1}$. Then

$$\int_{-1}^1 Q = \int_{-1}^1 Gp_n + \int_{-1}^1 R = \langle G, p_n \rangle + \sum_{j=1}^n A_j R(\alpha_j) = 0 + \sum_{j=1}^n A_j R(\alpha_j),$$

using $p_n \perp \mathcal{P}_{n-1}$ and the defining property of the A_j . But $p_n(\alpha_j) = 0$, so $R(\alpha_j) = Q(\alpha_j)$, giving the result.

(ii) Set $W(x) = \prod_{j=1}^n (x - \beta_j)$, a monic polynomial of degree n . For any $R \in \mathcal{P}_{n-1}$ the product WR lies in $\mathcal{P}_{2n-1}$ and vanishes at every β_j , so

$$\langle W, R \rangle = \int_{-1}^1 WR = \sum_{j=1}^n B_j W(\beta_j) R(\beta_j) = 0.$$

Hence $W \in \mathcal{P}_n$ is orthogonal to $\mathcal{P}_{n-1}$. Since $p_0, \dots, p_n$ is an orthonormal basis of $\mathcal{P}_n$ and $p_0, \dots, p_{n-1}$ spans $\mathcal{P}_{n-1}$, the orthogonal complement of $\mathcal{P}_{n-1}$ in $\mathcal{P}_n$ is one-dimensional and spanned by p_n . So W is a scalar multiple of p_n , and the β_j are the roots of p_n . $\square$

Doubling the degree of exactness for free is impressive, but the real payoff is the following, which shows that the objection to Newton–Cotes evaporates.

Theorem 44.8.5

With the notation of Theorem 44.8.4, write $G_n f = \sum_{j=1}^n A_j f(\alpha_j)$.

- (i) $A_j > 0$ for each j .
- (ii) $\sum_{j=1}^n A_j = 2$.
- (iii) If $f \in C([-1, 1])$ and $P \in \mathcal{P}_{2n-1}$, then $\left| \int_{-1}^1 f - G_n f \right| \leq 4 \|f - P\|_\infty$.

(iv) If $f \in C([-1, 1])$ then $G_n f \rightarrow \int_{-1}^1 f(t) dt$ as $n \rightarrow \infty$.

Proof. (i) Fix k and let $w_k(t) = \prod_{j \neq k} (t - \alpha_j)^2$, a polynomial of degree $2n - 2 \leq 2n - 1$. By Theorem 44.8.4(i),

$$0 < \int_{-1}^1 w_k(t) dt = \sum_{j=1}^n A_j w_k(\alpha_j) = A_k w_k(\alpha_k),$$

since w_k vanishes at every α_j with $j \neq k$. As $w_k(\alpha_k) > 0$ we get $A_k > 0$.

(ii) Take $Q = 1$ in Theorem 44.8.4(i).

(iii) Since $\int_{-1}^1 P = G_n P$,

$$\begin{aligned} \left| \int_{-1}^1 f - G_n f \right| &= \left| \int_{-1}^1 (f - P) - \sum_j A_j (f(\alpha_j) - P(\alpha_j)) \right| \\ &\leq \int_{-1}^1 |f - P| + \sum_j |A_j| |f(\alpha_j) - P(\alpha_j)| \\ &\leq 2 \|f - P\|_\infty + \left(\sum_j A_j \right) \|f - P\|_\infty = 4 \|f - P\|_\infty, \end{aligned}$$

where we used (i) to drop the modulus signs on the A_j and (ii) to evaluate their sum.

(iv) Given $\varepsilon > 0$, Weierstrass's Theorem 44.6.7 gives a P with $\|f - P\|_\infty < \varepsilon/4$. For all n with $2n - 1 \geq \deg P$, part (iii) gives

$$\left| \int_{-1}^1 f - G_n f \right| < \varepsilon. \quad \square$$

It is worth carrying the construction out once, if only to see how modest the numbers are.

Example 44.8.6 (The Two-Point Gauss Rule)

Take $n = 2$. Gram-Schmidt gives $p_0(t) = 1/\sqrt{2}$ and, since $\langle t, p_0 \rangle = 0$ and $\int_{-1}^1 t^2 dt = \frac{2}{3}$, also $p_1(t) = \sqrt{3/2}t$. Next

$$q_2(t) = t^2 - \langle t^2, p_0 \rangle p_0(t) - \langle t^2, p_1 \rangle p_1(t) = t^2 - \frac{2/3}{\sqrt{2}} \cdot \frac{1}{\sqrt{2}} - 0 = t^2 - \frac{1}{3},$$

so the nodes are $\alpha_{1,2} = \pm 1/\sqrt{3}$. By symmetry $A_1 = A_2$, and Theorem 44.8.5(ii) gives $A_1 = A_2 = 1$. Thus

$$\int_{-1}^1 f(t) dt \approx f\left(-\frac{1}{\sqrt{3}}\right) + f\left(\frac{1}{\sqrt{3}}\right),$$

and Theorem 44.8.4 says that this is exact for every cubic. (One can check this by

hand: $\int_{-1}^1 t^2 dt = \frac{2}{3} = \frac{1}{3} + \frac{1}{3}$ and $\int_{-1}^1 t^3 dt = 0 = -3^{-3/2} + 3^{-3/2}$.)

Let us try it on $f(t) = e^t$, where $\int_{-1}^1 e^t dt = e - e^{-1} = 2.350402\dots$. The rule gives

$$e^{-1/\sqrt{3}} + e^{1/\sqrt{3}} = 2 \cosh\left(\frac{1}{\sqrt{3}}\right) = 2.342760\dots,$$

an error of 0.0076 from two evaluations of f . Simpson's rule, which is also exact on cubics, uses *three* evaluations and gives

$$\frac{1}{3}(e^{-1} + 4e^0 + e) = 2.362054\dots,$$

an error of 0.0117. So Gauss does better with less work, which is the whole point.

It is worth appreciating how the pieces fit together. Positivity of the weights (i) is what stops the errors from amplifying; it is a consequence of the choice of nodes, and it is exactly what fails for equally spaced nodes. Once we have positivity and (ii), the quadrature error is controlled by the best polynomial approximation error, and Weierstrass's theorem then guarantees convergence for *every* continuous f – with no smoothness assumptions at all.

§44.9 Distance and Compact Sets

This section is a digression, but a useful one: we construct a metric on the collection of compact sets. It provides some helpful background for Runge's theorem, and it will supply a striking application of the Baire category theorem later on.

Throughout we work in $\mathbb{R}^m$ with the usual metric, and all sets are non-empty and compact. Recall from Lemma 44.1.13 that $d(\mathbf{x}, A) = \inf_{\mathbf{a} \in A} \|\mathbf{x} - \mathbf{a}\|$ defines a continuous function of $\mathbf{x}$.

Lemma 44.9.1

Let E be a non-empty compact subset of $\mathbb{R}^m$ and $\mathbf{a} \in \mathbb{R}^m$. Then there is a point $\mathbf{e} \in E$ with $\|\mathbf{a} - \mathbf{e}\| = d(\mathbf{a}, E)$.

Proof. The map $\mathbf{x} \mapsto \|\mathbf{a} - \mathbf{x}\|$ is continuous on the compact set E , so attains its infimum by Theorem 44.1.10. $\square$

The nearest point need not be unique – take E to be a circle and $\mathbf{a}$ its centre – but it is unique if E is convex. Indeed if $\mathbf{u}, \mathbf{v} \in E$ both achieve the minimum distance ρ from $\mathbf{a}$ and $\mathbf{u} \neq \mathbf{v}$, then $\frac{1}{2}(\mathbf{u} + \mathbf{v}) \in E$ and, by the parallelogram law,

$$\left\| \mathbf{a} - \frac{\mathbf{u} + \mathbf{v}}{2} \right\|^2 = \rho^2 - \frac{1}{4} \|\mathbf{u} - \mathbf{v}\|^2 < \rho^2,$$

a contradiction.

Lemma 44.9.2

Let $E, F \subseteq \mathbb{R}^m$ be non-empty.

- (i) If E and F are compact, there exist $\mathbf{e} \in E, \mathbf{f} \in F$ with $\|\mathbf{e} - \mathbf{f}\| \leq \|\mathbf{x} - \mathbf{y}\|$ for all $\mathbf{x} \in E, \mathbf{y} \in F$.

(ii) The same holds if E is compact and F is closed.

(iii) It may fail if E and F are merely closed.

Proof. (i) The function $(\mathbf{x}, \mathbf{y}) \mapsto \|\mathbf{x} - \mathbf{y}\|$ is continuous on the compact set $E \times F$.

(ii) Choose $R > 0$ with $E \subseteq \overline{B}(\mathbf{0}, R)$ and $F \cap \overline{B}(\mathbf{0}, R) \neq \emptyset$. Set $F_R = F \cap \overline{B}(\mathbf{0}, 3R)$, a non-empty compact set. By (i) there are $\mathbf{e} \in E$, $\mathbf{f} \in F_R$ minimising the distance over $E \times F_R$, and $\|\mathbf{e} - \mathbf{f}\| \leq 2R$. If $\mathbf{y} \in F \setminus F_R$ then $\|\mathbf{x} - \mathbf{y}\| \geq 3R - R = 2R$ for $\mathbf{x} \in E$, so the minimum over $E \times F$ is achieved too.

(iii) Take $E = \{(x, 1/x) : x > 0\}$ and $F = \{(-x, 1/x) : x > 0\}$. Both are closed, $\|\mathbf{x} - \mathbf{y}\| > 0$ for all $\mathbf{x} \in E$, $\mathbf{y} \in F$, but taking x large shows the infimum is 0. $\square$

§44.9.1 The Hausdorff Metric

We would like a notion of distance between compact sets. The first thing one writes down is

$$\tau(E, F) = \inf_{\mathbf{e} \in E} d(\mathbf{e}, F) = \inf\{\|\mathbf{e} - \mathbf{f}\| : \mathbf{e} \in E, \mathbf{f} \in F\}.$$

This is symmetric and non-negative, and by Lemma 44.9.2 we have $\tau(E, F) = 0$ if and only if $E \cap F \neq \emptyset$. So it fails the axiom $\tau(E, F) = 0 \Rightarrow E = F$ rather badly, and it also fails the triangle inequality: with $A = \{1\}$, $B = \{1, 2\}$, $C = \{2\}$ we have $\tau(A, C) = 1$ but $\tau(A, B) + \tau(B, C) = 0$.

The trouble is that an infimum only notices the closest pair of points. Let us try a supremum instead:

$$\sigma(E, F) = \sup_{\mathbf{e} \in E} d(\mathbf{e}, F).$$

This is non-negative, and $\sigma(E, F) = 0$ if and only if $d(\mathbf{e}, F) = 0$ for every $\mathbf{e} \in E$, that is (as F is closed) if and only if $E \subseteq F$. So σ measures ‘how far E sticks out of F ’, and is emphatically not symmetric. But it does obey the triangle inequality.

Lemma 44.9.3

For non-empty compact E, F, G we have $\sigma(E, G) \leq \sigma(E, F) + \sigma(F, G)$.

Proof. Let $\mathbf{e} \in E$. By Lemma 44.9.1 choose $\mathbf{f} \in F$ with $\|\mathbf{e} - \mathbf{f}\| = d(\mathbf{e}, F)$. For any $\mathbf{g} \in G$,

$$d(\mathbf{e}, G) \leq \|\mathbf{e} - \mathbf{g}\| \leq \|\mathbf{e} - \mathbf{f}\| + \|\mathbf{f} - \mathbf{g}\| = d(\mathbf{e}, F) + \|\mathbf{f} - \mathbf{g}\|.$$

Taking the infimum over $\mathbf{g} \in G$ gives $d(\mathbf{e}, G) \leq d(\mathbf{e}, F) + d(\mathbf{f}, G) \leq \sigma(E, F) + \sigma(F, G)$, and taking the supremum over $\mathbf{e} \in E$ finishes the proof. $\square$

Symmetrising now gives what we want.

Definition 44.9.4 (Hausdorff Metric)

Let $\mathcal{K}$ be the collection of non-empty compact subsets of $\mathbb{R}^m$. For $E, F \in \mathcal{K}$ set

$$\rho(E, F) = \sigma(E, F) + \sigma(F, E) = \sup_{\mathbf{e} \in E} \inf_{\mathbf{f} \in F} \|\mathbf{e} - \mathbf{f}\| + \sup_{\mathbf{f} \in F} \inf_{\mathbf{e} \in E} \|\mathbf{e} - \mathbf{f}\|.$$

We call ρ the **Hausdorff metric**.

here $F \subseteq E$, so $\sigma(F, E) = 0$ while $\sigma(E, F)$ is large

Theorem 44.9.5

ρ is a metric on $\mathcal{K}$.

Proof. Clearly $\rho \geq 0$ and ρ is symmetric. If $\rho(E, F) = 0$ then $\sigma(E, F) = \sigma(F, E) = 0$, so $E \subseteq F$ and $F \subseteq E$, giving $E = F$; and conversely. The triangle inequality follows from Lemma 44.9.3 applied twice:

$$\begin{aligned} \rho(E, G) &= \sigma(E, G) + \sigma(G, E) \\ &\leq (\sigma(E, F) + \sigma(F, G)) + (\sigma(G, F) + \sigma(F, E)) \\ &= \rho(E, F) + \rho(F, G). \square \end{aligned}$$

What makes ρ genuinely useful is that it is complete. We need two preliminary observations.

Lemma 44.9.6

Suppose $K_1 \supseteq K_2 \supseteq K_3 \supseteq \cdots$ are non-empty compact subsets of $\mathbb{R}^m$ and let $K = \bigcap_{p \geq 1} K_p$. Then K is non-empty and compact, and $\rho(K_p, K) \rightarrow 0$.

Proof. K is closed (an intersection of closed sets) and bounded, hence compact. To see it is non-empty, pick $\mathbf{k}_p \in K_p$ for each p . All the $\mathbf{k}_p$ lie in the compact set K_1 , so some subsequence $\mathbf{k}_{p(j)} \rightarrow \mathbf{k}$. For each fixed q we have $\mathbf{k}_{p(j)} \in K_q$ for all j with $p(j) \geq q$, and K_q is closed, so $\mathbf{k} \in K_q$. Hence $\mathbf{k} \in K$.

Since $K \subseteq K_p$ we have $\sigma(K, K_p) = 0$, so $\rho(K_p, K) = \sigma(K_p, K)$. Suppose this does not tend to 0. Then there is an $\varepsilon > 0$, a subsequence $p(j)$, and points $\mathbf{x}_{p(j)} \in K_{p(j)}$ with $d(\mathbf{x}_{p(j)}, K) \geq \varepsilon$. Passing to a further subsequence, $\mathbf{x}_{p(j)} \rightarrow \mathbf{x}$, and exactly as above $\mathbf{x} \in K$. But $d(\cdot, K)$ is continuous, so $d(\mathbf{x}, K) \geq \varepsilon > 0$, contradicting $\mathbf{x} \in K$. $\square$

Lemma 44.9.7

If $K \subseteq \mathbb{R}^m$ is compact and $r \geq 0$, then $K + \overline{B}(\mathbf{0}, r) = \{\mathbf{x} + \mathbf{y} : \mathbf{x} \in K, \|\mathbf{y}\| \leq r\}$ is compact.

Proof. It is clearly bounded. If $\mathbf{x}_n + \mathbf{y}_n \rightarrow \mathbf{c}$ with $\mathbf{x}_n \in K$ and $\|\mathbf{y}_n\| \leq r$, pass to a subsequence with $\mathbf{x}_{n(j)} \rightarrow \mathbf{x} \in K$; then $\mathbf{y}_{n(j)} \rightarrow \mathbf{c} - \mathbf{x}$, so $\|\mathbf{c} - \mathbf{x}\| \leq r$ and $\mathbf{c} \in K + \overline{B}(\mathbf{0}, r)$. $\square$

Theorem 44.9.8

The Hausdorff metric ρ is complete on $\mathcal{K}$.

Proof. By Lemma 44.1.3(ii) it suffices to show that any sequence (E_n) in $\mathcal{K}$ with $\rho(E_n, E_{n+1}) \leq 100^{-n}$ converges. Set

$$K_n = E_n + \overline{B}(\mathbf{0}, 10 \cdot 100^{-n}),$$

which is compact by Lemma 44.9.7. Since $\sigma(E_{n+1}, E_n) \leq \rho(E_n, E_{n+1}) \leq 100^{-n}$, every point of E_{n+1} lies within 100^{-n} of E_n , that is $E_{n+1} \subseteq E_n + \overline{B}(\mathbf{0}, 100^{-n})$. Hence

$$K_{n+1} \subseteq E_n + \overline{B}(\mathbf{0}, 100^{-n}) + \overline{B}(\mathbf{0}, 10 \cdot 100^{-n-1}) \subseteq E_n + \overline{B}(\mathbf{0}, 2 \cdot 100^{-n}) \subseteq K_n.$$

By Lemma 44.9.6 the set $K = \bigcap_n K_n$ is a non-empty compact set with $\rho(K_n, K) \rightarrow 0$. Finally $E_n \subseteq K_n$ and every point of K_n is within $10 \cdot 100^{-n}$ of E_n , so $\rho(E_n, K_n) \leq 10 \cdot 100^{-n} \rightarrow 0$, and therefore

$$\rho(E_n, K) \leq \rho(E_n, K_n) + \rho(K_n, K) \rightarrow 0. \quad \square$$

§44.10 Runge's Theorem

Weierstrass's theorem tells us that every continuous real function on $[a, b]$ is a uniform limit of polynomials. Is there a complex analogue? Cauchy's theorem answers with a resounding no.

Example 44.10.1

Let $\overline{D} = \{z : |z| \leq 1\}$ and $f(z) = \bar{z}$. Then $\sup_{z \in \overline{D}} |f(z) - P(z)| \geq 1$ for every polynomial P .

Indeed, let C be the contour $\theta \mapsto e^{i\theta}$, $0 \leq \theta \leq 2\pi$. By Cauchy's theorem $\int_C P(z) dz = 0$, so

$$2\pi \|f - P\|_\infty \geq \left| \int_C (\bar{z} - P(z)) dz \right| = \left| \int_C \bar{z} dz \right| = \left| \int_0^{2\pi} e^{-i\theta} \cdot ie^{i\theta} d\theta \right| = 2\pi.$$

That example is unfair: $\bar{z}$ is nowhere analytic, and we know that a uniform limit of analytic functions is analytic. So let us ask for analytic f . Cauchy's theorem still causes trouble.

Example 44.10.2

Let $T = \{z : \frac{1}{2} \leq |z| \leq 2\}$ and $f(z) = 1/z$, which is analytic on the open set $\Omega = \{z : 0 < |z| < 3\} \supseteq T$. Then $\sup_{z \in T} |f(z) - P(z)| \geq 1$ for every polynomial P ,

since with C as above,

$$2\pi \|f - P\|_\infty \geq \left| \int_C \left(\frac{1}{z} - P(z) \right) dz \right| = |2\pi i| = 2\pi.$$

The obstruction here is that T has a hole, and f misbehaves inside it. So the best we can hope for is a theorem about sets without holes, and the following turns out to be the right notion.

Definition 44.10.3 (Path-Connectedness)

A set $U \subseteq \mathbb{C}$ is **path-connected** if, given $z_0, z_1 \in U$, we can find a continuous $\gamma : [0, 1] \rightarrow U$ with $\gamma(0) = z_0$ and $\gamma(1) = z_1$.

Theorem 44.10.4 (Runge)

Let $\Omega \subseteq \mathbb{C}$ be open and $f : \Omega \rightarrow \mathbb{C}$ analytic. Suppose $K \subseteq \Omega$ is compact with $\mathbb{C} \setminus K$ path-connected. Then given $\varepsilon > 0$ there is a polynomial P with

$$\sup_{z \in K} |f(z) - P(z)| < \varepsilon.$$

Note that this is genuinely stronger than Taylor's theorem, which says only that f is uniformly approximable by polynomials on any *disc* contained in Ω ; Runge's theorem is a global statement. (And there is no hope of simply expanding in a Taylor series: on $\Omega = \{z : 10^{-2} < |z| < 1\} \setminus (-\infty, 0]$ the function $1/z$ is analytic and bounded but is not given by any single power series.)

The proof falls into three steps. First we express f on K as a sum of contour integrals along segments lying outside K ; then we approximate each such integral by a finite sum of simple poles; then we show that each simple pole can be pushed off to infinity and replaced by a polynomial. The last step is where path-connectedness enters.

§44.10.1 Step One: A Contour Representation

Lemma 44.10.5

Let $\Omega \subseteq \mathbb{C}$ be open and $K \subseteq \Omega$ compact and non-empty. Then we can find finitely many line segments $l_1, \dots, l_M$, each contained in $\Omega \setminus K$, such that

$$f(z) = \sum_{r=1}^M \frac{1}{2\pi i} \int_{l_r} \frac{f(w)}{w - z} dw$$

for every $z \in K$ and every analytic $f : \Omega \rightarrow \mathbb{C}$. Moreover $d(K, l_1 \cup \dots \cup l_M) > 0$.

Proof. Since K is compact and $\mathbb{C} \setminus \Omega$ is closed and disjoint from K , Lemma 44.9.2(ii) gives a $\delta > 0$ with $|k - u| \geq 100\delta$ for all $k \in K$ and $u \notin \Omega$ (if $\Omega = \mathbb{C}$, take any $\delta > 0$).

Tile the plane by the closed squares of side δ with corners in $\delta\mathbb{Z} + i\delta\mathbb{Z}$, and let Γ be the (finite) collection of those squares which meet K . Every $S \in \Gamma$ satisfies

$S \subseteq K + \overline{B}(0, 2\delta) \subseteq \Omega$, so f is analytic on a neighbourhood of each $S \in \Gamma$. Write $G = \bigcup_{S \in \Gamma} S$. If $z \in K$ then every square containing z meets K and so lies in Γ ; as the squares containing z cover a neighbourhood of z , we get $K \subseteq \text{Int } G$.

Now fix $z \in \text{Int } G$ which does not lie on the boundary of any square of the tiling. Then z lies in the interior of exactly one square S_0 , and $S_0 \in \Gamma$ since $z \in G$. Orienting each ∂S anticlockwise, Cauchy's integral formula and Cauchy's theorem give

$$\frac{1}{2\pi i} \int_{\partial S} \frac{f(w)}{w-z} dw = \begin{cases} f(z) & S = S_0, \\ 0 & S \in \Gamma, S \neq S_0, \end{cases}$$

so summing over $S \in \Gamma$ yields $f(z) = \sum_{S \in \Gamma} \frac{1}{2\pi i} \int_{\partial S} \frac{f(w)}{w-z} dw$.

Each edge of the tiling which is shared by two squares of Γ is traversed once in each direction, so those contributions cancel. Let $l_1, \dots, l_M$ be the remaining edges – the edges of squares of Γ whose neighbouring square is not in Γ – with their induced orientations. Then

$$f(z) = \sum_{r=1}^M \frac{1}{2\pi i} \int_{l_r} \frac{f(w)}{w-z} dw$$

for all such z . Each l_r lies in Ω , and $l_r \cap K = \emptyset$: if l_r met K then the square on its far side would meet K too and would belong to Γ , so l_r would have cancelled. Since $\bigcup_r l_r$ and K are disjoint compact sets, Lemma 44.9.2(i) gives $d(K, \bigcup_r l_r) > 0$.

Finally, both sides of the displayed identity are continuous functions of z on the open set $\text{Int } G$ (for the right-hand side, because the integrands have denominators bounded away from zero there). They agree on $\text{Int } G$ minus the union of the grid lines, which is dense in the open set $\text{Int } G$. Hence they agree on all of $\text{Int } G \supseteq K$. $\square$

§44.10.2 Step Two: Approximation by Simple Poles

Lemma 44.10.6

Let Ω be open, $K \subseteq \Omega$ compact, and $f : \Omega \rightarrow \mathbb{C}$ analytic. Given $\varepsilon > 0$ we can find N , complex numbers $A_1, \dots, A_N$ and points $\alpha_1, \dots, \alpha_N \in \Omega \setminus K$ such that

$$\left| f(z) - \sum_{n=1}^N \frac{A_n}{z - \alpha_n} \right| \leq \varepsilon$$

for all $z \in K$.

Proof. By Lemma 44.10.5 it suffices to approximate a single term $\frac{1}{2\pi i} \int_l \frac{f(w)}{w-z} dw$, where l is a segment disjoint from K and contained in Ω . Parametrise l by $\gamma(t) = w_0 + t(w_1 - w_0)$ for $t \in [0, 1]$, so that

$$\frac{1}{2\pi i} \int_l \frac{f(w)}{w-z} dw = \int_0^1 F(t, z) dt, \quad F(t, z) = \frac{1}{2\pi i} \cdot \frac{f(\gamma(t))(w_1 - w_0)}{\gamma(t) - z}.$$

Since $d(K, l) > 0$, the function F is continuous on the compact set $[0, 1] \times K$, hence uniformly continuous there by Theorem 44.1.12. So given $\eta > 0$ there is an m with $|F(t, z) - F(r/m, z)| < \eta$ whenever $t \in [r/m, (r+1)/m]$ and $z \in K$. Therefore

$$\left| \int_0^1 F(t, z) dt - \frac{1}{m} \sum_{r=0}^{m-1} F(r/m, z) \right| \leq \eta$$

for all $z \in K$, and the Riemann sum is exactly of the form $\sum_r \frac{A_r}{z - \alpha_r}$ with $\alpha_r = \gamma(r/m) \in l \subseteq \Omega \setminus K$ and suitable constants A_r . Doing this for each of the M segments with $\eta = \varepsilon/M$ completes the proof. $\square$

§44.10.3 Step Three: Pushing Poles to Infinity

Everything now reduces to the following statement, which is where the topology of K finally matters.

Lemma 44.10.7

Let $K \subseteq \mathbb{C}$ be compact with $\mathbb{C} \setminus K$ path-connected. Then for every $\alpha \notin K$ and every $\varepsilon > 0$ there is a polynomial P with $|P(z) - \frac{1}{z-\alpha}| < \varepsilon$ for all $z \in K$.

Write $\Lambda(K)$ for the set of $\alpha \notin K$ with this property. We must show $\Lambda(K) = \mathbb{C} \setminus K$, and we do it in three moves.

Proof. (a) $\Lambda(K)$ contains all sufficiently large α . Choose R with $K \subseteq B(0, R/2)$. If $|\alpha| \geq R$ then for $z \in K$,

$$\frac{1}{z-\alpha} = \frac{-1}{\alpha(1-z/\alpha)} = -\frac{1}{\alpha} \sum_{n=0}^{\infty} \left(\frac{z}{\alpha}\right)^n,$$

and since $|z/\alpha| \leq \frac{1}{2}$ on K the series converges uniformly on K by the Weierstrass M -test. Its partial sums are polynomials, so $\alpha \in \Lambda(K)$.

(b) $\Lambda(K)$ is ‘locally closed under small moves’. Suppose $\alpha \in \Lambda(K)$ and $|\alpha - \beta| < \frac{1}{2}d(\alpha, K)$. Put $\delta = d(\alpha, K)$, so $|z - \alpha| \geq \delta$ for $z \in K$. Then for $z \in K$,

$$\frac{1}{z-\beta} = \frac{1}{(z-\alpha) - (\beta-\alpha)} = \frac{1}{z-\alpha} \cdot \frac{1}{1 - \frac{\beta-\alpha}{z-\alpha}} = \sum_{n=0}^{\infty} \frac{(\beta-\alpha)^n}{(z-\alpha)^{n+1}},$$

and since $\left|\frac{\beta-\alpha}{z-\alpha}\right| \leq \frac{1}{2}$ on K the series converges uniformly on K . So given $\varepsilon > 0$ we

can find N with

$$\left| \frac{1}{z - \beta} - \sum_{n=0}^N \frac{(\beta - \alpha)^n}{(z - \alpha)^{n+1}} \right| < \frac{\varepsilon}{2} \quad (z \in K).$$

Now $\alpha \in \Lambda(K)$ means $(z - \alpha)^{-1}$ is uniformly approximable on K by polynomials; hence so is each power $(z - \alpha)^{-(n+1)}$ (a product of uniformly bounded uniformly approximable functions is uniformly approximable), and hence so is the finite sum. Choosing a polynomial within $\varepsilon/2$ of it gives $\beta \in \Lambda(K)$.

(c) Path-connectedness. Let $\beta \notin K$. By (a) choose α_0 with $|\alpha_0|$ large enough that $\alpha_0 \in \Lambda(K)$. Since $\mathbb{C} \setminus K$ is path-connected there is a continuous $\gamma : [0, 1] \rightarrow \mathbb{C} \setminus K$ with $\gamma(0) = \alpha_0$, $\gamma(1) = \beta$. The image $\gamma([0, 1])$ is compact and disjoint from the compact set K , so by Lemma 44.9.2(i) there is a $\delta > 0$ with $d(\gamma(t), K) \geq 4\delta$ for all t . Also γ is uniformly continuous, so there is an N with $|\gamma(s) - \gamma(t)| < \delta$ whenever $|s - t| \leq 1/N$. Setting $w_j = \gamma(j/N)$ we have $|w_j - w_{j+1}| < \delta \leq \frac{1}{2}d(w_j, K)$, so by (b) and induction $w_0 \in \Lambda(K)$ gives $w_N = \beta \in \Lambda(K)$. $\square$

Proof of Runge's theorem. Given $\varepsilon > 0$, Lemma 44.10.6 provides A_n and $\alpha_n \notin K$ with $\left| f(z) - \sum_{n=1}^N \frac{A_n}{z - \alpha_n} \right| \leq \varepsilon/2$ on K . By Lemma 44.10.7 each $\frac{1}{z - \alpha_n}$ is within $\frac{\varepsilon}{2N(1+|A_n|)}$ of a polynomial P_n uniformly on K . Then $P = \sum_n A_n P_n$ satisfies $\sup_K |f - P| < \varepsilon$. $\square$

§44.10.4 An Application: Pointwise Limits Need Not Be Continuous

If analytic functions converge *uniformly*, the limit is analytic. It is natural to ask whether uniformity is really needed, and Runge's theorem lets us answer emphatically.

Example 44.10.8

Let $D = \{z : |z| < 1\}$ and define $f : \mathbb{C} \rightarrow \mathbb{C}$ by $f(0) = 0$ and

$$f(re^{i\theta}) = r^{3/2}e^{3i\theta/2} \quad (r > 0, 0 < \theta \leq 2\pi).$$

Then f is not continuous on D (approaching a positive real x from above gives $x^{3/2}$, from below gives $-x^{3/2}$), yet there are polynomials P_n with $P_n(z) \rightarrow f(z)$ for every $z \in D$.

Proof. The function f is analytic on $\Omega = \mathbb{C} \setminus [0, \infty)$, being a branch of $z^{3/2}$ there. For $n \geq 1$ let $f_n(z) = f(z - i/n)$, which is analytic on $\Omega_n = \mathbb{C} \setminus (\frac{i}{n} + [0, \infty))$, and let

$$K_n = \{z : |z| \leq 1, d(z, \frac{i}{n} + [0, \infty)) \geq \frac{1}{n^2}\}.$$

Then K_n is compact, $K_n \subseteq \Omega_n$, and $\mathbb{C} \setminus K_n$ is path-connected: K_n is a closed disc with a slit-shaped neighbourhood removed, and any point of the complement can be joined to infinity by going along the slit and out. By Runge's theorem there is a polynomial P_n with $\sup_{z \in K_n} |f_n(z) - P_n(z)| \leq 2^{-n}$.

Now fix z with $|z| < 1$. If z is a non-negative real then $d(z, \frac{i}{n} + [0, \infty)) = \frac{1}{n} \geq \frac{1}{n^2}$, so $z \in K_n$ for every n . Otherwise $d(z, [0, \infty)) = c > 0$ and so $d(z, \frac{i}{n} + [0, \infty)) \geq$

$c - \frac{1}{n} \geq \frac{1}{n^2}$ for all large n . Either way $z \in K_n$ eventually, and then

$$|P_n(z) - f(z)| \leq 2^{-n} + |f(z - i/n) - f(z)| \rightarrow 0,$$

since $z - i/n \rightarrow z$ from below, and f is continuous from below across the positive real axis (as $\theta \rightarrow 2\pi^-$ we get $r^{3/2}e^{3i\pi} = -r^{3/2}$, which is the assigned value at $\theta = 2\pi$); at $z = 0$ we simply have $f(-i/n) = n^{-3/2}e^{9i\pi/4} \rightarrow 0 = f(0)$. $\square$

§44.11 Odd Numbers

According to Von Neumann, ‘in mathematics you don’t understand things, you just get used to them’. The real line is a case in point. A single innocuous-looking axiom – every bounded increasing sequence converges – calls into being an object of indescribable complexity. We know that $\mathbb{R}$ is uncountable; on the other hand, if our alphabet has n symbols then there are at most n^m phrases of length exactly m , so the collection of *describable* real numbers is a countable union of finite sets, and hence countable. Almost every real number cannot be described at all.

In this section we look at a few of the prettier shells: numbers we can describe, and about which we can say something.

§44.11.1 Irrationality

Theorem 44.11.1

The number e is irrational.

Proof. Suppose $e = p/q$ with $p, q \in \mathbb{N}$. Recall $e = \sum_{r=0}^{\infty} \frac{1}{r!}$. Consider

$$N = q! \left(e - \sum_{r=0}^q \frac{1}{r!} \right) = q! e - \sum_{r=0}^q \frac{q!}{r!}.$$

Now $q! e = q! p/q = (q-1)! p$ is an integer, and each $q!/r!$ with $r \leq q$ is an integer, so $N \in \mathbb{Z}$. On the other hand

$$0 < N = q! \sum_{r=q+1}^{\infty} \frac{1}{r!} = \sum_{k=1}^{\infty} \frac{q!}{(q+k)!} \leq \sum_{k=1}^{\infty} \frac{1}{(q+1)^k} = \frac{1}{q} \leq 1,$$

and the inequality $q!/(q+k)! \leq (q+1)^{-k}$ is strict for $k \geq 2$, so $0 < N < 1$. There is no such integer. $\square$

The proof of the corresponding statement for π is harder, and rests on the following computation.

Lemma 44.11.2

Write $f_n(x) = x^n(\pi - x)^n$. Then

$$\int_0^{\pi} f_n(x) \sin x \, dx = n! \sum_{j=0}^n a_j \pi^j$$

for some integers a_j (depending on n).

Proof. Expanding, $f_n(x) = \sum_{r=0}^n \binom{n}{r} (-1)^r \pi^{n-r} x^{n+r}$, a polynomial with terms of degrees between n and $2n$. So $f_n^{(k)}(0) = 0$ for $k < n$ and for $k > 2n$, while for $n \leq k \leq 2n$ only the term with $n+r = k$ survives and

$$f_n^{(k)}(0) = k! \binom{n}{k-n} (-1)^{k-n} \pi^{2n-k}.$$

Since $n \leq k$, the number $k!/n!$ is an integer, so $f_n^{(k)}(0) = n! m_k \pi^{2n-k}$ for some $m_k \in \mathbb{Z}$, and the exponent $2n-k$ lies between 0 and n . Moreover $f_n(\pi-x) = f_n(x)$, so $f_n^{(k)}(\pi) = (-1)^k f_n^{(k)}(0)$ is of the same shape.

Now integrate by parts twice. Writing $I_k = \int_0^\pi f_n^{(k)}(x) \sin x \, dx$,

$$\begin{aligned} I_k &= \left[-f_n^{(k)}(x) \cos x \right]_0^\pi + \int_0^\pi f_n^{(k+1)}(x) \cos x \, dx \\ &= f_n^{(k)}(\pi) + f_n^{(k)}(0) + \int_0^\pi f_n^{(k+1)}(x) \cos x \, dx, \end{aligned}$$

and $\int_0^\pi f_n^{(k+1)} \cos x \, dx = \left[f_n^{(k+1)} \sin x \right]_0^\pi - I_{k+2} = -I_{k+2}$. Hence

$$I_k = f_n^{(k)}(\pi) + f_n^{(k)}(0) - I_{k+2}.$$

Since $f_n^{(k)} \equiv 0$ for $k > 2n$, we have $I_k = 0$ for $k > 2n$, and iterating the recursion downwards from $k = 0$ expresses $I_0 = \int_0^\pi f_n \sin x \, dx$ as an integer combination of the numbers $f_n^{(k)}(0)$ and $f_n^{(k)}(\pi)$. Each of these is $n!$ times an integer times a power π^j with $0 \leq j \leq n$, which is the claim. $\square$

Theorem 44.11.3

The number π is irrational.

Proof. Write $P_n(X) = \sum_{j=0}^n a_j X^j \in \mathbb{Z}[X]$ as in Lemma 44.11.2, so that the integral $\int_0^\pi f_n(x) \sin x \, dx$ equals $n! P_n(\pi)$. On $(0, \pi)$ we have $x^n(\pi-x)^n \sin x > 0$, so this integral is strictly positive. On the other hand, by AM–GM we have $x(\pi-x) \leq (\pi/2)^2$, so

$$0 < n! P_n(\pi) = \int_0^\pi f_n(x) \sin x \, dx \leq \int_0^\pi \left(\frac{\pi}{2}\right)^{2n} \, dx = \pi \left(\frac{\pi^2}{4}\right)^n.$$

Suppose now $\pi = p/q$ with $p, q \in \mathbb{N}$. Since $\deg P_n \leq n$, the number $q^n P_n(p/q)$ is an integer, and it is strictly positive, so $q^n P_n(\pi) \geq 1$. Hence

$$n! \leq q^n P_n(\pi) \leq \pi \left(\frac{q\pi^2}{4}\right)^n.$$

But $C^n/n! \rightarrow 0$ for every constant C , so this fails for large n . $\square$

Faced with a proof like that, the reader may cry ‘how did you think of looking at f_n ?’ The honest answer is ‘I did not, I learnt it from somebody else’; but even granting that we could not have invented it in a thousand years, once presented with it we can see a path which might have led there. We are all familiar with the fact that $\int_0^\pi x^n \sin x \, dx$ takes the form $U(\pi)$ for a polynomial U of degree at most n with integer coefficients, and hence so does $\int_0^\pi Q(x) \sin x \, dx$ for any $Q \in \mathbb{Z}[X]$. If $\pi = p/q$ then $q^n U(\pi)$ is an integer. So we experiment, trying to squeeze $\int_0^\pi Q(x) \sin x \, dx$ between 0 and 1 in the manner of our proof for e ; the factor $n!$ appears because we need the integral to be very small, and the symmetric choice $x^n(\pi - x)^n$ is the natural one.

It is worth remembering that after three hundred years we still do not know whether Euler’s constant

$$\gamma = \lim_{N \rightarrow \infty} \left(\sum_{n=1}^N \frac{1}{n} - \log N \right)$$

is irrational.

§44.11.2 Transcendence

If the rationals are the best understood numbers, the algebraic numbers are the next best understood.

Definition 44.11.4 (Algebraic and Transcendental)

A real number α is **algebraic** if it is a root of some non-zero polynomial with integer coefficients. Otherwise α is **transcendental**.

Multiplying up denominators, α is algebraic if and only if it is a root of a non-zero polynomial with rational coefficients.

Lemma 44.11.5

The set of algebraic numbers is countable. Consequently transcendental numbers exist, and indeed the transcendental numbers are uncountable.

Proof. For each n and each bound B there are finitely many integer polynomials of degree at most n with all coefficients at most B in modulus, and each has at most n roots. So the algebraic numbers are a countable union of finite sets, hence countable. Since $\mathbb{R}$ is uncountable, the complement is uncountable. $\square$

This argument is Cantor’s, and it is beautiful but entirely non-constructive: it tells us that transcendentals abound while showing us none. Historically, the first proof came earlier, and is due to Liouville. It is longer, but it produces actual examples. The key point is that algebraic numbers are *badly approximable* by rationals.

Theorem 44.11.6 (Liouville)

Let α be an irrational root of a polynomial $P(X) = a_n X^n + \cdots + a_0$ with $a_j \in \mathbb{Z}$, $n \geq 1$ and $a_n \neq 0$. Then there is a constant $c = c(\alpha) > 0$ such that

$$\left| \alpha - \frac{p}{q} \right| \geq \frac{c}{q^n}$$

for all $p, q \in \mathbb{Z}$ with $q \geq 1$.

Proof. Since P has finitely many roots, we can find $\delta > 0$ such that P has no root other than α in $J = [\alpha - \delta, \alpha + \delta]$. As P' is continuous on the compact set J , it is bounded there, say $|P'| \leq M$ with $M > 0$; by the mean value theorem $|P(t) - P(s)| \leq M|t - s|$ for $s, t \in J$.

Let $p, q \in \mathbb{Z}$ with $q \geq 1$. Suppose first that $p/q \in J$. Then $P(p/q) \neq 0$, since α is the only root of P in J and α is irrational. But $q^n P(p/q) = \sum_j a_j p^j q^{n-j}$ is an integer, so $|q^n P(p/q)| \geq 1$ and hence $|P(p/q)| \geq q^{-n}$. Therefore

$$\left| \alpha - \frac{p}{q} \right| \geq \frac{1}{M} |P(\alpha) - P(p/q)| = \frac{|P(p/q)|}{M} \geq \frac{1}{Mq^n}.$$

If instead $p/q \notin J$ then $\left| \alpha - \frac{p}{q} \right| > \delta \geq \delta/q^n$. So $c = \min\{1/M, \delta\}$ works. $\square$

The content of the theorem is best seen geometrically. Rationals with denominator q are spaced $1/q$ apart, so we should expect to be able to find one within $1/(2q)$ of α , and the theory of continued fractions in the next section will do much better, giving one within $1/q^2$. Liouville's theorem says that for an algebraic α of degree n we can never do better than c/q^n : around each algebraic number there is a forbidden zone which the good rational approximations may not enter.

Turning this on its head: if a number *can* be approximated absurdly well by rationals, it cannot be algebraic.

Theorem 44.11.7

The number $\gamma = \sum_{j=0}^{\infty} \frac{1}{10^{j!}} = 1.110001000000000000000001\dots$ is transcendental.

Proof. First, γ is irrational: its decimal expansion consists of 1's in the places $j!$ and 0's elsewhere, and so is neither terminating nor eventually periodic (the gaps between consecutive 1's grow without bound).

Let $N \geq 1$ and put $\frac{p_N}{q_N} = \sum_{j=0}^N 10^{-j!}$, where $q_N = 10^{N!}$ and $p_N \in \mathbb{N}$. Then

$$0 < \gamma - \frac{p_N}{q_N} = \sum_{j=N+1}^{\infty} 10^{-j!} \leq \sum_{k=(N+1)!}^{\infty} 10^{-k} = \frac{10}{9} \cdot 10^{-(N+1)!} \leq \frac{2}{q_N^{N+1}},$$

using $(N+1)! = (N+1) \cdot N!$, so that $10^{-(N+1)!} = q_N^{-(N+1)}$.

Suppose γ were algebraic, of degree n say, and let $c > 0$ be as in Theorem 44.11.6.

Then for every N ,

$$\frac{c}{q_N^n} \leq \left| \gamma - \frac{p_N}{q_N} \right| \leq \frac{2}{q_N^{N+1}}, \quad \text{so} \quad c \leq \frac{2}{q_N^{N+1-n}}.$$

Taking $N \geq n+1$ and letting $N \rightarrow \infty$, the right-hand side tends to 0 (as $q_N \rightarrow \infty$), contradicting $c > 0$. $\square$

Remark. Replacing γ by $\sum_{j \geq 0} \varepsilon_j 10^{-j!}$ with $\varepsilon_j \in \{1, 2\}$ gives an uncountable family of such numbers, all transcendental by the same argument. So Liouville's method also proves that there are uncountably many transcendentals, and this time we can point at them.

Numbers which admit approximations of this quality are called **Liouville numbers**. They are, in a precise sense, very rare – the set of them has Lebesgue measure zero – yet they are the only transcendentals we can construct with bare hands. As one might expect, proving that a *naturally occurring* number is transcendental is much harder. Hermite proved that e is transcendental, and Lindemann adapted his method to show that π is transcendental, thereby settling the two-thousand-year-old problem of squaring the circle in the negative. These proofs are not part of this course; Alan Baker's *Transcendental Number Theory* contains accessible (but miraculous) versions of both.

§44.12 The Baire Category Theorem

The theorem of this section is much more useful than its somewhat abstract formulation makes it appear. The informal version is this. We work in a non-empty complete metric space (X, d) , and we have a list of properties $P_1, P_2, \dots$ which points might have. Suppose each P_j is *stable* (if x has P_j then so does everything sufficiently close to x) while $\neg P_j$ is *unstable* (however close we look to any point, we can find something with P_j). Then there is a single point which has *all* of the properties at once.

That is a remarkable thing to be able to say. It means that to prove the existence of an object with infinitely many strange properties, it is enough to show that each property individually is achievable by a small perturbation. We shall use it to construct nowhere differentiable functions, and to construct compact sets which are simultaneously very thin and very rich.

Theorem 44.12.1 (Baire Category Theorem)

Let (X, d) be a non-empty complete metric space and let $U_1, U_2, \dots$ be open sets whose complements have empty interior. Then $\bigcap_{j \geq 1} U_j \neq \emptyset$.

Note that ' U_j is open and U_j^c has empty interior' says exactly that U_j is open and dense.

Proof. Since U_1^c has empty interior, $U_1 \neq \emptyset$; choose $x_1 \in U_1$, and since U_1 is open choose $\delta_1 \in (0, 1)$ with $\overline{B}(x_1, 4\delta_1) \subseteq U_1$.

Now proceed inductively. Given x_n and $\delta_n > 0$, the ball $B(x_n, \delta_n)$ is not contained in U_{n+1}^c (which has empty interior), so we may choose $x_{n+1} \in U_{n+1}$ with $d(x_n, x_{n+1}) < \delta_n$. Since U_{n+1} is open we may then choose δ_{n+1} with $0 < \delta_{n+1} \leq \delta_n/4$ and $\overline{B}(x_{n+1}, 4\delta_{n+1}) \subseteq U_{n+1}$.

Then $d(x_n, x_{n+1}) < \delta_n \leq 4^{1-n}\delta_1$, so $\sum_n d(x_n, x_{n+1}) < \infty$ and (x_n) is Cauchy; by completeness $x_n \rightarrow x$ for some $x \in X$. Moreover, for $m > n$,

$$d(x_n, x_m) \leq \sum_{r=n}^{m-1} d(x_r, x_{r+1}) \leq \delta_n \left(1 + \frac{1}{4} + \frac{1}{16} + \cdots\right) \leq 2\delta_n,$$

so letting $m \rightarrow \infty$ gives $d(x_n, x) \leq 2\delta_n$, whence $x \in \overline{B}(x_n, 4\delta_n) \subseteq U_n$. As n was arbitrary, $x \in \bigcap_n U_n$. $\square$

Taking complements gives an equivalent statement which is often the more convenient one.

Theorem 44.12.2

Let (X, d) be a non-empty complete metric space and let $F_1, F_2, \dots$ be closed sets with empty interior. Then $\bigcup_{j \geq 1} F_j \neq X$.

And the informal version we began with is the following.

Theorem 44.12.3

Let (X, d) be a non-empty complete metric space and let $P_1, P_2, \dots$ be properties such that for each j :

- (i) if x has property P_j then there is an $\varepsilon > 0$ such that every y with $d(x, y) < \varepsilon$ has property P_j ;
- (ii) given $x \in X$ and $\varepsilon > 0$, we can find y with $d(x, y) < \varepsilon$ having property P_j .

Then there is an $x_0 \in X$ having every property $P_1, P_2, \dots$

Proof. Let $U_j = \{x : x \text{ has } P_j\}$. Condition (i) says U_j is open and (ii) says U_j is dense, so U_j^c is closed with empty interior. Apply Theorem 44.12.1. $\square$

Baire's theorem has given rise to some standard, and rather unfortunate, terminology.

Definition 44.12.4 (Category)

Let (X, d) be a metric space.

- (i) A set $E \subseteq X$ is **nowhere dense** if $\text{Cl } E$ has empty interior.
- (ii) A set E is of **first category** if it is contained in a countable union of closed sets with empty interior.
- (iii) A set which is not of first category is said to be of **second category**.

The nomenclature is poor – there is nothing categorical about it, and ‘second category’ tells one nothing – so I shall try to avoid saying ‘second category’ and speak of ‘not of first category’ instead. If everything outside a set of first category has some property, I shall say that **quasi-all** points have that property. Sets of first category are the topological analogue of null sets: small, but small in a sense which has nothing to do with measure.

Lemma 44.12.5

Let (X, d) be a metric space.

- (i) If X is non-empty and complete and $E \subseteq X$ is of first category, then $E \neq X$; indeed $E^c \neq \emptyset$.
- (ii) A countable union of sets of first category is of first category.

Proof. (i) is Theorem 44.12.2. (ii) is because a countable union of countable unions is a countable union. $\square$

§44.12.1 Uncountability, Again**Definition 44.12.6**

Let (X, d) be a metric space and $E \subseteq X$. A point $x \in E$ is **isolated** in E if there is a $\delta > 0$ with $B(x, \delta) \cap E = \{x\}$. We say E has **no isolated points** if no point of E is isolated in E .

Theorem 44.12.7

A non-empty complete metric space with no isolated points is uncountable.

Proof. Suppose $X = \{x_1, x_2, \dots\}$ is countable. Each singleton $F_n = \{x_n\}$ is closed, and has empty interior precisely because x_n is not isolated (every ball about x_n contains another point of X). By Theorem 44.12.2, $\bigcup_n F_n \neq X$, contradicting the enumeration. $\square$

Corollary 44.12.8

$\mathbb{R}$ is uncountable. More generally, a non-empty closed subset of $\mathbb{R}$ with no isolated points is uncountable.

Proof. $\mathbb{R}$ is complete with no isolated points. A closed subset of a complete space is complete. $\square$

This proof is much closer to Cantor's original argument than the diagonal argument of Part IA, and it has the advantage of avoiding extraneous notions like decimal expansions.

§44.12.2 Nowhere Differentiable Functions

Banach was a master of the Baire category theorem, and the following is one of his results. Recall from Theorem 44.6.6 that $C([0, 1])$ with the uniform norm is a non-empty complete metric space.

Theorem 44.12.9 (Banach)

The set of functions in $C([0, 1])$ which are differentiable at at least one point is of first category. In particular, continuous nowhere differentiable functions exist.

The key is to replace ‘differentiable somewhere’ by something closed.

Lemma 44.12.10

If $f : [0, 1] \rightarrow \mathbb{R}$ is continuous and differentiable at some $x \in [0, 1]$, then there is an $M > 0$ with $|f(x) - f(s)| \leq M|x - s|$ for all $s \in [0, 1]$.

Proof. Since $(f(s) - f(x))/(s - x) \rightarrow f'(x)$ as $s \rightarrow x$, there is a $\delta > 0$ with

$$\left| \frac{f(s) - f(x)}{s - x} - f'(x) \right| \leq 1 \quad \text{whenever } 0 < |s - x| < \delta,$$

and hence $|f(s) - f(x)| \leq (1 + |f'(x)|)|s - x|$ for such s . If $|s - x| \geq \delta$ then $|f(s) - f(x)| \leq 2\|f\|_\infty \leq \frac{2\|f\|_\infty}{\delta}|s - x|$. Take M to be the larger of the two constants. $\square$

So let

$$E_m = \{f \in C([0, 1]) : \exists x \in [0, 1] \text{ with } |f(x) - f(s)| \leq m|x - s| \text{ for all } s \in [0, 1]\}.$$

By Lemma 44.12.10, every function differentiable somewhere lies in some E_m . So it suffices to show each E_m is closed with empty interior.

Lemma 44.12.11

E_m is closed in $C([0, 1])$.

Proof. Suppose $f_r \in E_m$ and $\|f_r - f\|_\infty \rightarrow 0$. For each r pick $x_r \in [0, 1]$ with $|f_r(x_r) - f_r(s)| \leq m|x_r - s|$ for all s . By compactness of $[0, 1]$, pass to a subsequence with $x_{r(k)} \rightarrow x$. Then for any $s \in [0, 1]$, writing r for $r(k)$,

$$\begin{aligned} |f(x) - f(s)| &\leq |f(x) - f(x_r)| + |f(x_r) - f_r(x_r)| + |f_r(x_r) - f_r(s)| + |f_r(s) - f(s)| \\ &\leq |f(x) - f(x_r)| + 2\|f - f_r\|_\infty + m|x_r - s|. \end{aligned}$$

Letting $k \rightarrow \infty$, the first term tends to 0 by continuity of f , the second by uniform convergence, and the third to $m|x - s|$. Hence $|f(x) - f(s)| \leq m|x - s|$ for all s , so $f \in E_m$. $\square$

Lemma 44.12.12

E_m has empty interior: given $f \in C([0, 1])$ and $\varepsilon > 0$, there is an $h \notin E_m$ with $\|h - f\|_\infty < \varepsilon$.

Proof. The idea is to move first from f to a very nice function, and then from the nice function to a very bad one.

By the Weierstrass approximation theorem there is a polynomial g with $\|g - f\|_\infty < \varepsilon/3$. Being a polynomial, g is continuously differentiable, so $|g'| \leq M$ on $[0, 1]$ for some M , and hence $|g(s) - g(t)| \leq M|s - t|$ for all s, t .

Now set

$$h(t) = g(t) + \frac{\varepsilon}{3} \cos(2\pi Nt)$$

for an integer N to be chosen. Certainly $\|h - f\|_\infty < \varepsilon$. Let $t_k = k/(2N)$ for $0 \leq k \leq 2N$, so that $\cos(2\pi N t_k) = (-1)^k$ and

$$|h(t_{k+1}) - h(t_k)| = \left| g(t_{k+1}) - g(t_k) \mp \frac{2\varepsilon}{3} \right| \geq \frac{2\varepsilon}{3} - \frac{M}{2N}.$$

Choose N so large that $M/(2N) \leq \varepsilon/3$ and $N > 3m/\varepsilon$. Then $|h(t_{k+1}) - h(t_k)| \geq \varepsilon/3$ for every k .

Now let $x \in [0, 1]$ be arbitrary, and pick k with $t_k \leq x \leq t_{k+1}$. By the triangle inequality

$$\max \{ |h(t_k) - h(x)|, |h(t_{k+1}) - h(x)| \} \geq \frac{1}{2} |h(t_{k+1}) - h(t_k)| \geq \frac{\varepsilon}{6},$$

while $|t_k - x|, |t_{k+1} - x| \leq \frac{1}{2N} < \frac{\varepsilon}{6m}$. So for some $s \in \{t_k, t_{k+1}\}$ we have $|h(x) - h(s)| \geq \varepsilon/6 > m|x - s|$. Since x was arbitrary, $h \notin E_m$. $\square$

Proof of Theorem 44.12.9. By Lemmas 44.12.11 and 44.12.12 each E_m is closed with empty interior, so $\bigcup_m E_m$ is of first category and, by Lemma 44.12.5, is not all of $C([0, 1])$. Any $f \notin \bigcup_m E_m$ is, by Lemma 44.12.10, differentiable nowhere. $\square$

Notice what a strange proof this is. We have shown that quasi-all continuous functions are nowhere differentiable – that the differentiable functions, which are the only ones anybody ever draws, form a vanishingly small part of $C([0, 1])$ – without exhibiting a single nowhere differentiable function. One can of course write one down: Weierstrass's original example was

$$W(t) = \sum_{k=0}^{\infty} a^k \cos(b^k \pi t)$$

for suitable $0 < a < 1$ and odd integers b with $ab > 1$. Here are the partial sums for $a = 1/2$, $b = 3$ up to $k = 0, 1, 2$ and 4. Each new term adds wiggles which are smaller in amplitude but far steeper, and in the limit the graph has a corner at every point.

partial sums to $k = 0$, $k = 1$, $k = 2$, $k = 4$

§44.12.3 Perfect Nowhere Dense Sets

Here is a second, and rather different, application. A closed subset of $\mathbb{R}$ with no isolated points is uncountable, by the corollary above. Are there such sets which are nevertheless nowhere dense – containing no interval at all? The Cantor set is one; but we can prove existence without constructing anything, by applying Baire's theorem in a space of sets.

Let $\mathcal{K}$ denote the collection of non-empty compact subsets of $[0, 1]$, with the Hausdorff

metric ρ of the previous section. Since the compact subsets of $[0, 1]$ form a closed subset of the space of compact subsets of $\mathbb{R}$, Theorem 44.9.8 tells us that $(\mathcal{K}, \rho)$ is a non-empty complete metric space.

Lemma 44.12.13

For $k \geq 1$ let $\mathcal{E}_k = \{E \in \mathcal{K} : \exists x \in E \text{ with } (x - \frac{1}{k}, x + \frac{1}{k}) \cap E = \{x\}\}$.

- (i) $\mathcal{E}_k$ is closed in $(\mathcal{K}, \rho)$.
- (ii) $\mathcal{E}_k$ has empty interior.
- (iii) The collection of compact sets possessing an isolated point is of first category in $\mathcal{K}$.

Proof. (i) Let $E_r \in \mathcal{E}_k$ with $\rho(E_r, E) \rightarrow 0$, and pick $x_r \in E_r$ with $(x_r - \frac{1}{k}, x_r + \frac{1}{k}) \cap E_r = \{x_r\}$. Passing to a subsequence, $x_r \rightarrow x$; since $d(x_r, E) \leq \sigma(E_r, E) \rightarrow 0$ and E is closed, $x \in E$.

Suppose $y \in E$ with $y \neq x$ and $|x - y| < \frac{1}{k}$. Put $4\eta = \frac{1}{k} - |x - y| > 0$. Since $\sigma(E, E_r) \rightarrow 0$ we can find $y_r \in E_r$ with $|y_r - y| \rightarrow 0$. For r large we have $|x_r - y_r| < |x - y| + 2\eta < \frac{1}{k}$ and $y_r \neq x_r$ (as $|x - y| > 0$), so y_r lies in $(x_r - \frac{1}{k}, x_r + \frac{1}{k}) \cap E_r$ and differs from x_r . This contradiction shows $(x - \frac{1}{k}, x + \frac{1}{k}) \cap E = \{x\}$, so $E \in \mathcal{E}_k$.

(ii) Let $E \in \mathcal{K}$ and $\varepsilon > 0$. Take $0 < \eta < \varepsilon$ and set $F = \{x \in [0, 1] : d(x, E) \leq \eta\}$, which is a non-empty compact subset of $[0, 1]$ with $E \subseteq F$, so $\sigma(E, F) = 0$ and $\sigma(F, E) \leq \eta$, giving $\rho(E, F) \leq \eta < \varepsilon$. But F has no isolated points at all: if $x \in F$, take $e \in E$ with $|x - e| \leq \eta$; the whole segment between e and x lies in F , and if $x = e$ then one of $[x, x + \eta] \cap [0, 1]$, $[x - \eta, x] \cap [0, 1]$ is a non-degenerate interval contained in F . Either way every neighbourhood of x meets $F \setminus \{x\}$. So $F \notin \mathcal{E}_k$.

(iii) A compact set has an isolated point if and only if it lies in $\mathcal{E}_k$ for some k , so the collection in question is $\bigcup_k \mathcal{E}_k$, a countable union of closed sets with empty interior. $\square$

Lemma 44.12.14

For integers $k \geq 1$ and $0 \leq j < k$, let $\mathcal{F}_{j,k} = \{E \in \mathcal{K} : E \supseteq [\frac{j}{k}, \frac{j+1}{k}]\}$. Then $\mathcal{F}_{j,k}$ is closed with empty interior, and the collection of compact subsets of $[0, 1]$ with non-empty interior is of first category.

Proof. Write $I = [\frac{j}{k}, \frac{j+1}{k}]$. If $E_r \in \mathcal{F}_{j,k}$ and $\rho(E_r, E) \rightarrow 0$, then for $y \in I$ we have $y \in E_r$, so $d(y, E) \leq \sigma(E_r, E) \rightarrow 0$ and hence $y \in E$; thus $E \in \mathcal{F}_{j,k}$ and $\mathcal{F}_{j,k}$ is closed.

For empty interior, let $E \in \mathcal{K}$ and $\varepsilon > 0$. If $E \notin \mathcal{F}_{j,k}$ we are done. Otherwise $E \supseteq I$; let a be the midpoint of I , choose $0 < \eta < \min\{\varepsilon, \frac{1}{2k}\}$ and set $F = E \setminus (a - \eta, a + \eta)$. Then F is compact and non-empty (it still contains the endpoints of I), $\sigma(F, E) = 0$, and every removed point is within η of $a \pm \eta \in F$, so $\sigma(E, F) \leq \eta$ and $\rho(E, F) \leq \eta < \varepsilon$. But $a \notin F$, so $F \notin \mathcal{F}_{j,k}$.

Finally, a compact $E \subseteq [0, 1]$ has non-empty interior if and only if it contains some non-degenerate interval, hence some $[\frac{j}{k}, \frac{j+1}{k}]$; so the collection of such E is

$$\bigcup_{j,k} \mathcal{F}_{j,k}.$$

□

Theorem 44.12.15

Quasi-all non-empty compact subsets of $[0, 1]$ have empty interior and no isolated points. In particular such sets exist, and by Theorem 44.12.7 they are uncountable.

Proof. By Lemmas 44.12.13 and 44.12.14 the sets we wish to exclude form a union of two sets of first category, hence a set of first category, which by Lemma 44.12.5 is not all of $\mathcal{K}$. □

Sets which are closed with no isolated points are called *perfect*; if they make pretty pictures they are called *fractals*. The reader is not obliged to remember either name.

§44.12.4 Pointwise Convergence and Boundedness

Our last application concerns the gap between pointwise and uniform convergence. Recall the ‘witch’s hat’ functions $f_n : [0, 1] \rightarrow \mathbb{R}$,

$$f_n(x) = \begin{cases} 2^{n+1}x & 0 \leq x \leq 2^{-(n+1)}, \\ 2 - 2^{n+1}x & 2^{-(n+1)} < x \leq 2^{-n}, \\ 0 & \text{otherwise,} \end{cases}$$

which satisfy $f_n(x) \rightarrow 0$ for every x while $\|f_n\|_\infty = 1$ for every n : the hat becomes narrower but never shorter, and slides off to the left.

The trouble is confined to a shrinking interval, and one might hope that pointwise convergence forces uniform convergence somewhere. Alas, it does not.

Lemma 44.12.16

There exist $g_n \in C([0, 1])$ with $\|g_n\|_\infty \leq 1$ and $g_n(x) \rightarrow 0$ for every $x \in [0, 1]$, such that (g_n) fails to converge uniformly on every non-degenerate interval $I \subseteq [0, 1]$.

Proof. Enumerate the subintervals of $[0, 1]$ with distinct rational endpoints as $[a_1, b_1]$, $[a_2, b_2]$, $\dots$, and let $p_1, p_2, \dots$ be distinct primes. Define $g_m = 0$ unless $m = p_k^r$ for some $k, r \geq 1$ (which determines k and r uniquely), and in that case

$$g_{p_k^r}(x) = \begin{cases} 2^{-k} f_r\left(\frac{x - a_k}{b_k - a_k}\right) & x \in [a_k, b_k], \\ 0 & \text{otherwise.} \end{cases}$$

Since $f_r(0) = f_r(1) = 0$, each g_m is continuous, and clearly $\|g_m\|_\infty \leq 2^{-k} \leq 1$.

Pointwise convergence: fix x and $\varepsilon > 0$, and choose K with $2^{-K} < \varepsilon$. For $k > K$ we have $|g_{p_k^r}(x)| \leq 2^{-k} < \varepsilon$, whatever r may be. For each of the finitely many $k \leq K$ we have $f_r(y) \rightarrow 0$ as $r \rightarrow \infty$ for each fixed y , so there is an R_k with $|g_{p_k^r}(x)| < \varepsilon$ whenever $r \geq R_k$. Hence $|g_m(x)| \geq \varepsilon$ for at most finitely many m , and $g_m(x) \rightarrow 0$.

Non-uniformity: any non-degenerate interval I contains some $[a_k, b_k]$, and

$$\sup_{x \in [a_k, b_k]} |g_{p_k^r}(x)| = 2^{-k}$$

for every r , so g_m does not tend to 0 uniformly on I . $\square$

In spite of this, Baire's theorem gives a remarkable positive result: the failure can never be one of *size*.

Theorem 44.12.17 (Osgood)

Let $f_n \in C([0, 1])$ with $f_n(x) \rightarrow 0$ for every $x \in [0, 1]$. Then given $\varepsilon > 0$ there is a non-degenerate interval $(a, b) \subseteq [0, 1]$ and an N such that $|f_n(x)| \leq \varepsilon$ for all $n \geq N$ and all $x \in (a, b)$.

Proof. For $n \geq 1$ set

$$E_n = \{x \in [0, 1] : |f_m(x)| \leq \varepsilon \text{ for all } m \geq n\} = \bigcap_{m \geq n} f_m^{-1}([- \varepsilon, \varepsilon]),$$

an intersection of closed sets and hence closed. Since $f_m(x) \rightarrow 0$ for each x , every x lies in some E_n , so $\bigcup_n E_n = [0, 1]$. Now $[0, 1]$ is a non-empty complete metric space, so by Theorem 44.12.2 not every E_n can have empty interior. Take N with E_N containing an interval (a, b) . $\square$

Corollary 44.12.18 (Uniform Boundedness)

Let $f_n \in C([0, 1])$ with $f_n(x) \rightarrow 0$ for every x . Then there is a non-degenerate interval (a, b) and an $M > 0$ with $|f_n(x)| \leq M$ for all $n \geq 1$ and all $x \in (a, b)$.

Proof. Apply Theorem 44.12.17 with $\varepsilon = 1$ to get (a, b) and N with $|f_n| \leq 1$ on (a, b) for $n \geq N$. The finitely many remaining functions $f_1, \dots, f_{N-1}$ are each bounded on $[0, 1]$, so $M = \max\{1, \|f_1\|_\infty, \dots, \|f_{N-1}\|_\infty\}$ works. $\square$

Comparing this with Lemma 44.12.16, we see that the functions g_n constructed there are as bad as pointwise-convergent sequences are permitted to be: they refuse to converge uniformly on any interval, but they cannot be allowed to blow up on every interval as well. This is the elementary ancestor of the principle of uniform boundedness in Part II Linear Analysis, which is proved by exactly the same Baire category argument in a Banach space.

§44.13 Continued Fractions

We are used to writing real numbers as decimals, but there are other ways of specifying a real number which are often more convenient and always more interesting. The oldest

is the method of continued fractions.

Suppose x is irrational with $0 < x < 1$. Then $1/x > 1$ is irrational, so there is a unique integer $N(x) \geq 1$ with

$$\frac{1}{N(x)+1} < x < \frac{1}{N(x)}, \quad \text{that is} \quad N(x) = \left\lfloor \frac{1}{x} \right\rfloor,$$

and setting $T(x) = \frac{1}{x} - \lfloor \frac{1}{x} \rfloor$ we have $0 < T(x) < 1$, $T(x)$ irrational, and

$$x = \frac{1}{N(x) + T(x)}.$$

We may now do the same thing to $T(x)$, obtaining $T(x) = \frac{1}{NT(x) + T^2(x)}$, and so

$$x = \frac{1}{N(x) + \frac{1}{NT(x) + T^2(x)}} = \frac{1}{N(x) + \frac{1}{NT(x) + \frac{1}{NT^2(x) + T^3(x)}}} = \dots,$$

and so on indefinitely. We call

$$\cfrac{1}{N(x) + \cfrac{1}{NT(x) + \cfrac{1}{NT^2(x) + \cfrac{1}{NT^3(x) + \ddots}}}}$$

the **continued fraction expansion** of x . For the moment this is nothing more than a pretty way of writing down the sequence of positive integers $N(x), NT(x), NT^2(x), \dots$; in the next subsection we shall show that it can be assigned a numerical value, and that the value is x . For a general irrational y we prefix the integer part, writing the expansion of y as $\lfloor y \rfloor$ followed by the expansion of $y - \lfloor y \rfloor$.

The same procedure works for rationals, except that it may stop. Let us see why.

Example 44.13.1

Take $x = 100/37$. Then

$$\begin{aligned} \frac{100}{37} &= 2 + \frac{26}{37} = 2 + \frac{1}{\frac{37}{26}} = 2 + \frac{1}{1 + \frac{11}{26}} = 2 + \frac{1}{1 + \frac{1}{\frac{26}{11}}} = 2 + \frac{1}{1 + \frac{1}{2 + \frac{4}{11}}} \\ &= 2 + \frac{1}{1 + \frac{1}{2 + \frac{1}{2 + \frac{3}{4}}}} = 2 + \frac{1}{1 + \frac{1}{2 + \frac{1}{2 + \frac{1}{1 + \frac{1}{3}}}}} \end{aligned}$$

$$= 2 + \frac{1}{1 + \frac{1}{2 + \frac{1}{2 + \frac{1}{1 + \frac{1}{3}}}}}.$$

Lemma 44.13.2

The continued fraction algorithm applied to a rational number is Euclid's algorithm, and in particular it terminates.

Proof. Suppose at some stage we are looking at r_k/s_k with $0 < r_k < s_k$ coprime positive integers, and we write

$$\frac{r_k}{s_k} = \frac{1}{a_k + \frac{r_{k+1}}{s_{k+1}}}, \quad a_k = \left\lfloor \frac{s_k}{r_k} \right\rfloor.$$

Then $s_k/r_k = a_k + r_{k+1}/s_{k+1}$, so $s_{k+1} = r_k$ and $s_k = a_k s_{k+1} + r_{k+1}$ with $0 \leq r_{k+1} < s_{k+1}$. That is exactly one step of the Euclidean algorithm applied to the pair (s_k, r_k) , and r_{k+1} is the remainder. Since $s_1 > s_2 > \dots$ is a strictly decreasing sequence of positive integers, the process stops. (Coprimality is preserved, again as in Euclid's algorithm.) $\square$

Consequently a number with a non-terminating continued fraction expansion is irrational, and this gives a rather satisfying proof of an old fact.

Theorem 44.13.3

$\sqrt{2}$ is irrational.

Proof. We have $\sqrt{2} = 1 + (\sqrt{2} - 1)$ and

$$\sqrt{2} - 1 = \frac{(\sqrt{2} - 1)(\sqrt{2} + 1)}{\sqrt{2} + 1} = \frac{1}{1 + \sqrt{2}} = \frac{1}{2 + (\sqrt{2} - 1)}.$$

So writing $\beta = \sqrt{2} - 1 \in (0, 1)$ we have $\beta = \frac{1}{2+\beta}$, and the continued fraction algorithm applied to β produces $N(\beta) = 2$ and $T(\beta) = \beta$ again. It therefore never terminates, giving

$$\sqrt{2} = 1 + \frac{1}{2 + \frac{1}{2 + \frac{1}{2 + \ddots}}},$$

and by Lemma 44.13.2 the number $\sqrt{2}$ cannot be rational. $\square$

§44.13.1 Gauss's Observation

Before we make sense of the value of a continued fraction, here is a beautiful aside. The decimal expansion has a map behind it too: if $x \in [0, 1)$ and $Dx = 10x - \lfloor 10x \rfloor$, then the digits of x are read off by iterating D , and if X is uniformly distributed on $[0, 1]$ then so is DX – which is why the digits of a ‘random’ number are independent and uniform.

What is the analogue for continued fractions? The map T does *not* preserve the uniform distribution. Gauss found the distribution it does preserve.

Lemma 44.13.4 (Gauss)

Let X be a random variable on $[0, 1)$ with density

$$f(x) = \frac{1}{\log 2} \cdot \frac{1}{1+x}.$$

Then TX has the same density.

Proof. First, f is a density: $\int_0^1 \frac{dx}{\log 2(1+x)} = \frac{\log 2}{\log 2} = 1$. Now for $0 \leq a \leq 1$,

$$\begin{aligned} \Pr(TX \leq a) &= \Pr\left(\frac{1}{X} - \left\lfloor \frac{1}{X} \right\rfloor \leq a\right) = \sum_{n=1}^{\infty} \Pr\left(n \leq \frac{1}{X} \leq n+a\right) \\ &= \sum_{n=1}^{\infty} \Pr\left(\frac{1}{n+a} \leq X \leq \frac{1}{n}\right) = \frac{1}{\log 2} \sum_{n=1}^{\infty} \int_{1/(n+a)}^{1/n} \frac{dx}{1+x} \\ &= \frac{1}{\log 2} \sum_{n=1}^{\infty} \left[\log\left(1 + \frac{1}{n}\right) - \log\left(1 + \frac{1}{n+a}\right) \right]. \end{aligned}$$

Both parts telescope. Summing to N ,

$$\begin{aligned} \sum_{n=1}^N (\log(n+1) - \log n) &= \log(N+1), \\ \sum_{n=1}^N (\log(n+1+a) - \log(n+a)) &= \log(N+1+a) - \log(1+a), \end{aligned}$$

so the partial sum is $\log(N+1) - \log(N+1+a) + \log(1+a) \rightarrow \log(1+a)$ as $N \rightarrow \infty$. Hence

$$\Pr(TX \leq a) = \frac{\log(1+a)}{\log 2} = \int_0^a f(x) dx. \quad \square$$

Corollary 44.13.5

With X as above, for each $m \geq 0$ and each $j \geq 1$,

$$\Pr(NT^m X = j) = \frac{1}{\log 2} \int_{1/(j+1)}^{1/j} \frac{dx}{1+x} = \frac{1}{\log 2} \log\left(\frac{(j+1)^2}{j(j+2)}\right) \sim \frac{1}{j^2 \log 2}$$

as $j \rightarrow \infty$.

Proof. By Lemma 44.13.4, $T^m X$ has the same density as X , and $NY = j$ if and only if $\frac{1}{j+1} < Y \leq \frac{1}{j}$. Evaluating the integral gives $\frac{1}{\log 2} \left(\log \frac{j+1}{j} - \log \frac{j+2}{j+1} \right)$, which is the stated logarithm; and $\log \frac{(j+1)^2}{j(j+2)} = \log \left(1 + \frac{1}{j^2+2j} \right) \sim j^{-2}$. $\square$

With a little more work (which we shall not do) one can show that if X has Gauss's density then $NX, NTX, NT^2X, \dots$ are independent and identically distributed; and it is true, though harder, that if Y is merely *uniform* on $[0, 1]$ then the proportion of the first M partial quotients of Y which equal j still tends to the above value. So in a 'typical' continued fraction the digit 1 appears about 41% of the time, and large partial quotients are rare.

§44.13.2 Convergents

We now return to the question of what a continued fraction *means*.

Definition 44.13.6

Let a_0 be an integer and $a_1, a_2, \dots$ strictly positive integers. The associated **convergents** are the rationals

$$\frac{p_n}{q_n} = a_0 + \frac{1}{a_1 + \frac{1}{a_2 + \frac{1}{\ddots + \frac{1}{a_n}}}}.$$

Evaluating from the bottom up is the natural thing to try. Write

$$\frac{r_k}{s_k} = a_k + \frac{1}{a_{k+1} + \frac{1}{\ddots + \frac{1}{a_n}}},$$

so that $r_n = a_n$, $s_n = 1$, and

$$\frac{r_k}{s_k} = a_k + \frac{1}{r_{k+1}/s_{k+1}} = \frac{a_k r_{k+1} + s_{k+1}}{r_{k+1}}, \quad \text{i.e.} \quad \begin{pmatrix} r_k \\ s_k \end{pmatrix} = \begin{pmatrix} a_k & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} r_{k+1} \\ s_{k+1} \end{pmatrix}.$$

Hence

$$\begin{pmatrix} p_n \\ q_n \end{pmatrix} = \begin{pmatrix} r_0 \\ s_0 \end{pmatrix} = \begin{pmatrix} a_0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} a_1 & 1 \\ 1 & 0 \end{pmatrix} \cdots \begin{pmatrix} a_{n-1} & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} a_n \\ 1 \end{pmatrix}.$$

Similarly $\begin{pmatrix} p_{n-1} \\ q_{n-1} \end{pmatrix}$ is the same product with the last factor replaced by $\begin{pmatrix} 1 \\ 0 \end{pmatrix}$, so putting the two columns side by side,

$$\begin{pmatrix} p_n & p_{n-1} \\ q_n & q_{n-1} \end{pmatrix} = \begin{pmatrix} a_0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} a_1 & 1 \\ 1 & 0 \end{pmatrix} \cdots \begin{pmatrix} a_n & 1 \\ 1 & 0 \end{pmatrix}.$$

This is the pay-off for recasting things in matrix form: every fact we want now falls out.

Theorem 44.13.7

With p_n, q_n as above (and the conventions $p_{-1} = 1, q_{-1} = 0$):

- (i) $p_{n+1} = a_{n+1}p_n + p_{n-1}$ and $q_{n+1} = a_{n+1}q_n + q_{n-1}$;
- (ii) $p_n q_{n-1} - q_n p_{n-1} = (-1)^{n+1}$, and in particular p_n and q_n are coprime;
- (iii) $\frac{p_n}{q_n} - \frac{p_{n-1}}{q_{n-1}} = \frac{(-1)^{n+1}}{q_n q_{n-1}}$;
- (iv) $q_n \geq F_{n+1} \rightarrow \infty$, where F_m is the m th Fibonacci number;
- (v) $\frac{p_0}{q_0} < \frac{p_2}{q_2} < \frac{p_4}{q_4} < \dots < \dots < \frac{p_5}{q_5} < \frac{p_3}{q_3} < \frac{p_1}{q_1}$, and $p_n/q_n \rightarrow \alpha$ for some real α with $\left| \alpha - \frac{p_n}{q_n} \right| \leq \frac{1}{q_n q_{n+1}}$.

Proof. (i) Multiply the matrix identity for $n+1$ as

$$\begin{pmatrix} p_{n+1} & p_n \\ q_{n+1} & q_n \end{pmatrix} = \begin{pmatrix} p_n & p_{n-1} \\ q_n & q_{n-1} \end{pmatrix} \begin{pmatrix} a_{n+1} & 1 \\ 1 & 0 \end{pmatrix}$$

and read off the first column.

(ii) Take determinants: each factor $\begin{pmatrix} a_k & 1 \\ 1 & 0 \end{pmatrix}$ has determinant -1 , and there are $n+1$ of them, so $p_n q_{n-1} - q_n p_{n-1} = (-1)^{n+1}$. Any common factor of p_n and q_n would divide this.

(iii) Divide (ii) by $q_n q_{n-1}$.

(iv) By (i), $q_{n+1} = a_{n+1}q_n + q_{n-1} \geq q_n + q_{n-1}$, with $q_0 = 1$ and $q_1 = a_1 \geq 1$, so induction gives $q_n \geq F_{n+1}$.

(v) From (i) and (iii),

$$\begin{aligned} \frac{p_{n+1}}{q_{n+1}} - \frac{p_{n-1}}{q_{n-1}} &= \left(\frac{p_{n+1}}{q_{n+1}} - \frac{p_n}{q_n} \right) + \left(\frac{p_n}{q_n} - \frac{p_{n-1}}{q_{n-1}} \right) \\ &= \frac{(-1)^{n+2}}{q_{n+1}q_n} + \frac{(-1)^{n+1}}{q_n q_{n-1}} = \frac{(-1)^{n+1}}{q_n} \left(\frac{1}{q_{n-1}} - \frac{1}{q_{n+1}} \right), \end{aligned}$$

which has the sign of $(-1)^{n+1}$ since $q_{n+1} > q_{n-1}$. So the even convergents increase and the odd ones decrease. By (iii) every even convergent is below every odd one, so both are bounded monotone sequences and converge; and since $\left| \frac{p_n}{q_n} - \frac{p_{n-1}}{q_{n-1}} \right| = \frac{1}{q_n q_{n-1}} \rightarrow 0$ by (iv), the two limits agree, say to α . As α lies between p_n/q_n and p_{n+1}/q_{n+1} , we get $\left| \alpha - \frac{p_n}{q_n} \right| \leq \frac{1}{q_n q_{n+1}}$. $\square$

So a continued fraction does converge, and it converges in the pleasantest possible way: the convergents alternate around the limit, so each one gives an error bound for the previous one. It remains to check that when we start with a number x we get back to x .

Lemma 44.13.8

If $x \in (0, 1)$ is irrational and $a_1 = N(x)$, $a_2 = NT(x)$, $\dots$ are the partial quotients produced by the continued fraction algorithm (with $a_0 = 0$), then $p_n/q_n \rightarrow x$.

Proof. Truncating the algorithm at stage n gives x exactly as the continued fraction with entries $a_0, a_1, \dots, a_n + T^n(x)$ in place of $a_0, \dots, a_n$, where $0 < T^n(x) < 1$. Increasing a partial quotient a_n increases p_n/q_n when n is even and decreases it when n is odd (this is immediate from the fact, used repeatedly, that $t \mapsto \frac{1}{a+t}$ is decreasing on $t \geq 0$, and that these substitutions are nested). It follows that

$$\frac{p_{2k}}{q_{2k}} < x < \frac{p_{2k-1}}{q_{2k-1}}$$

for every k . As both sides tend to the limit α of Theorem 44.13.7(v), we get $x = \alpha$. $\square$

§44.13.3 Convergents Are the Best Approximations

The convergents are not merely good approximations: they are the best possible ones for their size of denominator.

Lemma 44.13.9

Let $u, v \in \mathbb{Z}$ with $1 \leq v \leq q_n$, and suppose $\left| \frac{u}{v} - \frac{p_{n+1}}{q_{n+1}} \right| \leq \frac{1}{q_n q_{n+1}}$. Then $v = q_n$ and (provided $q_{n+1} > 2$) $u = p_n$.

Proof. First, $\frac{u}{v} \neq \frac{p_{n+1}}{q_{n+1}}$: since p_{n+1}, q_{n+1} are coprime this would force $q_{n+1} \mid v$, impossible as $1 \leq v \leq q_n < q_{n+1}$. Hence $|uq_{n+1} - vp_{n+1}| \geq 1$ and

$$\left| \frac{u}{v} - \frac{p_{n+1}}{q_{n+1}} \right| = \frac{|uq_{n+1} - vp_{n+1}|}{vq_{n+1}} \geq \frac{1}{vq_{n+1}} \geq \frac{1}{q_n q_{n+1}}.$$

So both inequalities are equalities: $v = q_n$ and $|uq_{n+1} - q_n p_{n+1}| = 1$. But also $|p_n q_{n+1} - q_n p_{n+1}| = 1$ by Theorem 44.13.7(ii), so subtracting gives $(u - p_n)q_{n+1} \in \{0, \pm 2\}$, and if $q_{n+1} > 2$ this forces $u = p_n$. $\square$

Theorem 44.13.10

Let α be the value of the continued fraction with convergents p_n/q_n , and suppose $q_{n+1} > 2$. Then

$$\left| \alpha - \frac{p_n}{q_n} \right| \leq \left| \alpha - \frac{p}{q} \right|$$

for all integers p, q with $1 \leq q \leq q_n$.

Proof. Since α lies between $\frac{p_n}{q_n}$ and $\frac{p_{n+1}}{q_{n+1}}$, we have

$$\left| \alpha - \frac{p_n}{q_n} \right| + \left| \alpha - \frac{p_{n+1}}{q_{n+1}} \right| = \left| \frac{p_n}{q_n} - \frac{p_{n+1}}{q_{n+1}} \right| = \frac{1}{q_n q_{n+1}}.$$

Suppose $1 \leq q \leq q_n$ and $\left| \alpha - \frac{p}{q} \right| < \left| \alpha - \frac{p_n}{q_n} \right|$. Then

$$\left| \frac{p}{q} - \frac{p_{n+1}}{q_{n+1}} \right| \leq \left| \frac{p}{q} - \alpha \right| + \left| \alpha - \frac{p_{n+1}}{q_{n+1}} \right| < \left| \alpha - \frac{p_n}{q_n} \right| + \left| \alpha - \frac{p_{n+1}}{q_{n+1}} \right| = \frac{1}{q_n q_{n+1}},$$

so by Lemma 44.13.9 we get $q = q_n$ and $p = p_n$, contradicting the strict inequality. $\square$

Corollary 44.13.11

If x is irrational, there are infinitely many pairs of integers (u, v) with $v \geq 1$ and

$$\left| x - \frac{u}{v} \right| < \frac{1}{v^2}.$$

Proof. Take $u = p_n$, $v = q_n$. By Theorem 44.13.7(v) and $q_{n+1} > q_n$,

$$\left| x - \frac{p_n}{q_n} \right| \leq \frac{1}{q_n q_{n+1}} < \frac{1}{q_n^2},$$

and $q_n \rightarrow \infty$ gives infinitely many distinct pairs. $\square$

This should be compared with Liouville's Theorem 44.11.6, which says that an algebraic irrational of degree n satisfies $|x - p/q| \geq cq^{-n}$. For $n = 2$ the two statements are in direct competition, and neither can be improved to the point of contradicting the other: quadratic irrationals are approximable to order q^{-2} and no better.

§44.13.4 Badly Approximable Numbers

Large partial quotients a_j produce large jumps in $q_{n+1} = a_{n+1}q_n + q_{n-1}$, and hence unusually good approximations. So the most *resistant* number to rational approximation should be the one whose partial quotients are all as small as possible.

Example 44.13.12 (The Golden Ratio)

Let

$$\sigma = \frac{1}{1 + \frac{1}{1 + \frac{1}{1 + \ddots}}}.$$

Then $\sigma = \frac{1}{1+\sigma}$, so $\sigma^2 + \sigma - 1 = 0$ and (taking the positive root) $\sigma = \frac{\sqrt{5}-1}{2} = 1/\varphi$, where $\varphi = \frac{1+\sqrt{5}}{2}$ is the golden ratio.

Here every $a_j = 1$, so by Theorem 44.13.7(i) we have $p_{n+1} = p_n + p_{n-1}$ and $q_{n+1} = q_n + q_{n-1}$. With $a_0 = 0$ we get $p_0 = 0$, $q_0 = 1$, $p_1 = q_1 = 1$, and induction gives

$$p_n = F_n, \quad q_n = F_{n+1},$$

where $F_0 = 0$, $F_1 = 1$, $F_{m+1} = F_m + F_{m-1}$ are the Fibonacci numbers. Theorem 44.13.7(ii) becomes the identity $F_{n+1}F_{n-1} - F_n^2 = (-1)^n$.

Solving the recurrence, $F_m = \frac{1}{\sqrt{5}} (\varphi^m - (-\varphi)^{-m})$. Since $\sigma\varphi = 1$, a short computation gives

$$\sigma - \frac{F_n}{F_{n+1}} = \frac{\sigma F_{n+1} - F_n}{F_{n+1}} = \frac{(-1)^n \varphi^{-n} (1 + \varphi^{-2})}{\sqrt{5} F_{n+1}},$$

and as $F_{n+1} \sim \varphi^{n+1}/\sqrt{5}$ this gives

$$\left| \sigma - \frac{p_n}{q_n} \right| \sim \frac{1}{\sqrt{5} q_n^2}.$$

So the convergents to σ approximate it to order q^{-2} and to no better order – the constant $1/\sqrt{5}$ is exactly what the general theory guarantees, and not a whit more. This lets us prove that σ is *badly approximable*.

Proposition 44.13.13

There is an $m > 0$ such that $\left| \sigma - \frac{p}{q} \right| > \frac{m}{q^2}$ for all integers p and all $q \geq 1$.

Proof. Fix p, q with $q \geq 1$, and let n be least with $q \leq q_n$ and $q_{n+1} > 2$. By Theorem 44.13.10,

$$\left| \sigma - \frac{p}{q} \right| \geq \left| \sigma - \frac{p_n}{q_n} \right| \geq \frac{c}{q_n^2}$$

for some constant $c > 0$, by Example 44.13.12. By minimality of n (and $q_n = q_{n-1} + q_{n-2} \leq 2q_{n-1}$) we have $q_n \leq 2q_{n-1} \leq 2q$ for all n beyond the first couple, so $\left| \sigma - \frac{p}{q} \right| \geq \frac{c}{4q^2}$. Adjusting the constant to deal with the finitely many small cases gives the result. $\square$

Hardy and Wright's *An Introduction to the Theory of Numbers* contains a chapter on approximation by rationals in which, among many other things, it is shown that σ really is the most resistant of all irrationals in this sense. If I were asked to nominate a single book to be taken away by somebody leaving professional mathematics but wishing to keep up an interest in the subject, that book would be my first choice.

A Nice, But Starred, Formula

This subsection is not examinable, but it is too pretty to leave out. Continued fractions generalise in many directions; here is one of them. We are used to approximating a function by polynomials; sometimes it is better to approximate by a *rational* function P/Q , and if approximation by polynomials leads to Taylor series, approximation by rational functions leads to something like continued fractions. Lambert found the following.

Theorem 44.13.14 (Lambert)

Let

$$R_n(x) = \frac{x}{1 - \frac{x^2}{3 - \frac{x^2}{5 - \frac{x^2}{\ddots - \frac{x^2}{2n-1}}}}}.$$

Then $R_n(x) \rightarrow \tan x$ as $n \rightarrow \infty$ for all real x with $|x| \leq 1$.

The proof runs along lines which will now be familiar. One first generalises the matrix identity: if p_n, q_n are defined by

$$\begin{pmatrix} p_n & b_n p_{n-1} \\ q_n & b_n q_{n-1} \end{pmatrix} = \begin{pmatrix} a_0 & b_0 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} a_1 & b_1 \\ 1 & 0 \end{pmatrix} \cdots \begin{pmatrix} a_n & b_n \\ 1 & 0 \end{pmatrix},$$

then p_n/q_n is the generalised continued fraction with numerators b_j and denominators a_j , and

$$p_n = a_n p_{n-1} + b_{n-1} p_{n-2}, \quad q_n = a_n q_{n-1} + b_{n-1} q_{n-2}.$$

One then writes

$$S_n(x) = \frac{1}{2^n n!} \int_0^x (x^2 - t^2)^n \cos t \, dt$$

and checks, by integrating by parts twice in the manner of Lemma 44.11.2, that $S_n(x) = q_n(x) \sin x - p_n(x) \cos x$ where p_n, q_n satisfy exactly the recurrences

$$p_n(x) = (2n-1)p_{n-1}(x) - x^2 p_{n-2}(x), \quad q_n(x) = (2n-1)q_{n-1}(x) - x^2 q_{n-2}(x)$$

with $p_0 = 0, q_0 = 1, p_1(x) = x, q_1 = 1$. These are the recurrences for the continued fraction above, and the estimate $|S_n(x)| \leq \frac{|x|^{2n+1}}{2^n n!} \rightarrow 0$ then gives $p_n(x)/q_n(x) \rightarrow \tan x$.

§44.14 Winding Numbers

We all know that complex analysis has a great deal to say about the number of times a curve goes round a point. In this final section we make the notion precise without using any complex analysis at all, and then use it to give a second proof of two theorems from earlier in the course. The moral will be that parts of complex analysis are really topology in disguise.

§44.14.1 Lifting

Write $\mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}$. The basic fact is that a continuous path on the circle can be followed continuously by an angle.

Theorem 44.14.1 (Path Lifting)

Let $g : [0, 1] \rightarrow \mathbb{T}$ be continuous with $g(0) = e^{i\theta_0}$. Then there is a unique continuous $\theta : [0, 1] \rightarrow \mathbb{R}$ with $\theta(0) = \theta_0$ and $g(t) = e^{i\theta(t)}$ for all t .

Proof. For *existence*, note first that on the half-plane $H = \{z : \operatorname{Re} z > 0\}$ we have a continuous argument function

$$\arg(u + iv) = \arctan(v/u) \in (-\frac{\pi}{2}, \frac{\pi}{2}),$$

satisfying $w = |w|e^{i\arg w}$ and $\arg 1 = 0$.

Now g is uniformly continuous by Theorem 44.1.12, so we may choose N with $|g(s) - g(t)| < 1$ whenever $|s - t| \leq 1/N$. Fix r and $t \in [\frac{r}{N}, \frac{r+1}{N}]$. Then $\left| \frac{g(t)}{g(r/N)} - 1 \right| = |g(t) - g(r/N)| < 1$, and a point of $\mathbb{T}$ within distance 1 of 1 has positive real part, so $g(t)/g(r/N) \in H$. We may therefore define θ successively on the intervals $[\frac{r}{N}, \frac{r+1}{N}]$ by

$$\theta(t) = \theta\left(\frac{r}{N}\right) + \arg\left(\frac{g(t)}{g(r/N)}\right),$$

starting from $\theta(0) = \theta_0$. This is continuous on each interval, agrees at the shared endpoints, and satisfies $e^{i\theta(t)} = e^{i\theta(r/N)} \cdot \frac{g(t)}{g(r/N)} = g(t)$ by induction on r .

For *uniqueness*, suppose $\psi, \phi : [0, 1] \rightarrow \mathbb{R}$ are continuous with $e^{i\psi(t)} = e^{i\phi(t)}$ for all t . Then $\frac{\psi - \phi}{2\pi}$ is a continuous function on $[0, 1]$ taking values in $\mathbb{Z}$; since $[0, 1]$ is connected and $\mathbb{Z}$ is discrete, it is constant. If in addition $\psi(0) = \phi(0)$, the constant is 0. $\square$

Corollary 44.14.2

If $\gamma : [0, 1] \rightarrow \mathbb{C} \setminus \{0\}$ is continuous with $\gamma(0) = |\gamma(0)|e^{i\theta_0}$, then there is a unique continuous $\theta : [0, 1] \rightarrow \mathbb{R}$ with $\theta(0) = \theta_0$ and $\gamma(t) = |\gamma(t)|e^{i\theta(t)}$.

Proof. Apply Theorem 44.14.1 to $g(t) = \gamma(t)/|\gamma(t)|$, which is continuous since γ never vanishes. $\square$

Definition 44.14.3 (Winding Number)

Let $\gamma : [0, 1] \rightarrow \mathbb{C} \setminus \{0\}$ be continuous and let θ be as in Corollary 44.14.2. We define the **winding number** of γ about 0 to be

$$w(\gamma, 0) = \frac{\theta(1) - \theta(0)}{2\pi}.$$

By the uniqueness in Theorem 44.14.1, any two choices of θ differ by a constant, so $w(\gamma, 0)$ is well defined. From now on we shall only be interested in **closed** curves, that is those with $\gamma(0) = \gamma(1)$.

Lemma 44.14.4

If γ is closed then $w(\gamma, 0) \in \mathbb{Z}$, and every integer arises.

Proof. $\gamma(0) = \gamma(1)$ gives $e^{i\theta(0)} = e^{i\theta(1)}$, so $\theta(1) - \theta(0) \in 2\pi\mathbb{Z}$. For the converse take $\gamma(t) = e^{2\pi i n t}$, for which $\theta(t) = 2\pi n t$ and $w(\gamma, 0) = n$. $\square$

Winding numbers behave exactly as one would hope under multiplication.

Lemma 44.14.5

If $\gamma_1, \gamma_2 : [0, 1] \rightarrow \mathbb{C} \setminus \{0\}$ are continuous, then $w(\gamma_1\gamma_2, 0) = w(\gamma_1, 0) + w(\gamma_2, 0)$.

Proof. Suppose $\gamma_j(t) = |\gamma_j(t)|e^{i\theta_j(t)}$ with θ_j continuous. Then

$$\gamma_1(t)\gamma_2(t) = |\gamma_1(t)\gamma_2(t)|e^{i(\theta_1(t)+\theta_2(t))},$$

and $\theta_1 + \theta_2$ is continuous, so it is a valid choice of angle function for the product $\gamma_1\gamma_2$. $\square$

§44.14.2 Walking the Dog

Lemma 44.14.6 (Dog Walking Lemma)

Let $\gamma_1, \gamma_2 : [0, 1] \rightarrow \mathbb{C}$ be continuous closed curves with $\gamma_1(t) \neq 0$ and $|\gamma_2(t)| < |\gamma_1(t)|$ for all t . Then $\gamma_1 + \gamma_2$ never vanishes and

$$w(\gamma_1 + \gamma_2, 0) = w(\gamma_1, 0).$$

Proof. Write $\gamma_1 + \gamma_2 = \gamma_1 \left(1 + \frac{\gamma_2}{\gamma_1}\right)$. Since $\left|\frac{\gamma_2(t)}{\gamma_1(t)}\right| < 1$, the curve $\eta = 1 + \frac{\gamma_2}{\gamma_1}$ takes values in $\{z : \operatorname{Re} z > 0\}$, and in particular never vanishes; hence neither does $\gamma_1 + \gamma_2$. By Lemma 44.14.5,

$$w(\gamma_1 + \gamma_2, 0) = w(\gamma_1, 0) + w(\eta, 0),$$

so it suffices to show $w(\eta, 0) = 0$. But on $\{\operatorname{Re} z > 0\}$ we may take $\theta(t) = \arg \eta(t) \in (-\frac{\pi}{2}, \frac{\pi}{2})$ as our continuous angle function, so $|\theta(1) - \theta(0)| < \pi$; as η is closed, $\theta(1) - \theta(0) \in 2\pi\mathbb{Z}$, forcing $\theta(1) = \theta(0)$. $\square$

The name comes from the following picture. A man walks round a closed path γ_1 which avoids a lamp-post at the origin, taking his dog with him on a lead of length always shorter than his own distance from the lamp-post. The dog's path is $\gamma_1 + \gamma_2$. Then, however much the dog dashes about, man and dog go round the lamp-post the same number of times.

The lemma is really a statement about small perturbations. The right way to say ‘small perturbation’ in general is the following.

Definition 44.14.7 (Homotopy)

Let $\gamma_0, \gamma_1 : [0, 1] \rightarrow \mathbb{C} \setminus \{0\}$ be closed curves. We say γ_0 and γ_1 are **homotopic** through closed curves avoiding 0 if there is a continuous $\Gamma : [0, 1]^2 \rightarrow \mathbb{C} \setminus \{0\}$ with

$$\Gamma(s, 0) = \Gamma(s, 1) \quad \forall s, \quad \Gamma(0, t) = \gamma_0(t) \quad \forall t, \quad \Gamma(1, t) = \gamma_1(t) \quad \forall t.$$

We write $\gamma_0 \simeq \gamma_1$; it is easy to check that $\simeq$ is an equivalence relation.

Theorem 44.14.8 (Dog Walking Along a Canal)

If $\gamma_0 \simeq \gamma_1$ then $w(\gamma_0, 0) = w(\gamma_1, 0)$.

Proof. Let Γ be a homotopy. Since $|\Gamma|$ is continuous and strictly positive on the compact set $[0, 1]^2$, it attains a strictly positive minimum, so there is a $\delta > 0$ with $|\Gamma(s, t)| \geq 8\delta$ everywhere. Also Γ is uniformly continuous, so we may find N with

$$|\Gamma(s, t) - \Gamma(s', t')| < \delta \quad \text{whenever } |s - s'|, |t - t'| \leq \frac{1}{N}.$$

Set $\tau_r(t) = \Gamma(r/N, t)$ for $0 \leq r \leq N$, a closed curve avoiding 0. Then for every t ,

$$|\tau_{r+1}(t) - \tau_r(t)| < \delta < 8\delta \leq |\tau_r(t)|,$$

so by the dog walking Lemma 44.14.6 (with $\gamma_1 = \tau_r$ and $\gamma_2 = \tau_{r+1} - \tau_r$) we get $w(\tau_{r+1}, 0) = w(\tau_r, 0)$. Chaining these,

$$w(\gamma_0, 0) = w(\tau_0, 0) = w(\tau_1, 0) = \cdots = w(\tau_N, 0) = w(\gamma_1, 0). \quad \square$$

§44.14.3 Two Old Theorems Again

The following is the workhorse: a non-zero winding number on the boundary forces a zero inside.

Corollary 44.14.9

Let $f : \overline{B}(0, R) \rightarrow \mathbb{C}$ be continuous with $f(z) \neq 0$ for $|z| = R$, and define $\gamma(t) = f(Re^{2\pi it})$. If $w(\gamma, 0) \neq 0$ then $f(z) = 0$ for some z with $|z| < R$.

Proof. Suppose f has no zero in $\overline{B}(0, R)$. Then $\Gamma(s, t) = f(sRe^{2\pi it})$ is a continuous map $[0, 1]^2 \rightarrow \mathbb{C} \setminus \{0\}$ with $\Gamma(s, 0) = \Gamma(s, 1)$, so it is a homotopy from the constant curve $t \mapsto f(0)$ to γ . The constant curve has winding number 0, so by Theorem 44.14.8 $w(\gamma, 0) = 0$, a contradiction. $\square$

Theorem 44.14.10 (Fundamental Theorem of Algebra, again)

Every non-constant complex polynomial has a root.

Proof. We may assume $P(z) = z^n + \sum_{j=0}^{n-1} a_j z^j$ with $n \geq 1$. Choose any $R > 1$ which also exceeds $\sum_{j=0}^{n-1} |a_j|$, and set

$$\gamma_1(t) = R^n e^{2\pi i n t}, \quad \gamma_2(t) = \sum_{j=0}^{n-1} a_j R^j e^{2\pi i j t},$$

so that $\gamma_1 + \gamma_2$ is the curve $t \mapsto P(Re^{2\pi it})$. For every t ,

$$|\gamma_2(t)| \leq \sum_{j=0}^{n-1} |a_j| R^j \leq R^{n-1} \sum_{j=0}^{n-1} |a_j| < R^n = |\gamma_1(t)|,$$

so by Lemma 44.14.6 we get $w(\gamma_1 + \gamma_2, 0) = w(\gamma_1, 0) = n \neq 0$. Now Corollary 44.14.9 gives a root in $B(0, R)$. $\square$

This is the same idea as our very first proof in Theorem 44.1.14, but the bookkeeping is now done by the winding number rather than by hand. Finally, we recover the no retraction theorem, and with it Brouwer's fixed point theorem in two dimensions.

Theorem 44.14.11

There is no continuous $f : \overline{D} \rightarrow \partial D$ with $f(z) = z$ for all $z \in \partial D$.

Proof. Suppose such an f existed and set $\Gamma(s, t) = f(se^{2\pi it})$ for $s, t \in [0, 1]$. This is continuous, satisfies $\Gamma(s, 0) = \Gamma(s, 1)$, and never vanishes since $|f| \equiv 1$ on ∂D . So Γ is a homotopy through closed curves avoiding 0 between $t \mapsto \Gamma(0, t) = f(0)$, a constant curve of winding number 0, and $t \mapsto \Gamma(1, t) = f(e^{2\pi it}) = e^{2\pi it}$, which has winding number 1. This contradicts Theorem 44.14.8. $\square$

It is worth comparing the two proofs of the no retraction theorem. The one via Sperner's lemma is combinatorial, elementary, and generalises to $\mathbb{R}^n$ with only cosmetic changes; the one just given is slicker, but is tied to the plane, because the whole notion of a winding number is.

More generally, the contents of this section show that some of what one learns in a complex analysis course – the argument principle, Rouché's theorem, the fundamental theorem of algebra – is really a special case of general topological facts about continuous maps, and has nothing to do with differentiability. Other parts of the subject, such as Taylor's theorem and Cauchy's theorem itself, depend crucially on the fact that we are dealing with the very restricted class of functions satisfying the Cauchy–Riemann equations. In traditional courses this distinction appears late, if at all; Beardon's *Complex*

Analysis shows that it is possible to do things differently, and is well worth a look.
